The mechanisms of antiseizure actions of VNS are unknown in the human, but animal studies have indicated that VNS has multiple activities. Human clinical studies have shown that VNS changes the cerebrospinal fluid (CSF) concentration of inhibitory and stimulatory neurotransmitters and activates specific areas of the brain that generate or regulate cortical seizure activity through increased blood flow. It is believed that the long-term intermittent antiepileptic effects of VNS involve neurotransmitters and or neurochemicals.¹⁸

The VNS device is relatively safe. The most common side effect associated with stimulation is hoarseness, voice alteration, increased cough, pharyngitis, dyspnea, dyspepsia, and nausea. Serious adverse effects reported include infection, nerve paralysis, hypoesthesia, facial paresis, left vocal cord paralysis, left facial paralysis, left recurrent laryngeal nerve injury, urinary retention, and low-grade fever. Overall, in the VNS studies, the percentage of patients who achieved a 50% or greater reduction in their seizure frequency (responders) ranged from 23% to 50%.

Surgery is the treatment of choice in selected patients with refractory focal epilepsy.¹⁹ The success rate is reported to be between 80% and 90% in properly selected patients. It has been shown that surgery reduces the risk of epilepsy-associated death, and it may also improve depression and anxiety in refractory epilepsy patients.^{20,21} A National Institutes of Health Consensus Conference identified three absolute requirements for surgery. They are (1) an absolute diagnosis of epilepsy, (2) failure on an adequate trial of drug therapy, and (3) definition of the electroclinical syndrome. A focus in the temporal lobe has the best chance for a positive outcome; however, extratemporal foci can be excised successfully in more than 75% of patients. The procedure is not without risk. Learning and memory can be impaired postoperatively, and general intellectual abilities are also affected in a small number of patients. Surgery may be particularly useful in children with intractable epilepsy. Patients may need to continue to receive AED therapy for a period of time following successful epilepsy surgery, but they may be able to use a reduced dose of their AEDs.^{19,22}

The ketogenic diet was devised in the 1920s. It is high in fat and low in carbohydrates and protein and thus leads to acidosis and ketosis. Protein and calorie intake are set at levels that will meet requirements for growth. Most of the calories are provided in the form of heavy cream and butter, and no sugar is allowed. Vitamins and minerals are supplemented. Medium-chain triglycerides can be substituted for the dietary fats. Fluids are also controlled. It requires strict control and parent compliance. Although some centers find the diet useful for refractory patients, others have found that it is poorly tolerated by patients. Long-term effects have included kidney stones, increased bone fractures, and adverse effects on growth.²³ Recently a modified Atkins diet has been found to be effective in the treatment of intractable pediatric epilepsy.²⁴

■ PHARMACOLOGIC THERAPY

Optimal management of epilepsy, therefore, requires that AED treatment be individualized. Specifically, different patient groups (e.g., children, women of child-bearing potential, and the elderly) may be better suited to receive one AED than another by virtue not only of seizure type but also of susceptibility or relative risk for certain adverse effects. These issues will be highlighted further below.

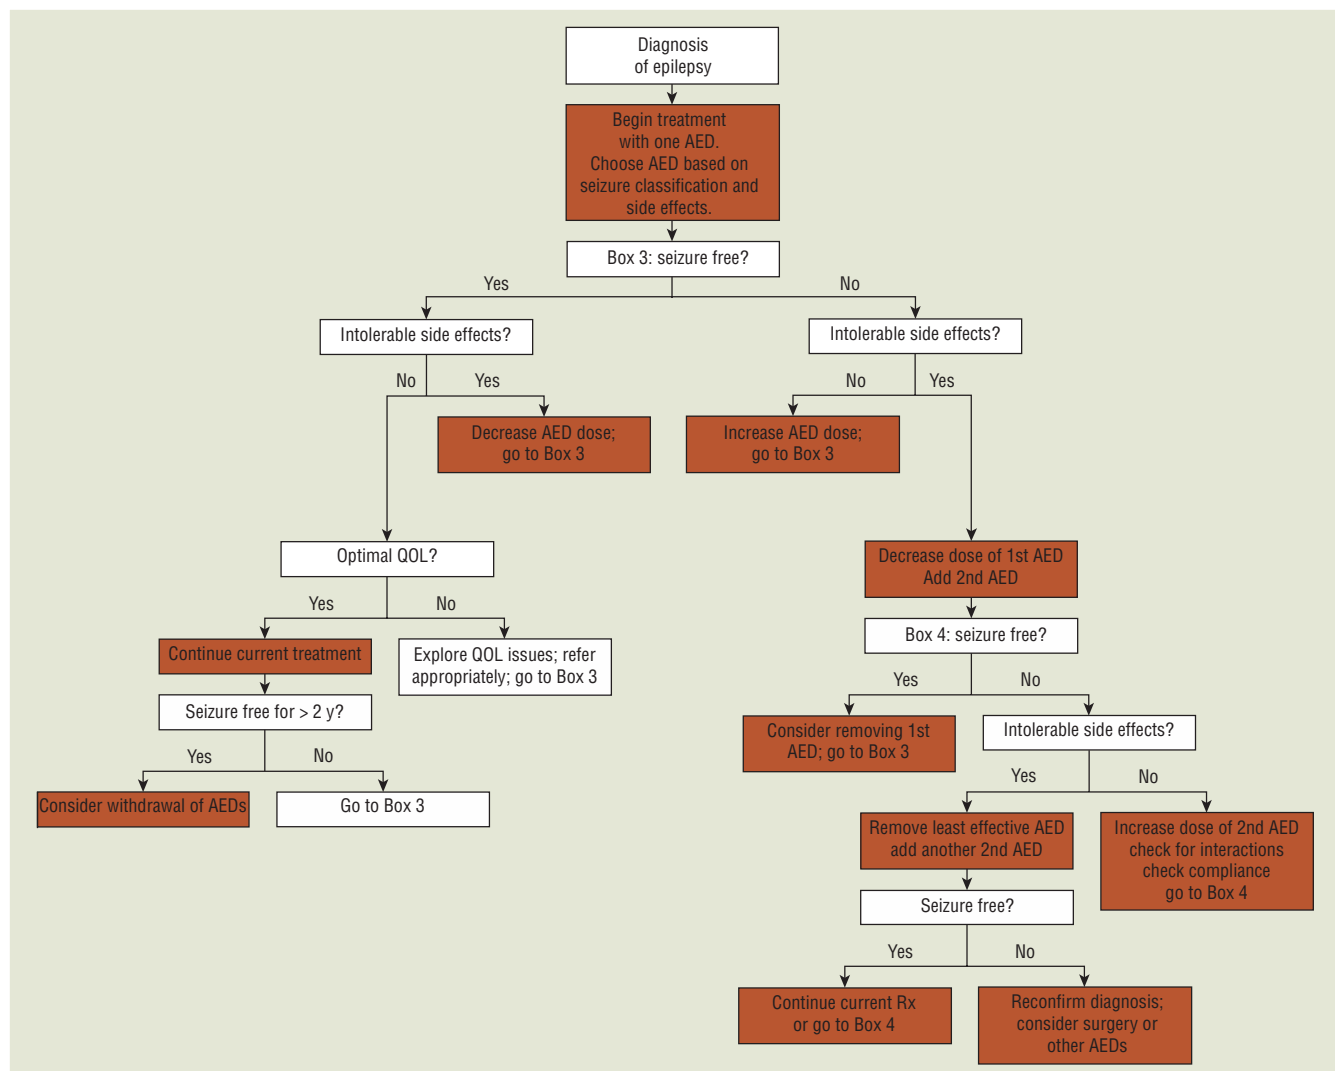

FIGURE 58-1. Algorithm for the treatment of epilepsy. (AED, antiepileptic drug; QOL, quality of life.)

7 Selection and optimization of AED therapy require not only an understanding of drug mechanism(s) of action and spectrum of clinical activity but also an appreciation of pharmacokinetic variability as well as patterns of drug-related adverse effects. An AED must demonstrate efficacy for the specific seizure type being treated. The drug treatments of first choice depend on the type of epilepsy, as well as on the interface between drug-specific adverse effects and patient preferences. Ultimately, AED effectiveness is the result of the interaction of each of these factors. A suggested algorithm for a general approach to the treatment of epilepsy is shown in Fig. 58-1.

Table 58-3 provides evidenced-based treatment recommendations by three professional/regulatory bodies.²⁵⁻²⁹ In addition, recommendations from a U.S. panel of experts, which included more recent drug treatment data compared to the AAN-American Epilepsy Society (AES) recommendations are included.³⁰

The mechanism of action of most AEDs can be categorized as either affecting ion channels, augmenting inhibitory neurotransmission, or modulating excitatory neurotransmission. The ion channels affected include the sodium and calcium channels. Augmentation in inhibitory neurotransmission includes increasing CNS concentrations of GABA, whereas efforts to decrease excitatory neurotransmission are primarily focused on decreasing (or antagonizing) glutamate and aspartate neurotransmission. AEDs that are effective against GTC and partial seizures probably reduce sustained repetitive firing of action potentials by delaying recovery of sodium channels from activation. Drugs that reduce corticothalamic T-type calcium cur-

rents are effective against generalized absence seizures. Myoclonic seizures respond to drugs that enhance GABA_A receptor inhibition. In addition to mechanism of action, awareness of pharmacokinetic properties (Table 58-4), adverse effects (Table 58-5), AED-AED interactions (Table 58-6), and AED metabolic pathway as well as inducer or inhibitory effects on liver (Table 58-7) can aid in the optimization of AED therapy. Pharmacokinetic interactions are a common complicating factor in AED selection. Interactions can occur in any of the pharmacokinetic processes: absorption, distribution, or elimination. Caution should be used when AEDs are added to or withdrawn from a drug regimen.

Adverse effects of AEDs can be divided into acute and chronic (see Table 58-5). Acute effects can be dose/serum concentration-related or idiosyncratic. Concentration-dependent effects are common and troublesome but not usually life-threatening. Neurotoxic adverse effects are encountered commonly and can include sedation, dizziness, blurred or double vision, difficulty with concentration, and ataxia. In many cases these effects can be alleviated by decreasing drug dose or avoided in some cases by increasing the drug very slowly. Most idiosyncratic reactions owing to an allergic reaction are mild, but they can be more serious if the hypersensitivity involves one or more organ systems. Other idiosyncratic side effects including hepatitis or blood dyscrasias are serious but rare.

Acute organ failure, if it is going to occur, generally occurs within the first 6 months of AED therapy. Unfortunately, screening laboratory evaluations of blood and urine typically are not helpful in

AED, antiepileptic drug.

Data from French et al.^{25,26} and Leppik.³²

predicting or detecting the early stage of severe reactions and generally are not recommended in asymptomatic patients. Laboratory assessment including white blood cell counts and liver function tests may be reasonable if the patient reports an unexplained illness (e.g., lethargy, vomiting, fever, or rash).³⁴ It is important to recognize that adverse effects can occur despite serum concentrations being within the proposed therapeutic range.³⁵

Another potential long-term adverse effect of AED treatment is osteomalacia and osteoporosis.³⁶ The bone disorders associated with AED use consist of a heterogeneous group of disorders. These include findings ranging from asymptomatic high-turnover disease, with findings of normal bone mineral density, to markedly decreased bone mineral density sufficient to warrant the diagnosis of osteoporosis. While the etiology of these osteopathies is still uncertain, it has been hypothesized that certain drugs, including phenytoin, phenobarbital, carbamazepine, oxcarbazepine, and valproic acid, may interfere with vitamin D metabolism. Whether the other AEDs are associated with

these effects is as yet unknown. Common laboratory findings in these patients include elevated bone-specific alkaline phosphatase concentration and decreased serum calcium and 25-OH vitamin D concentrations. Patients receiving these drugs should receive supplemental vitamin D and calcium, as well as bone mineral density testing if other risk factors for osteoporosis are present.

The comparative effects of AEDs on cognition have been difficult to evaluate because of differences or inconsistencies in study design, included seizure types, control for serum drug concentrations, and the neuropsychologic tests used. In general, there are not large differences between the older drugs,^{37,38} although the barbiturates phenobarbital and primidone appear to cause more cognitive impairment than other commonly used AEDs. Phenytoin, particularly when serum concentrations are above the commonly accepted therapeutic range, may have a greater effect on motor function and speed. Among the older AEDs, valproic acid may cause less impairment of cognition. Improvement in cognition has been reported in patients switched from phen-

ytoin or phenobarbital to this agent. However, these improvements are subtle and may not be pronounced if patients are in the same relative area of the therapeutic range. Patients changed from polytherapy to monotherapy also may demonstrate improvement in cognition. Some of the newer agents are believed to cause fewer neurobehavioral or cognitive effects. Among the newer AEDs, gabapentin and lamotrigine have been shown in several studies to cause fewer cognitive impairments as compared with older agents, such as carbamazepine.^{39,40,41} Conversely, topiramate may cause substantial cognitive

impairment, particularly when used at high doses or during rapid dose escalation.⁴¹ In addition, these patients may not be fully aware of their deficits.^{42,43} Finally, in some cases, AED treatment itself has been suggested to cause worsening of seizures. This can result from either improper selection of an AED for a specific seizure type or syndrome or can represent a paradoxical toxic effect of the drug.⁴⁴

Because most adult patients have localization-related (partial-onset) seizures, the most widely used AEDs traditionally have been carbamazepine, phenobarbital, phenytoin, and valproic acid. For CP seizures, these AEDs have similar efficacy.^{45,46} Of these, carbamazepine and phenytoin are the most commonly prescribed AEDs for use in partial seizures in the United States. In large part, this preference is based on data derived from two landmark trials conducted through the Veterans Administration (VA) Epilepsy Cooperative Study Group. In the first of these trials, patients with new-onset partial or generalized epilepsy were randomized to receive either carbamazepine, phenobarbital, phenytoin, or primidone.⁴⁵ At the end of 3 years, patients who received either carbamazepine or phenytoin were equally likely and patients on phenobarbital or primidone were least likely to have remained on their originally assigned treatment. Thus, carbamazepine and phenytoin were considered the drugs of first choice in patients with new-onset partial or generalized seizures. Carbamazepine was associated with fewer side effects. A followup study using almost identical methods compared carbamazepine and valproic acid.⁴⁶ Carbamazepine- and valproic acid-treated groups had equal retention rates for tonic-clonic seizures. Carbamazepine was superior to valproic acid for partial seizures. Valproic acid caused slightly more adverse effects.

Based in large part on the earlier VA cooperative trials, carbamazepine traditionally has been recognized as the AED of first choice for partial seizures. Several of the newer-generation AEDs may prove to be reasonable alternatives. The newer antiepileptic drugs were first approved as adjunctive therapy for patients with refractory partial seizures. Monotherapy trials with several of these newer agents including lamotrigine, gabapentin, topiramate, and oxcarbazepine have been completed.^{47–49} Comparisons between lamotrigine and older agents including carbamazepine and phenytoin as initial monotherapy in partial seizures have been conducted in Europe, and the results suggest comparable effectiveness and perhaps better tolerability for lamotrigine, particularly in elderly patients. Results from a recently completed VA cooperative trial designed to compare gabapentin, lamotrigine, and carbamazepine in newly diagnosed elderly patients found that gabapentin efficacy is comparable with that of both lamotrigine and carbamazepine, and in fact is better tolerated than carbamazepine and equal to lamotrigine in this population.⁵⁰ Clinical data suggest that in newly diagnosed patients, oxcarbazepine is as effective as phenytoin, valproic acid, and immediate-release carbamazepine, with perhaps fewer adverse effects. Interestingly, close examination of the conversion to monotherapy trials suggests that oxcarbazepine demonstrates efficacy even in patients who previously had an inadequate response to carbamazepine, in spite of their structural similarity.

In addition, several monotherapy trials using an active control or pseudoplacebo design also have been performed. Although these study designs do provide evidence of efficacy for the newer drugs, because the comparison is between active drug and placebo in patients who continue to have seizures in spite of current treatment with standard AEDs, it is difficult to compare the efficacy of the newer drugs directly with the older AEDs. A meta-analysis designed to compare some of the newer AEDs found that because of wide and overlapping confidence intervals for both efficacy and tolerability outcome measures, no statistically significant differences between agents could be found.⁵¹ Generally speaking, the newer AEDs appear to have comparable efficacy to the older agents and are perhaps better tolerated.

TABLE 58-7 AED Elimination Pathways and Major Effect on Hepatic Enzymes

AED	Major Hepatic Enzymes	Renal Elimination (%)	Induced	Inhibited
Carbamazepine	CYP3A4; CYP1A2; CYP2C8	<1	CYP1A2; CYP2C; CYP3A; GT	None

AED, antiepileptic drug; CYP, cytochrome P450 isoenzyme system; GT, glucuronyltransferase.

Data from Faught⁴¹ and Leppik⁴² with permission.

To date, among the newer-generation agents, lamotrigine, oxcarbazepine, and topiramate have received FDA approval for use as monotherapy in patients with partial seizures. Phenobarbital and primidone are also useful in partial seizures, but sedation and cognitive adverse effects limit their utility. Felbamate, which has monotherapy approval, is effective but has been associated with some significant side effects. Interpretation of monotherapy trials with the newer AEDs can be daunting owing to the unique study designs and specific patient populations employed. Although a complete discussion of this topic is beyond the scope of this chapter, several reviews and analyses have been published.⁴⁷

Primarily generalized seizures such as absence seizures may respond differently pharmacologically than other seizure types. Phenytoin, phenobarbital, and carbamazepine, although effective in GTC and partial seizures, are ineffective in treating absence seizures, and in some cases, can precipitate an increase in seizure activity. Absence seizures are best treated with ethosuximide, valproic acid, and perhaps lamotrigine. Levetiracetam, topiramate, or zonisamide also can be effective, although further clinical data are needed to confirm this. Gabapentin and tiagabine do not appear to be effective in treating absence seizures. If the patient has a combination of absence and other generalized or partial seizures, valproic acid is the preferred first choice because it is the only AED effective for absence and other seizure types. If valproic acid is ineffective in treating a mixed seizure disorder that includes absence, ethosuximide should be used in combination with another AED.

The traditional treatment of tonic-clonic seizures is phenytoin or phenobarbital; however, the use of carbamazepine and valproic acid is increasing because these AEDs have a lower incidence of side effects and equal efficacy. Valproic acid generally is considered the drug of first choice for atonic seizures and for juvenile myoclonic epilepsy. Lamotrigine and perhaps topiramate and zonisamide can be alternative agents for these seizure types. Levetiracetam has recently received FDA approval as adjunctive treatment of myoclonic seizures in patients with juvenile myoclonic epilepsy.

In most cases, selection of specific AED will depend on multiple factors, including seizure type, unique patient characteristics, and the expected adverse-effect/pharmacokinetic profile of each AED. An important clinical question remains as to the precise role of the newer-generation drugs. Although several studies would suggest that at least some of the newer agents may have comparable efficacy, as well as improved tolerability compared to the older drugs, definitive comparative studies with all agents are lacking.

Although most of the older AEDs have published therapeutic ranges, the serum concentration should be viewed as a tool with which to optimize therapy for an individual patient, not as a therapeutic end point in and of itself. The serum concentration is a target that should be correlated with clinical outcome. The desired response is the cessation of seizures without side effects. Seizure control can occur before the “minimum” of the published range is achieved, and side effects can appear before the “maximum” of the range is achieved. Some patients may need and tolerate concentrations beyond the maximum. The therapeutic range for AEDs can be different for different seizure types. Serum concentrations may need to be higher to control CP seizures than to control tonic-clonic seizures. Clinicians should define a therapeutic range for an individual patient above which there are side effects and below which the patient experiences seizures. Serum levels can be useful to document lack of efficacy, loss of efficacy, noncompliance, and to determine how much room there is to increase a dose based on expected toxicity. Depending on the AED, they can also be useful in patients with significant renal and/or hepatic disease, patients taking multiple drugs, and women who are pregnant or taking oral contraceptives. To date, therapeutic concentration ranges have not been established conclusively for the newer-generation AEDs.

■ THERAPEUTIC CONSIDERATIONS IN THE ELDERLY AND YOUNG

Use of AEDs in the elderly and young can pose special challenges.⁵² Avoidance of AEDs that interact with other medications that the elderly are taking is of utmost importance. Many of the drugs are inducers or inhibitors of the CYP450 system, which can affect the therapeutic drug level of concomitant drugs that can ultimately have a detrimental outcome. Hypoalbuminemia is a common occurrence in the elderly, which can make monitoring and adjustment of serum drug levels of highly albumin-bound AEDs, such as phenytoin, valproic acid, and tiagabine, problematic. The elderly also experience body mass changes such as an increase in fat to lean body mass or decrease in body water, which can affect the volume of distribution of some drugs, and therefore possibly the elimination half-life of the drug. In addition, declining renal and/or hepatic function can occur in the elderly, which can require a lower dose of the AED. Lastly, the pharmacodynamic response to AEDs can change as the patient ages because elderly patients may be more sensitive to various neurocognitive adverse effects of these drugs.

Elderly patients may demonstrate efficacy (e.g., control of seizures) at relatively lower serum concentrations as well.

For neonates and infants, an increase in the total body water to body fat ratio and a decrease in serum albumin and α -acid glycoprotein can result in volume of distribution changes that can affect the elimination half-life of the AEDs. In addition, newborns up to the age of 2 to 3 years display decreased efficiency in renal elimination, with the newborn having the most significant impairment. Hepatic activity is also reduced in this population. However, by age 2 to 3 years, hepatic activity is more robust than that seen in adults. Therefore, children require higher doses of many of the antiepileptics than adults, whereas neonates and infants require lower doses.

■ THERAPEUTIC CONSIDERATIONS IN WOMEN (AND MEN)

Many hormones influence brain electrical excitability, and the steroid hormones estrogen and progesterone may interact in complex ways to alter neuronal excitability and protein synthesis.⁵³ Estrogen has a seizure-activating effect, whereas progesterone exerts a seizure-protective effect. Estrogen has an inhibitory effect on GABA receptors, potentiates excitatory glutaminergic activity, and can promote the development of kindling. Progesterone has the opposite effect and appears to potentiate GABA receptor activity and reduce neuronal discharge rates. AEDs, especially hepatic metabolizing enzyme inducers, increase the metabolism of steroid hormones and induce the production of sex hormone-binding globulin. This may lead to decreases in the unbound fraction of the hormone. Enzyme-inducing AEDs, including topiramate and oxcarbazepine at higher doses, can cause treatment failures in women taking oral contraceptives owing to induction of the metabolism of both ethinyl estradiol and progesterone. A supplemental form of birth control, in addition to oral contraceptives, is advised if breakthrough bleeding occurs. Valproic acid, benzodiazepines, and most of the newer AEDs, such as gabapentin, levetiracetam, tiagabine, and zonisamide, are not enzyme inducers and have not been associated with this effect.

In some women, vulnerability to seizures is highest just before and during the menstrual flow (catamenial seizures) and at the time of ovulation. The risk of catamenial epilepsy is estimated at 12.5%, but it can occur in as many as 50% of women with epilepsy. This pattern of seizure exacerbation can be related to progesterone withdrawal and changes in the estrogen-to-progesterone ratio. Conventional AEDs should be tried first in these women. Intermittent acetazolamide also has been used but with variable and limited success. Hormonal therapy with progestational agents, particularly cyclic natural progesterone therapy, also can be effective. Reproductive endocrine disorders are common in women with epilepsy and include menstrual irregularity, infertility, sexual dysfunction, and possibly an increased risk of polycystic ovary syndrome.⁵⁴ Potential mechanisms for these disturbances include disruption of the hypothalamic-pituitary-adrenal (HPA) axis via seizure discharges in limbic structures and/or AEDs.⁵⁴ AEDs, particularly the enzyme-inducing agents (e.g., carbamazepine, phenytoin, and phenobarbital), also may affect HPA function by altering the metabolism of the neuroactive sex hormones, including testosterone. Although a definitive causal relationship has not yet been established, an apparent increased incidence of polycystic ovary syndrome has been suggested for women with epilepsy who are receiving valproic acid.⁵⁴

Pregnancy raises several concerns, including the possibility of increased maternal seizures, pregnancy complications, and adverse fetal outcome.⁵⁵ Approximately 25% to 30% of women have increased seizures during pregnancy, whereas seizures decrease in a similar number. Increased seizure activity may result from either a direct effect on seizure threshold or a reduction in AED concentration. An increase in clearance has been reported for phenytoin,

carbamazepine, phenobarbital, ethosuximide, lamotrigine, oxcarbazepine, and clonazepam. Protein binding also may be altered. The altered disposition of AEDs can begin as early as the first 10 weeks of pregnancy and can take up to 4 weeks postpartum to return to normal. The return to the nonpregnant metabolism and binding requires longer for carbamazepine and phenobarbital than it does for phenytoin.

There is a higher incidence of adverse pregnancy outcomes in women with epilepsy. Although the risk of congenital malformations is 4% to 6% (twice as high as in nonepileptic women), more than 90% of pregnancies in epileptic mothers have satisfactory outcomes. Older data, much of which included AED polytherapy, indicated that barbiturates and phenytoin are associated with congenital heart malformations, orofacial clefts, and other malformations. Valproic acid and carbamazepine are associated with spina bifida (neural tube defect) and hypospadias. From these data the risk of neural tube defect with valproic acid and carbamazepine has been estimated to be 0.5% to 1%, respectively, and appears to be related to drug exposure during gestational days 0 to 28. Other adverse pregnancy outcomes associated with maternal seizures, but not necessarily caused by AEDs, are growth, psychomotor, and mental retardation. Women with epilepsy are also more likely to have miscarriages, and 10% to 20% of infants are born with low birth weight. Guidelines have been developed for counseling and managing pregnant women with epilepsy.

Many of these teratogenic effects can be prevented by adequate folate intake; therefore, prenatal vitamins with folic acid (~0.4–5 mg/day) should be given to any woman of child-bearing potential who is taking AEDs.⁵⁵ Higher folate doses should be used in women with a history of a previous pregnancy with a neural tube defect. Higher AED doses and serum concentrations, polytherapy, and a family history of birth defects appear to increase the teratogenic risk. Deciding on the most effective single-drug treatment prior to conception is vitally important. New AEDs are reported to be less teratogenic, and animal reproductive toxicology studies appear to be favorable. At present, clinical data are still limited, and more experience is needed before the true risk (or lack thereof) can be determined. However, multiple registries worldwide are currently collecting prospective data on the outcome of pregnancies in users of newer and older AEDs. To date, results indicate that valproic acid mono- as well as polytherapy appears to cause a significantly higher rate of fetal malformations compared to the other AEDs, especially at doses greater than 1,400 mg/day.^{56,57} Some AEDs also can lead to neonatal hemorrhagic disorder, which can be prevented by the administration of vitamin K 10 mg orally, given to the mother daily during the last month of pregnancy.

Although AEDs pass into the breast milk, the concentrations are very low, and the infant receives a subtherapeutic dose. In general, knowledge of the degree of protein binding of a given AED can allow for prediction of breast milk accumulation. Taking AEDs with less protein binding results in more accumulation in breast milk. Treatment with AEDs is not necessarily a reason to discourage breast-feeding. It is advisable that women taking any AED (particularly barbiturates or benzodiazepines) closely observe infants for signs of excess sedation, irritability, or poor feeding.⁵⁵

The perimenopausal period can be associated with worsening of seizures, possibly owing to fluctuations in sex hormones. At menopause, seizures actually can improve, particularly in women who previously presented with a catamenial pattern. The effect of hormone-replacement therapy on seizure control is still unclear, but clinicians should monitor for seizure exacerbation in women receiving supplemental estrogen.

It appears from recent data that men with epilepsy have reduced fertility and that carbamazepine, oxcarbazepine, and valproic acid are associated with sperm abnormalities in these men. In addition,

TABLE 58-8 AED Dosing and Target Serum Concentration Ranges

	Trade Name	Usual Initial Dose	Usual Maximum Daily Dose	Target Serum Concentration Range
Barbiturates				
Mephobarbital	Mebaral	50–100 mg/day	400–600 mg	Not defined
Phenobarbital	Various	1–3 mg/kg/day (10–20 mg/kg LD)	180–300 mg	10–40 mcg/mL
Primidone	Mysoline	100–125 mg/day	750–2,000 mg	5–10 mcg/mL
Benzodiazepines				
Clonazepam	Klonopin	1.5 mg/day	20 mg	20–80 ng/mL
Clorazepate	Tranxene	7.5–22.5 mg/day	90 mg	Not defined
Diazepam	Valium	PO: 4–40 mg IV: 5–10 mg	PO: 4–40 mg IV: 5–30 mg	100–1,000 ng/mL
Lorazepam	Ativan	PO: 2–6 mg IV: 0.05 mg/kg IM: 0.05 mg/kg	PO: 10 mg IV: 0.044 mg/kg	10–30 ng/mL
Hydantoins				
Ethotoin	Peganone	<1,000 mg/day	2,000–4,000 mg with food	15–50 mcg/mL
Mephentyoin	Mesantoin	50–100 mg/day	200–800 mg	25–40 mcg/mL
Phenytoin	Dilantin	PO: 3–5 mg/kg (200–400 mg) (15–20 mg/kg LD)	PO: 500–600 mg	Total: 10–20 mcg/mL Unbound: 0.5–3 mcg/mL
Succinimides				
Ethosuximide	Zarontin	500 mg/day	500–2,000 mg	40–80 mcg/mL
Methsuximide	Celontin	300 mg/day	300–1,200 mg	N-desmethyl metabolite 10–40 mcg/mL
Other				
Carbamazepine	Tegretol	400 mg/day	400–2,400 mg	4–14 mcg/mL
Felbamate	Felbatol	1,200 mg/day	3,600 mg	40–100 mcg/mL ^a
Gabapentin	Neurontin	900 mg/day	4,800 mg	4–16 mcg/mL ^a
Lamotrigine	Lamictal	25 mg every other day if on VPA; 25–50 mg/day if not on VPA	100–150 mg if on VPA; 300–500 mg if not on VPA	4–20 mcg/mL ^a
Levetiracetam	Keppra	500–1,000 mg/day	3,000–4,000 mg	5–40 mcg/mL ^{ab}
Oxcarbazepine	Trileptal	300–600 mg/day	2,400–3,000 mg	12–30 mcg/mL ^a (MHD)
Pregabalin	Lyrica	150 mg/day	600 mg	Not defined
Tiagabine	Gabitril	4–8 mg/day	80 mg	100–300 mcg/mL ^a
Topiramate	Topamax	25–50 mg/day	200–1,000 mg	2–25 mcg/mL
Valproic acid	Depakene Depakote Depacon	15 mg/kg (500–1,000 mg)	60 mg/kg (3,000–5,000 mg)	50–150 mcg/mL ^a
Zonisamide	Zonegran	100–200 mg/day	600 mg	10–40 mcg/mL ^a

AED, antiepileptic drug; IM, intramuscular; LD, loading dose; MHD, 10-monohydrate derivative; PO, orally; VPA, valproic acid.

^aBased on data from clinical trials—no established therapeutic ranges.

Data from Leppik³² and Bourgeois.³³

valproic acid seems to cause testicular atrophy resulting in reduced testosterone volume.⁵⁸

CLINICAL CONSIDERATIONS WITH SPECIFIC DRUGS

Tables 58–4 through 58–9 list specific data (including pharmacokinetics, adverse effects, AED interactions, metabolism, and dosing) for each of the commonly used AEDs. Below we summarize the

relative properties, advantages, and disadvantages, and perspectives as to the place in therapy of each of these agents.

Carbamazepine

Pharmacology and Mechanism of Action The exact mechanism by which carbamazepine suppresses seizure spread is obscure, although it is believed to act primarily through inhibition of voltage-gated sodium channels. In addition, interaction with voltage-gated calcium and potassium channels can also contribute to its activity.⁵⁹

TABLE 58-9 Phenytoin Dosage Forms

Dosage Form	Salt or Acid	Extended or Prompt	Amount of Acid Available
Dilantin capsules 100 mg 30 mg	Phenytoin sodium	Extended	92 mg 27 mg
Dilantin suspension 125 mg/5 mL	Phenytoin acid	Prompt	125 mg/5 mL
Dilantin Infatabs 50 mg	Phenytoin acid	Prompt	50 mg
Phenytoin injectable 50 mg/mL	Phenytoin sodium	Prompt	46 mg/mL
Fosphenytoin 50 mg PE/mL			50 mg PHT equivalents/mL
Phenytek capsules 200 mg 300 mg	Phenytoin sodium	Extended	184 mg 276 mg
Phenytoin capsules (generic)	Phenytoin sodium	Prompt	92 mg

PE, phenytoin equivalents; PHT, phenytoin.

Pharmacokinetics The absorption of carbamazepine from immediate-release tablets is slow and erratic because of its low water solubility. There is also a large variability in the peak-to-trough concentrations of up to 40%. There is no first-pass metabolism. Food, especially fat, may enhance the bioavailability of carbamazepine. The suspension dosage form is absorbed faster than the tablets.⁶⁰ Controlled-release (Tegretol-XR) and sustained-release (Carbatrol) preparations are also available. These dosage forms are bioequivalent in twice-daily (every 12 hours) dosing to dosing four times daily (every 6 hours) with immediate-release carbamazepine. Compared with immediate-release carbamazepine, both these formulations have lower peaks and higher troughs, which can decrease side effects and improve seizure control. Carbatrol has also been shown to improve quality-of-life measurements compared to the immediate-release product.⁶¹ Patients should be told to take Tegretol-XR with food and that the casing will be excreted in the feces. Tegretol-XR cannot be broken or crushed. Tegretol-XR and Carbatrol appear to be bioequivalent; however, there is less variability in the absorption of Carbatrol.⁶⁰

Carbamazepine is a neutral and highly lipophilic drug that results in high body tissue binding. It binds to α_1 -acid glycoprotein and to albumin. The major metabolite is carbamazepine-10,11-epoxide, which has anticonvulsant activity in animals and humans.⁶⁰ The formation of the 10,11-epoxide is influenced by concurrent use of other enzyme-inducing or enzyme-inhibiting drugs; thus the 10,11-epoxide concentration may change with the administration of other drugs (e.g., valproate and felbamate) with no change in parent carbamazepine concentration.⁶⁰

Carbamazepine induces its own metabolism (autoinduction) thereby decreasing its half-life after chronic therapy.⁶⁰ The presence of enzyme-inducing drugs reduces the half-life even more. The enzyme-induction effect begins within 3 to 5 days of the initiation of therapy and takes 21 to 28 days to complete. Therefore, it is possible to achieve initial concentrations that are within the therapeutic range but have concentrations fall despite continued therapy with good compliance. Some patients who respond well to initial therapy may be labeled refractory or noncompliant if the autoinduction phenomenon is not considered. The autoinduction reverses rapidly if therapy with carbamazepine is discontinued temporarily. Carbamazepine also displays diurnal variation in its serum level with the evening level lower than the morning level.

Adverse Effects Side effects of carbamazepine can fluctuate daily, paralleling the rise and decline of serum concentrations. Neurosensory side effects (e.g., diplopia, blurred vision, nystagmus, ataxia, unsteadiness, dizziness, and headache) are the most common, occurring in 35% to 50% of patients. These side effects are more common during initiation of therapy and can dissipate with continued treatment. Carbamazepine can also cause nausea, which can either be caused by a local effect of the drug on the GI tract, in which case food may help, or caused by an effect on the brainstem, which may ultimately require discontinuation of the drug. Dosage manipulation, including the use of the controlled- or sustained-release preparations, should be tried before the patient is considered to be intolerant of carbamazepine. Carbamazepine can cause hyponatremia, the incidence of which increases with age, however, its occurrence is lower than that seen with oxcarbazepine. Periodic determinations of serum sodium concentration are recommended, especially in the elderly.⁶⁰

Leukopenia is the most common hematologic side effect. An incidence as high as 10% has been reported. Leukopenia usually is transient, even when the drug is continued, and can be caused by a redistribution of white blood cells (WBCs) rather than a decrease in their production. In about 2% of patients, the leukopenia is persistent, but even patients with WBC counts of $3,000/\text{mm}^3$ or less do not seem to have an increased incidence of infection. A clinical guide is to continue carbamazepine therapy unless the WBC count

drops to less than $2,500/\text{mm}^3$ and the absolute neutrophil count drops to less than $1,000/\text{mm}^3$.⁶⁰

Drug Interactions Because of concentration-dependent efficacy and side effects, drug interactions with carbamazepine often are very significant. Drugs that inhibit CYP 3A4 potentially may increase carbamazepine serum concentrations. Carbamazepine may interact with other drugs by inducing their metabolism.

Dosing and Administration The variable contributions of the 10,11-epoxide metabolite and free-carbamazepine concentrations have restricted a precise definition of the therapeutic range. Loading doses of carbamazepine are indicated only for critically ill patients. During dosage titration, it should be remembered that carbamazepine clearance increases with time. Doses may be started at one-fourth to one-third the anticipated maintenance dose and increased every 2 to 3 weeks. Because of the auto- and heteroinduction of carbamazepine metabolism, it is necessary to administer the drug two to four times per day. The controlled- and sustained release formulations provide fewer peak-to-trough fluctuations, which can improve adherence, reduce side effects, and improve seizure control. Carbamazepine tablets should not be stored in places where they would be exposed to high heat and high humidity.⁶⁰

Advantages Carbamazepine has been well studied. Oral immediate- and extended-release solid and liquid dosage forms are available. The oral solid dosage form is available as an immediate-release tablet and as a sustained-release capsule and a controlled-release tablet. The sustained- and controlled-release dosage forms allow for twice-daily dosing to reduce the peak-to-trough fluctuations. Compared with other first-generation AEDs, carbamazepine causes minimal cognitive impairment.

Disadvantages Carbamazepine has an active metabolite that can contribute to efficacy and toxicity. Other drugs can alter the concentration of this metabolite without changing the concentration of the parent carbamazepine. It induces its own metabolism, which requires careful dosage titration. It also induces the metabolism of other medications, and other drugs may interact with it and/or the active metabolite. There is no parenteral formulation. There are clinically meaningful CNS side effects including sedation and nausea. One prospective study, however, did find fewer side effects with the sustained release formulation compared to the immediate release formulation.⁶¹ When ingested during the first trimester by pregnant women, carbamazepine has been associated with a 1% risk of spina bifida. Chronic carbamazepine use also has been associated with alterations in bone mineral density in some studies and decreases in 25-hydroxy (OH) vitamin D. The generic formulations of immediate-release tablets have been associated with breakthrough seizures when brands have been switched.

Place in Therapy Carbamazepine should be considered a first-line therapy for patients with newly diagnosed partial seizures and for patients with primary generalized convulsive seizures who are not in an emergent situation.

Ethosuximide

Pharmacology and Mechanism of Action The exact mechanism of action of ethosuximide remains elusive, however, it is believed to exert its main action through inhibition of T-type calcium channels.⁵⁹

Pharmacokinetics Metabolism occurs in the liver by hydroxylation, and the metabolites are believed to be inactive. There is some evidence of a nonlinear metabolic process at higher concentrations.

Adverse Effects The most frequently reported side effects are nausea and vomiting (up to 40%), and these symptoms may be

minimized by administration of smaller doses and more frequent dosing.⁶²

Drug Interactions Because ethosuximide is not protein bound, displacement interactions do not occur. Valproic acid may inhibit the metabolism of ethosuximide, but only if the metabolism of ethosuximide is near saturation.⁶³

Dosing and Administration A loading dose of ethosuximide is not required. Titration over 1 to 2 weeks to maintenance doses of 20 mg/kg per day usually results in therapeutic concentrations. Data suggest that patients can be managed successfully on once-a-day therapy; however, gastrointestinal distress appears to be dose-related, and the total daily dose is usually divided into two equal doses.⁶⁰

Advantages This drug is very effective in the treatment of absence seizures. It is generally well tolerated and has few pharmacokinetic interactions.

Disadvantages Ethosuximide has a very narrow spectrum of activity.

Place in Therapy Ethosuximide is still a first-line treatment for absence seizures.

Felbamate

Pharmacology and Mechanism of Action At therapeutic doses felbamate appears to act by blocking *N*-methyl-D-aspartate (NMDA) synaptic responses and by modulating GABA_A receptors. At higher doses it may modulate sodium channels and inhibit high-voltage activated calcium channels.⁵⁹

Pharmacokinetics Felbamate is rapidly and well absorbed. The absorption is unaffected by food or antacids. Approximately 40% to 50% of a dose of felbamate is metabolized by hydroxylation and conjugation pathways in the liver, with the remainder being excreted unchanged in the urine. Felbamate displays linear pharmacokinetics.⁶⁴

Adverse Effects The most frequently reported side effects with felbamate prior to marketing were anorexia, weight loss, insomnia, nausea, and headache (sometimes severe). Anorexia and weight loss may be especially problematic in children and in patients with diminished caloric intake. After marketing, felbamate was found to be associated with aplastic anemia and acute liver failure. The onset was between 68 and 354 days of therapy. The approximate rate of occurrence of aplastic anemia is 1 in 3,000 and of hepatitis is 1 in 10,000. Data suggest a possible increased risk for aplastic anemia in patients, especially women, with a history of cytopenia, AED allergy or significant toxicity, viral infection, and/or immunologic problems.^{25,26,65}

Drug Interactions Depending on the drug, felbamate affects the metabolism of the older AEDs through either inhibition or induction. Interactions with warfarin and felbamate also have been reported.⁶⁴

Dosing and Administration The initial starting dose of felbamate is increased at 2-week intervals.

Advantages Felbamate has a unique mechanism of action. It is approved for treating atonic seizures in patients with the Lennox-Gastaut syndrome and is effective in treating patients with partial seizures.

Disadvantages The use of felbamate is limited by the association with aplastic anemia and hepatotoxicity, as well as multiple drug interactions.

Place in Therapy This agent should be reserved for patients not responding to other AEDs.

Gabapentin

Pharmacology and Mechanism of Action Gabapentin was designed to be a GABA agonist but does not react at the GABA receptor, alter GABA uptake, or interfere with GABA transaminase. Gabapentin appears to bind to an amino acid carrier protein and appears to act at a unique receptor. Gabapentin inhibits high-voltage activated calcium channels.⁵⁹ It elevates human brain GABA levels, possibly via alterations in GABA synthesis or reversal of the neuronal GABA transporter, resulting in nonvesicular release of GABA.⁶⁶

Pharmacokinetics Gabapentin is a substrate of the L-amino acid carrier protein in the gut (system L), as well as in the CNS.⁶⁷ This amino acid carrier protein transports the drug across the gut membrane by an active process. The binding of gabapentin to this system is saturable, and gabapentin therefore displays dose-dependent bioavailability that appears to vary considerably between individuals.⁶⁸ Food, including protein-rich meals, does not appear to interfere with gabapentin oral absorption.⁶⁹ Concentrations in human CSF are 5% to 35% of plasma levels, and tissue concentrations are approximately 80% of plasma levels.

Because gabapentin is eliminated exclusively by the kidneys, dosage adjustments are necessary in patients with significantly impaired renal function. In anuric patients, 35% of gabapentin is removed by dialysis.⁷⁰

Adverse Effects Fatigue, somnolence, dizziness, and ataxia are the most frequently reported side effects. Aggressive behavior has been reported in children.⁷¹ The CNS effects of gabapentin are generally less than those of traditional AEDs. A withdrawal reaction characterized by anxiety, insomnia, nausea, sweating, and increased pain has also been reported with abrupt discontinuation in patients taking it for pain.

Drug Interactions Gabapentin does not induce or inhibit liver enzymes; therefore, drug interactions are not likely to occur with gabapentin. There is a 10% reduction in the clearance of gabapentin in patients taking cimetidine and a 20% reduction in the bioavailability if aluminum antacids are taken simultaneously with gabapentin. These interactions are unlikely to be clinically significant.

Dosing and Administration Typical starting doses of gabapentin are 300 mg at bedtime on the first day, increasing to 900 mg/day over 3 days. Faster titration rates (e.g., starting at 300 to 900 mg three times daily) have been well tolerated.⁷² Data from a pharmacokinetic study suggest gabapentin should be given at least four times a day when the total daily dose is 3,600 mg or greater.⁷³ Gabapentin does not appear to be absorbed rectally. Patients with end-stage renal disease maintained on hemodialysis should receive an initial 300- to 400-mg dose with 200 to 300 mg gabapentin given after every 4 hours of hemodialysis.⁷⁰

Advantages Gabapentin has multiple mechanisms of action and is mechanistically different from first-generation AEDs. It is not metabolized and is excreted unchanged by the kidney. Gabapentin has the additional advantages of a broad therapeutic index with minimal CNS adverse effects and no drug interactions. Doses can be escalated rapidly.

Disadvantages Gabapentin is absorbed by an active process that saturates at higher doses. This may require more frequent daily dosing for patients who need doses greater than 3,600 mg/day. Doses exceeding the 3,600 mg/day maximum listed in the package insert may be required in some patients to achieve seizure remission. There is no parenteral formulation.

Place in Therapy Gabapentin is a second-line agent for patients with partial seizures who have failed initial treatment. In addition, although monotherapy trials have no proven efficacy in previously

diagnosed refractory patients, there may be a role for this drug in patients with less severe seizure disorders, such as new-onset partial epilepsy, particularly in the elderly patient. Gabapentin also has been shown to be useful in the treatment of chronic pain and other nonepileptic conditions.

Lamotrigine

Pharmacology and Mechanism of Action A primary mechanism of action for lamotrigine appears to be inhibition of voltage-dependent sodium channels, however, the drug also inhibits high voltage-activated calcium channels.⁵⁹

Pharmacokinetics Lamotrigine is completely and rapidly absorbed, with a bioavailability of 98%. Food does not significantly affect drug absorption. Lamotrigine is also absorbed following rectal administration, although the mean area under the curve (AUC) is approximately 50% of that achieved by oral administration. Lamotrigine clearance is higher in children and lower in the elderly compared with young adults. There are only modest differences in the pharmacokinetics of lamotrigine in the elderly versus younger subjects. Hepatic disease, depending on severity, can influence lamotrigine pharmacokinetics. Approximately 17% of a lamotrigine dose can be removed by hemodialysis, with the half-life being reduced to approximately 13 hours. For patients on dialysis, the half-life is much more prolonged between dialyses (57.4 hours) but shorter during dialysis (13 hours).⁷⁴ The half-life is prolonged in patients with renal failure.

Adverse Effects The most frequently reported side effects of lamotrigine include diplopia, drowsiness, ataxia, and headache.⁷⁵ Adverse effects are more common when lamotrigine is given in combination with other AEDs (e.g., diplopia when given concomitantly with carbamazepine or tremor with valproic acid) as compared with monotherapy, and they can be pharmacodynamic in nature. Lamotrigine can cause rash, which usually appears in the first 3 to 4 weeks of therapy. Patients with a history of developing a rash with another AED are more likely to develop a rash.⁷⁶ The rash typically is generalized, erythematous, and morbilliform and frequently is mild to moderate in severity. However, a Stevens-Johnson reaction also has been reported. Some rashes, especially those which develop early, can necessitate the withdrawal of lamotrigine.⁷⁷ Risk factors for the emergence of more serious rashes appear to be concomitant use of valproic acid and situations where high initial doses or rapid dosage escalation is used. Data from several European monotherapy trials suggest that when dosed appropriately, the incidence of rash from lamotrigine is similar to that of older agents such as carbamazepine and phenytoin. The incidence is higher in children than in adults.

Drug Interactions Lamotrigine does not inhibit liver enzymes and has a low potential for pharmacokinetic interactions with other drugs. It has been found to decrease the bioavailability of the progesterone component (levonorgestrel) of a combination oral contraceptive by 19%. The clinical relevance of this interaction has not been determined.⁷⁸

Concomitant treatment with oral contraceptives can lead to a reduction in the serum concentrations of lamotrigine because of an induction of lamotrigine glucuronidation by the ethinyl estradiol component of the pill.⁷⁹ In addition lamotrigine serum levels can significantly increase during the week off oral contraceptive treatment in some patients on cyclic therapy.⁸⁰

Valproic acid substantially inhibits the metabolism of lamotrigine, with maximal inhibition of lamotrigine metabolism occurring at valproic acid doses and serum concentrations of 500 mg/day and 40 to 50 mcg/mL, respectively.⁷⁵ A pharmacodynamic interaction can occur with concurrent carbamazepine therapy, leading to an increase in CNS side effects.

Dosing and Administration In patients who are taking enzyme-inducing drugs, lamotrigine can be started more rapidly than in patients receiving valproic acid. The maintenance doses are also different. These different doses are critical owing to the relationship between rash, concomitant valproic acid treatment, and the dose escalation rate. Removal of inducers from a lamotrigine regimen may necessitate decreases in lamotrigine doses, whereas removal of valproic acid can necessitate an increase in the lamotrigine dose. A dispersible tablet is available for patients who cannot swallow an oral solid dosage form.^{25,26,65}

Advantages Lamotrigine is potentially a broad-spectrum AED, having efficacy in partial seizures as well as several types of generalized seizures. A pediatric dosage form is available. It neither induces nor inhibits the metabolism of other AEDs. Lamotrigine has linear pharmacokinetics and is not highly protein bound. Lamotrigine appears to be generally well tolerated in both children and elderly patients and does not cause weight gain.

Disadvantages Lamotrigine is associated with rash, especially in patients who start at a high dose, have rapid dose escalation, and/or are taking concurrent valproic acid. Therefore, the initial doses must be low (lower if the patient is on valproic acid) and escalated slowly in order to maximize patient safety. There is no parenteral dosage form.

Place in Therapy Lamotrigine is useful as both adjunctive treatment in patients with partial seizures and as monotherapy. Lamotrigine appears to have comparable effectiveness with more traditional AEDs such as carbamazepine and phenytoin when used as monotherapy. In addition, lamotrigine may be a useful alternative in patients with primary generalized seizure types such as absence and as adjunctive therapy for patients with primary GTC seizures, the latter of which is an approved indication.

Levetiracetam

Pharmacology and Mechanism of Action Levetiracetam, an S-enantiomer pyrrolidone derivative, is chemically unrelated to other available AEDs. Although the precise mechanism of action of levetiracetam has yet to be delineated, it is known that this drug is not active in the classic models used to test antiepileptic drugs. The drug binds in the brain to the synaptic vesicle protein SV2A, which is believed to be important in its activity.⁸¹ This agent may have a unique mechanism of action, including reduction in high-voltage activated calcium ion (Ca^{2+}) currents and delayed-rectifier potassium ion (K^{+}) currents, as well as a unique action on GABA currents. There is some limited evidence that levetiracetam may have *antiepileptogenic effects*, meaning that this compound may be able to prevent the development of epilepsy under certain circumstances.⁸² Clinical confirmation of this animal research is still needed, however.

Pharmacokinetics Levetiracetam is rapidly and completely absorbed following oral administration. The absorption of the drug is not significantly affected by food or enteral nutrition formulas.⁸³ Renal elimination of unchanged parent drug accounts for the majority of drug clearance (66%), with the remainder being metabolized in blood via nonhepatic enzymatic hydrolysis of an acetamide group to inactive metabolites.⁸⁴ This metabolic pathway does not involve either the CYP450 or UGT isozyme systems. Because this drug is eliminated renally, clinicians should anticipate age-related reductions in clearance in elderly patients. Conversely, levetiracetam clearance appears to be approximately 40% higher in children than in adults. In addition patients with severe liver cirrhosis should initially receive one-half the recommended starting dose because of a 57% decrease in clearance of the drug.⁸⁵ Currently, data are sparse regarding serum concentration–effect relationships, so the role of therapeutic drug level monitoring remains unclear.

Adverse Effects Adverse effects appear to be modest, with sedation, fatigue, and coordination difficulties being the most common CNS effects. In children and young adults, behavioral disorders including agitation, irritability or somnolence/lethargy are the most frequently reported central nervous side effects.⁸⁶ The mechanism underlying these effects is unknown. Formal studies evaluating the cognitive effects of this medication have not yet been conducted.^{25,26,65}

Drug Interactions Levetiracetam neither inhibits nor induces the CYP450, UGT, or epoxide hydrolase enzyme systems, and in-vitro data predict a low potential for pharmacokinetic interactions. Levetiracetam does not appear to interact with other AEDs, warfarin, digoxin, or oral contraceptive drugs.^{87,88}

Dosing and Administration Levetiracetam is available orally as well as parenterally, the latter for maintenance dosing only. The intravenous (IV) product has not been tested for intramuscular (IM) use, and therefore should not be administered IM. The typical initial dose is given twice daily, with dosage increments every 2 weeks. In order to minimize CNS side effects, clinicians can consider initiating the drug at one-half this rate. The IV formulation should be given at the same frequency and dose as the oral product. Although not FDA approved, the oral dose of levetiracetam has been titrated rapidly up to 3,000 mg in 3 days in some intractable seizure patients with improvement seen in their seizures after day 2.⁸⁹

Advantages Levetiracetam has a novel, although unknown, mechanism of action. It has linear pharmacokinetics and is not metabolized by the cytochrome P450 system. No significant drug interactions, including with oral contraceptives, have been reported. Initial doses can be effective. The drug appears to be well tolerated, with transient sedation being the most troublesome adverse effect in most individuals.

Disadvantages Dose adjustments are needed for patients with decreased renal function, and slower dose escalation may be needed to avoid CNS adverse effects. Behavioral problems can limit therapy in some patients.

Place in Therapy Currently, levetiracetam is indicated for patients with partial seizures who have failed initial therapy. Its role as monotherapy for partial seizures remains to be clarified. The drug was recently approved as adjunctive treatment for myoclonic seizures in patients with juvenile myoclonic epilepsy. Its role as adjunctive treatment in other generalized seizures disorders remains to be defined.

Oxcarbazepine

Pharmacology and Mechanism of Action Oxcarbazepine, which is structurally related to carbamazepine, is a prodrug that is rapidly converted to a 10-monohydrate derivative (MHD), which is the active component. The mechanism of action of oxcarbazepine is similar to that of carbamazepine and perhaps lamotrigine. Oxcarbazepine and MHD block voltage-sensitive sodium channels, modulate the voltage-activated calcium currents, and increase potassium conductance. Interestingly, however, oxcarbazepine can display differing affinities for both sodium channels and Ca^{2+} channels compared with older drugs such as carbamazepine.⁹⁰ Whereas carbamazepine may modulate L-type Ca^{2+} channels, oxcarbazepine appears to modulate N- and P-type Ca^{2+} channels.⁹¹ Whether these differences lead to differing patterns of clinical effectiveness is still uncertain. It has no significant interactions with brain neurotransmitters or modulation of receptor sites.

Pharmacokinetics Oxcarbazepine is absorbed completely and is metabolized extensively by noninducible cytosolic ketoreductase to MHD.⁹² The MHD is inactivated by glucuronide conjugation and eliminated by the kidneys. Oxcarbazepine and its active metabolite do not undergo autoinduction. The relationship between dose and

serum concentration is linear. Children 2 to 6 years of age need larger doses to achieve the same serum concentration, suggesting a more rapid clearance. The maximal drug concentration (C_{max}) and bioavailability of MHD in elderly volunteers were higher than in younger volunteers, and the elimination rate was slower, possibly reflecting decreased renal elimination. Patients with significant renal impairment may require a dosage reduction.

Adverse Effects Oxcarbazepine has been in clinical use worldwide since 1990 and was marketed in more than 50 countries prior to approval in the United States. In U.S. clinical trials the most frequently reported adverse events were dizziness, nausea, headache, diarrhea, vomiting, upper respiratory tract infections, constipation, dyspepsia, ataxia, and nervousness. In comparative trials, oxcarbazepine generally caused fewer side effects than phenytoin, valproic acid, or carbamazepine. Dizziness may be more common in elderly patients than in young adults. CNS adverse effects appear to be far more common at doses greater than 1,200 mg/day. Hyponatremia, defined as a plasma sodium concentration of less than 125 mmol/L, has been reported in up to 25% of patients taking oxcarbazepine and occurs more often in elderly patients. The incidence of hyponatremia with oxcarbazepine is higher than that seen with carbamazepine. Clinicians should be particularly watchful in patients receiving concomitant sodium-depleting drugs such as diuretics. Hyponatremia appears to occur less frequently in children. Clinicians should consider monitoring serum sodium levels following the initiation of oxcarbazepine, and they should instruct patients regarding the symptoms of hyponatremia. Approximately 25% to 30% of patients who develop a rash with carbamazepine will experience a similar reaction with oxcarbazepine.^{25,26,65} The tolerability of oxcarbazepine has not been compared with that of extended-release formulations of carbamazepine that have lower peaks and potentially fewer side effects than immediate-release carbamazepine formulations.

Drug Interactions Oxcarbazepine decreases the bioavailability of ethinyl estradiol and levonorgestrel.⁹³ Women concurrently taking oral contraceptives should be counseled about the potential for contraceptive failure. Unlike carbamazepine, there are no interactions between cimetidine, erythromycin, or warfarin and oxcarbazepine. The administration of oxcarbazepine in doses greater than 1,200 mg with phenytoin has resulted in a 40% increase in the concentration of phenytoin, consistent with inhibition of CYP450 2C19. Oxcarbazepine treatment also may cause modest declines in lamotrigine serum concentrations, suggesting induction of UGT isozymes.⁹⁴

The replacement of carbamazepine with oxcarbazepine may result in a drug interaction because an enzyme-inducing drug is being removed.

Dosing and Administration Doses and titration schedules differ in regards to whether the drug is used for mono- or adjunctive therapy in adults vs children. Although not FDA approved, doses up to 60 mg/kg/day have been used in infants and children younger than 4 years of age to successfully control partial-onset seizures.⁹⁵ In patients being converted from carbamazepine, the typical maintenance dose of oxcarbazepine is 1.5 times the carbamazepine dose.

Advantages The efficacy of oxcarbazepine is comparable with that of carbamazepine, phenytoin, and valproic acid. It may be better tolerated than phenytoin as monotherapy and therefore less likely to be discontinued.⁹⁶ It has been approved in many countries, and there is broad international experience with this drug.

Disadvantages About 30% of patients who have experienced a rash with carbamazepine have a cross-reaction with oxcarbazepine. There are more reports of hyponatremia with oxcarbazepine, especially in patients at risk. Replacing carbamazepine with oxcarbazepine can result in interactions owing to the removal of carbamazepine. Enzyme-inducing drugs can increase the clearance of MHD. This

drug is not likely to be effective in seizure types where carbamazepine is ineffective, such as absence or myoclonic seizures.

Place in Therapy Oxcarbazepine is indicated for use as monotherapy or adjunctive therapy in the treatment of partial seizures in adults and as monotherapy and adjunctive therapy in the treatment of partial seizures in patients as young as 4 years of age with epilepsy. It is also a potential first-line drug for patients with primary generalized convulsive seizures. Oxcarbazepine can also be effective in patients not demonstrating a response to carbamazepine.

Phenobarbital

Pharmacology and Mechanism of Action Phenobarbital may elevate seizure threshold by interacting with GABA receptors to facilitate intrinsic chloride channel function, as well as by blocking high voltage-activated calcium channels. Some of the drug's activity may also be caused by its ability to block α -amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) and kainate receptors.⁵⁹

Pharmacokinetics Phenobarbital is absorbed rapidly and completely regardless of whether it is given orally, intramuscularly, or rectally.⁶³ It penetrates the brain at a rate comparable with that of phenytoin, and peak concentrations are achieved 3 to 20 minutes after an IV dose.

Drugs affecting liver enzymes can alter phenobarbital metabolism, but phenobarbital clearance is not affected by liver blood flow. The elimination of phenobarbital is linear. Because tubular reabsorption of phenobarbital is pH dependent, the amount excreted renally can be increased by giving diuretics and urinary alkalinizers.⁶³ Clearance decreases in the elderly.⁹⁷

Adverse Effects CNS side effects are the primary factors limiting the use of phenobarbital. Tolerance usually develops to initial complaints of fatigue, drowsiness, sedation, and depression. In children, paradoxically, the primary side effect is hyperactivity. Phenobarbital also may cause porphyria and rash, including serious rashes such as Stevens-Johnson.⁹⁸

Drug Interactions Phenobarbital is a potent enzyme inducer and can increase the elimination of any drug metabolized by CYP450- or UGT-mediated metabolism. Cimetidine and chloramphenicol inhibit phenobarbital metabolism, necessitating a decrease in dose. Ethanol increases the metabolism of phenobarbital.⁶³

Dosing and Administration In nonacute situations, phenobarbital should be started in low doses and titrated upward. The dose-concentration relationship is linear. Because the half-life of phenobarbital is long, doses can be given once daily, and bedtime dosing may minimize CNS depression.

Advantages Phenobarbital has linear and predictable pharmacokinetics. Multiple dosage forms (e.g., oral solid, oral liquid, IM, and IV) are available, and it is the most inexpensive AED.

Disadvantages Phenobarbital is associated with significant side effects. These include delayed intellectual development and hyperactivity in children and significant cognitive impairment in adults. It is an enzyme inducer and interacts with many other drugs metabolized by the cytochrome P450 system. Phenobarbital has a very long half-life, and dosage adjustments should not be made more often than every 2 to 3 weeks. The parenteral product contains 67% to 75% propylene glycol and 10% alcohol, which can result in significant respiratory depression and hypotension if infused too rapidly.

Place in Therapy Phenobarbital is the drug of choice for neonatal seizures but in other situations is reserved for patients who have failed therapy with other AEDs. It may be useful given intravenously in refractory status epilepticus.

Phenytoin

Pharmacology and Mechanism of Action The primary mechanism of action of phenytoin is believed to be caused by its ability to inhibit voltage-dependent sodium channels.⁵⁹

Pharmacokinetics The pharmacokinetics of phenytoin are complex and fascinating. For a more in-depth understanding, the reader is referred to a more extensive review.⁹⁹ The oral absorption of phenytoin is almost complete. Dissolution is the rate-limiting step, and absorption may be saturable at higher doses, such as those used for oral loading doses. Absorption following IM administration of phenytoin is erratic and delayed, and IM injections are painful, however, IM absorption following fosphenytoin is rapid and well tolerated.

Phenytoin enters the brain rapidly and is redistributed to other body tissues, including breast milk and the placenta. Phenytoin competes for albumin sites with other highly protein bound drugs. It is essential to know the patient's serum albumin level in interpreting the serum concentrations of phenytoin.¹⁰⁰ Patients with significant renal dysfunction will have altered phenytoin protein binding. Obesity increases the volume of distribution of phenytoin.

Phenytoin is metabolized in the liver by parahydroxylation. The major isoforms responsible for the metabolism of phenytoin are CYP 2C9 and CYP 2C19; the former displays polymorphism, which may affect the response to phenytoin.⁵⁹ Phenytoin displays Michaelis-Menton pharmacokinetics, which means that the metabolism of phenytoin saturates at doses used clinically. The clinical importance of this is that a small change in dose can result in a disproportionately large increase in serum concentrations, potentially leading to toxicity. In some patients the metabolism of phenytoin can saturate even at low serum concentrations within the therapeutic range. The metabolism of phenytoin decreases with age.

Adverse Effects When phenytoin is initiated, the CNS depressant effects can result in lethargy, fatigue, incoordination, blurred vision, higher cortical dysfunction, and drowsiness. These effects usually are transient and can be minimized by slow dosage titration. At very high concentrations greater than 50 mcg/mL, phenytoin can exacerbate seizures.

It is difficult to determine whether the chronic side effects of phenytoin are concentration- or duration-dependent. One of the more common chronic side effects is gingival hyperplasia. Good oral hygiene can minimize gingival hyperplasia and should be encouraged. Other chronic effects include vitamin D deficiency, osteomalacia, carbohydrate intolerance, immunologic disturbances, hypothyroidism, and peripheral neuropathy. Phenytoin is associated with rare hypersensitivity or idiosyncratic reactions resulting in rashes, Stevens-Johnson syndrome, pseudolymphoma, bone marrow suppression, lupus-like reactions, and hepatitis.¹⁰¹

Drug Interactions Phenytoin is associated with numerous drug interactions involving altered absorption, metabolism, and protein binding that can enhance or reduce its effects. Phenytoin is an inducer of both CYP450 and UGT isozymes. The absorption of phenytoin can be increased or decreased with the administration of food depending on the composition of the meal. The bioavailability of phenytoin suspension can be decreased in patients receiving continuous enteral nutrient tube feedings. However, a single-dose study of simultaneous administration of enteral feeding found no difference in phenytoin bioavailability, suggesting that the mechanism was something other than physical contact.⁹⁹

Phenytoin decreases folic acid absorption, and folic acid enhances the clearance of phenytoin. Replacement of folic acid can reduce phenytoin concentration and result in loss of efficacy.⁹⁹

Dosing and Administration Four dosage forms are available for oral administration of phenytoin (see Table 58–9), and changing

dosage forms can lead to changes in phenytoin serum concentrations. Whether or not a dosage form uses the parent drug or salt form should be considered when changing from one dosage form to another. Phenytoin capsules are designated as immediate-release or extended-release. Only the extended-release capsules should be used in once-a-day dosing. Particle size rather than formulation may determine the rate of absorption. Phenytek has also been marketed in the United States as an extended-release dosage form of phenytoin.

If oral administration is not feasible, IV administration of phenytoin is preferred, as IM administration can cause tissue necrosis. Fosphenytoin is a prodrug for phenytoin and is available as a parenteral dosage form. It is very water-soluble and is converted rapidly to phenytoin systemically. Fosphenytoin can be given rapidly intravenously and intramuscularly with reliable absorption and minimal pain. It is significantly better tolerated than phenytoin.

Because of saturable absorption, an oral loading dose, such as 20 mg/kg, should be divided by four and given at 6-hour intervals. Subsequent dosage adjustments should be done cautiously owing to its nonlinear elimination. One author has suggested that if the serum concentration is less than 7 mcg/mL, the daily dose should be increased by 100 mg; if the serum concentration is between 7 and 12 mcg/mL, the daily dose can be increased by 50 mg; and if the serum concentration is greater than 12 mcg/mL, the daily dose can be increased by 30 mg or less. These increases are reported to result in less than 10% of patients achieving a phenytoin serum concentration greater than 25 mcg/mL.¹⁰²

Advantages Phenytoin has been used for more than 65 years, and its risk-to-benefit ratio is well established. It is available in oral solid, oral liquid, extended-release oral solid, and parenteral (phenytoin and fosphenytoin) dosage forms, allowing flexibility in dosing and use in emergent situations. In some patients the extended release dosage form can be given once a day with good seizure control.

Disadvantages Phenytoin displays Michaelis-Menton pharmacokinetics, meaning that the metabolism saturates at doses given clinically. This makes phenytoin a challenging drug to dose. Also, phenytoin is an inducer of cytochrome P450 isozymes, is metabolized by cytochrome P450 enzymes, and is highly protein bound. Therefore, many drug interactions are associated with coadministration of this agent. Phenytoin is associated with multiple significant adverse effects.

Place in Therapy Phenytoin has long been a first-line AED for primary generalized convulsive and partial seizures. Its use in therapy may be reevaluated as more experience is gained with newer AEDs.

Pregabalin

Pharmacology and Mechanism of Action Pregabalin's mechanism of action is unknown, however, it is proposed that the binding of the drug to the subunit of the voltage-gated calcium channel may be responsible for a large part of its activity. This binding results in a decrease in the release of several excitatory neurotransmitters including glutamate, noradrenaline, substance P, and calcitonin gene-related peptide (CGRP).¹⁰³

Pharmacokinetics Pregabalin is a substrate of the L-amino acid carrier protein in the CNS. It does not display dose-dependent bioavailability. Food decreases the rate but not the bioavailability of the drug.¹⁰⁴

Pregabalin is eliminated from the body primarily by renal excretion as an unchanged drug, and therefore dosage adjustment is required in patients with significantly impaired renal function. In anuric patients, 50% of the dose is removed by hemodialysis.¹⁰⁴

Adverse Effects Dizziness, somnolence, ataxia, blurred vision, and weight gain are the most frequently reported side effects. It is

not known if pregabalin causes aggressive behavior in children. A withdrawal reaction characterized by anxiety, nervousness, and irritability has been noted in patients being treated for generalized anxiety on abrupt discontinuation of the drug.¹⁰⁵

Drug Interactions Because pregabalin is predominantly excreted unchanged in the urine and undergoes negligible metabolism in humans, drug interactions are unlikely to occur.

Dosing and Administration Starting doses of pregabalin are divided into twice or thrice daily intervals. The manufacturer recommends that patients with end-stage renal disease maintained on hemodialysis should receive a 25 to 75 mg daily dose with 25 to 75 mg given after every 4 hours of hemodialysis.

Advantages Pregabalin is somewhat more potent than gabapentin without the dose-limited gastrointestinal absorption properties. The drug has minimal CNS side effects and no drug interactions.

Disadvantages Pregabalin is a controlled substance class V. Like gabapentin it can cause weight gain and peripheral edema especially as the dose is increased. There is no parenteral formulation available.

Place in therapy Pregabalin is a second-line agent for patients with partial seizures who have failed initial treatment. Pregabalin is also useful in the treatment of chronic neuropathic pain and generalized anxiety disorder.¹⁰⁵

Tiagabine

Pharmacology and Mechanism of Action Tiagabine is a potent and specific inhibitor of GABA uptake into glial and other neuronal elements. Thus, tiagabine enhances the action of GABA by decreasing its removal from the synaptic space.¹⁰⁶

Pharmacokinetics Tiagabine is absorbed quickly and nearly completely after oral administration. There is a linear relationship between daily doses and serum concentrations. Children eliminate tiagabine slightly faster than adults. Subjects with hepatic impairment have higher and more prolonged plasma concentrations of total and unbound drug. Renal dysfunction does not change its pharmacokinetics.¹⁰⁶ Tiagabine displays diurnal elimination, i.e., lower evening serum levels compared to morning levels.

Adverse Effects The most frequently reported adverse effects of tiagabine are dizziness, asthenia, nervousness, tremor, diarrhea, and depression. Adverse events usually are mild to moderate in severity and transient, and most were associated with dose titration.¹⁰⁷ CNS side effects can be diminished by taking tiagabine with food, thus slowing the absorption rate. Tiagabine has increased the incidence of nonconvulsive status epilepticus in patients with chronic refractory partial epilepsy.¹⁰⁸ In addition, there have been reports of status epilepticus or new onset seizures occurring in patients without a history of epilepsy, which is noted in the manufacturer's drug labeling.

Drug Interactions Food decreases the rate but not the extent of absorption. Tiagabine is displaced from protein by naproxen, salicylates, and valproate. However, tiagabine does not displace phenytoin, valproic acid, amitriptyline, tolbutamide, or warfarin.¹⁰⁶

Dosing and Administration A clear dose-response has been demonstrated, and the minimal effective adult dose level is 30 mg/day. The initial dose is increased weekly.

Advantages Tiagabine has a specific, known mechanism of action. It is the first drug marketed in the United States that acts only on GABA reuptake. This drug has linear pharmacokinetics and is not reported to interact with other drugs.

Disadvantages Initially high and rapid dosage escalation is associated with increased CNS side effects. Therefore, the drug must be

started at a low dose and titrated gradually to patient response. Lower doses may be needed in patients with liver disease. Tiagabine is metabolized by CYP450 3A4 enzymes, and other drugs may alter its clearance. There is no parenteral formulation.

Place in Therapy Tiagabine is considered a second-line therapy for patients with partial seizures who have failed initial therapy. It does not appear to have a role in primary generalized seizure types.

Topiramate

Pharmacology and Mechanism of Action Topiramate is a sulfamate-substituted monosaccharide that has multiple modes of action involving voltage-dependent sodium channels, GABA receptor subunits, high voltage calcium channels, and kainate/AMPA subunits.⁵⁹ The drug also inhibits the enzyme carbonic anhydrase, although this activity does not appear to play a major role in its mechanism of action.⁵⁹

Pharmacokinetics Although generally considered to have linear absorption and elimination pharmacokinetics, a greater than proportional increase in both maximal peak concentration and area under the plasma-concentration-versus-time curve has been observed and probably is explained by saturable binding of the drug to erythrocytes.¹⁰⁹ Approximately 50% of the dose is excreted unchanged renally; however, its metabolism is increased by approximately 50% when topiramate is given with enzyme-inducing AEDs. Renal tubular reabsorption may be involved prominently in the renal handling of topiramate.¹¹⁰

Adverse Effects The main adverse events of topiramate are ataxia, impaired concentration, memory difficulties, attentional deficits, confusion, dizziness, fatigue, paresthesia, somnolence, and “thinking abnormally,” which rarely has included psychosis. Most of these occurred during rapid titration and at higher doses.¹¹¹ Word-finding difficulties can be a problem with topiramate and can occur in a significant number of patients, especially patients with left posterior temporal lobe epilepsy or simple partial seizures.¹¹² There can be an increased incidence of cognitive dysfunction in patients receiving concomitant therapy with topiramate, valproic acid, or phenobarbital. Nephrolithiasis has occurred in 1.5% of patients receiving topiramate, which is two to four times the incidence in the general population. Patients should be encouraged to maintain adequate fluid intake in order to minimize this problem. Topiramate can cause metabolic acidosis. Risk factors for this condition include patients with renal disease, those with severe respiratory disorders, status epilepticus, diarrhea, surgery, and ketogenic diet. It has been observed at doses as low as 50 mg/day. Metabolic acidosis in part may explain the anorexia and weight loss seen with this drug.⁶⁵

Drug Interactions Oral clearance of digoxin is slightly increased when topiramate is added. Topiramate coadministration can result in increased phenytoin serum concentrations in some patients, an effect consistent with in-vitro studies showing an inhibitory effect of topiramate on the CYP 2C19 isoform. The variable response can be explained by the intersubject variability in the proportion of phenytoin clearance attributed to CYP 2C19 metabolism and whether the patient is a homozygous or heterozygous carrier of the mutant allele responsible for the CYP 2C9 and/or CYP 2C19 “poor metabolizer” phenotype. Topiramate can modestly increase the oral clearance of valproic acid and increase formation of the 4-ene-valproic acid (VPA) metabolite. However, the clinical significance of this interaction is unclear. Topiramate increases the clearance of ethinyl estradiol in a dose-dependant manner. Topiramate doses of less than 200 mg/day are unlikely to alter oral contraceptive pharmacokinetics.¹¹³

Dosing and Administration Topiramate should be titrated slowly to avoid adverse events with dosage increments every 1 to 2 weeks.

For patients on other AEDs, doses of greater than 600 mg/day do not appear to lead to improved efficacy and can cause increased adverse effects; however, higher doses can prove beneficial to individual patients who tolerate them.¹¹⁴

Advantages Topiramate has multiple mechanisms of action and is a broad-spectrum AED. The kidney mainly eliminates it, although some liver metabolism occurs, especially if given concomitantly with enzyme inducers. It has linear pharmacokinetics and few drug interactions.

Disadvantages With rapid dosage escalation, topiramate can compromise cognitive functioning, including impaired word finding and short-term memory. Therefore, low initial doses should be used, and the dose must be titrated slowly. Renal stones and weight loss also have been associated with topiramate use. The dose should be decreased in patients with renal failure. There is no parenteral formulation.

Place in Therapy Topiramate is a first-line AED for patients with partial seizures. The drug is also approved for the treatment of tonic-clonic seizures in primary generalized epilepsy.

Valproic Acid/Divalproex Sodium

Pharmacology and Mechanism of Action Initially it was believed that valproic acid increased GABA by inhibiting its degradation or by activating its synthesis. Although this may explain in part the effects of valproic acid, the time course for the increase in GABA compared with the onset of anticonvulsant effects indicates that alterations of the synthesis and degradation of GABA do not fully explain the antiseizure activity of valproic acid. It has been proposed that valproic acid may potentiate postsynaptic GABA responses, may have a direct membrane-stabilizing effect, and may affect potassium channels.¹¹⁵

Pharmacokinetics Valproic acid appears to be absorbed completely from available oral dosage forms when administered on an empty stomach.¹¹⁵ However, the rate of absorption differs among preparations. Peak concentrations occur in 0.5 to 1 hour with the syrup, 1 to 3 hours with the capsule, and 2 to 6 hours with the enteric-coated tablet.¹¹⁵ The extended-release formulation (Depakote-ER) is FDA approved for use in both patients with migraine headache and epilepsy. It should be noted, however, that the bioavailability of this formulation is approximately 15% less than that of enteric-coated divalproex sodium (Depakote).

Valproic acid is extensively bound to albumin, and this binding is saturable. Accordingly, the valproic acid free fraction will increase as the total serum concentration increases. Because of this saturable binding, measurement of unbound serum concentrations may be a better monitoring parameter than the total valproic acid serum concentration, especially at higher concentrations or in patients with hypoalbuminemia.⁶³

The primary route of valproic acid metabolism is β -oxidation, although up to 40% of a dose may be excreted as the glucuronide. At least 10 metabolites of valproic acid have been identified. Some of these may have weak anticonvulsant activity, and at least one metabolite may be responsible for the hepatotoxicity reported with valproic acid. One of the lesser oxidative metabolites, 4-ene-VPA, causes significant hepatotoxicity in rats. The formation of this metabolite is increased when valproic acid is given with enzyme-inducing drugs.¹¹⁵ Valproic acid displays diurnal elimination with lower evening serum levels occurring than morning levels.

Adverse Effects The most frequently reported side effects are gastrointestinal complaints (up to 20%), including nausea, vomiting, and anorexia, as well as weight gain. Pancreatitis is rare. The gastrointestinal complaints may be minimized but not totally alleviated with the enteric-coated formulation or by giving the drug with food.

Alopecia and hair changes are temporary, and hair growth returns even with continued dosing. Weight gain can be significant for many patients and is associated with an increase in fasting insulin and leptin serum levels.¹¹⁶ The increase in serum insulin is believed to be caused by the inhibition of metabolism of insulin by the liver.¹¹⁷ This has led to the development of insulin resistance in obese male and female subjects.¹¹⁵ Valproic acid causes minimal cognitive impairment.¹¹⁵

The most serious side effect reported with valproic acid is hepatotoxicity. Hyperammonemia is common (50%) but does not necessarily imply liver damage; however, fatalities have been attributed to valproic acid hepatotoxicity. Most deaths have occurred in patients who were younger than 2 years of age, mentally retarded, and receiving multiple AEDs. Hepatotoxicity occurred early in the course of therapy. Patients who complain of nausea, vomiting, lethargy, anorexia, and edema in the first 6 to 12 months of therapy should have liver function tests done. Multiple-AED therapy can alter the metabolism of valproic acid, leading to increased formation of the potentially liver-toxic 4-ene-VPA. Valproic acid has been shown to alter carnitine metabolism, and it has been postulated that a deficiency of carnitine alters fatty acid oxidation that could lead to both liver toxicity and hyperammonemia.¹¹⁸ However, valproic acid hepatotoxicity has occurred in a patient taking supplemental carnitine, and a prospective study demonstrated no effect on well-being when carnitine was added. Although carnitine can ameliorate hyperammonemia in part, it is expensive, and there are only limited data to support routine supplemental use in patients taking valproic acid.¹¹⁹

Thrombocytopenia and alterations in platelet aggregation occur in the patients receiving valproic acid, and these phenomena are related to serum concentration. These blood coagulopathies can occur more frequently in children than in adults.¹²⁰

Drug Interactions Because it is highly protein bound, other highly protein-bound drugs can displace valproic acid. Free fatty acids and aspirin can alter valproic acid binding by displacement.

Valproic acid is an enzyme inhibitor that can inhibit specific cytochrome P450 isozymes, epoxide hydrolase, and UGT isozymes. The addition of valproic acid to phenobarbital results in a 30% to 50% decrease in the clearance of phenobarbital and significant toxicity if the dose of phenobarbital is not reduced.

Dosing and Administration Valproic acid in some patients may have a half-life sufficiently long to permit once-daily dosing with enteric-coated divalproex, more frequent dosing is the norm. Based on half-life data, twice-daily dosing is feasible with any valproic acid dosage form; however, children and other patients taking enzyme inducers can require dosing three to four times daily.⁶³ The serum concentration-dose relationship is curvilinear (e.g., the concentration-dose ratio decreases with increasing dose) probably because of increasing free concentrations and a resulting increase in clearance.⁶³

Valproic acid is available as a soft gelatin capsule, an enteric-coated tablet, a syrup, a “sprinkle capsule,” an extended-release formulation designed for once-daily dosing, and an IV formulation for replacement of oral therapy or in situations where rapid loading of valproic acid is deemed necessary.¹¹⁵ This parenteral formulation must not be given intramuscularly because it can cause tissue necrosis. The sprinkle capsule, designed to be opened and mixed with food, has a slower rate of absorption, which results in fewer fluctuations in the peak-to-trough ratio. The syrup is absorbed more rapidly than any solid dosage form. The enteric-coated tablet is not sustained-release; it consists of sodium divalproex, which must be metabolized in the gut to valproic acid. It is enteric coated to reduce the incidence of gastrointestinal distress. The enteric coating does cause delayed absorption, although once the enteric coating dissolves, sodium divalproex has absorption, metabolism, and elimination rates similar to those of the gelatin capsule. If a patient is switched from Depakote to Depakote-ER, the dose should be increased by 14% to 20%. Depakote-ER may be given once daily.

Advantages Valproic acid is available in multiple dosage formulations. The IV formulation is especially well tolerated. It has a wide therapeutic index and can be considered a broad-spectrum AED. It also can be useful in other neurologic or psychiatric disorders, including migraine headache and bipolar disorder.

Disadvantages Some patients report significant weight gain with valproic acid, and this can limit compliance. Valproic acid is also associated with other side effects, such as alopecia, tremor, pancreatitis, polycystic ovary disease, and thrombocytopenia. It has been associated with hepatic necrosis in young children. Valproic acid is an enzyme inhibitor and is involved in multiple drug-drug interactions.

Place in Therapy Valproic acid is first-line therapy for primary generalized seizures such as myoclonic, atonic, and absence seizures. It can be used as both monotherapy and adjunctive therapy for partial seizures, and it can be very useful in patients with mixed seizure disorders.

Zonisamide

Pharmacology and Mechanism of Action Zonisamide, a synthetic 1,2-benzisoxazole derivative classified as a sulfonamide, is chemically different from other AEDs. In animal testing it was demonstrated to be a broad-spectrum AED. It is believed to exert its antiepileptic effect by inhibition of slow sodium channels, by blockade of T-type Ca^{2+} channels, and possibly by inhibition of glutamate release. It also has a weak carbonic anhydrase inhibitory effect.¹²¹

Pharmacokinetics Zonisamide is well absorbed reaching a maximum peak concentration in 2 to 5 hours. Zonisamide is metabolized by CYP 3A4 and to a much lesser extent by CYP 2C19 and CYP 3A5. Approximately 30% is excreted unchanged in the urine. Zonisamide is distributed to most tissues, but the drug is concentrated in the red blood cells. Zonisamide crosses the placenta. The concentration in breast milk is similar to that in the plasma.¹²¹

Adverse Effects The most common adverse effects of zonisamide include somnolence, dizziness, anorexia, headache, nausea, agitation, word-finding difficulties, and irritability. Adverse effects may be more common during rapid dose escalation. Because zonisamide is structurally related to sulfonamides, hypersensitivity reactions can occur (0.02% of patients), and zonisamide should be used with caution (if at all) in patients with a confirmed history of allergy to sulfonamide compounds. A 2.6% incidence of symptomatic kidney stones has been reported in patients treated in the United States.¹²² Because of reports of modest, reversible declines in renal function in some patients, monitoring of renal function may be advisable for certain patients. Oligohidrosis has been reported. In addition, modest weight loss has been reported with this agent.^{25,26,65}

Drug Interactions Zonisamide does not inhibit or induce the cytochrome P450 system.

Dosing and Administration Daily doses should be increased every 2 weeks to response. Zonisamide is stable for 48 hours when mixed with water, apple juice, or pudding for patients who have trouble swallowing oral solid dosage forms.

Advantage Zonisamide has multiple mechanisms of action and may be a broad-spectrum AED. There is broad international experience with this drug. It has a very long half-life, which is suitable for once- or twice-daily dosing. Once-daily dosing is associated with more fluctuations around the mean concentration and perhaps more side effects. Patients may experience modest weight loss with this drug.

Disadvantage The dose of zonisamide should be titrated slowly to patient response. Renal stones and oligohidrosis also have been

associated with zonisamide. In addition, cognitive impairment can occur, especially if dosage is escalated rapidly.

Place in Therapy Zonisamide is currently approved for the adjunctive treatment of partial seizures. Thus far, insufficient data exist to support its use as initial monotherapy. Zonisamide is potentially effective in a variety of partial and primary generalized seizure types.

PHARMACOECONOMIC CONSIDERATIONS

CLINICAL CONTROVERSY

The place in therapy of the newer drugs is still being determined. The cost of the newer AEDs generally is much higher than that of the older drugs. Given that, in general, the efficacy of the newer drugs is comparable with that of the older agents, many clinicians (and patients) have been slow to adopt this newer generation of drugs. It is important to recognize that overall effectiveness encompasses both efficacy and tolerability assessments. Generally speaking, the newer generation of AEDs possess fewer adverse effects and seems to be better tolerated than older, far less expensive agents such as the barbiturates. Some may also have less costly long-term adverse effects such as effects on bone metabolism or the fetus, and they may cause fewer drug interactions, which require higher doses of drugs to avoid treatment failures. These differences may well justify the difference in cost, however, this needs to be determined on an individual basis.

The direct costs of epilepsy include the cost of the drug, treatment of adverse events, emergency room visits, drug levels, laboratory tests, physician visits, rehabilitation, and transportation. Indirect costs include the costs associated with time lost from work, the inability to get a job, decreased productivity, and mortality.

It is difficult to assess the entire cost of epilepsy to society. Pashko and coworkers,¹²³ using a cohort of Pennsylvania Medicaid patients, estimated that the total direct cost of epilepsy is in excess of \$10 billion annually, with the majority of the per-patient costs incurred for inpatient hospitalization (uncontrolled seizures or treatment-related toxicity). Another study suggested that the direct costs of epilepsy made up approximately 37% of the total costs, with indirect costs accounting for the remainder.¹²⁴ This study also indicated that the costs were much less for a patient who is well controlled than for a patient who is poorly controlled. Drug costs in the Pashko study accounted for approximately 10% of the total costs of epilepsy. In another study, the cost-effectiveness of some of the newer drugs (lamotrigine, vigabatrin, and gabapentin) was estimated for the first year of drug therapy. There was little difference in initial costs, but gabapentin, with fewer adverse effects, resulted in cost savings.¹²⁵ The methodology used in this study has been criticized. There have been no pharmacoeconomic studies comparing the older, less expensive AEDs with the newer, more expensive drugs.

Providing the best quality of life possible is a treatment goal for patients with epilepsy, although maintaining a balance between side effects and the number of seizures experienced by patients is very important.¹²⁶ Quality of life also takes into account all the concerns of patients with epilepsy, including their social and economic concerns. This can best be assessed by the patient. Complete seizure freedom leads to the best quality of life. In one study, driving was listed as the most important concern by 28% of patients, followed by employment (21%), independence (9%), safety (6%), AED side effects (5%), seizure unpredictability (5%), and seizure avoidance (5%).¹²⁷ Assessment of quality of life as a therapeutic outcome ultimately may be more meaningful than measuring blood levels of the AEDs. It is clear that the cheapest drugs in epilepsy (e.g., phenobarbital) are not the best because of the number of side effects. Drug therapy that would

control seizures, decrease side effects, improve the quality of life, and reduce the use of other healthcare resources would be cost-effective. Because epilepsy treatment continues to be highly individualized, the drug or combination of drugs that controls seizures with the least number of side effects will be the drug of choice for that patient no matter how expensive the drug acquisition cost.

Because many patients with epilepsy require minimal variation in blood concentrations to prevent seizures and avoid side effects, generic prescribing for epilepsy remains controversial. One study suggested that the money saved by generic prescribing is outweighed by the negative health gain for the person with epilepsy, increased work in general practice, and increased social costs.¹²⁸

EVALUATION OF THERAPEUTIC OUTCOMES

A therapeutic range should be established for each patient. This range should define concentrations that result in minimal side effects and optimal seizure control. This therapeutic plasma concentration range should be used to identify the appropriate patient-specific dose. Patients should be monitored chronically for seizure control, comorbid conditions, social adjustment (including quality-of-life assessments), drug interactions, compliance, and adverse effects. Periodic screening for comorbid neuropsychiatric disorders such as depression and anxiety is also important. Clinical response is more important than the serum drug concentration.

Outcomes can be assessed by prospective clinical monitoring, drug utilization review, and quality-of-life assessments. Clinical monitoring involves identifying the number and type of seizures. Patients should be given a seizure diary, and the severity as well as the frequency of seizures should be monitored. There should be a decrease in the number and/or severity of seizures. Patients should be questioned regularly to determine whether they are seizure-free. It is important to recall that perhaps as many as 30% of patients will be intractable to current pharmacologic treatments. In these patients, if the clinician has determined that AED dosage has been maximized, one should consider either AED combination therapy or, potentially, evaluation for epilepsy surgery or the vagal nerve stimulator.

The treatment of epilepsy begins with a careful identification of the seizure type and selection of the most appropriate AED. Therapy should be initiated slowly, except in life-threatening situations, to avoid acute toxicity. Although most patients can be managed successfully on monotherapy, some patients' seizures remain uncontrolled despite the use of multiple AEDs. Some patients may be genetically refractory to AED therapy. The newer AEDs, as adjunctive therapy or monotherapy, offer additional opportunity to achieve complete seizure control. There is a continuing need for new AEDs and additional research in this area.

KEY CONCEPTS

- 1 Status epilepticus (SE) is a neurologic emergency that is associated with significant morbidity and mortality.
- 2 Generalized convulsive status epilepticus (GCSE) is defined as any recurrent or continuous seizure activity lasting longer than 30 minutes in which the patient does not regain baseline mental status. Any seizure that does not stop within 5 minutes should be treated as impending SE.
- 3 There are two types of status epilepticus, GCSE and nonconvulsive status epilepticus (NCSE). GCSE is the most common type.
- 4 Most GCSE develops in patients with no history of epilepsy; however, a patient with preexisting epilepsy may experience GCSE as a result of acute anticonvulsant withdrawal, metabolic disorder, concurrent illness, or progression of neurologic disease.
- 5 Although the pathophysiology of GCSE is unknown, experimental models have shown that there is a dramatic decrease in γ -aminobutyric acid (GABA)-mediated inhibitory synaptic transmission and that glutamatergic excitatory synaptic transmission sustains the seizures.
- 6 General treatment includes patient stabilization, adequate oxygenation, preservation of cardiorespiratory function, management of systemic complications, and aggressive assessment of underlying causes.
- 7 The main purpose of treatment is to prevent or decrease morbidity and mortality of prolonged seizures. Pharmacologic treatment needs to be rapid and aimed at terminating both electrical and clinical seizures. The probability of poorer outcomes increases with increased length of electrographic seizure activity.
- 8 Lorazepam is the preferred benzodiazepine in treatment of GCSE because of its long duration of action.
- 9 Currently, the hydantoins (phenytoin and fosphenytoin) are the long-acting anticonvulsants used most frequently. Either phenytoin or fosphenytoin should be given concurrently with benzodiazepines.
- 10 The maximum rate of infusion for phenytoin and fosphenytoin in adults is 50 mg/min and 150 mg PE/min, respectively.

- 11 If GCSE is not controlled by two first-line agents (benzodiazepine plus hydantoin or phenobarbital), the GCSE is considered to be refractory. In these cases, newer anticonvulsants and/or pharmacologically induced coma should be used.

INTRODUCTION

1 Status epilepticus (SE) is a common neurologic emergency that is associated with brain damage and death. 2 The traditional definition, provided by the International League Against Epilepsy Classification of Epileptic Seizures, defines SE as (1) any seizure lasting longer than 30 minutes whether or not consciousness is impaired or (2) recurrent seizures without an intervening period of consciousness between seizures.¹ Clinically, this definition has limited use particularly in the case of GCSE, as the average seizure is less than 2 minutes; and only 40% of seizures lasting 10 to 29 minutes cease without treatment.^{2,3} Pharmacoresistance^{4,5} and mortality³ significantly increase with increased seizure duration. Therefore, aggressive treatment of seizures lasting 5 minutes or more is strongly recommended. 3 SE can present in several forms (Table 59–1), including GCSE and NCSE.¹

NCSE occurs in approximately 25% of those with SE and is characterized by a fluctuating or continuous “twilight” state that produces altered consciousness and/or behavior (e.g., lethargy, decreased mental function). An altered electroencephalogram (EEG) is the most important diagnostic and management tool.⁶ In most instances, a benzodiazepine and/or valproate remain drugs of choice for NCSE.⁶ Although intravenous (IV) hydantoin or phenobarbital can be tried in patients who fail to respond, general anesthesia or barbiturate coma is not appropriate.⁶ The reader is referred to several reviews for a more comprehensive discussion of NCSE and its pharmacologic management.^{6,7}

GCSE is the most common and severe form of SE and is characterized by repeated primary or secondary generalized seizures that involve both hemispheres of the brain and are associated with a persistent postictal state. This chapter will focus on the epidemiology, pathophysiology, presentation, and management of GCSE.

EPIDEMIOLOGY

It is difficult to determine the incidence of GCSE because most studies fail to consider the patient’s age, seizure etiology, and type or duration of the seizure. The worldwide incidence is thought to range between 1.2 and 5 million cases per year, with an annual incidence of 100,000 to 152,000 cases each year in the United States.⁸ GCSE has no predilection for gender or socioeconomic status but does occur more frequently in nonwhites across all ages.⁹ Most episodes of GCSE occur in individuals with no history of epilepsy; however, approximately 5%

of adults and 10% to 25% of children with epilepsy will develop GCSE.⁷ The incidence of GCSE is highest in the very young (younger than 1 year of age) and the elderly (older than 60 years of age).

ETIOLOGY

Precipitating events for GCSE vary among studies and generally reflect different populations and referral patterns. ⁴ Most episodes that occur in known epileptics occur because of acute anticonvulsant withdrawal, a metabolic disorder or concurrent illness, or progression of a preexisting neurologic disease. Common etiologies and mortality rates for pediatric and adult populations are shown in Table 59-2.^{9,10} Precipitating events for GCSE are divided into those with and without neurologic structural lesions or those with a precipitating injury or insult. Cases with structural lesions or those with a specific neurologic insult are associated with a poor prognosis.

There are major differences in etiologies for pediatric and adult patients (see Table 59-2). During their first few weeks of life, infants who are born to addicted mothers can develop drug withdrawal seizures. Other neonates can develop GCSE because of a pyridoxine deficiency, which should resolve within hours following treatment with IV pyridoxine (100 mg). Acute encephalopathy and metabolic disorders are the major causes of GCSE in patients younger than 1 year of age. In young children, the cause is frequently a nonspecific illness such as fever and/or a viral illness. Unless accompanied by an underlying neurologic abnormality, fever-induced GCSE is less likely to be associated with sequelae.

The most frequent precipitating events in adults are cerebrovascular disease, withdrawal of anticonvulsants, and low anticonvulsant serum concentrations. Cerebrovascular disease is the leading cause of GCSE in those who have their first seizures after age 60. A number of prescription, over-the-counter, and recreational drugs should be considered in anyone with new-onset GCSE. Elevated

TABLE 59-2 Etiology and Mortality for Pediatric and Adult Cases of Status Epilepticus

Etiology	Number of Cases (% Mortality) <i>n</i> = 200 Cases of Pediatric SE	Number of Cases (% Mortality) <i>n</i> = 512 Cases of Adult SE
Type I (no structural lesion)

^aMore than half of remote causes were congenital malformations and CVA in pediatric and adult patients, respectively.Data from DeLorenzo et al.^{9,10}

anticonvulsant serum concentration or rapid anticonvulsant withdrawal can also precipitate GCSE.

MORBIDITY

GCSE is harmful to the brain and is associated with morbidity. However, whether the morbidity results from the underlying etiology or the GCSE itself remains to be determined. Most contend that the GCSE is responsible for the morbidity. Neuronal damage in animal models is evident following 30 to 60 minutes of GCSE regardless of the inducing stimulus, and most animals progress to the development of epilepsy following a prolonged seizure. Interestingly, inhibiting the neuronal damage associated with seizures does not prevent the development of epilepsy, suggesting that the seizures themselves may be harmful. It is difficult to establish a relationship between GCSE and long-term outcomes. This is largely because it is difficult to weigh the effects of seizure type, etiology, duration, concurrent physiologic events, and therapy or lack thereof. However, it has been shown that patients with a history of prolonged febrile seizures who later developed epilepsy share similar histopathologic changes (i.e., hippocampal sclerosis) to those found in animal models of GCSE.^{11,12} In these cases the period between the initial GCSE and the first epileptic seizure may be months to decades, suggesting that there may be a link between GCSE and the development of epilepsy. Importantly, studies of GCSE show that the currently available anticonvulsants do not reproducibly prevent the development of epilepsy following prolonged seizures.^{11,13}

Patients who develop epilepsy following prolonged GCSE are less likely to experience remission of their seizures and may have decreased cognitive and memory function, mental retardation, or neurologic deficits.⁸ Most studies have found that younger children, the elderly, and those with preexisting epilepsy have a higher propensity for sequelae.

MORTALITY

The estimated mortality rate in the United States following GCSE ranges between 22,000 and 42,000 individuals per year.¹⁰ Recent

estimates suggest a mortality rate of up to 10% in children,¹⁴ 20% in adults,⁸ and 38% in the elderly.⁹ When compared with other populations, neonates with seizures have a higher mortality and more neurologic sequelae.

Table 59–2 summarizes the etiology for GCSE and their corresponding mortality rates.^{9,11} Interestingly, the mortality associated with many etiologies is significantly greater in adults than in children. Unresponsive patients may die from GCSE, but more frequently they die from the acute illness that precipitated the GCSE. For example, patients with serious central nervous system (CNS) structural changes (e.g., hemorrhage, stroke) have a poor prognosis, whereas those (i.e., 80%–90%) with no structural lesion generally respond to IV phenytoin.

Two variables that affect outcome are the time between onset of GCSE and the initiation of treatment and the duration of the seizure. Mortality significantly increases with increased seizure duration being 2.6% for those with seizures 10 to 29 minutes versus 19% for those with seizures lasting longer than 30 minutes.² GCSE lasting longer than 60 minutes have a higher mortality rate (32%) than seizures lasting less than 60 minutes (2.5%).¹⁰ Mortality has decreased over the past decade and probably reflects a recognition of the need to initiate sequenced therapy immediately, and a greater understanding of the pathogenesis of GCSE.

PATHOGENESIS

Seizures occur when the excitatory neurotransmission overcomes inhibitory impulses in one or more brain regions (i.e., neural networks). Most seizures are brief (less than or equal to 5 minutes), largely because the brain's inhibitory mechanisms restore the balance of normal neurotransmission.¹⁴ It is unknown why the mechanisms that control normal brain homeostasis fail. However, when seizures occur in close succession or the magnitude of the proconvulsant stimulus is severe, compensatory mechanisms can be overwhelmed and lead to GCSE.

5 Although the exact cellular mechanisms responsible for the production of abnormal neural impulses are unknown, it appears that seizure initiation is caused by an imbalance between excitatory (e.g., glutamate, calcium, sodium, substance P, and neurokinin B) and inhibitory neurotransmission (e.g., GABA, adenosine, potassium, neuropeptide Y, opioid peptides, and galanin).¹⁴ Seizure maintenance associated with GCSE is largely caused by glutamate acting on postsynaptic *N*-methyl-D-aspartate (NMDA) and α -amino-3-hydroxy-5-methyl-isoxazole-4-propionate (AMPA)/kainate receptors. Most of what is known about GCSE has focused on gated ion channels, with less known about receptor–second messenger systems (e.g., metabotropic glutamate receptors).¹⁴

During GCSE, glutamate activation of the NMDA and AMPA receptors causes opening of the gated calcium and sodium channels, respectively. Entry of the respective ions causes neuronal depolarization. Sustained depolarization may maintain GCSE and eventually cause neuronal death through calcium-, free radical-, and kinase-mediated events.¹¹ Although drugs acting as NMDA and AMPA receptor antagonists seem attractive for the treatment of GCSE, it is likely that glutamate is not the sole mechanism for GCSE and that other mechanisms become increasingly important as the duration of seizures increases.

GABA_A postsynaptic receptors control chloride channels to produce hyperpolarization (inhibition) of the postsynaptic cell membrane. These receptors have binding sites for GABA and select anticonvulsants (e.g., phenobarbital and benzodiazepines) and enhance GABA_A-mediated chloride inhibitory currents. It was previously thought that a decrease in presynaptic GABA led to prolonged seizures; however, it is currently held that GABA concentrations increase during the early phases of GCSE and continue to be elevated

during late GCSE. Prolonged seizures lead to decreased inhibitory GABA_A-receptor density because of postsynaptic receptor endocytosis. Additionally, GABA_A receptors may be modified during SE, such that there is decreased response to both endogenous GABA and GABA agonists.¹² Clinically, this can influence response to both benzodiazepines and phenobarbital in that their relative potencies can be reduced up to tenfold if seizures persist for more than 30 minutes.¹² A similar phenomenon occurs with sodium channel antagonists (phenytoin); however, the magnitude of resistance is believed to be less.¹⁴

PATHOPHYSIOLOGY

As GCSE continues, there are systemic alterations, progression of motor phenomena, and development of specific EEG findings.¹⁵ Two distinct and predictable phases have been identified. Phase I occurs during the first 30 minutes of seizure activity, and phase II begins 60 minutes later. Although these systemic complications affect the prognosis of GCSE, a prolonged seizure can destroy neurons independent of these systemic events.¹¹ In fact, the systemic effects of induced seizures in animals can be blocked, but the damage to the neocortex, cerebellum, and hippocampus persists.

During phase I, each seizure produces marked increases in plasma epinephrine, norepinephrine, and steroid concentrations that can cause hypertension, tachycardia, and cardiac arrhythmias.¹⁵ Within minutes, arterial systolic pressures can rise to above 200 mm Hg, and heart rate can increase by 83 beats per minute. Although blood pressure returns to normal within 60 minutes, mean arterial pressure does not fall below 60 mm Hg; hence, cerebral perfusion pressure is not compromised. In animals, cerebral blood flow is also increased, thereby protecting neurons from hypoxic injury.

Seizure-induced increases in sympathetic and parasympathetic stimulation of the heart, in the presence of a hypoxic myocardium, can result in ventricular arrhythmias. Autonomic neuron stimulation can cause a release of insulin and glucagon. Concurrently, circulating catecholamines cause an elevation of hepatic cyclic adenosine monophosphate, producing glycogenolysis. Although the patient can be hyperglycemic initially, serum glucose concentration begins to fall.

Seizure-induced muscular contractions and hypoxia cause lactic acid release, which can produce a severe acidosis that can be accompanied by hypotension and shock. Muscle contractions can be so severe that rhabdomyolysis with secondary hyperkalemia and acute tubular necrosis can occur. The airway can be obstructed, and the patient can become cyanotic or hypoxic at any time. Additionally, an increase in salivation and tracheal and pulmonary secretions can cause aspiration pneumonia. Although transient pleocytosis can develop, it should not be attributed to SE until infectious causes have been eliminated.

Between seizures, the EEG slows, and blood pressure normalizes. Although metabolic demands are increased, the brain is able to adequately compensate. If seizures exceed 60 minutes (phase II), the EEG ictal discharge and clonic motor activity become continuous, and the patient begins to decompensate. Despite elevated levels of catecholamines, the patient can become hypotensive. During the late phase, autoregulation of cerebral blood flow becomes dependent on mean arterial pressure and begins to fail. There continues to be an excessive consumption of oxygen and glucose; however, compensatory mechanisms are no longer able to keep up with demands.

During phase II, the serum glucose concentration may be normal or decreased. Profound hypoglycemia, secondary to hyperinsulinemia, can occur in patients with hepatic dysfunction or in those with reduced glycogen stores. Hyperthermia and respiratory deterioration with hypoxia and ventilatory failure can develop. There also may be metabolic and biochemical complications, including respiratory and metabolic acidosis, hyperkalemia, hyponatremia, and azotemia. There is increased sweating and salivation. This has important

clinical ramifications in that a patient's seizures can seem to terminate without treatment or when an ineffective therapy is given.

CLINICAL CONTROVERSY

The choice of long-acting anticonvulsant to give following the initial benzodiazepine is controversial. According to the Working Group on Status Epilepticus, phenytoin should be used in seizures that recur after treatment with a benzodiazepine.¹⁴ Although this has been the practice for decades, no studies have documented the superiority of a hydantoin over other anticonvulsants. Thus, it is questionable if a hydantoin should be administered alone, in larger doses, or at all when seizures recur following benzodiazepine administration.

CLINICAL PRESENTATION AND DIAGNOSIS

Accurate diagnosis requires observation, physical examination, laboratory assessment, EEG, and neurologic imaging. The nature and duration of the seizure should be obtained, and a diagnosis of GCSE should not be made until a clinician has observed at least one seizure. Most patients have an altered consciousness that ranges from obtunded to marked lethargy and somnolence with pronounced eyes-open unresponsiveness and waxy rigidity. Motor features can include muscle contractions, extensor or flexor posturing, and spasms. Over time, the clinical manifestations become less apparent, and the diagnosis requires careful assessment.

In addition to an assessment of language and cognitive abilities, the physical and neurological examinations should assess motor, sensory, and reflex abnormalities, pupillary response, asymmetry, and posturing. The patient should also be examined for secondary injuries (e.g., tongue lacerations, shoulder dislocations, head and facial trauma).

Laboratory tests are essential to the diagnosis of various etiologies. Hypoglycemia, hyponatremia, hypernatremia, hypomagnesemia, hypocalcemia, and renal failure all can cause seizures. A urine drug screen can help eliminate the possibility of illicit drug use or drug overdose. Serum drug concentration(s) should be obtained in those on chronic anticonvulsants, because high concentrations of certain medications can induce seizures, and low concentrations can reflect noncompliance or rapid drug withdrawal. A baseline serum concentration is necessary to determine whether a loading dose of a specific anticonvulsant is required. Assessment of other laboratory parameters (e.g., albumin, renal function, and hepatic function) that affect anticonvulsant dosing also can be useful. An EEG is a valuable diagnostic tool, particularly in those with prolonged GCSE in whom clinically apparent seizures are not always evident, but therapy should not be delayed while awaiting testing or results.

Once seizures have stopped it is important to determine if the patient is febrile or has a systemic or CNS infection. Many physiologic consequences of GCSE (e.g., leukocytosis, pleocytosis, and hyperthermia) produce symptoms that can be confused with other conditions. If a CNS infection is suspected, empiric antibiotics should be started, and a spinal tap should be performed. Computed tomography (CT) or magnetic resonance imaging (MRI) should be obtained to rule out vascular, neoplastic, or infectious etiologies.

CLINICAL PRESENTATION OF GCSE

Symptoms

- Impaired consciousness (e.g., lethargy to coma)
- Disorientation once GCSE is controlled
- Pain associated with injuries (e.g., tongue lacerations, shoulder dislocations, head trauma)

Early Signs

- Generalized convulsions
- Acute injuries or CNS insults that cause extensor or flexor posturing
- Hypothermia or fever suggestive of intercurrent illnesses (e.g., sepsis or meningitis)
- Incontinence
- Normal blood pressure or hypotension and respiratory compromise

Late Signs

- Clinical seizures may or may not be apparent
- Pulmonary edema with respiratory failure
- Cardiac failure (dysrhythmias, arrest, cardiogenic shock)
- Hypotension or hypertension
- Disseminated intravascular coagulation, multisystem organ failure
- Rhabdomyolysis
- Hyperpyrexia

Initial Laboratory Tests

- Complete blood count (CBC) with differential
- Serum chemistry profile (e.g., electrolytes, calcium, magnesium, glucose, serum creatinine, alanine aminotransferase [ALT], aspartate aminotransferase [AST])
- Urine drug/alcohol screen
- Blood cultures
- Arterial blood gas to assess for metabolic and respiratory acidosis
- Serum drug concentration if previous anticonvulsant suspected or known

Other Diagnostic Tests

- Spinal tap if CNS infection suspected
- EEG should be obtained on presentation and once clinical seizures are controlled
- CT with and without contrast
- MRI
- Radiograph if indicated to diagnose fractures
- Electrocardiogram (ECG), especially if ingestion confirmed

TREATMENT

Generalized Convulsive Status Epilepticus

■ DESIRED OUTCOMES

The short-term desired outcomes are (1) immediate termination of all clinical and electrical seizure activity, (2) no clinically significant adverse effects from therapy, and (3) lack of recurrent seizure activity. 7 The long-term desired outcomes are to minimize or avoid the likelihood of pharmacoresistant epilepsy and/or the development of neurologic sequelae that significantly impact quality of life.

■ NONPHARMACOLOGIC THERAPY

Vital signs should be assessed, an adequate and protected airway should be established, ventilation should be maintained, and oxy-

gen should be administered. Frequent arterial blood gas determinations should be done to assess for metabolic acidosis, which should be treated with sodium bicarbonate if the pH is less than 7.2. Assisted ventilation should be used to correct respiratory acidosis.

Some patients might continue to have electrical seizures in the absence of clinical motor manifestations. For those who continue to have altered consciousness after clinical control of their seizures, an EEG should be performed. Although hypoglycemia is a rare cause of GCSE, adults should be given 50 mL of a 50% dextrose solution, and children should receive 1 mL/kg of a 25% dextrose solution.^{7,8,14} Because Wernicke encephalopathy can develop in alcoholics, adults should receive IV thiamine (100 mg) prior to glucose.¹⁴ Serum glucose concentration should be determined to assess the need for further supplementation.

■ PHARMACOLOGIC THERAPY

When a seizure does not stop automatically within 5 minutes, or when doubt exists regarding the diagnosis, patients should be treated as if they have GCSE. Figure 59–1 provides an algorithm for the treatment of GCSE.

6 There are four immediate goals in the management of GCSE: (1) patient stabilization, including adequate oxygenation, preservation of cardiorespiratory function, and management of systemic complications; (2) accurate diagnosis of the subtype of GCSE and identification of precipitating factors; (3) termination of clinical and electrical seizures as early as possible; and (4) prevention of seizure recurrence. The three most commonly used classes of anticonvulsants for the initial treatment of GCSE are the benzodiazepines, hydantoins, and barbiturates.

Benzodiazepines

The benzodiazepines are effective initial therapy in most patients with GCSE and should be administered as soon as possible. Generally, one or two IV doses will stop seizures within 2 to 3 minutes.⁸ Diazepam, lorazepam, and midazolam are equally effective; therefore the preferred benzodiazepine is determined by differences in the pharmacokinetic and pharmacoeconomic profiles.

Diazepam is an extremely lipophilic moiety with a large volume of distribution (1 to 2 L/kg).¹⁴ Although its initial distribution into the brain occurs within seconds, it rapidly redistributes into fat, causing its CNS half-life to be less than 1 hour and its duration of effect to be less than 30 minutes.¹⁴ If diazepam is the sole anticonvulsant, the rapid decrease in brain concentration can cause seizure recurrence; hence, a longer-acting anticonvulsant (e.g., phenytoin or phenobarbital) should also be given. The initial dose of diazepam (Table 59–3) can be repeated if the patient does not respond within 5 minutes.¹⁴

8 Most practitioners consider lorazepam the benzodiazepine of choice.^{8,14} It is less lipid soluble than diazepam and takes longer to achieve peak concentrations in the brain; however, its minimal redistribution into fat results in a longer duration of action (i.e., 12 to 24 hours).^{8,14} It also has a higher-affinity binding to the benzodiazepine receptor than diazepam.

Initial lorazepam dosing can be found in Table 59–3. This dose can be repeated if the patient does not respond in 5 minutes.¹⁴ Patients chronically on a benzodiazepine (e.g., clonazepam) might have developed tolerance and could require larger doses for response. If successful, lorazepam can provide seizure protection for up to 24 hours. Diazepam and lorazepam cause vein irritation and should be diluted with an equal volume of compatible diluent before administration. Both diazepam and lorazepam contain propylene glycol, which can cause dysrhythmia and hypotension if administered too rapidly.¹⁴ Because of slow and erratic absorption, they should not be given intramuscularly.

Midazolam is water-soluble and diffuses rapidly into the brain. Unfortunately, it has an extremely short half-life and must be given by continuous infusion. Various routes of administration (e.g., buccal, and intramuscular [IM]) have been used successfully to terminate seizures rapidly when IV access cannot be established. Buccal administration is performed easily, and the volume of fluid is small enough (e.g., 2 to 5 mL) that aspiration is unlikely. Because of its increased solubility, IM midazolam has a more reliable absorption than either diazepam or lorazepam. In fact, some practitioners have recommended that IM midazolam be given by emergency personnel as first-line treatment in the out-of-hospital setting.¹⁶

All benzodiazepines can impair consciousness and interfere with neurologic assessment. Although rare, brief (less than 1 minute) cardiorespiratory depression can occur and can necessitate assisted ventilation or require intubation. This is especially true if a benzodiazepine is used concomitantly with a barbiturate. Hypotension secondary to a reduction in vasomotor tone can occur following large doses.⁸

Phenytoin

9 A hydantoin is the second-line agent in GCSE that is unresponsive to the benzodiazepines or in seizures that recur after successful treatment with a benzodiazepine.⁸ Although it is effective in terminating seizures in 40% to 91% of patients,¹⁴ it can be inferior to lorazepam, phenobarbital, or diazepam plus phenytoin at stopping GCSE within 20 minutes of their infusion.^{17,18} Phenytoin has a long half-life (20 to 36 hours) and causes less respiratory depression and sedation than the benzodiazepines or phenobarbital;¹⁴ however, it cannot be delivered rapidly enough to be considered a first-line single agent.

Injectable phenytoin should be diluted to less than or equal to 5 mg/mL in normal saline. Microcrystals will precipitate if it is mixed in a glucose-containing solution. The vehicle (40% propylene glycol) can cause administration-related hypotension and cardiac arrhythmias. These effects are more likely to occur if large loading doses are given to elderly individuals with preexisting cardiac disease or in critically ill patients with marginal blood pressure.¹⁴ Vital signs and an ECG should be obtained during administration. The infusion rate should be slowed if the QT interval widens or if hypotension or arrhythmias develop.¹⁴ **10** The maximum rate of infusion is 50 mg/min in adults and 3 mg/kg/min in children weighing less than 50 kg (110 lb).¹⁹ The rate should not exceed 25 mg/min in the elderly.

Suggested IV loading doses of phenytoin are provided in Table 59–3.¹⁴ A reduction in the loading dose is recommended for elderly patients,¹⁴ and a larger loading dose is required in obese patients.²⁰ If the patient has been on phenytoin prior to admission and the serum concentration is known, this should be considered in determining a loading dose. Although some advocate the administration of an additional 5 mg/kg in those with unresponsive GCSE, there is no evidence that this will be beneficial. This practice can cause concentrations to exceed the reference range and produce toxicity. Because phenytoin has poor lipid solubility and enters the brain slowly, it can take up to 60 minutes before the pharmacodynamic effect is apparent. This delay is important when considering administration of a second 5 mg/kg loading dose. Therapeutic serum concentrations, 10 to 20 mg/L, generally do not persist more than 24 hours; hence, maintenance doses (see Table 59–3) should be started within 12 to 24 hours of the loading dose.

Phenytoin has an alkaline pH, which is associated with pain and burning during infusion; phlebitis can occur with chronic infusion, and tissue necrosis is likely on infiltration. IM administration is not recommended because absorption is delayed and erratic, and phenytoin can crystallize in tissue. Oral loading doses have been used in patients not actively seizing; it may take 4 to 12 hours before

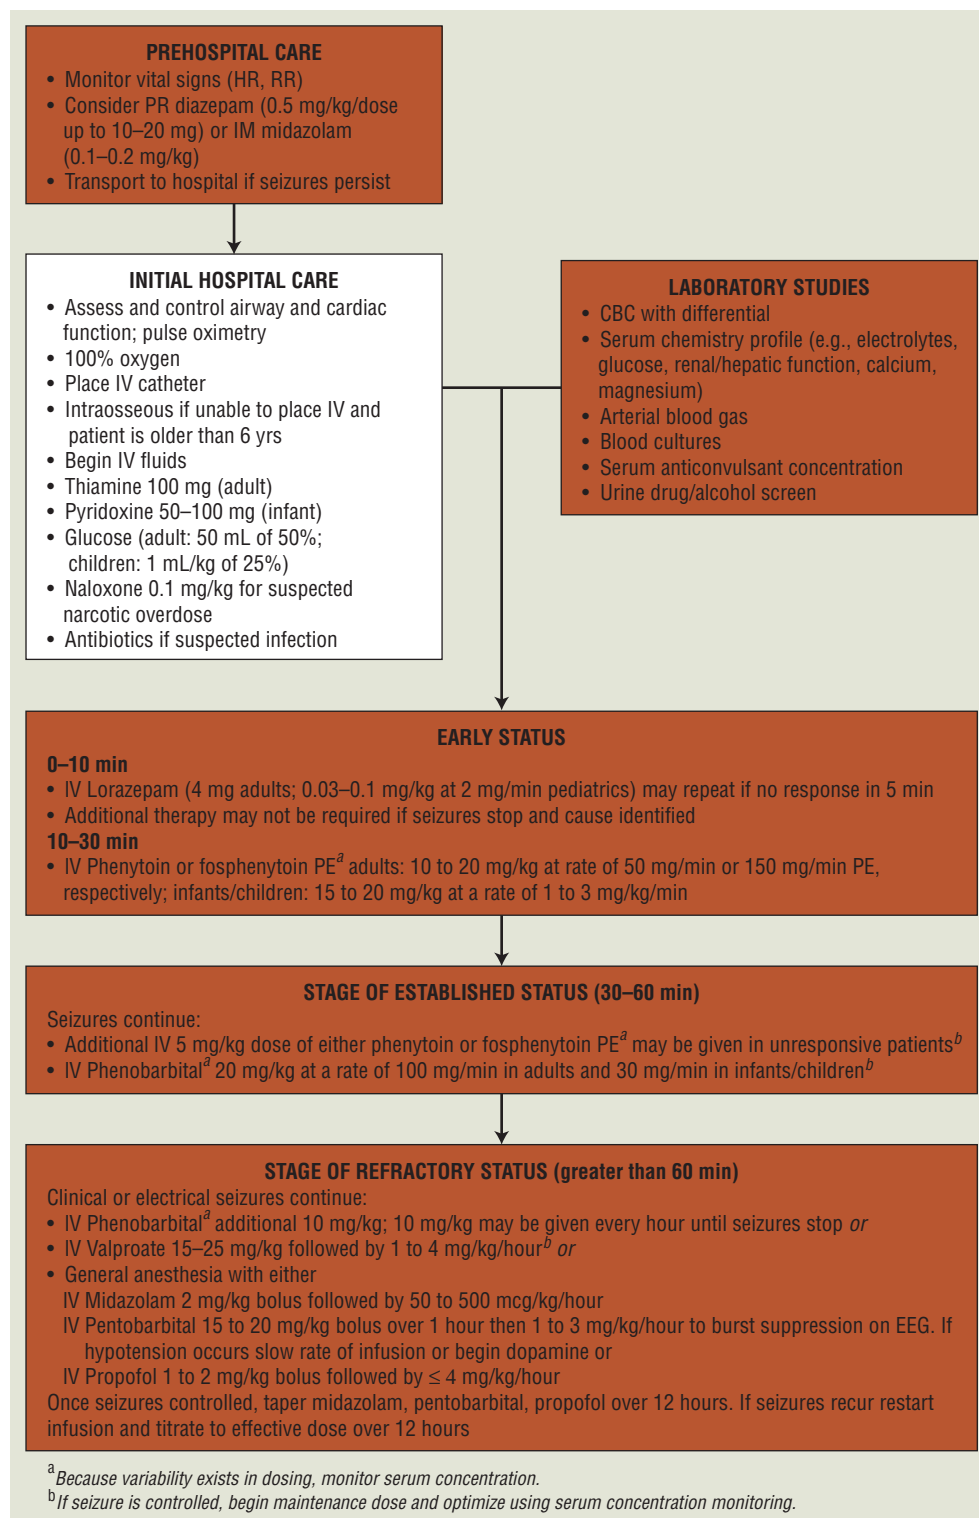

FIGURE 59-1. Algorithm for the treatment of GCSE. (CBC, complete blood count; EEG, electroencephalogram; GCSE, generalized convulsive status epilepticus; HR, heart rate; PR, per rectum; RR, respiratory rate.)

adequate serum concentrations are obtained; therefore, this practice is not recommended.

Fosphenytoin

Fosphenytoin, a water-soluble phosphate ester, has no known pharmacologic activity.²¹ It does not contain propylene glycol and is compatible with most common IV fluids. Prior to IV administration it should be diluted in 5% dextrose or normal saline to a

concentration of 1.5 to 25 mg phenytoin equivalents/mL.²¹ It is converted rapidly (7 to 15 minutes) and completely (100%) to phenytoin by blood and tissue phosphatases after IV and IM dosing.²¹ The conversion delay was a concern initially; however, this time is offset by high protein binding, saturable binding at high concentrations, and the rapid rate of infusion.²¹

Nystagmus, dizziness, and ataxia are the most frequent adverse events and are attributed to phenytoin. The frequency of ECG or blood pressure changes is less than that for phenytoin. Nonallergic

TABLE 59-3 Medications Used in the Initial Treatment of GCSE

Anticonvulsant (Route)	Loading Dose (Maximum Dose)		Rate of Infusion		Maintenance Dose	
	Adult	Pediatric	Adult	Pediatric	Adult	Pediatric
Diazepam (IV bolus)	0.25 mg/kg ^{a,b,c} (40 mg)	0.25–0.5 mg/kg ^{a,c} (0.75 mg/kg)	<5 mg/min	<5 mg/min	Not used	Not used
Fosphenytoin IV	15–20 mg PE/kg	15–20 mg PE/kg	150 mg PE/min	3 mg PE/kg/min	4–5 mg PE/kg/day	5–10 mg PE/kg/day
Lorazepam (IV bolus)	4 mg ^{a,b,c} (8 mg)	0.1 mg/kg ^{a,c} (4 mg)	2 mg/min	2 mg/min	Not used	Not used
Midazolam IV	200 mcg/kg ^{a,d}	150 mcg/kg ^{a,d}	0.5–1 mg/min	2–3 min	50–500 mcg/kg/h ^e	60–120 mcg/kg/h ^e

Phenytoin IV	10–20 mg/kg ^f	10–20 mg/kg ^f	50 mg/min ^g	1–3 mg/kg/min	4–5 mg/kg/day ^e	5–10 mg/kg/day ^e

GCSE, generalized convulsive status epilepticus; PE, phenytoin equivalents.

^aDoses can be repeated every 10 to 15 minutes until the maximum dosage is given.

^bInitial doses in the elderly are 2 to 5 mg.

^cLarger doses can be required if patients chronically on a benzodiazepine (e.g., diazepam).

^dCan be given by the intramuscular, rectal, or buccal routes.

^eTitrate dose as needed.

^fAdminister additional loading dose based on serum concentration.

^gThe rate should not exceed 25 mg/min in elderly patients and those with known atherosclerotic cardiovascular disease.

paresthesia and pruritus of the face and groin are unique to fosphenytoin and are related to dose and infusion rate, and rarely require discontinuation of fosphenytoin. These side effects typically subside within 5 to 10 minutes after the infusion.²¹

Fosphenytoin should be dosed using PE, thereby obviating the need for interconversion between phenytoin and fosphenytoin. The loading dose and rates of administration of fosphenytoin can be found in Table 59–3. Because of delays in achieving adequate phenytoin serum concentrations, a loading dose should not be given intramuscularly unless IV access is impossible. Continuous ECG, blood pressure, and respiratory status monitoring is recommended for all loading doses of fosphenytoin.

Fosphenytoin serum concentrations are of no clinical value. Serum phenytoin concentrations are the end point for therapeutic drug monitoring, and the desired serum concentration range is the same as that for phenytoin. Fosphenytoin cross-reacts with some phenytoin immunoassays causing an overestimation of phenytoin concentration; hence, blood should not be obtained for at least 2 hours after IV and 4 hours after IM administration.²¹

CLINICAL CONTROVERSY

The debate continues as to which hydantoin is preferred in GCSE. Although phenytoin has been used for decades, it is associated with a variety of problems related to its formulation. Conversely, fosphenytoin is associated with less infusion pain and IV-site complications and fewer hemodynamic effects than phenytoin. Although most practitioners believe that fosphenytoin is clearly a “better” formulation, many struggle with the advantages of fosphenytoin, given its cost.

Phenobarbital

There are three different opinions regarding the use of phenobarbital in GCSE. Because barbiturates cause CNS and respiratory depression, as well as hypotension, most contend that phenobarbital should be the third-line agent when a benzodiazepine plus phenytoin has failed.⁸ Others suggest that the barbiturates are as safe and effective as other anticonvulsants and should be the drug of choice after a benzodiazepine has been given. Still others support the continuous-infusion midazolam as the third-line anticonvulsant before the barbiturates.²²

Although two studies found phenobarbital as effective as diazepam plus phenytoin¹⁷ and lorazepam alone or diazepam plus phenytoin in patients with GCSE,¹⁸ the Working Group on Status Epilepticus

recommends that phenobarbital be given after a benzodiazepine plus phenytoin has failed.¹⁴ Currently, most practitioners agree that phenobarbital is the long-acting anticonvulsant of choice in patients with a hypersensitivity to the hydantoins or in those with cardiac conduction abnormalities.

Phenobarbital has biphasic distribution into body organs.²³ During phase I, the drug distributes into highly vascular organs, but it does not distribute into the brain. With the exception of fat, phenobarbital distributes throughout the body during phase II²³; hence lean body mass should be used in calculating doses in obese patients.²³ Although the highest brain concentrations occur 12 to 60 minutes after an IV dose,²³ seizures are controlled within minutes of the loading dose.¹⁸ The loading and maintenance dose are given in Table 59–3. When necessary, larger loading doses (30 mg/kg) have been used in neonates without adverse effects. If the initial loading dose does not stop the seizures within 20 to 30 minutes, an additional 10 to 20 mg/kg can be given. If seizures continue, a third 10 mg/kg load can be given.²⁴ Phenobarbital exhibits first-order linear pharmacokinetics, and there is no maximum dose beyond which further doses are likely to be ineffective.²⁴ Once GCSE is controlled, the maintenance dose should be started within 12 to 24 hours.

Although injectable phenobarbital contains propylene glycol, it can be given more rapidly than phenytoin (see Table 59–3). Phenobarbital can be given IM, but its rate of absorption is too slow to be effective. Phenobarbital can depress consciousness and respiration. The risk of apnea and hypopnea can be more profound in patients treated initially with benzodiazepines.^{8,14} If significant hypotension develops, the infusion should be slowed or stopped.¹⁴

TREATMENT OF REFRACTORY GCSE

11 When adequate doses of a benzodiazepine, hydantoin, or barbiturate have failed, the condition is termed *refractory*.²² Approximately 10% to 15% of patients will develop refractory GCSE, and approximately 30% of patients whose seizures are “clinically” controlled will have persistent electrical manifestations after administration of these anticonvulsants. When a patient develops refractory GCSE, an intense search should be performed for an acute or progressive cause.

It should be remembered that the longer GCSE lasts, the harder it is to treat and that failure to treat aggressively early in the course of disease increases the likelihood of nonresponse.¹⁴ There is no consensus regarding the anticonvulsant of choice, sequencing of therapy, or treatment of refractory GCSE. Regardless of this, the goal is to stop electrical epileptiform activity.

Approaches used include the continuous infusion of a benzodiazepines, medically induced coma, valproate, levetiracetam, topiramate,

TABLE 59-4 Medications Used to Treat Refractory GCSE

Anticonvulsant (Route)	Loading Dose		Infusion Duration		Maintenance Dose	
	Adult	Pediatric	Adult	Pediatric	Adult	Pediatric
Levetiracetam IV	500–1,000 mg	NA	33–66 mg/min	NA	750–9,000 mg/day	NA
Lidocaine IV	50–100 mg	1 mg/kg (maximum dose = 3–5 mg/kg in first hour)	≤2 minutes	≤2 minutes	1.5–3.5 mg/kg/h	1.2–3 mg/kg/h
Midazolam IV	200 mcg/kg ^a	150 mcg/kg ^a	0.5–1 mg/min	0.5–1 mg/min	50–500 mcg/kg/h ^b	60–120 mcg/kg/h ^b
Pentobarbital IV	10–20 mg/kg	15–20 mg/kg	Over 1–2 hours	Over 1–2 hours	1–5 mg/kg/h ^b	1–5 mg/kg/h ^b
Propofol IV	2 mg/kg	3 mg/kg	Over 10 seconds	Over 20–30 seconds	5–10 mg/kg/h	2–18 mg/kg/h ^c
Topiramate PO	300–1,600 mg	5–10 mg/kg	NA	NA	400–1,600 mg/day	5–10 mg/kg/day
Valproate IV	15–45 mg/kg	20–25 mg/kg	3 mg/kg/min	3 mg/kg/min	1–4 mg/kg/h ^b	1–4 mg/kg/h ^b

GCSE, generalized convulsive status epilepticus; NA, not available; PO, orally.

^aDoses can be repeated twice every 10 to 15 minutes until the maximum dosage is given.

^bTitrate dose as needed.

^cGenerally recommended not to exceed a dose of 4 mg/kg/h and a duration of 48 hours.

mate, propofol, paraldehyde, or lidocaine. Doses for these agents can be found in Table 59–4. A meta-analysis compared midazolam, propofol, and pentobarbital in refractory GCSE.²⁵ Overall response rates were significantly greater in those treated with pentobarbital (92%) compared to midazolam (80%) and propofol (73%). Break-through seizures were more commonly observed with midazolam (51%) versus propofol (15%) and pentobarbital (12%). Although pentobarbital had a greater response rate, clinically significant hypotension was more common than with the other agents. Mortality rates were similar for the three drugs.

Benzodiazepines

Some practitioners advocated that midazolam should be the first-line agent in refractory GCSE.²² Table 59–4 contains the loading and maintenance doses of midazolam. Most patients respond to these doses within an hour, but the continuous-infusion rate should be increased every 15 minutes in those who do not. Because tachypnea can develop, frequent increases in the infusion rate can be necessary, and dosing should be guided by EEG response.²²

Once GCSE is terminated, dosages can be decreased by 1 mcg/kg/min every 2 hours. Successful discontinuation is enhanced by maintaining the patient's phenytoin and phenobarbital serum concentration(s) above 20 mg/L and 40 mg/L.²² Because of midazolam's short half-life, patients can return to consciousness more rapidly than those receiving larger doses of more sedating anticonvulsants (e.g., phenytoin, phenobarbital). Generally, continuous-infusion midazolam has been well tolerated, with few cases of hypotension and respiratory depression seen. Hypotension and poikilothermia can occur and can require supportive therapies.

Large-dose continuous-infusion lorazepam and diazepam also have been used successfully in patients unresponsive to phenytoin or phenobarbital.²⁶ Lorazepam contains propylene glycol, which can accumulate in patients receiving continuous infusions. It has been noted to cause a marked osmolar gap, metabolic acidosis, and renal toxicity, which was attributed to the infusion of propylene glycol.^{27–29}

CLINICAL CONTROVERSY

The positioning of midazolam among the medications used to treat GCSE is controversial. Some investigators recommend that midazolam should be the anticonvulsant of first choice and, therefore, should be used in lieu of lorazepam; others argue that it should be used after a hydantoin has failed; still others recommend it only for refractory GCSE.

Medically Induced Coma

If there is an inadequate response to large doses of midazolam, anesthetizing the patient to suppress the cerebral ictal discharge is recommended.^{14,25} Although it is likely that the patient is already being mechanically ventilated, intubation and respiratory support are mandatory during barbiturate coma. Because hypotension is a concern, it is essential that vital signs be monitored continuously. A short-acting barbiturate (usually either pentobarbital or thiopental) generally is preferred because it allows a more rapid reversal of coma.

Several sources note that the initial loading dose of pentobarbital is 5 mg/kg.¹⁴ However, this dose is inadequate to produce the serum concentrations (30 to 40 mg/L) necessary to induce an isoelectric EEG. Pentobarbital should be initiated with a loading dose of at least 10 to 20 mg/kg over 1 to 2 hours²⁵ (see Table 59–4). If hypotension occurs during the loading dose, the rate of administration should be slowed, or dopamine should be administered. The loading dose should be followed immediately by a continuous infusion.¹⁴ Rates are typically begun at 1 mg/kg/h and titrated as needed up to a dose of 5 mg/kg/h. The maintenance infusion should be increased gradually until there is evidence of burst suppression on EEG (i.e., isoelectric EEG) or prohibitive adverse effects occur. Although the duration of barbiturate coma in most studies has been 2 to 3 days, pentobarbital coma has been used safely for 53 days in an 18-year-old patient.³⁰ To avoid complications (e.g., pneumonia, pulmonary edema), the pentobarbital should be discontinued as soon as possible. Twelve hours after a burst-suppression pattern is obtained, the rate of pentobarbital infusion should be titrated downward every 2 to 4 hours to enable the clinician to determine if the patient's GCSE is in remission. It is important to have other anticonvulsants at therapeutic amounts before pentobarbital is withdrawn so that the risk of seizure recurrence is minimized. Because pentobarbital is a potent hepatic enzyme inducer, doses of most concurrent anticonvulsants will need to be larger than usual maintenance doses. The patient will need to be monitored for side effects as deinduction occurs and anticonvulsant concentrations increase. This can take up to a month after pentobarbital's discontinuation.

Valproate

Limited human data exist regarding the use of valproate in refractory GCSE. Although an IV dosage form has been approved by the FDA, it is not approved for GCSE. A number of loading and continuous-infusion doses (see Table 59–4) have been used to treat GCSE in both adult^{31–33} and pediatric patients.^{33,34} One study suggested the need to consider the effects of enzyme-inducing anticonvulsants when dosing valproate.³⁴ This group recommended that the continuous-

infusion rate be determined by the presence of concurrent anticonvulsants (no inducers present, 1 mg/kg/h; one or more inducers [e.g., phenytoin, phenobarbital], 2 mg/kg/h; and inducers and pentobarbital coma, 4 mg/kg/h).

Although the manufacturer originally recommended IV valproate be given no faster than 20 mg/min, much faster rates have been studied (2 to 6 mg/kg/min) and are used for administration of the loading dose.^{34,35} Currently, the manufacturer recommends that IV valproate be administered at a rate of 3 mg/kg/min. In general, IV valproate has been well tolerated, with no cases of respiratory depression. Hemodynamic instability is extremely rare, but patients' vital signs should be monitored closely during the loading dose.

Propofol

Propofol is extremely lipid soluble, has a large volume of distribution, and has a very rapid onset of action. Its extremely short half-life promotes rapid awakening on drug discontinuation. Propofol has comparative efficacy to midazolam in refractory GCSE.^{25,36} Doses can be found in Table 59–4. Although controversial, it has been associated with progressive metabolic acidosis, hemodynamic instability, and bradyarrhythmias that are refractory to aggressive pharmacologic treatments.³⁷ Finally, a normal adult dose can provide over 1,000 calories per day as lipid at a cost to the patient that may exceed \$800 per day.

Other Agents

Oral topiramate has been given in adults (300–1,600 mg/day) and in children (5–10 mg/kg/day most reports, up to 25 mg/kg/day in one) for 2 to 5 days.^{38–43} Response tends to be delayed hours to days. Crushing the tablets and dissolving them in small amounts of water is needed in that no parenteral formulation is available. Because topiramate can induce metabolic acidosis and kidney stones, monitoring acid–base status and adequate hydration are recommended. Once seizures are controlled, doses should be tapered to a tolerable maintenance dose.

Oral doses of levetiracetam (750–9,000 mg/day) have been given in case series; however, doses larger than 3,000 mg/day do not add additional efficacy.⁴⁴ Levetiracetam is not hepatically metabolized and is minimally protein bound, which makes drug–drug interactions unlikely. Recently, an IV form of levetiracetam was approved.

Lidocaine has been used in refractory GCSE, but its use is not recommended unless other agents have failed.⁴⁵ It is administered intravenously and has a rapid onset of action. Table 59–4 gives the recommended initial loading and continuous-infusion doses. Although the reference serum concentration range for the antiarrhythmic effects of lidocaine is 2 to 6 mg/L, the reference range for GCSE has not been established. Serum lidocaine concentrations should be monitored to avoid drug accumulation and toxicity. CNS toxicity (e.g., fasciculations, visual disturbances, and tinnitus) can occur at concentrations between 6 and 8 mg/L; seizures and obtundation can develop when concentrations exceed 8 mg/L.

Halothane, isoflurane, ketamine, and other inhaled anesthetics have been shown to produce EEG suppression; however, these gases are difficult to deliver outside the operating room and require the presence of an anesthesiologist. No proven advantages have been shown over traditional anticonvulsants (e.g., barbiturate coma or continuous-infusion benzodiazepine), and these gases can increase intracranial pressure. If used, dosing is titrated to obtain EEG burst suppression. It is also prudent to validate that the patient does not have a low serum-magnesium concentration, because magnesium deficiency can lower the seizure threshold.

PHARMACOECONOMIC CONSIDERATIONS

The estimated reimbursement of GCSE varies greatly based on the age of the individual and the GCSE etiology. A population study showed

that the median and quartile reimbursements for GCSE are \$8,417 (25th percentile—\$5,592; 75th percentile—\$21,155).⁴⁶ Median reimbursements were significantly greater for those 17 to 45 years of age (\$14,689), those with acute CNS injury (\$16,919), and those withdrawing from alcohol or anticonvulsants (\$11,239). Lowest median reimbursements were found in those 0 to 16 years of age (\$6,140) and those with non-CNS injury (\$6,669). For patients with length of stays shorter than 1 week, average reimbursements are \$7,000 but increased to \$32,907 if the stay was longer than 1 week. For patients staying 1 month or more, reimbursements were more than \$60,000. Compared with other acute disorders (myocardial infarction, congestive heart failure, and intracranial hemorrhage), reimbursements for GCSE are 1.6- to 1.9-fold greater.

A number of economic issues can have an impact on formulary considerations. Clearly, there are intra- and interclass differences in medication costs and in ancillary tests or technologies associated with select therapies. For example, if one assumes five treatment options and hypothetically initiates anticonvulsant therapy in a patient weighing 70 kg (154 lb), the following differences in average wholesale prices are noted:

- Diazepam (20 mg) plus generic phenytoin (1 g): \$19.33
- Lorazepam alone (8 mg): \$8.96
- Midazolam alone (0.25 mg/kg load, 0.1 mg/kg/h): \$64.77
- Generic phenytoin (1 g) alone: \$14.47
- Diazepam (20 mg) plus fosphenytoin PE (1 g): \$158.06
- Phenobarbital (20 mg/kg) alone: \$20.89
- IV valproate (25 mg/kg load, 1 mg/kg/h): \$106.40

Although many practitioners have heralded the arrival of fosphenytoin as an important therapeutic advancement, it has created a fiscal and ethical dilemma for many institutions. Fosphenytoin is associated with less infusion pain and fewer IV-site complications and hemodynamic adverse effects than phenytoin; however, the cost of this agent (\$149/g PE versus \$14.47/g phenytoin) has caused many practitioners and administrators to struggle with the practical and ethical importance of the increased safety profile relative to the cost of the product to an institution. When evaluating the difference in cost of these two agents, it is important to remember that phenytoin requires the placement of two IV catheters because of its incompatibility with many solutions and medications that are given concurrently. Additionally, some practitioners are giving fosphenytoin intramuscularly in the emergency room for non-SE indications and thereby avoiding the placement of a catheter and use of an infusion device. Many institutions fail to consider the expense associated with a tissue infiltration of phenytoin. Should an infiltration of phenytoin cause tissue necrosis that necessitates plastic surgery or amputation, the expense of a single multimillion-dollar lawsuit likely will offset the difference between phenytoin and fosphenytoin cost to several institutions.

There is little difference in expense if one advocates phenobarbital over midazolam as third-line therapy, but it might be argued that a patient who experiences phenobarbital-induced respiration depression ultimately may be more expensive to the health system. Finally, a 24-hour infusion of propofol to the same patient will cost in excess of \$800.

EVALUATION OF THERAPEUTIC OUTCOMES

Initial success is defined as termination of all clinical and electrical seizure activity, but ultimate success is measured by the patient's quality of life. The morbidity and mortality associated with GCSE are affected by the underlying etiology; however, these can be minimized by the rapid implementation of a rational therapeutic plan. An EEG is an extremely important tool that not only allows practitioners to

determine when abnormal electrical activity has been aborted but also can assist in determining which anticonvulsant was effective. Because many of the anticonvulsants affect the cardiorespiratory system, it is imperative that vital signs (e.g., heart rate, respiratory rate, and blood pressure) be monitored during drug infusion. It also may be necessary to monitor the ECG in some patients. Finally, it is imperative that the infusion site be assessed for any evidence of infiltration before and during administration of phenytoin. Information regarding the patient's past medical and drug history and imaging studies (e.g., MRI) also can help to determine if there is a defined etiology for the original episode of GCSE. This information then can be used to guide future medication therapy, as well as help in determining if the patient is at risk for a poor outcome.

CONCLUSION

Our understanding of the cellular basis, physiology, and neuropathology of GCSE continues to evolve. Over the past decade, research into an activated cascade of pathophysiologic changes in neurotransmission, GABAergic inhibition, and NMDA receptor channel-mediated events has enhanced our understanding of this disorder. Although anticonvulsants will continue to be the mainstay of therapy in terminating seizures, specific agents including antagonists of excitatory amino acid neurotransmitters (e.g., glutamate and calcium channel blockers) and agonists of inhibitory neurotransmitters (GABA) may help to block further neuronal damage beyond the epileptogenic focus. Likewise, additional trials investigating the role of newer anticonvulsants in GCSE are warranted.

Acute Management of the Brain Injury Patient

BRADLEY A. BOUCHER AND SHELLY D. TIMMONS

KEY CONCEPTS

- 1 Cerebral ischemia is the key pathophysiologic event triggering secondary neuronal injury following severe traumatic brain injury (TBI). Intracellular accumulation of calcium is postulated to be a central pathophysiologic process in amplifying and perpetuating secondary neuronal injury via inhibition of cellular respiration and enzyme activation.
- 2 *Guidelines for the Management of Severe Brain Injury*, published by the Brain Trauma Foundation/American Association of Neurological Surgeons, serves as the foundation on which clinical decisions in managing adult neurotrauma patients are based; comparable guidelines for infants, children, and adolescents also have been published.
- 3 Correcting and preventing early hypotension (systolic blood pressure less than 90 mm Hg) and hypoxemia (PaO₂ less than 60 mm Hg) are primary goals during the initial resuscitative and intensive care of severe TBI patients.
- 4 The principal monitoring parameter for severe TBI patients within the intensive care environment is intracranial pressure (ICP). Cerebral perfusion pressure (CPP) is also a critical monitoring parameter and should be maintained between 50 and 60 mm Hg (greater than 40 mm Hg in pediatric patients) through the use of fluids, vasopressors, and/or ICP normalization therapy.
- 5 Nonspecific pharmacologic treatment in the management of intracranial hypertension should include analgesics, sedatives, antipyretics, and paralytics under selected circumstances.
- 6 Specific pharmacologic treatment in the management of intracranial hypertension includes mannitol, furosemide, and high-dose pentobarbital. Neither routine use of corticosteroids nor aggressive hyperventilation (i.e., PaCO₂ less than 25 mm Hg) should be used in the management of intracranial hypertension.
- 7 Use of phenytoin for the prophylaxis of posttraumatic seizures usually should be discontinued after 7 days if no seizures are observed.
- 8 Numerous investigational strategies (e.g., calcium antagonists, glutamate antagonists, antioxidants, and free-radical scavengers) targeted at interrupting the pathophysiologic cascade of

events occurring following severe TBI have been employed, but no proven therapeutic benefits have been identified.

Traumatic brain injury (TBI) has been referred to as America's "silent epidemic" and is currently the leading cause of death and disability among children and young adults in the industrialized world.^{1,2} Based on an ever-growing understanding of TBI pathophysiology, clinicians and scientists share an optimism that patient outcomes can be improved through the use of evidence-based management guidelines presently and administration of neuroprotective agents in the future. This chapter summarizes TBI epidemiology and pathophysiology and highlights guidelines and systematic reviews of the literature pertaining to the management of severe TBI patients.

EPIDEMIOLOGY

It is estimated that approximately 1.4 million persons sustain a TBI each year in the United States, resulting in 235,000 hospital admissions and 50,000 deaths annually.² Importantly, more than 5.3 million Americans currently live with disabilities as a result of their TBI, highlighting the enormous physical and emotional toll of this health-care problem in the United States.² The economic effects of acute neurotrauma are also enormous, with estimates of spending on TBI patients requiring hospitalization of \$60 billion in the United States in 2000.³ Economic costs to society from lost productivity are astronomical. While the frequency of TBI remains high, the annual mortality rate following TBI has decreased from nearly 25 per 100,000 to 19.4 per 100,000 population since 1979.⁴ Falls are the leading cause of TBI (28%), whereas motor vehicle accidents result in the greatest number of TBI-related hospitalizations and deaths overall.² Fall-related TBIs caused the greatest number of deaths in patients 75 years of age and older.² Furthermore, TBI-related mortality in males exceeds that in females threefold.²

PATHOPHYSIOLOGY

PRIMARY BRAIN INJURY

The neurologic sequelae of brain trauma can occur instantaneously as a consequence of the primary injury or can result from secondary injuries that follow within minutes, hours, or days.¹ Primary injury involves the external transfer of kinetic energy to various structural components of the brain (e.g., neurons, nerve synapses, glial cells, axons, and cerebral blood vessels). The biomechanical forces responsible for primary brain injury can be classified broadly as contact (e.g., blunt-object blow, penetrating-missile injuries) and acceleration/deceleration (e.g., instantaneous brain movements following motor vehicle accidents).¹ Primary injuries are categorized further as focal

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

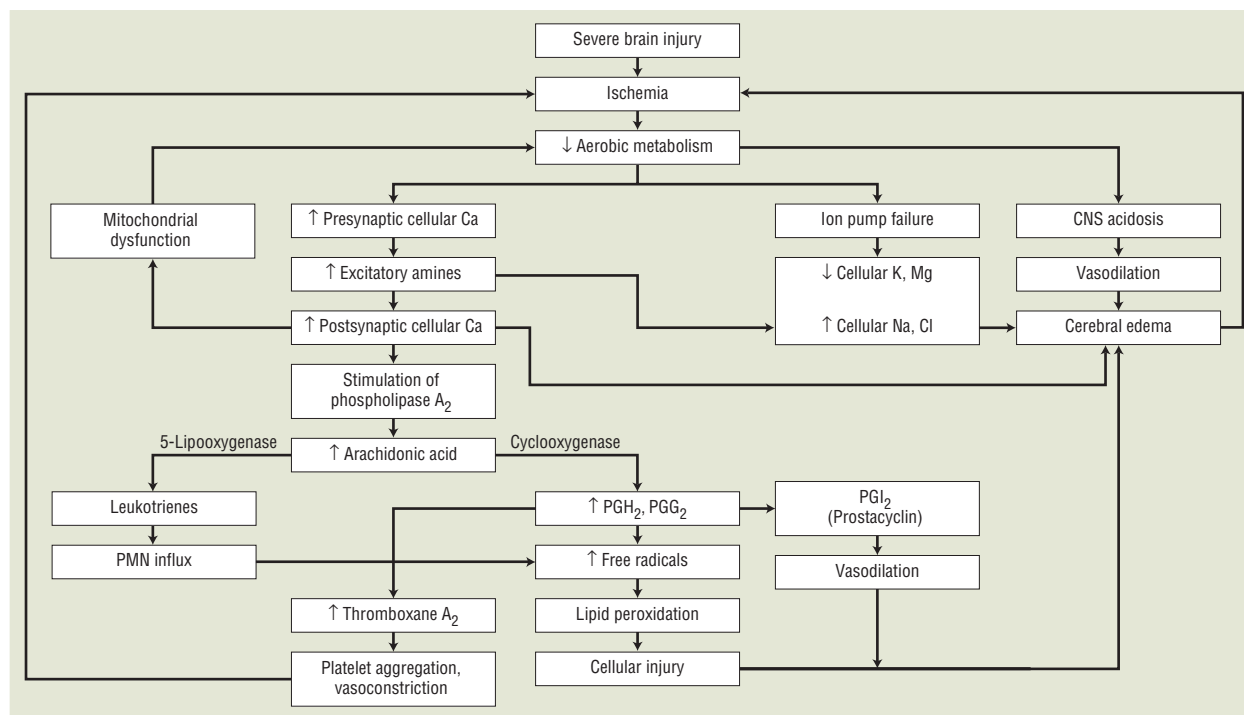

FIGURE 60-1. Schematic illustration of the cascade of biochemical events proposed to occur following severe neurotrauma (secondary brain injury). (Ca, calcium; Cl, chloride; CNS, central nervous system; K, potassium; Mg, magnesium; Na, sodium; PG, prostaglandin; PMN, polymorphonucleocyte.)

(e.g., contusions, hematomas) or diffuse.⁵ The latter usually are associated with shearing or stretch forces, which primarily affect axons within the brain (i.e., diffuse axonal injury).^{5,6} The type of primary injury (i.e., focal versus diffuse) will be a major factor as to which of the secondary injury mechanisms discussed below will predominate following a TBI; however, many patients, especially those involved in high-speed accidents sustain both types of injury.⁷

SECONDARY BRAIN INJURY

1 A complex sequence of pathophysiologic events precipitated by primary brain injury may seriously disrupt the normal central nervous system (CNS) balance between oxygen supply and demand.⁷ Hypotension during the early posttraumatic period is a major contributor to this imbalance and a primary determinant of outcome.^{1,5} The end result of this imbalance may be cerebral ischemia, the key pathophysiologic event triggering secondary injury.⁷ Figure 60-1 is a simplified schematic of the processes that constitute secondary brain injury and their various interrelationships. The brain is particularly susceptible to ischemia because of its normally high resting energy requirement and its limited capacity to store oxygen, glucose, and high-energy phosphate compounds (e.g., adenosine triphosphate). Ischemia following brain injury typically occurs in the first 6 to 24 hours following the insult.⁸ Thereafter, patients can have hyperemia from days 1 to 3.⁸ Vasoconstriction also can occur.⁸ These phenomena can result in imbalances in cerebral oxygen delivery (CDO_2) and consumption (CMRO_2), processes that are closely autoregulated under normal circumstances. Factors that can diminish cerebral oxygen supply following brain injury include cerebral edema, expanding mass lesions (e.g., epidural, subdural, and intracerebral hematomas), cerebral vasospasm, and loss of vasoregulatory control. Vasogenic cerebral edema can develop as a consequence of cerebral capillary endothelial damage and disruption of the blood-brain barrier.⁷ With cytotoxic and vasogenic edema comes expansion of the intracellular and extracellular fluid spaces, respectively. Elevated intracranial pressure (ICP) is the most detrimental consequence of cerebral edema formation and occurs as the brain tissue volume increases within the

nondistensible skull. A significant increase in ICP may further compromise cerebral blood flow (CBF) and extend cytotoxic edema. Hence an increase in ICP can be self-perpetuating unless this cycle is reversed. Hypoxemia can further exacerbate local decreases in cerebral oxygen supply following acute respiratory failure and systemic hypotension. Metabolic demand also can increase following neurotrauma secondary to seizures, agitation, and temperature elevation.

Brain tissue affected by focal ischemia can have a dense core surrounded by a marginally viable region. If adequate CBF is restored, the affected tissue may recover; however, sustained ischemia can result in further loss of cellular integrity and eventual cell death. The loss of ionic homeostasis is postulated to be a key event in fostering secondary brain injury within this ischemic region. Cellular influx of sodium, chloride, and water (i.e., cytotoxic edema) with a corresponding efflux of potassium and magnesium occurs with sodium-potassium-adenosine triphosphatase ($\text{Na}^+\text{-K}^+\text{-ATPase}$) pump dysfunction.⁷ An influx of calcium into the presynaptic terminal ends of damaged neurons is mediated by N-type voltage-sensitive calcium channels. This, in turn, is postulated to stimulate excessive release of the excitatory amines glutamate and aspartate from the affected neurons.⁶ The result is ongoing stimulation of postsynaptic cells, which can result in an extension of neurotoxicity and cell death. Influx of calcium and additional sodium is stimulated by activation ionophore receptors including the N-methyl-D-aspartate (NMDA) receptor.⁷ Calcium influx and its intracellular accumulation initiate a number of events that amplify and perpetuate secondary neuronal injury. High intracellular concentrations of calcium result in mitochondrial dysfunction, which further inhibits cellular respiration, a process already affected by ischemic and/or hypoxic insults.⁷ A second major deleterious effect of calcium is to stimulate activation of autodestructive enzymes, including phosphatases, kinases, lipases, and proteases, such as calpain, and caspases.^{6,7,9} The effect of phospholipase A_2 stimulation includes formation of several arachidonic acid metabolites derived from membrane lipids: thromboxane A_2 , prostaglandins, and leukotrienes.⁷ The subsequent effects of these metabolites are lipid peroxidation and the formation of reactive oxygen species.^{1,7} Recent data suggest that this event occurs very early after injury (e.g., before hospitalization), which

may limit the effectiveness of exogenously administered antioxidants.¹⁰ A common end point with the release of excitatory amines, increases in intracellular calcium, and oxygen free radical generation is apoptosis or programmed cell death and nonprogrammed cellular necrosis.^{7,11,12} Cells with a more elaborate dendritic structure (e.g., cortical neurons, hippocampal cells) may be more vulnerable to the effects of apoptosis.¹³ Cell-mediated injury involving inflammatory mediators (e.g., cytokines, platelet-activating factor, etc.), nitric oxide, and cell adhesion molecules is yet another possible mechanism involved in secondary neuronal injury.⁷ Among the cell lines implicated are polymorphonuclear neutrophils, platelets, endothelial cells, and macrophages. Noteworthy is that limited data suggest that activation of some inflammatory mediators may actually be beneficial such that the relative balance of the mediators versus absolute concentrations may be the most significant pathophysiologic factor following TBI.^{14,15} Stimulation of platelet aggregation, vasodilation, and vasoconstriction, intravascularly, also may occur. Lastly, data suggest that there may be a genetic vulnerability to the effects of TBI.^{6,16} For example, preliminary evidence indicates that this may be related to faster recovery of aspartate uptake from the cerebrospinal fluid and the cerebrospinal fluid lactate-to-pyruvate ratio in TBI patients in the absence of the apolipoprotein E₄ allele.¹⁷ Noteworthy is that this is the same protein that has been associated with the deleterious effects of various types of Alzheimer disease.⁶

CLINICAL PRESENTATION OF ACUTE BRAIN INJURY

General

- Level of consciousness on admission ranges from awake and alert to completely unresponsive (i.e., GCS 15 to 3, respectively).

Symptoms

- Posttraumatic amnesia (e.g., greater than 1 hour), increasing dizziness, a moderate to severe headache, nausea/vomiting, limb weakness, or paresthesia may indicate more severe injury.

Signs

- CSF otorrhea or rhinorrhea and seizures may indicate more severe injury.
- A rapid deterioration in mental status strongly suggests the presence of an expanding lesion within the skull.
- Severe TBI may be accompanied by significant alterations or instability in vital signs, including abnormal breathing patterns (e.g., apnea, Cheyne-Stokes respirations, tachypnea), hypertension, or bradycardia.

Laboratory Tests

- ABGs indicating hypoxia (i.e., decreased PaO₂) or hypercapnia (i.e., increased PaCO₂) may indicate compromised ventilation.
- A positive blood ethanol concentration and/or positive urine drug screen indicates that drug intoxication may be affecting the patient's mental status in addition to the TBI.
- Electrolyte disturbances can cause alterations in mental status, and their effects may interfere with assessment of neurological status relative to brain lesion.

Other Diagnostic Tests

- CT of the head is an important diagnostic tool for detecting the presence of mass lesions.

CLINICAL PRESENTATION

The Glasgow Coma Scale (GCS) is the most widely used system to grade the arousal and functional capacity of the cerebral cortex.^{5,18} The GCS defines the level of consciousness according to eye opening, motor response, and verbal response (Table 60–1). A GCS score of 15 corresponds to a normal neurologic examination. GCS scores of 3 to 8, 9 to 12, and 13 to 15 are consistent with severe, moderate, and mild brain injury, respectively.⁵ The possibility of ethanol or drug intoxication, hypotension, hypoxia, postictal state, or hypothermia altering the neurologic examination always should be considered. Because narcotics and muscle relaxants affect the neurologic examination, they should not be administered, if at all possible, until the initial examination is complete. Simple, rapidly attainable clinical variables that are predictive of survival include patient age, GCS score (especially the motor score), pupillary reactivity, presence or absence of a hematoma, subarachnoid hemorrhage, midline shift, and appearance of the ventricular cisterns found on a computed tomography (CT) scan of the head.¹⁹

TREATMENT

Traumatic Brain Injury

2 In July 1995, the Brain Trauma Foundation (BTF) published an extensive document entitled *Guidelines for the Management of Severe Brain Injury* as a joint initiative with the Guidelines Committee of the American Association of Neurological Surgeons (AANS), the Joint Section on Neurotrauma and Critical Care of the AANS, and the Congress of Neurological Surgeons, with a subsequent revision in 2000 and a third revision pending publication.²⁰ This landmark publication established for the first time a comprehensive series of evidence-based standards, guidelines, and options for the care of severe TBI patients. A recent survey suggested that significant changes consistent with the BTF/AANS guidelines in the acute management of TBI patients have occurred since 1991, providing indirect evidence as to their overall impact on patient care.²¹ Since then guidelines addressing prehospital TBI management,²² surgical management,²³ and management of penetrating brain injury have been published,

and the European Brain Injury Consortium has issued guidelines for the management of severe TBI in adults.²⁴ Furthermore, TBI management guidelines for infants, children, and adolescents have been developed.²⁵ In addition, a series of systematic reviews addressing TBI management emanating from The Cochrane Library has been published.^{26–31} These reviews have rigorously evaluated the literature for essentially all the major conventional TBI strategies. The recommendations emanating from the published guidelines on TBI management and published systematic reviews are highlighted throughout the remaining portion of this chapter. Until further clinical studies become available, recommendations from the published guidelines should serve as the foundation upon which all clinical decisions in managing severe TBI are based.⁶ Nonetheless, it should be noted that the majority of the guidelines are based on class II evidence (primarily prospective clinical trials) and class III evidence (primarily retrospective clinical trials). Few class I evidence studies (i.e., prospective, randomized, controlled trials) are available for traumatic brain injury. Recommendations provided in this chapter pertain to adults and children unless specifically noted to the contrary.

■ DESIRED OUTCOMES

The overall goal in TBI management is not only reduction in morbidity and mortality but also optimization of long-term functional outcome for these patients. This requires careful attention to the following short-term therapeutic goals: (a) establishment of an adequate airway and maintenance of ventilation and circulation during the initial period of resuscitation and evaluation, (b) maintenance of balance between CDO_2 and CMRO_2 , (c) prevention or attenuation of secondary neuronal injury, and (d) prevention and/or treatment of associated medical complications.

■ INITIAL RESUSCITATION

The first priority in the unconscious patient is the establishment of an airway, which ensures adequate oxygenation and prevents aspiration.^{5,32} **3** Thereafter, restoration of circulating blood volume and maintenance of systolic arterial pressure greater than 90 mm Hg are of utmost importance.¹ In pediatric patients, the systolic arterial pressure goal should be greater than 70 mm Hg + ($2 \times$ age in years).²⁵ Correcting and preventing early hypotension (systolic arterial pressure less than 90 mm Hg) and hypoxia (partial pressure alveolar oxygen [PaO_2] less than 60 mm Hg) are essential because these two factors are among the most powerful predictors of outcome.²⁰ Isotonic saline (0.9% normal saline) and lactated Ringer solution are generally advocated as initial resuscitation fluids of choice in TBI patients.²⁰ However, some clinicians believe that hypertonic saline (e.g., 3% or 7.5% saline) is beneficial in the resuscitation of TBI patients.³³ In children, the recommended infusion rate for 3% saline is 0.1 to 1 mL/kg per hour.²⁵ Clinical studies have yielded equivocal results relative to superiority over isotonic solutions.^{1,34,35} Vasopressors and inotropic agents may be needed to maintain an adequate mean arterial pressure (MAP) if hypotension persists after adequate restoration of intravascular volume. Figure 60–2 is an algorithm summarizing treatment priorities in the initial management of acute TBI.

■ POSTRESUSCITATIVE CARE

Following successful resuscitation, priorities shift toward diagnostic evaluation of intracranial and extracranial injuries and emergent surgical intervention as needed. Evacuation of intracranial hematomas (i.e., epidural, subdural, and intracerebral hematomas) is essential to control ICP and improve outcome. Elevation of depressed skull fractures and debridement of penetrating wound tracts are other important emergent surgical procedures in TBI patients. Decompressive

craniectomies (i.e., removal of variable amount of skull bone) with or without temporal or frontal lobectomy may be considered in patients with increases in ICP refractory to more conservative measures.¹ The beneficial effects of routine decompressive surgery in adult TBI patients to date are controversial.³⁶ Nonetheless, improved outcomes with decompressive surgery in pediatric patients have generally yielded more favorable results.³⁶ Continuous ICP monitoring (e.g., intraventricular catheter, intraparenchymal fiberoptic catheter) is indicated in patients with a GCS score of less than or equal to 8 with an abnormal admission CT scan, in selected patients with abnormal CT scans and higher GCS scores, or in high-risk severe TBI patients with a normal CT scan (i.e., age greater than 40 years, motor posturing, systolic arterial pressure less than 90 mm Hg).²⁰ Intraventricular catheters have a therapeutic advantage over the other alternatives but are associated with a higher complication rate and can be difficult to place in the setting of the swollen brain. Specifically, cerebrospinal fluid can be drained using this device as a means to lower ICP.^{1,5} Continuous ICP monitoring is the only means to objectively evaluate the success of therapies used to decrease ICP. Once the ICP exceeds 20 to 25 mm Hg, therapy should be initiated to decrease ICP below 20 mm Hg.^{20,25} Aggressive use of ICP monitors in academic trauma centers across the United States was associated with a reduction in mortality risk as well as a shorter length of stay among survivors.³⁷ A recent study in Europe, however, demonstrated results at variance with the U.S. study; that is, no improvement in outcome in TBI patients managed with a higher therapeutic intensity level.³⁸ The use of historical controls in the U.S. study or other differences in patient management could explain the conflicting results from these two studies. Jugular venous oxygen saturation (Sjvo_2) monitoring is advocated by some practitioners for detection of global cerebral hypoxia (i.e., adequacy of CBF relative to CMRO_2), although it is technically difficult to achieve consistent results, and is not currently addressed within the BTF/AANS guidelines.³⁹ Hence its role remains confined predominantly to use in academic centers and for research.^{5,39,40} Cerebral microdialysis techniques have been used successfully as research tools to measure the cerebral extracellular chemistry of TBI patients.⁴¹ Although the widespread use of this methodology by general clinical practices has been slow, the use of brain tissue oxygen monitoring in TBI patients is gaining momentum.^{6,42} Recently, the roles of several biochemical markers of TBI (e.g., S-100 protein, neuron-specific enolase) were also reviewed.⁴³ The usefulness of these or other proteins for the detection of secondary injury in TBI and/or as a treatment-monitoring parameter is yet to be elucidated.

4 Another important monitoring parameter for severe TBI patients within the intensive care environment is the cerebral perfusion pressure (CPP). The CPP is the difference between MAP and ICP (i.e., $\text{CPP} = \text{MAP} - \text{ICP}$). Maintenance of an acceptable CPP has been postulated to be critical in reducing cerebral ischemia and secondary injury. The BTF/AANS guidelines originally recommended that CPP be maintained greater than 70 mm Hg based on a number of studies that demonstrated decreased morbidity and mortality in patients whose CPP was actively sustained above 70 to 80 mm Hg.²⁰ However, in 2003, the BTF/AANS issued an updated recommendation that CPP be maintained at 60 mm Hg or more.⁴⁴ In the upcoming guideline revision, maintaining a range of CPP between 50 and 70 mm Hg is suggested as the optimal strategy, tailoring the desired range within those parameters to the individual patient. In children, the recommended CPP goal is greater than 40 mm Hg.²⁵ Furthermore, the updated recommendation is that aggressive attempts to maintain CPP greater than 70 mm Hg in adults should be avoided in the absence of cerebral ischemia because of the risk of the acute respiratory distress syndrome.^{20,45} One recent study challenges the relative importance of CPP in TBI patients, suggesting that the primary focus should be on lowering the ICP to less than 20 mm Hg.⁴⁶ In essence, the results of this clinical investigation were that an ICP of 20 mm Hg

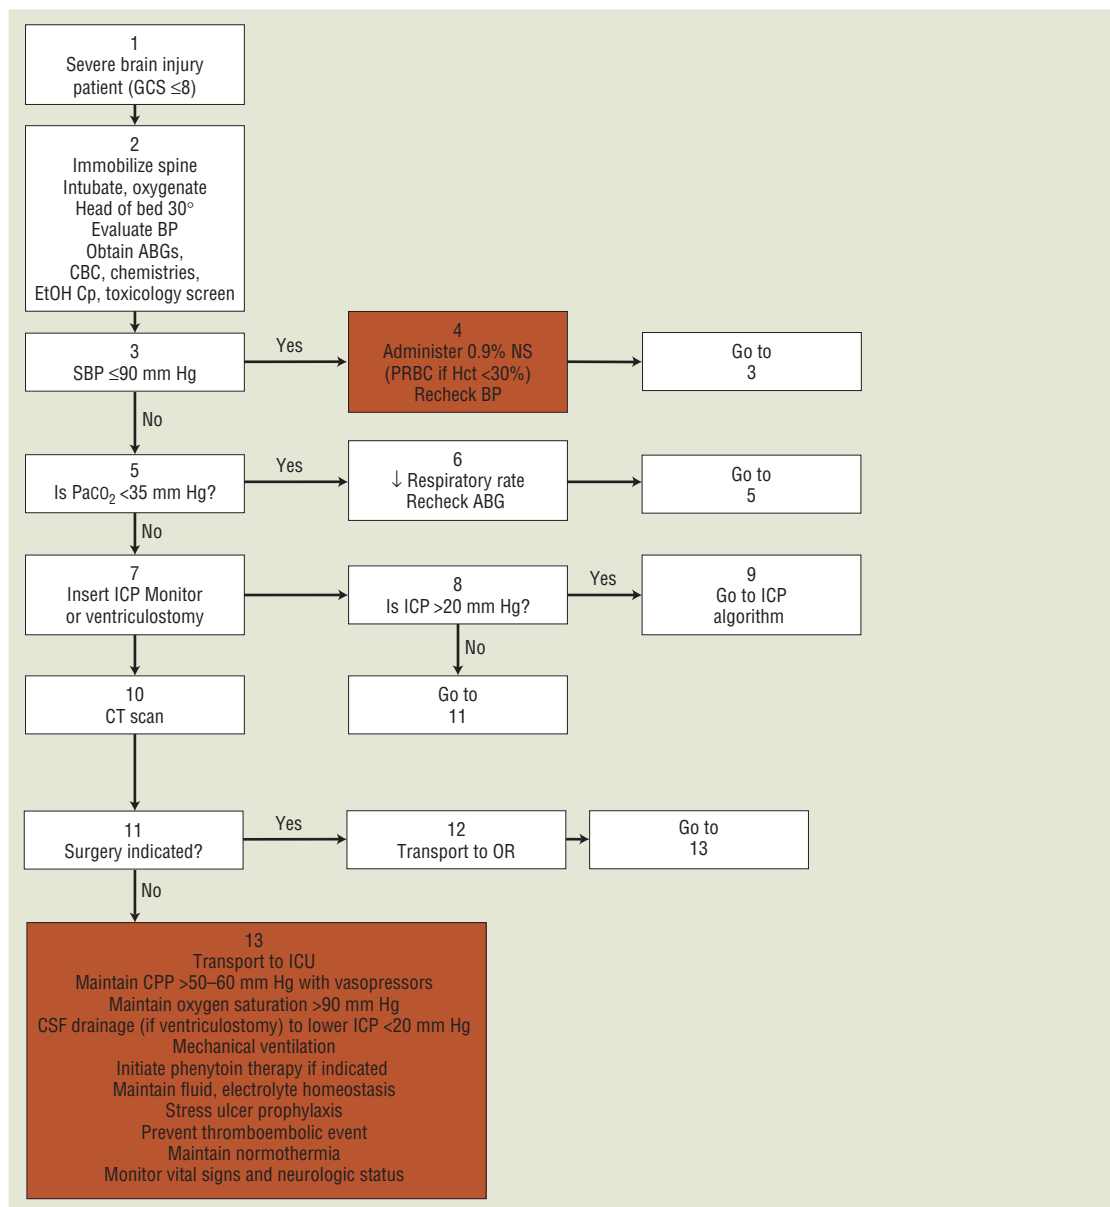

FIGURE 60-2. Algorithm for the acute management of the traumatic brain injury patient. or more was the most powerful predictor of neurologic deterioration as long as the CPP was maintained above 60 mm Hg.⁴⁶

The goal CPP can be achieved by increasing MAP through the use of fluids and/or vasopressors or by lowering elevated ICP. The goal of volume expansion should be euolemia as well as avoidance of a hyposmolar state and negative fluid balance.^{25,34,47} If the hematocrit is below 30%, transfusion of packed red blood cells is indicated.¹ Volume status should be targeted to a central venous pressure of 7 to 12 cm H₂O if invasive monitoring is employed.¹ After achievement of euolemia, the patient's head should be elevated at 30° to promote venous drainage and decrease ICP. If restoration of the intravascular volume is inadequate in elevating MAP to an acceptable level, hypertension should be induced using vasopressors or inotropic support. The drugs employed most commonly to induce hypertension are dopamine, phenylephrine, and

norepinephrine.¹ Patients should be monitored for renal dysfunction, lactic acidosis, and signs of peripheral ischemia when these agents are used, especially at large doses.

TREATMENT

Intracranial Hypertension

■ GENERAL PHARMACOLOGIC STRATEGIES

5 The use of analgesics, sedatives, and paralytics has an important primary role in the management of intracranial hypertension (Fig. 60–3).⁴⁸ This is related directly to the association of pain, agitation, excessive muscle movement, and resisting mechanical ventilation with

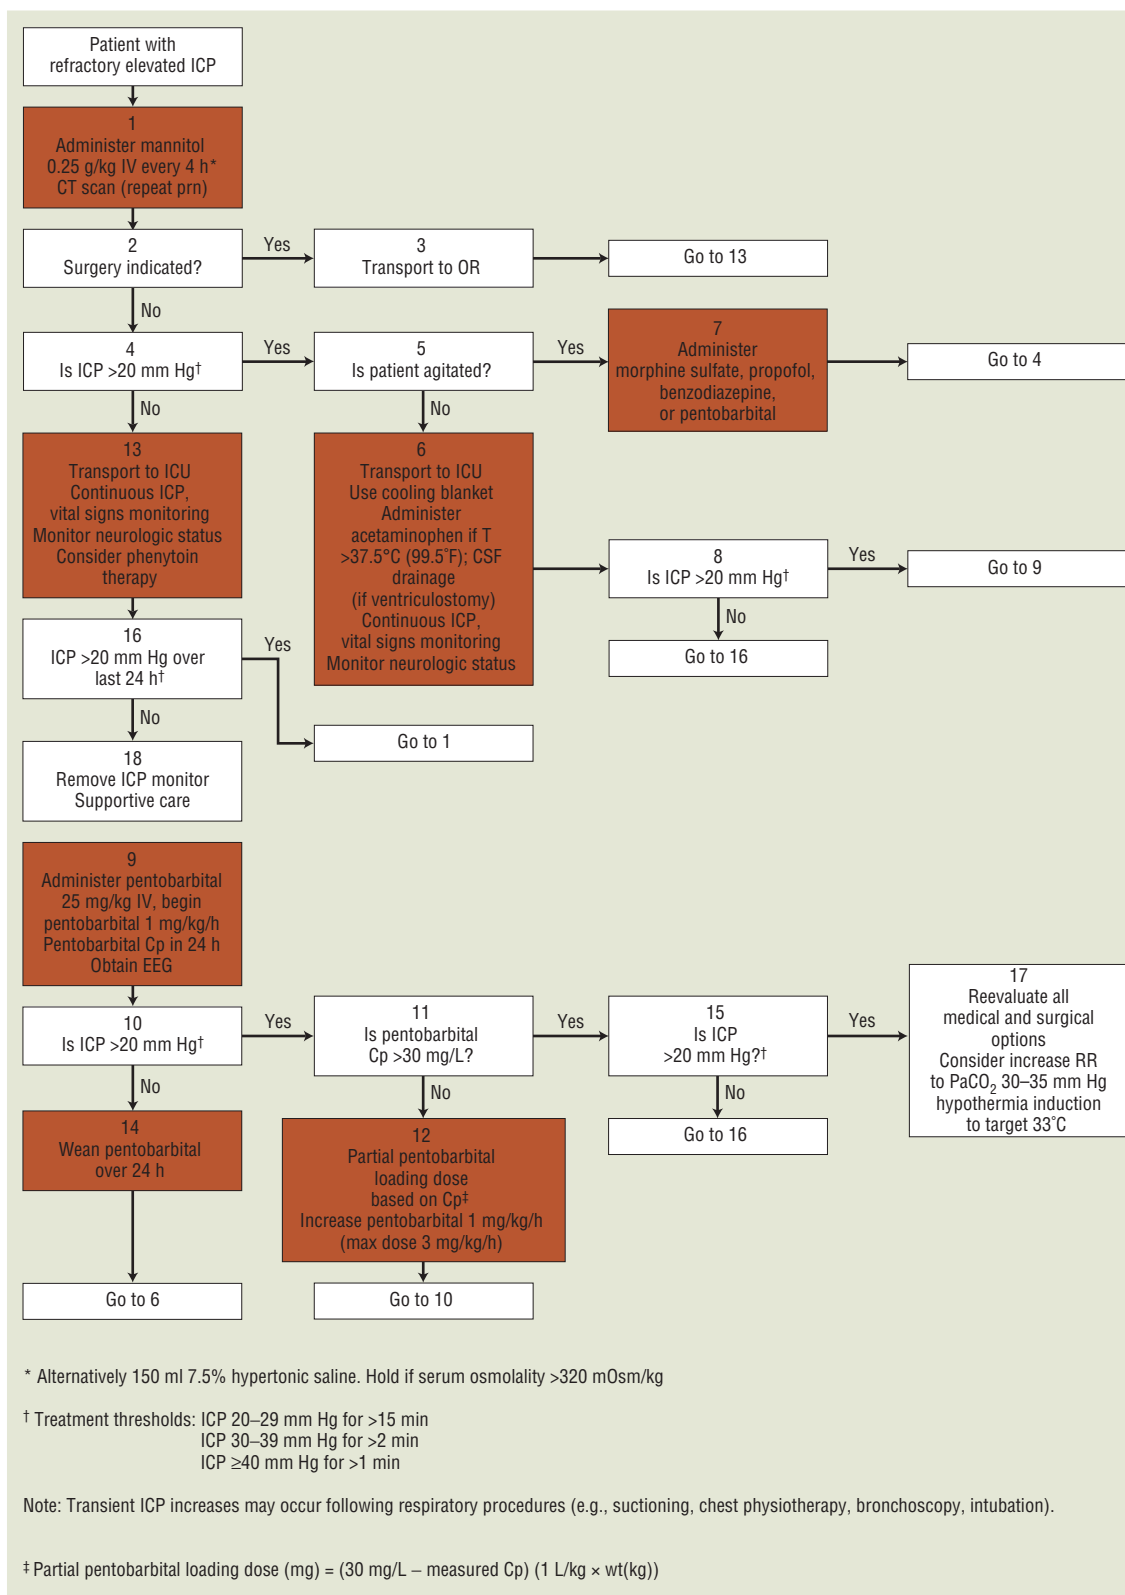

FIGURE 60-3. Algorithm for the management of increased intracranial pressure. (Cp, plasma concentration; CSF, cerebral spinal fluid; CT, computerized tomography; EEG, electroencephalogram; ICP, intracranial pressure; ICU, intensive care unit; OR, operating room; PaCO₂, partial pressure of arterial blood carbon dioxide; T, temperature; RR, respiratory rate.) By permission of the American College of Clinical Pharmacy.)

transient increases in ICP. Nonetheless, there have been no studies of the effect of sedation on outcome in patients with severe TBI.²⁰ Morphine sulfate is the most commonly used analgesic and sedative in this setting.⁵ Propofol has become the sedative of choice in TBI

patients among many clinicians because of its ease of titration, rapidly reversible effects on discontinuation, and possible neuroprotective effects.^{5,49,50} Although it is used for sedation in infants and children who are mechanically ventilated in the ICU setting, the Food and Drug

Administration required that the manufacturer labeling contain specific information that propofol is not approved for sedation of pediatric patients admitted to an intensive care unit (ICU). This is partly a result of the publication of 10 case reports of fatal metabolic acidosis in critically ill children who received propofol.⁵¹ While a direct association between propofol and metabolic acidosis remains unclear, symptoms tend to occur with large doses (greater than 4.8 to 30 mg/kg per hour) and prolonged infusions (longer than 48 to 72 hours). Likewise, long-term infusions in excess of 5 mg/kg per hour should be used cautiously in TBI patients based on a recently published case report series suggesting an association between propofol and cardiac failure.⁵² Triglyceride concentrations also should be monitored in patients receiving prolonged propofol infusions and/or high dosages of propofol considering its lipid emulsion formulation and the potential for inducing hypertriglyceridemia under these conditions. Alternative sedatives include etomidate (particularly useful in rapid-induction anesthesia), intermittent low-dose pentobarbital, and short-acting benzodiazepines (e.g., midazolam), especially if there is a reasonable suspicion of alcohol withdrawal as the underlying etiology of the agitation.⁵ The potential for these agents to decrease MAP and CPP must be monitored closely. Additionally, the cumulative sedative effects of longer-acting drugs, especially benzodiazepines, must be taken into account. The use of any sedative agent also must be weighed against its potential to obscure the neurologic examination of the patient. Interference with the neurologic examination is also associated with paralytic agents. Prophylactic neuromuscular blockade (i.e., unrelated to ICP control) is not recommended based on evidence indicating increased complications (e.g., pneumonia, prolonged paralysis) and length of stay following use of paralytic agents.⁵

■ HYPERVENTILATION

6 The practice of prolonged aggressive hyperventilation (PaCO_2 less than 25 mm Hg) to decrease ICP is no longer recommended.²⁰ Hyperventilation acutely decreases systemic and cerebral PaCO_2 . The resulting hypocapnia, in turn, induces cerebral vasoconstriction, thereby decreasing CBF and cerebral blood volume.⁵³ For decades, it was a widely held belief that a reduction in cerebral blood volume and any accompanying decrease in ICP were beneficial. Nonetheless, a systematic review of the literature concluded that data are inadequate to ascertain potential benefit or harm from hyperventilation.³¹ Other studies have determined that severe TBI patients with normocapnia, compared to those receiving aggressive hyperventilation, have an improved outcome at 3 and 6 months.²⁰ Furthermore, recent evidence using microdialysis and local CBF techniques suggests that aggressive hyperventilation may increase extracellular glutamate, a mediator of secondary injury, and lactate concentrations.⁵⁴ Despite the decrease in CBF during hyperventilation, no detrimental decrease in CMRO_2 was observed in a recent study.⁵³ Nonetheless, the potential for decreased CBF to increase the possibility for cerebral ischemia must be weighed. In consideration of the equivocal data relative to the merits of therapeutic hyperventilation in TBI patients, BTF/AANS guidelines recommend that PaCO_2 be maintained near 35 mm Hg, especially during the first 24 hours.²⁰ Thereafter, a PaCO_2 in the range of 30 to 35 mm Hg may be used if ICP control is inadequate.^{1,25,50} Aggressive hyperventilation (25 to 30 mm Hg) for brief periods may be considered as second-tier therapy in the setting of refractory intracranial hypertension or in the initial management of patients with signs of cerebral herniation.^{20,25} Cerebral tissue oxygen perfusion monitoring may be used to guide the use of this therapeutic intervention.

■ HYPOTHERMIA

Hyperthermia also should be avoided in TBI patients because patients with elevated temperatures have poorer outcomes than normothermic patients.^{1,25,55} Hence aggressive maintenance of a core tempera-

ture of less than 37.5°C (99.5°F) using acetaminophen, nonsteroidal antiinflammatory drugs, and cooling blankets is indicated for patients following severe TBI. Several experimental cooling techniques, including intravascular cooling for use in TBI patients refractory to conventional management strategies, were discussed in a recent review of this topic.⁵⁵

Although hypothermia has been discussed for nearly 50 years as a cerebral protective maneuver in TBI patients, a resurgence of interest has been fueled by the results of several preliminary studies in the early 1990s demonstrating trends in improvement in mortality and morbidity rates in severe TBI patients randomized to receive mild to moderate hypothermia. However, in the most extensive investigation to date, TBI patients randomized to receive hypothermia ($n = 199$) within 6 hours of injury (target body temperature 33°C [91.4°F]) and maintained for 48 hours did not have significantly improved outcomes compared with a normothermia group of TBI patients ($n = 196$) at 6 months.⁵⁶ Two meta-analyses confirm these results, concluding that hypothermia is not beneficial in the management of TBI patients.^{28,56,57} Regardless, a systematic review of the literature did discern potential benefits in reducing mortality and poor neurologic outcomes based on data combined from 12 trials.⁵⁸ Depth and duration of hypothermia, as well as the rate of rewarming after discontinuation of hypothermia, are additional factors that may affect outcomes with this therapeutic maneuver in TBI patients.^{58,59} The mechanism underlying a protective effect of hypothermia is likely multifactorial, although a reduction in CMRO_2 is offered most frequently as the basis of any therapeutic benefits. Potential side effects of hypothermia include coagulation disturbances, infectious complications, and cardiac arrhythmias.^{57,58} An increase in ICP also may occur secondary to hypothermia-associated shivering that can be prevented with neuromuscular blocking agents. Unfortunately, these agents are also associated with potential adverse events, as discussed previously. Considering these latter risks and equivocal data from clinical trials to date, hypothermia should continue to be considered an investigational treatment.

CLINICAL CONTROVERSY

The optimal initial strategy for acutely lowering increased ICP in TBI patients is equivocal. While the osmotic diuretics have traditionally been used as first-line therapy, use of hypertonic saline solutions is advocated by some clinicians. Not only does hypertonic saline result in plasma volume expansion, but attenuation of immunologic and biochemical events may also be responsible for some of its beneficial effects.

■ OSMOTIC AGENTS

6 Although a number of osmotic diuretics (e.g., urea, glycerol) can be used to decrease ICP, mannitol is unquestionably the most widely employed.¹ Despite the common practice of administering mannitol to patients with suspected or actual increases in ICP following brain injury, no clinical trial comparing its effects against placebo have been performed.²⁶ The mechanisms responsible for mannitol's beneficial effects likely relate to (a) an immediate plasma-expanding effect that reduces blood viscosity and increases CBF and (b) establishment of an osmotic concentration gradient across an intact blood-brain barrier that decreases ICP as water diffuses from the brain into the intravascular compartment.²⁰ If the blood-brain barrier is disrupted as a result of injury, rebound elevations of ICP may occur with prolonged use of the osmotic agent because mannitol accumulates in the brain tissue, resulting in an increase in intracellular brain volume.⁵¹ Recommended doses of mannitol typically range from 0.25 to 1 g/kg intravenously every 4 hours.²⁰ However, two recent studies using larger bolus doses of mannitol (i.e., approximately 1.4 g/kg) revealed

improved clinical outcomes compared with TBI patients with temporal lobe hemorrhages and subdural hematomas treated with conventional dosages.^{26,60,61} These two studies not only address the importance of the mannitol dose for this indication, but they also represent the few data substantiating the benefits of mannitol despite its use in managing TBI for over 50 years.⁶²

Increased ICP is reduced within minutes following mannitol administration, and the duration of action ranges from 90 minutes to 6 hours, depending on the dose and the clinical conditions that are present.²⁰ To maximize benefit and minimize adverse events, it is generally recommended that mannitol be administered as a bolus and not as a continuous infusion in this setting.^{1,20} However, no clinical trials have directly compared these two administration techniques.⁶³ Intravenous furosemide (0.5 to 1 mg/kg) may be used in conjunction with mannitol in refractory cases.

Several adverse effects are associated with mannitol. In addition to hypotension resulting from its diuretic effect, a reversible acute renal dysfunction may occur in patients with previously normal renal function after long-term, large-dose administration, especially if the serum osmolality or serum sodium exceeds 320 mOsm/kg and 160 mEq/L, respectively.^{1,20} Hence monitoring and maintaining the serum osmolality and sodium, and replacing urinary fluid losses are important to minimize this adverse event. Mannitol should be avoided in patients with renal failure.^{5,25} Acute exacerbation of underlying congestive heart failure and pulmonary edema also may occur following rapid intravascular volume expansion. Furosemide is recommended as an alternative diuretic for lowering ICP in these latter patient groups.

Although hypertonic saline solutions have been advocated as a resuscitative fluid following TBI patients as previously mentioned, solutions ranging from concentrations of 3% to 23.4% have been used to acutely lower increased ICP.^{32,35} Not only do hypertonic saline solutions create an osmotic gradient in favor of reducing cerebral edema, but recent evidence suggests that they may also have beneficial vasoregulatory, immunologic, and neurochemical effects.^{15,64} A recent isovolume head-to-head comparison of 20% mannitol versus 7.5% hypertonic saline in 20 TBI patients refractory to nonspecific therapy (i.e., sedation, analgesia, body positioning) demonstrated significant improvement in the duration and number of elevated ICP episodes per day in those treated with hypertonic saline.⁶⁵ No differences in mortality or functional outcome were observed in this study between the two patient groups. Definitive superiority of hypertonic saline therapy compared with osmotic diuretics will require further investigation.

■ BARBITURATES

6 High-dose barbiturate therapy (i.e., *barbiturate coma*) has been used for decades in the management of increased ICP despite a lack of evidence documenting beneficial effects on patient morbidity and mortality.³⁰ Nonetheless, based largely on beneficial outcomes observed in a randomized clinical trial published in 1988, BTF/AANS and pediatric guidelines recommend that high-dose barbiturate therapy be considered in hemodynamically stable severe TBI patients refractory to maximal medical ICP-lowering therapy and decompressive surgery.^{20,25} Prophylactic use of barbiturates is not advocated in light of insufficient evidence supporting this practice and the potential for adverse events (e.g., hypotension).^{20,30} Several mechanisms responsible for the cerebral protective effects of barbiturates have been proposed. These include (a) lowering the regional CMRO₂ with a coupled reduction in CBF to these areas, (b) inhibition of lipid peroxidation, and (c) alteration of cerebral vascular tone.^{1,48} Prior to inducing a barbiturate coma, the severe TBI patient must be mechanically ventilated with continuous monitoring of arterial blood pressure, electrocardiogram, and ICP. Pentobarbital is the most commonly used barbiturate for this indication, although thiopental also has been used. Pentobarbital should be administered as an intravenous loading infusion totaling 25 mg/kg (i.e., 10 mg/kg over 30

minutes and then 5 mg/kg per hour for 3 hours), followed by a maintenance infusion of 1 to 2 mg/kg per hour.^{1,37} If the systolic blood pressure falls during the loading or maintenance infusions, the rate should be slowed temporarily and blood pressure support initiated. The goal of a barbiturate coma is to maintain ICP and CPP at the previously discussed target thresholds in addition to achieving a pentobarbital steady-state concentration of between 30 and 40 mg/L and electroencephalogram burst suppression. Initiation of barbiturate therapy withdrawal can occur when ICP has been controlled satisfactorily for 24 to 48 hours.²⁰ Barbiturates should be tapered over 24 to 72 hours to prevent ICP spikes.

Side effects associated with high-dose barbiturate therapy involve primarily the cardiovascular system. Hypotension caused by peripheral vasodilation may occur, necessitating decreasing the barbiturate dose or the administration of fluids and vasopressors to maintain blood pressure. A recent systematic review of the literature suggested that one of every four patients receiving barbiturate therapy will develop hypotension.³⁰ Gastrointestinal (GI) effects of barbiturates include decreased GI muscular tone and decreased amplitude of contraction. On emergence from coma, there may be a period of GI hypermotility. Care should be taken to avoid extravasation of pentobarbital and thiopental solutions because severe tissue damage may occur. Barbiturates should be administered by continuous infusion through a central line dedicated for this purpose. The potential for barbiturates to induce the hepatic drug metabolism of concurrent medications should also be considered. Lastly, the potential for prolonged interference with the proclamation of brain death in TBI patients meeting the locally accepted brain death neurologic criteria must be considered prior to the initiation of high-dose barbiturate therapy.

■ CORTICOSTEROIDS

6 Although corticosteroids are effective in preventing or reducing cerebral edema in patients with nontraumatic conditions producing vasogenic edema, most studies in TBI patients have not demonstrated that they lower ICP or improve outcome.²⁰ In addition, use of corticosteroids following TBI is associated with increased complications, including GI bleeding, glucose intolerance, electrolyte abnormalities, and infection. Based on several major randomized trials, the BTF/AANS adult and pediatric guidelines recommend that corticosteroids not be used as the only intervention with evidence supporting a treatment standard put forth in the 2000 version of the guidelines.^{24,25} Recent systematic reviews nonetheless have concluded that neither moderate benefits nor moderate harmful effects of corticosteroids in TBI patients can be excluded after review of all clinical trial data collected to date.⁶⁶ Noteworthy is that an international investigation known as the CRASH (Corticosteroid Randomization After Significant Head Injury) study was initiated in an attempt to define the merits of corticosteroid therapy in patients with TBI.⁶⁷ In this study 10,008 patients with a GCS score less than or equal to 14 were randomized to receive a 48-hour continuous infusion of methylprednisolone or placebo. Results of this study indicate a higher risk of death within 2 weeks of enrollment (relative risk: 1.18) in those patients receiving corticosteroids compared with patients receiving placebo ($P < 0.001$).⁶⁷ Thus, corticosteroids should not be used to treat TBI patients regardless of severity.^{20,27,67}

TREATMENT AND PROPHYLAXIS

Posttraumatic Seizures

It is generally agreed that patients who have experienced one or more seizures following a moderate to severe TBI should receive anticonvulsant therapy to avoid increases in CMRO₂ that occur with the onset of subsequent seizures and to prevent the development of (sometimes

subclinical) status epilepticus with associated increase in mortality. Initial therapy in these persons should consist of incremental intravenous doses of diazepam (5 to 40 mg adults; 0.1 to 0.5 mg/kg infants and children) or lorazepam (2 to 8 mg adults; 0.03 to 0.1 mg/kg infants and children) to terminate any active seizure activity followed by intravenous phenytoin to prevent seizure recurrence. Phenytoin dosing regimens for adults and pediatric patients include an intravenous loading dose of 15 to 20 and 10 to 15 mg/kg, respectively, followed by a maintenance dose of 5 mg/kg per day. Alternatively, fosphenytoin, a water-soluble phosphate ester of phenytoin, can be administered intravenously or intramuscularly using the same doses, specified as phenytoin equivalents. The merits of preventive anticonvulsant therapy in patients who have not had a seizure postinjury historically have been more controversial. Risk factors for early posttraumatic seizures (less than 7 days after injury) include a GCS score of less than 10, a cortical contusion, a depressed skull fracture, a subdural hematoma, an epidural hematoma, an intracerebral hematoma, a penetrating head wound, or a seizure within the first 24 hours of injury.²⁰ In a landmark randomized, placebo-controlled study, the incidence of early posttraumatic seizures in patients receiving placebo was 14.2% compared with 3.6% in patients receiving phenytoin ($P < 0.05$) without a significant increase in drug-related side effects.⁶⁸ **7** A systematic review of the literature corroborated these findings, estimating an improved pooled relative risk for early seizure prevention of 0.34 (95% confidence interval: 0.21 to 0.54) in patients receiving anticonvulsants.⁶⁹ Thus it is recommended that phenytoin (or, alternatively, carbamazepine) should be used to prevent seizures in TBI patients who are at high risk for the first 7 days after injury.^{20,25,70} Valproate therapy is not recommended based on a trend for higher mortality in a study comparing valproate-treated patients with those receiving phenytoin short-term therapy.⁷¹ The benefits of prophylactic anticonvulsants beyond 7 days have not been demonstrated, and thus their use for this indication is not recommended.^{24,69} Unfortunately, despite reducing the incidence of early seizures following brain injury, no beneficial effects have been documented for anticonvulsants on patient mortality or long-term disability.⁶⁹

■ SUPPORTIVE CARE

Although normalizing ICP and maintaining an adequate CPP are the highest priorities in preventing secondary injury following severe TBI, attention also must be given to preventing and/or treating systemic and extracranial complications. This includes careful ongoing fluid and electrolyte management.³⁵ Common electrolyte disturbances in TBI patients that should be monitored and treated aggressively include hyponatremia, hypomagnesemia, hypokalemia, and hypophosphatemia. Aggressive nutritional support of the TBI patient is another important therapeutic consideration.^{20,25} Evidence suggests that early feeding of TBI patients (i.e., by 7 days) may be associated with a trend toward better outcomes in terms of survival and disability.^{20,72} Infectious complications commonly encountered in severe TBI patients include nosocomial pneumonia, sepsis, urinary tract infections, and meningitis.¹ Treatment of these potentially devastating infections should be aggressive, with careful attention being paid to antibiotic blood-brain barrier penetration for intracranial infections. Other important therapeutic interventions include correction of any documented coagulopathy,⁴⁸ acute gastritis prophylaxis,⁵ and prevention of decubitus ulcers and contractures. Prevention of thromboembolic events is also extremely important supportive care in TBI patients.¹ This can be accomplished with the use of intermittent pneumatic compression devices initially with the initiation of systemic therapy (e.g., low-molecular-weight heparin) generally within 2 to 3 days thereafter.^{73–75} However, systemic anticoagulation must be used with caution in those patients with intracerebral hemorrhage, or in patients who may need to undergo craniotomy early in their course.

■ CLINICAL PATHWAYS/GUIDELINE IMPLEMENTATION

Use of clinical pathways and formal TBI management guidelines has been demonstrated to improve TBI patient outcomes and reduce institutional resource use. For example, implementation of a severe TBI clinical pathway resulted in a significant reduction in length of stay, ICU stay, and ventilator days among survivors at one institution.⁷⁶ Implementation of published TBI guidelines also has been demonstrated to have significant impact on patient outcomes compared with historical controls in three other institutions.^{77–79} Few practitioners would dispute the overall importance of integrating current evidence-based management guidelines into clinical practice as a means to optimize care and improve the functional outcome of TBI patients.⁸⁰

■ INVESTIGATIONAL THERAPY

8 The steady decrease in morbidity and mortality following severe neurotrauma over the last 30 years can be attributed largely to expeditious and aggressive management of events resulting in secondary injury (i.e., ischemia, hypoxia, increased ICP) using conventional treatment strategies.⁶ Numerous neuroprotective agents targeting specific pathophysiologic processes that are theorized to occur following severe TBI have been investigated over the last decade in an attempt to further enhance the prospects for a meaningful recovery. Prominent among these strategies have been attempts to modulate calcium influx through the administration of calcium antagonists^{29,81} and glutamate antagonists,^{6,81–84} and the use of antioxidants/free radical scavengers.^{81,85} Inhibitors of inflammatory mediators also are under consideration as neuroprotective agents.^{86,87} Unfortunately, none of these agents to date has demonstrated a significant reduction in morbidity or mortality following severe TBI in phase III clinical trials with the exception of nimodipine in a subset of patients.⁸⁸ Noteworthy is that a phase II pilot study recently demonstrated a decrease in mortality in 100 TBI patients randomized to receive a 3-day infusion of progesterone compared with placebo.⁸⁹ Corroboration of these results is required before this approach can be endorsed. Lastly, various growth factors, including brain-derived neurotrophic factor, nerve growth factor, neurotrophin-3, and erythropoietin,⁹⁰ may have a future role in the management of TBI by promoting nerve cell regeneration and differentiation.^{86,91} Such neurorestorative strategies can be classified as structural or functional.⁶ Importantly, such strategies may be the most fertile targets for genetic manipulation in the future and may have significant implications for post-TBI rehabilitation.⁶ Despite generally negative clinical trial findings to date, the search is likely to continue for neuroprotective agents that eventually may improve the long-term outcome in severe TBI patients.

CLINICAL CONTROVERSY

Interest in the use of CNS stimulants, such as methylphenidate and agents that modify the neurochemical balance within the brain, such as Parkinson's disease medications (e.g., amantadine, bromocriptine) and antidepressants following TBI, has existed for years. Relatively small studies using these approaches to improve the cognitive and behavioral outcomes in TBI patients have demonstrated potential benefits. Off-label use of these drugs in TBI patients following the acute phase of their management should be considered investigational until large scale, controlled trials document their utility.

■ OTHER TREATMENT STRATEGIES

The concept of administering commercially available CNS active agents off-label should presently be considered investigative therapy. One example is the use of CNS stimulants in the management and

rehabilitation of TBI patients. A comprehensive review of the use of methylphenidate relative to improving cognition in TBI was recently conducted. It was the opinion of the author that the literature does provide a degree of support for improvements in memory, attention, concentration, and mental processing in this patient subset, although results and study designs were highly variable for those investigations included in the analysis.⁹² Another example is the use of Parkinson disease medications (e.g., amantadine, bromocriptine, carbidopa/levodopa) in severe TBI patients in an attempt to enhance dopamine release and inhibit reuptake within the injured region of the brain. A review of amantadine following TBI patients indicated that improved cognition and reduced agitation were evident in the majority of patients studied.⁹³ A recent trial of the rivastigmine used for the treatment of Alzheimer disease demonstrated improved memory in a group of TBI patients with moderate to severe memory loss.⁹⁴ Antidepressants represent another class of agents that has been studied in TBI patients. Although intuitively appealing, routine administration of psychostimulants to improve cognitive outcomes in TBI patients or drugs that enhance the biochemical milieu within the CNS following a TBI should be done cautiously until large, well-controlled studies demonstrating beneficial effects are available. Additionally, the timing of administration of these drugs is controversial; the potential for cardiovascular side effects in the face of uncertain benefit would indicate that these drugs should be reserved for the after acute phase of treatment (i.e., weeks to months after injury).

EVALUATION OF THERAPEUTIC OUTCOMES

Table 60–2 summarizes the process for evaluation of therapeutic outcomes. Patients with severe TBI require ICU monitoring initially with the goals of maintaining or reestablishing neurologic and systemic homeostasis as well as readily detecting any neurologic deterioration. This requires frequent evaluation of the patient’s neurologic status (e.g., GCS) and measurement of vital signs, urine output, and

arterial oxygen saturation (as well as ICP in patients with an ICP monitor in place). Furthermore, careful attention must be paid to the potential for a variety of electrolyte, mineral, and acid–base disturbances, coagulopathies, and infections by obtaining various laboratory tests on a daily basis initially. The intensity of monitoring will be a function of the relative degree of neurologic and hemodynamic stability of the patient in the hours and days following the neurologic insult. Lastly, radiologic tests (e.g., CT scans) are essential not only for the initial diagnostic evaluation of TBI patients but also as a means to evaluate the etiology for any subsequent neurologic deterioration.

TABLE 60-2 Evaluation of Therapeutic Outcomes	
General	GCS: record hourly initially, decrease frequency as neurologic status stabilizes Vital signs (BP, HR, RR, temperature): record hourly initially, decrease frequency as neurologic status stabilizes Urine output: record hourly initially, decrease frequency as neurologic status stabilizes Arterial oxygen saturation: continuously while in intensive care unit
Risk of increased ICP	ICP: record hourly, decrease frequency as ICP stabilizes less than 20 mm Hg (usually not until 48–72 hours postinjury at a minimum) ^a CPP: record hourly, decrease frequency as CPP stabilizes in the desired range
Laboratory tests	Ethanol concentration and urine drug screen: on admission ABGs: daily at a minimum while intubated, repeated as needed based on pulmonary instability requiring ventilator setting changes CBC: daily while in intensive care unit Serum electrolytes (Na, K, Cl): daily while in intensive care unit; serum sodium and osmolality may be monitored as frequently as every 6 hours if osmotherapy (mannitol, furosemide, hypertonic saline) is being used Minerals (Mg, Ca, P): daily initially until concentrations stable
Radiologic procedures	CT scan: postresuscitation initially with repeat scan(s) as needed based on degree of neurologic instability (e.g., decrease in GCS) or initial CT appearance

ABG, arterial blood gas; BP, blood pressure; Ca, calcium; CBC, complete blood count; Cl, chloride; CPP, cerebral perfusion pressure; CSF, cerebrospinal fluid; CT, computed tomography GCS, Glasgow Coma Scale; HR, heart rate; ICP, intracranial pressure; K, potassium; Mg, magnesium; Na, sodium; P, phosphorus; RR, respiratory rate; TBI, traumatic brain injury.
^aContinuous monitoring mandated initially if technologically feasible.

KEY CONCEPTS

- 1 Thoughtful consideration for selection of initial therapy, management of drug dosing, and use of adjunctive therapies throughout the course of idiopathic Parkinson's disease (IPD) is necessary to optimize long-term therapeutic outcomes and minimize adverse effects.
- 2 The optimal time to start drug therapy in IPD varies, but in general, treatment is initiated when the disease begins to interfere with activities of daily living, employment, or quality of life.
- 3 Anticholinergic medication is useful for mild tremor-predominant IPD but should be used with caution in the elderly and in those with preexisting cognitive difficulties.
- 4 As monotherapy, amantadine and monoamine oxidase type B (MAO-B) inhibitors provide benefits in early IPD, but the symptomatic effect is less than that of dopamine agonists and carbidopa/levodopa (L-dopa).
- 5 Carbidopa/L-dopa is the most effective medication for symptomatic treatment and eventually all patients with IPD will require it.
- 6 Most carbidopa/L-dopa-treated patients will develop motor complications (e.g., fluctuations and dyskinesias).
- 7 MAO-B inhibitors and catechol-O-methyl-transferase inhibitors attenuate motor fluctuations in carbidopa/L-dopa treated patients.
- 8 Initial monotherapy with a dopamine agonist is effective and, compared to L-dopa, associated with less risk of developing motor complications but is more likely to cause psychiatric symptoms such as hallucinations and impulse control disorders.
- 9 Surgery is reserved for patients who require additional symptomatic relief or control of motor complications despite receiving medically optimized therapy.

The presence of tremor at rest, rigidity, bradykinesia, and postural instability (instability of balance) are considered the hallmark motor features of idiopathic Parkinson's disease (IPD). These clinical features of IPD were adeptly described in 1817 by James Parkinson.¹

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

EPIDEMIOLOGY

Up to 1 million individuals in the United States have IPD. The approximate annual incidence of IPD (i.e., number of persons diagnosed with IPD per year) is age-dependent and ranges from 10 per 100,000 persons in the sixth decade of life (i.e., 50–59 years of age) to 120 per 100,000 persons in the ninth decade of life (i.e., 80–89 years of age).^{2,3} Likewise, the prevalence of IPD also increases with age, affecting 1% of people older than age 65 years and 2.5% of those older than age 80 years. IPD is less frequent in patients younger than age 50 years and the usual age at time of diagnosis ranges between 55 and 65 years. A higher incidence is reported among males, with a male-to-female ratio of up to 2:1.

ETIOLOGY

The true etiology of IPD is unknown, but factors such as genetic constitution and toxin (intrinsic or extrinsic) exposure most likely play a role. In IPD, a key histopathologic feature is degeneration of dopaminergic neurons in the substantia nigra that project to the striatum (i.e., the nigrostriatal pathway).⁴ Additionally, neuronal vulnerability in IPD extends beyond the nigrostriatal pathway and includes specific neurons in autonomic ganglia, basal ganglia, spinal cord, and neocortex.⁵ In humans, administration of the compound 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) results in a form of parkinsonism. The MPTP compound is converted by monoamine oxidase (MAO)-B to 1-methyl-4-phenylpyridinium ion (MPP⁺), a potent neurotoxin in humans and animals. MPP⁺ is toxic to neurons by inhibiting mitochondrial complex 1 of the electron transport chain, which results in the generation of excessive reactive oxygen species and cell death.⁶ Several synthetic pesticides have a molecular structure similar to that of MPTP. Although IPD is sporadic in most instances, extensive epidemiologic research associates environmental factors, such as chronic exposure to pesticides and heavy metals (such as iron and manganese), rural living, and drinking well water, with small but demonstrable contributions to the risk for lifetime development of IPD.⁷ Interestingly, epidemiologic studies have consistently associated an inverse correlation between cigarette smoking and caffeine consumption for development of IPD.^{8,9}

Intrinsically, the substantia nigra pars compacta (SNc) is a region characterized by high levels of oxidative stress because free radicals are generated from dopamine autooxidation mediated by MAO (Fig. 61–1). Several antioxidative molecules (e.g., glutathione) are present in the SNc to limit damage produced by free-radical attack, but in IPD, such protection might be overwhelmed or impaired. Thus cellular damage from oxidant stress is implicated as an etiopathologic component of IPD.¹⁰ The SNc is also rich in iron and copper, essential cofactors in the biosynthesis and metabolism of dopamine. The oxidation–reduction cycle of iron can also generate

FIGURE 61-1. Dopamine metabolism results in hydrogen peroxide (H_2O_2) formation. If the glutathione system is deficient or excess hydrogen peroxide is present, hydrogen peroxide accepts an electron from ferrous iron (Fe^{2+}), forming ferric iron (Fe^{3+}) and the hydroxyl free radical (OH^\bullet). The hydroxyl free radical can cause lipid peroxidation, thereby damaging neuronal cell membranes. (DOPAC, 3,4-dihydroxyphenylacetic acid; GSH, glutathione; GSSG, glutathione disulfide; H_2O , water; OH^- , the hydroxide ion; MAO-B, monoamine oxidase B.)

free radicals and toxic metabolites (e.g., hydrogen peroxide) (Fig. 61-1). Apoptosis (programmed cell death), excitotoxicity, inflammation, mitochondrial dysfunction, nitric oxide toxicity, proteosomal dysfunction, and autophagic cellular mechanisms are also implicated etiopathologic mechanisms in IPD.

Genetics may play a significant role, particularly if IPD begins before age 50 years.^{11,12} More than a dozen gene mutations are associated with forms of parkinsonism. For example, autosomal dominant forms of parkinsonism are associated with mutations of the α -synuclein (*PARK1*) and *leucine-rich repeat kinase 2* (*LRRK*) genes. Autosomal recessive forms are associated with mutations of *parkin* and *PINK1* genes. Overall, these forms of genetically linked parkinsonisms constitute only a small percentage of total parkinsonism cases and their pathology and phenotypic aspects differ from that of IPD.

PATHOPHYSIOLOGY

In the SNc, the two hallmark histopathologic features of IPD are depigmentation of dopamine-producing neurons (i.e., loss of SNc neurons) and presence of Lewy bodies (neuronal cytoplasmic filamentous aggregates composed of the presynaptic protein α -synuclein) in the remaining SNc neurons. Lewy bodies appear in degenerating neurons in association with adjacent gliosis. Lewy pathology has been proposed to develop in a predictable anatomic distribution within the parkinsonian brain.⁵ In the preclinical (i.e., asymptomatic) stages of IPD, Lewy bodies are initially found in the medulla oblongata, locus coeruleus, raphe nuclei, and olfactory bulb. This may correlate with observations that anxiety, depression, and impaired olfaction is detectable in preclinical stages of IPD. As IPD progresses to clinical stages, Lewy pathology ascends to the midbrain (particularly the SNc) and accounts for development of motor features. In advanced stages, Lewy pathology spreads to the cortex, and this may correlate with behavioral and cognitive changes.

Pathologic findings reveal a correlation between the extent of nigrostriatal dopamine loss and the severity of certain IPD motor features (e.g., bradykinesia). The threshold for onset of clinically detectable IPD appears to be the loss of 70% to 80% of SNc neurons.¹³ Functional neuroimaging studies suggest compensatory responses, such as upregulation of dopamine synthesis and downregulation of synaptic dopamine reuptake, occur as adaptive mechanisms in preclinical and very early stages of IPD. These adaptive responses may

help to explain why IPD is relatively asymptomatic until profound depletion (70% to 80%) of SNc neurons has occurred.

Dopaminergic projections from the SNc to the striatum (putamen and caudate) synapse on two populations of dopamine receptor-mediated efferent neurons (referred to as the direct and indirect pathways), which, in turn, mediate motor activity via a complex neuronal circuit involving the extrapyramidal system (Fig. 61-2). In IPD, the degeneration of the SNc neurons results in reduced activity within these two efferent pathways. The direct pathway involves activation of striatal D_1 dopamine receptors (which are coupled to adenylate cyclase) and stimulates the inhibitory γ -aminobutyric acid (GABA)/substance P efferents to the globus pallidus interna (GPI) and substantia nigra pars reticulata. The GPI and substantia nigra pars reticulata efferents are inhibitory to the thalamus.¹⁴ In IPD, the reduced activation of D_1 receptors results in greater inhibition of the thalamus. The indirect pathway involves activation of striatal D_2 dopamine receptors (which are coupled to a guanosine triphosphate-binding protein that opens potassium channels to hyperpolarize neurons, thereby reducing the excitability of the neuron).¹⁴ Activation of striatal D_2 dopamine receptors inhibits GABA/enkephalin efferents (medium spiny neurons) to the globus pallidus externa. The globus pallidus externa projects GABA neurons to the subthalamic nucleus. Here, excitatory glutamatergic neurons project to the GPI.

FIGURE 61-2. A. The normal balance of the basal ganglia–thalamocortical circuit. B. With nigrostriatal degeneration (dashed line), there is loss of inhibition of the GPI by the direct pathway and activation of the GPI via the indirect pathway, resulting in decreased activation of the cortex. See text for details. (GPe, globus pallidus externa; GPI, globus pallidus interna; SNc, substantia nigra pars compacta; SNr, substantia nigra pars reticulata; STN, subthalamic nucleus; VA, ventroanterior nuclei of the thalamus; VL, ventrolateral nuclei of the thalamus.)

TABLE 61-1 Diagnostic Criteria for Idiopathic Parkinson's Disease and Differential Diagnosis

Idiopathic Parkinson's disease
<i>Clinically possible:</i> Presence of one of the following: resting tremor, rigidity, or bradykinesia
<i>Clinically probable:</i> Presence of at least two of the following: resting tremor, rigidity, or bradykinesia
<i>Clinically definite:</i> Presence of at least two of the following: resting tremor, rigidity, or bradykinesia and a positive response to antiparkinsonian pharmacotherapy
Essential tremor
Secondary parkinsonism
Pharmacotoxicity (drug-induced)
Antiemetics (e.g., metoclopramide, prochlorperazine)
Antipsychotics (e.g., phenothiazines, haloperidol, olanzapine, risperidone)
Other drugs (α -methyl-dopa, cinnarizine, flunarizine, tetrabenazine)
Environmental toxicity
Carbon monoxide poisoning
Manganese
Methanol
MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine)
Organophosphates
Infections
Human immunodeficiency virus-associated parkinsonism
Postencephalitic parkinsonism
Subacute sclerosing panencephalitis
Metabolic disorder
Hypothyroidism
Parathyroid abnormalities
Neoplasms, strokes, traumatic lesions involving the nigrostriatal pathways
Normal-pressure hydrocephalus
Parkinsonism with other neuronal system degenerations
Alzheimer's with parkinsonism
Corticobasal ganglionic degeneration
Creutzfeldt-Jakob's disease (CJD)
Dementia with Lewy bodies
Frontotemporal dementia
Progressive supranuclear palsy
Multiple-system atrophies
Striatonigral degeneration
Shy-Drager's syndrome
Olivopontocerebellar atrophy
Familial (hereditary) parkinsonism
Autosomal dominant
α -Synuclein gene mutation (PARK1)
Frontotemporal dementia parkinsonism (FTDP-17)
Levodopa responsive dystonia
Leucine-rich repeat kinase 2 (LRRK2) mutation
Rapid-onset dystonia parkinsonism (DYT12)
Spinocerebellar ataxias (SCA2, SCA3)
Autosomal recessive
Hallervorden-Spatz disease
Neuroacanthocytes
Niemann Pick type C
Wilson's disease
Young-onset parkinsonism (DJ-1, parkin, PINK1)
X-linked recessive
Fragile X tremor/ataxia syndrome (FXTAS)
Lubag (DYT3 or Filipino dystonia parkinsonism)
Waisman syndrome (X-linked parkinsonism with mental retardation)

GPI output is inhibitory on the glutamatergic thalamic projections. In IPD, the reduced activation of D₂ receptors translates into greater inhibition of the thalamus. In IPD, restoring activity at the D₂ receptor appears to be of more importance than the D₁ receptor for mediating clinical improvements. Overall, loss of the presynaptic nigrostriatal dopamine neurons in IPD results in inhibition of thalamic activity and reduced activation of the motor cortex. Dopaminergic therapies help to restore motor activity.

In addition to dopamine, the synaptic organization of the basal ganglia also involves a variety of other neurotransmitters and neuromodulators, including acetylcholine, adenosine, enkephalins, GABA, glutamate, serotonin, and substance P. The role for drug modulation of other neurotransmitters and receptor types (e.g., adenosine A_{2A} receptors) is currently being investigated.¹⁵

Atypical parkinsonian disorders, such as multiple system atrophy and progressive supranuclear palsy are characterized by damage to postsynaptic neurons and dopamine receptors. Therefore, these atypical parkinsonisms are markedly less responsive to dopaminergic therapies.

CLINICAL PRESENTATION

Although IPD is unmistakable in its advanced form, recognizing IPD during the early stages can be challenging. Clinically probable IPD can be diagnosed when at least two of the following are present: limb muscle rigidity, resting tremor (at 3 to 6 Hz and abolished by movement), or bradykinesia (Table 61-1).¹⁶ In early IPD, unilateral (asymmetry) of features is a conspicuous finding, but as the disease advances, features often become bilateral. For the diagnosis of IPD, other conditions must be reasonably excluded (Table 61-1). Medication-induced parkinsonism can mimic IPD, so it is important to establish if such medications have been used (especially drugs that block D₂ receptors, such as antipsychotics, metoclopramide, or phenothiazine antiemetics). Neurologic conditions that can be mistaken for IPD include atypical parkinsonisms (e.g., corticobasal ganglionic degeneration, multiple system atrophy, progressive supranuclear palsy) and essential tremor. Because the management and prognosis of IPD differs from these other conditions, an accurate diagnosis is important. When the diagnosis is in doubt, referral to a movement disorders specialist is recommended.

PRESENTATION OF IDIOPATHIC PARKINSON'S DISEASE

General Features

- For clinically probable IPD, the patient exhibits at least two of the following: resting tremor, rigidity, or bradykinesia. Asymmetric onset (unilaterality) of these features is usual.
- Postural instability (difficulty with maintaining balance) is more common in advanced IPD.

Motor Symptoms

- The patient experiences decreased manual dexterity, difficulty arising from a seated position, diminished arm swing during ambulation, dysarthria (slurred speech), dysphagia (difficulty with swallowing), festinating gait (tendency to pass from a walking to a running pace), flexed posture (axial, upper/lower extremities), "freezing" at initiation of movement, hypomimia (reduced facial animation), hypophonia (reduced voice volume), and micrographia (diminution of handwritten letters/symbols) (Fig. 61-3).

Autonomic and Sensory Symptoms

- The patient experiences bladder and anal sphincter disturbances, constipation, diaphoresis, fatigue, olfactory disturbance, orthostatic blood pressure changes, pain, paresthesia, paroxysmal vascular flushing, seborrhea, sexual dysfunction, and sialorrhea (drooling).

Mental Status Changes

- The patient experiences anxiety, apathy, bradyphrenia (slowness of thought processes), confusional state, dementia, depression, hallucinosis/psychosis (typically drug-induced), and sleep disorders (excessive daytime sleepiness, insomnia, obstructive sleep apnea, and rapid eye movement sleep behavior disorder).

Laboratory Tests

- No laboratory tests are available to diagnose IPD.

Other Diagnostic Tests

- Genetic testing is not routinely helpful.
- Neuroimaging may be useful for excluding other causes of parkinsonism.
- Medication history should be obtained to rule out drug-induced parkinsonism.

IPD develops insidiously and progressively worsens, although in some patients, clinical symptoms may remain stable for years. Over many years, symptoms may worsen to the point of severe disability, necessitating placement in a skilled nursing facility (especially with the development of dementia or frequent falling).

Tremor of an upper extremity occurring at rest (and occasionally a postural tremor) is often the sole presenting complaint; however, only two-thirds of patients with IPD have tremor on diagnosis, and some never develop this sign. Tremor in IPD is present most commonly in the hands, sometimes with a characteristic pill-rolling motion. Less commonly, tremor may involve the jaw, legs, and toes. Like other motor features of IPD, resting tremor often begins unilaterally and becomes bilateral with disease progression. Stressful or emotional (either negative or positive) situations often increase the tremor amplitude and severity. Usually, volitional movement abolishes resting tremor and it is absent during sleep. Although resting tremor is visibly noticeable in IPD and may cause social embarrassment for the patient, it often is the least physically disabling of the motor features.

Rigidity is the increased muscular resistance to passive range of motion and commonly affects the upper and lower extremities. If

tremor is present in the affected extremity, the rigidity is associated with a cogwheel or ratchet-like quality upon examination. Facial muscles also are affected, resulting in hypomimia (masking of facial expressions) that may be erroneously interpreted as apathy, depression, or unfriendliness.

Bradykinesia refers to slowness of movement. Movement in IPD is often slow throughout an intended action, and difficulty with the initiation of movement also occurs. A progressive slowing and decline in dexterity may impair tasks such as finger tapping and handwriting (see Fig. 61–3). Intermittent immobility (*freezing*) is another common characteristic. Freezing is especially likely to occur in situations such as when walking through a narrow doorway or initiating a turn. Patients also may experience a slow shuffling gait with difficulty halting their steps while in motion (*festinating gait*).

Postural instability, most common in advanced stages of IPD, is one of the most disabling problems of IPD because it increases the fall risk and is least amenable to pharmacotherapy. Testing for impaired postural responses by means of the pull test (in which a patient is unable to recover balance after sudden backward displacement at the shoulders) can help to identify the risk for falling. Many patients with impaired postural responses also have tendencies for propulsive gait (*festination*) and freezing, which increases the risk of falling.

Although IPD is known predominantly as a disorder of motor capabilities, neuropsychiatric abnormalities also develop. Intellectual deterioration is not inevitable in IPD; however, some patients deteriorate in a manner indistinguishable from Alzheimer's disease and other dementing conditions.¹⁷ IPD patients are also at increased risk for affective disorders such as anxiety and depression.¹⁸ Although the disabilities of IPD may provoke depression in some instances, the biochemical changes in the brain associated with IPD also may predispose for endogenous depression.

TREATMENT**Parkinson's Disease****■ DESIRED OUTCOMES**

The goal in the management of IPD is to improve motor and nonmotor symptoms so that patients are able to maintain the best possible quality of life. Specific objectives to consider when selecting an intervention include preservation of function and ability to perform activities of daily living; improvement of mobility; minimization of adverse effects and treatment complications; and improvement of nonmotor features such as cognitive impairment, depression, fatigue, and sleep disorders. To accomplish some of these objectives, consultation with a specialist is helpful (e.g., movement disorders, physical therapy, psychiatry, sleep medicine).

■ GENERAL APPROACH TO TREATMENT

1 Once a correct diagnosis of IPD is made, nonpharmacologic and pharmacologic interventions must be considered. Figure 61–4 illustrates a general treatment approach for early and advanced IPD and Tables 61–2 and 61–3 summarize antiparkinsonian medications and mechanisms of action. Treatment guidelines are updated frequently to keep up with new information and changes in treatment paradigms.^{19–23} Clinically proven neuroprotective agents for IPD are not yet available, so the currently available pharmacologic therapies are referred to as symptomatic (i.e., used to improve motor symptoms of IPD).

2 The definition of functional impairment is highly patient specific. Factors such as employment, lifestyle, and patients' desires must be considered when initiating pharmacotherapy. In general, initial monotherapy begins with a MAO-B inhibitor, or if the patient is "physiologically" young, a dopamine agonist. When additional

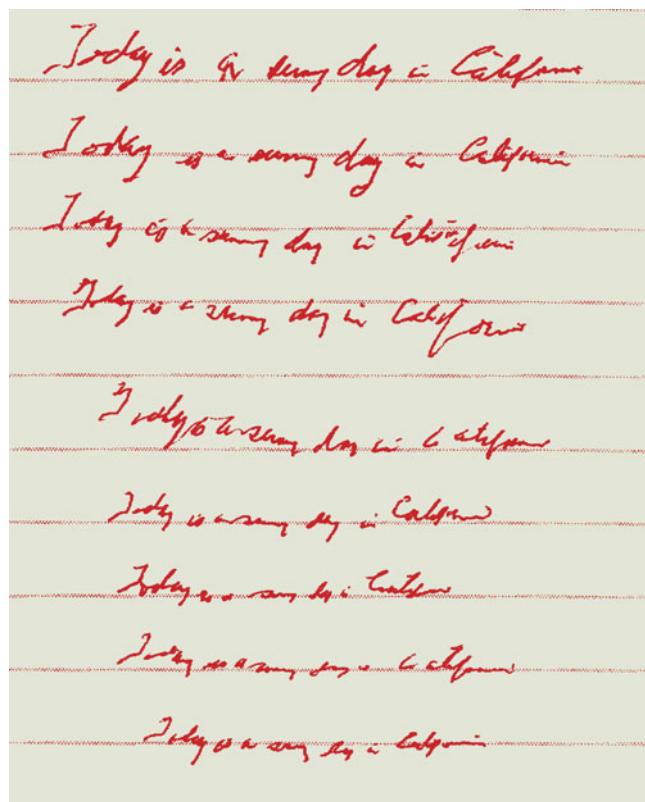

FIGURE 61-3. Example of micrographia in a patient with IPD. As the sentence, "Today is a sunny day in California" is repeatedly handwritten, progressive diminution of letter size occurs (micrographia). The height of each lined row is approximately 5/16 inches (8 mm). (Courtesy of Jack J. Chen, PharmD, and David M. Swope, MD.)

TABLE 61-2 Classification of Available Idiopathic Parkinson's Disease Treatments Based on Pharmacologic Mechanism^a

Anticholinergic
Benztropine
Trihexyphenidyl
Dopamine precursor and augmentation
Levodopa
Inhibit peripheral dopa decarboxylase
Carbidopa
Inhibit catechol-O-methyl-transferase
Entacapone
Tolcapone
Inhibit monoamine oxidase type B
Rasagiline
Selegiline
Dopamine receptor agonists
Apomorphine
Bromocriptine
Pramipexole
Ropinirole
Rotigotine
Miscellaneous
Amantadine

^aMarketed in the United States for idiopathic Parkinson's disease.

symptom relief is desired, addition of L-dopa should be considered. With the development of motor fluctuations, addition of a catechol-O-methyltransferase (COMT) inhibitor should be considered to extend L-dopa duration of activity, or if the patient is not already on a MAO-B inhibitor or dopamine agonist, addition of either one should be considered. For management of L-dopa induced dyskinesias, the addition of amantadine should be considered. Surgery is considered only in patients who need more symptomatic control or who are experiencing severe motor complications despite pharmacologically optimized therapy.

The treatment plan evolves as the disease progresses and must include consideration of short-term relief and long-term management. Factors that often guide selection of therapies include the “functional” age of the patient, cognitive status, severity of motor features, and response to any previous IPD therapies. Patient education should be communicated with realistic optimism. For example, it should be explained that although there is no cure for IPD, modern medicine has many medications that can provide relief of symptoms. Nonpharmacologic interventions such as exercise should be encouraged, and attention to nonmotor features of IPD should not be neglected.

■ PHARMACOLOGIC THERAPY

Anticholinergic Medications

3 Because dopamine tonically inhibits acetylcholine neurons in the striatum, the degeneration of nigrostriatal dopamine neurons also results in a relative increase of striatal cholinergic interneuron activity. This increased cholinergic activity (caused by dopamine depletion) is believed to contribute to the tremor of IPD. The anticholinergic drugs (e.g., benztropine and trihexyphenidyl) are considered effective against tremor but not more so than dopaminergic agents.^{19,20} Sometimes dystonic symptoms associated with IPD also will improve. Use of anticholinergic agents is limited because many patients develop intolerable side effects, necessitating dosage reduction or drug discontinuation. Common adverse effects include blurred vision, confusion, constipation, dry mouth, memory difficulty, sedation, and urinary retention. Younger patients are better able to tolerate anticholinergic side effects, whereas patients with

TABLE 61-3 Drugs Used in Parkinson's Disease

Generic Name	Trade Name	Dosage Range ^a (mg/day)	Dosage Forms (mg)
Anticholinergic drugs			
Benztropine	Cogentin	0.5–4	0.5, 1, 2
Trihexyphenidyl	Artane	1–6	2, 5
Carbidopa/levodopa products			
Carbidopa/L-dopa	Sinemet	300–1,000 ^b	10/100, 25/100, 25/250
Carbidopa/L-dopa ODT	Parcopa	300–1,000 ^b	10/100, 25/100, 25/250
Carbidopa/L-dopa CR	Sinemet CR	400–1,000 ^b	25/100, 50/200
Carbidopa/L-dopa/entacapone	Stalevo	600–1,600 ^c	12.5/50/200, 25/100/200, 37.5/150/200
Carbidopa	Lodosyn	25–75	25
Dopamine agonists			
Apomorphine	Apokyn	3–12	30 per 3 mL
Bromocriptine	Parlodel	15–40	2.5, 5
Pramipexole	Mirapex	1.5–4.5	0.125, 0.25, 0.5, 1, 1.5
Ropinirole	Requip	9–24	0.25, 0.5; 1, 2, 3, 4, 5
Rotigotine	Neupro	2–6	2, 4, 6
COMT inhibitors			
Entacapone	Comtan	200–1,600	200
Tolcapone	Tasmar	300–600	100, 200
MAO-B inhibitors			
Rasagiline	Azilect	0.5–1	0.5, 1
Selegiline	Eldepryl	5–10	5
Selegiline ODT	Zelapar	1.25–2.5	1.25, 2.5
Anticholinergic drugs			
Benztropine	Cogentin	0.5–4	0.5, 1, 2
Trihexyphenidyl	Artane	1–6	2, 5, 2/5 mL
Miscellaneous			
Amantadine	Symmetrel	200–300	100

COMT, catechol-O-methyltransferase; CR, controlled release; MAO, monoamine oxidase; ODT, orally disintegrating tablet.

^aDosages may vary beyond stated range.

^bDosages expressed as L-dopa component.

preexisting cognitive deficits and advanced age are less tolerant. Anticholinergic drugs can be used alone or in conjunction with L-dopa and other antiparkinson agents.

Amantadine

4 Amantadine provides modest symptomatic benefit. The precise mechanism of action of amantadine is unknown, but dopaminergic and nondopaminergic mechanisms, such as inhibition of glutamatergic N-methyl-D-aspartate (NMDA) receptors are implicated. Amantadine is typically administered 300 mg/day in divided doses. Amantadine is also useful for suppressing L-dopa-induced dyskinesia.²² The antidyskinetic properties of amantadine are presumed to be mediated by antiglutamate mechanisms. Amantadine is eliminated renally and a reduced dose should be administered when renal dysfunction is present (100 mg/day with creatinine clearances of 30 to 50 mL/min, 100 mg every other day for creatinine clearances of 15 to 29 mL/min, and 200 mg every 7 days for creatinine clearances of less than 15 mL/min and patients on hemodialysis).

Common side effects of amantadine include confusion, dizziness, dry mouth, and hallucinations. The elderly are particularly prone to develop confusion. Not uncommonly, amantadine may cause livedo reticularis, a diffuse mottling of the skin occurs in the upper or lower extremities and often accompanied by lower-extremity edema.

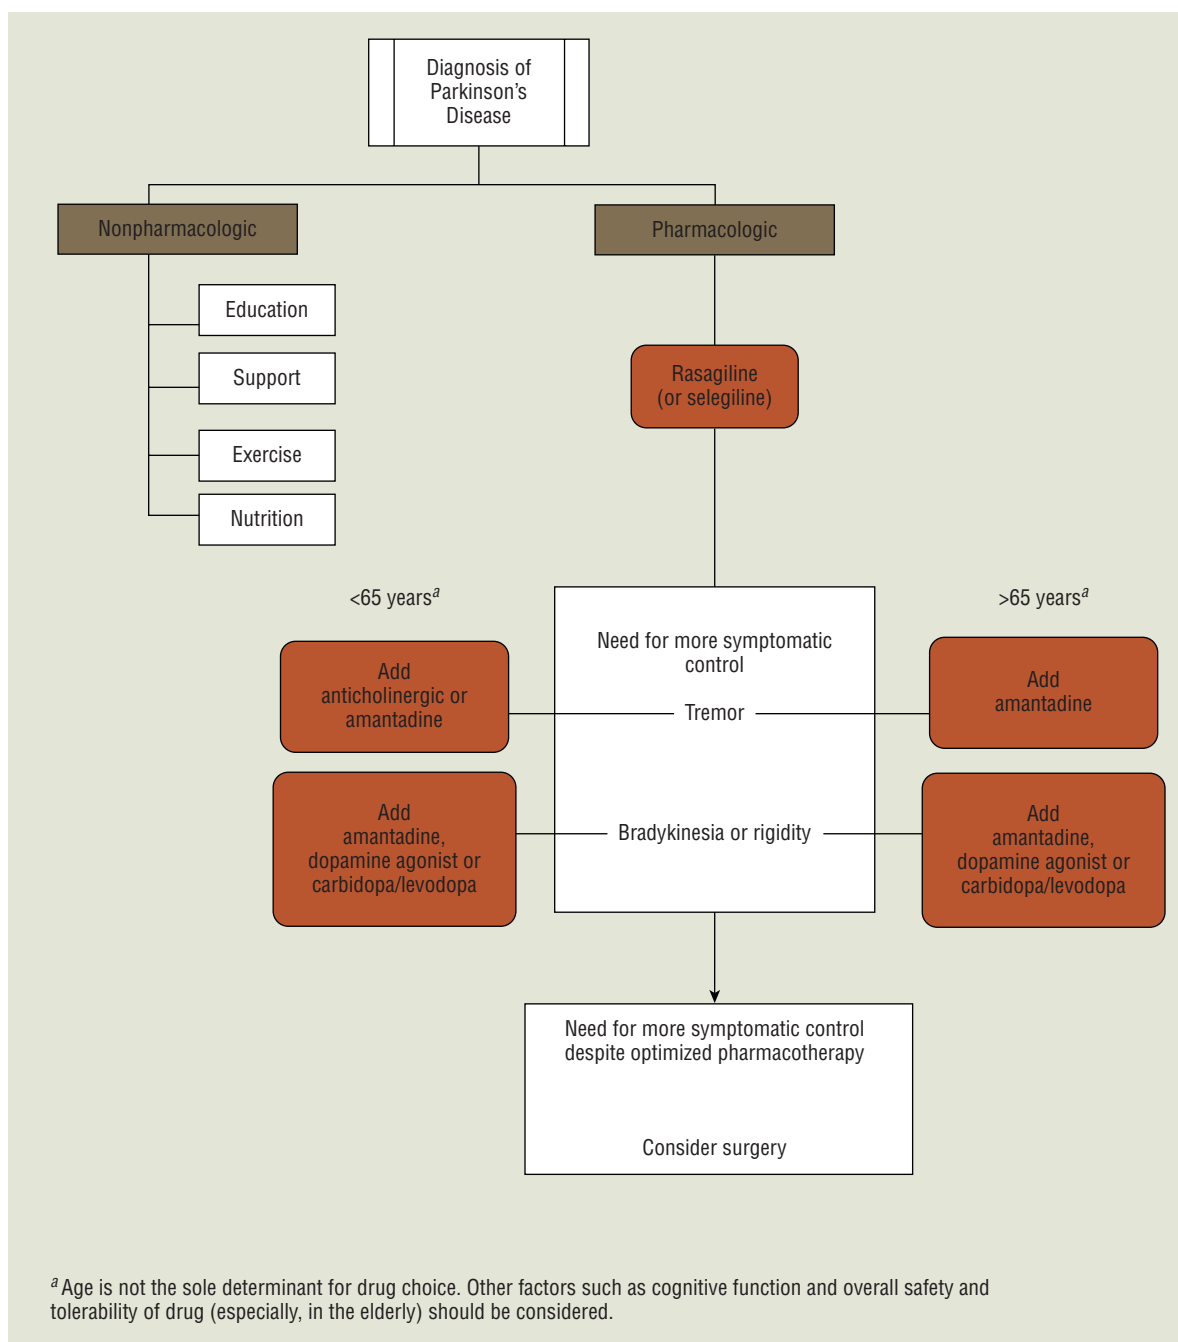

FIGURE 61-4. General approach to the management of early to advanced Parkinson's disease.

Carbidopa/L-Dopa

5 L-Dopa is the immediate precursor of dopamine and, in combination with a peripherally acting L-amino acid decarboxylase inhibitor (carbidopa or benserazide), remains the most effective drug for the symptomatic treatment of IPD.^{19,20} L-Dopa crosses the blood-brain barrier, whereas dopamine, carbidopa, and benserazide do not. The combination of L-dopa with carbidopa or benserazide, reduces the unwanted peripheral conversion of L-dopa to dopamine. As a result, increased amounts of L-dopa are transported into the brain, and peripheral adverse effects of dopamine, such as nausea, are reduced. In the SNc, L-dopa is converted, via decarboxylation, to dopamine by the enzyme L-amino acid decarboxylase (Fig. 61-5). The converted dopamine is stored in the presynaptic SNc neurons until stimulated to be released into the synaptic cleft where upon it binds to the D₁ and D₂ postsynaptic receptors. Dopamine activity is terminated primarily by reuptake back into the

presynaptic neuron by means of a dopamine transporter. The enzymes MAO and COMT also inactivate dopamine.

5 Regardless of what the initial therapeutic agent is, ultimately all patients with IPD will require L-dopa at some point. An initial maintenance L-dopa regimen of 300 mg/day (in divided doses and in combination with carbidopa or benserazide) often is adequate. With regards to carbidopa, about 75 mg/day is required to sufficiently inhibit the peripheral activity of L-amino acid decarboxylase, but some patients require more. Therefore the usual initial maintenance carbidopa/L-dopa regimen is 25/100 mg three times daily. As IPD progresses to more severe symptoms, use of higher dosages is required. There is no maximum allowable total daily L-dopa dose; however, the usual maximal dose needed by patients, even those with severe IPD, is 800 to 1,000 mg/day. Slow buildup of dose (e.g., increments of 100 mg L-dopa per week) can help to minimize treatment emergent side effects such as nausea, postural hypotension, sedation, vivid dreaming, and vomiting.

FIGURE 61-5. Dopamine metabolism in presynaptic dopamine neuron. (3OMD, 3-O-methyldopa; AC, adenylate cyclase; AD, aldehyde dehydrogenase; COMT, catechol-O-methyl transferase; D₁–D₃, dopamine receptors; DA, dopamine; DAT, dopamine transporter; DOPAC, 3,4-dihydroxyphenylacetic acid; HVA, homovanillic acid; L-AAD, L-aromatic amino acid decarboxylase; MAO-B, monoamine oxidase B; TH, tyrosine hydroxylase.)

For patients with difficulty swallowing tablets, an orally disintegrating tablet preparation of carbidopa/L-dopa is available. Although this formulation rapidly dissolves on contact with saliva, the carbidopa/L-dopa does not undergo transmucosal absorption and must reach the proximal duodenum for absorption.

Pharmacokinetics There is marked intra- and intersubject variability in the time to peak plasma concentrations after oral L-dopa and this may in part be attributed to differences in gastric emptying. Meals delay gastric emptying, whereas antacids (which decrease gastric acidity) promote gastric emptying. L-Dopa is absorbed primarily in the proximal duodenum by a saturable large neutral amino acid transport system. Competition for this transporter by dietary or supplemental large neutral amino acids (e.g., leucine, phenylalanine) can interfere with L-dopa bioavailability.

L-Dopa is not bound to plasma proteins. Active transport across the blood–brain barrier occurs by the large neutral amino acid transporter system. Because large amounts of dietary large neutral amino acids may compete for transport across the blood–brain barrier and interfere with the clinical response to L-dopa, separation of L-dopa administration with high protein meals has been recommended. However, in patients with early IPD, this interaction is generally not significant. In advanced IPD, special diets involving protein restriction or redistribution may improve L-dopa responsiveness and are sometimes implemented. A metabolite of L-dopa, 3-O-methyldopa, also competes for transport, but it is not clear how this affects L-dopa clinical response.

When peripheral decarboxylation of L-dopa is inhibited by carbidopa or benserazide, 3-O-methylation (via COMT) becomes the predominant catabolic pathway. The elimination half-life of L-dopa is about 1 hour, and this is extended to about 1.5 hours with the addition of carbidopa or benserazide. With the addition of a COMT inhibitor such as entacapone to carbidopa/L-dopa, the elimination half-life is extended to about 2 to 2.5 hours.

6 Motor Complications of L-Dopa Long-term L-dopa therapy is associated with a variety of motor complications, of which end-of-dose “wearing off” (motor fluctuations) and L-dopa peak-dose dyskinesias are the two most commonly encountered.²⁴ These motor complications can be disabling and challenging to manage. Approximately 10% of IPD patients will develop involuntary movements

TABLE 61-4 Common Motor Complications and Possible Treatments

Effect	Possible Treatments
End-of-dose “wearing off” (motor fluctuation)	Increase frequency of carbidopa/L-dopa doses; add either COMT inhibitor or MAO-B inhibitor or dopamine agonist; consider surgery
“Delayed on” or “no on” response	Give carbidopa/L-dopa on empty stomach; use carbidopa/L-dopa ODT; avoid carbidopa/L-dopa CR; use apomorphine subcutaneous; consider surgery
Start hesitation (“freezing”)	Increase carbidopa/L-dopa dose; add a dopamine agonist or MAO-B inhibitor; utilize physiotherapy along with assistive walking devices or sensory cues (e.g., rhythmic commands, stepping over objects)
Peak-dose dyskinesia	Provide smaller doses of carbidopa/L-dopa; add amantadine; consider surgery

COMT, catechol-O-methyltransferase; CR, controlled release; MAO, monoamine oxidase; ODT, orally disintegrating tablet.

ment.^{25,26} However, motor complications can occur by as few as 5 to 6 months after starting L-dopa therapy, especially if excessive doses are used initially.²⁷ Table 61-4 lists the motor complications associated with long-term treatment with carbidopa/L-dopa and suggested management strategies. Initiating therapy with the controlled-release form of carbidopa/L-dopa does not reduce the development of motor complications compared with standard-release carbidopa/L-dopa.²²

6 End-of-Dose Wearing Off. The terms “off” and “on” refer to periods of poor movement (i.e., return of tremor, rigidity, or slowness) and good movement, respectively. End-of-dose wearing off prior to a dose of medication is a common type of response fluctuation. This phenomenon is related to the increasing loss of neuronal storage capability for dopamine as well as the short half-life of L-dopa. Initially, exogenous L-dopa is taken up by the remaining presynaptic (SNc) neurons, converted to dopamine, and stored in synaptic vesicles. With progressive loss of presynaptic neurons, storage capacity, and synthesis of endogenously derived dopamine, patients become more dependent on exogenous L-dopa. Hence the peripheral pharmacokinetic properties of L-dopa increasingly become the determinant of central dopamine synthesis. With advancing IPD, the duration of action of a single carbidopa/L-dopa dose progressively shortens, and in some cases may produce benefits for as little as 1 hour. As a result, carbidopa/L-dopa needs to be given more frequently so as to minimize daytime off episodes and to maximize on time. In addition to administering L-dopa doses more frequently, other options are available (see Table 61-4). In particular, the addition of the COMT inhibitor entacapone or the MAO-B inhibitor rasagiline extends the action of L-dopa and either should be considered.²²

Alternatively, an oral dopamine agonist also can be added to a carbidopa/L-dopa regimen in an attempt to minimize the occurrence of wearing off. A subcutaneously administered short-acting dopamine agonist, apomorphine, is also available and possesses a rapid onset of effect (within 20 minutes) and may be used, as needed, for relief from off states.²⁸ A controlled-release (CR) L-dopa product is available that can extend the duration of the carbidopa/L-dopa effect, but it is not considered very effective for management of motor fluctuation.²² In addition, duodenal/jejunal L-dopa infusions produce constant and smoother stimulation of striatal dopamine receptors and thus stabilize response fluctuations.²⁹ Although some patients have been maintained on duodenal infusions for long periods of time, this invasive method of administration requires careful planning and is generally not used outside the research setting. If needed, sipping small amounts of carbidopa/L-dopa solution is an easier way to noninvasively titrate drug intake to optimal effect. A solution that is stable for 72 hours at room temperature can

be prepared by adding 10 tablets of carbidopa/L-dopa 10/100 (or 25/100) mg and 2 g crystalline ascorbic acid to 1 L of water.³⁰

Often, off episodes occur during the night, and patients will awaken in an off state (as a consequence of an overnight decline of drug levels). Bedtime administration of dopamine agonist or a drug formulation that provides sustained drug levels overnight (e.g., carbidopa/L-dopa CR, ropinirole CR, rotigotine transdermal patch) can help reduce nocturnal off episodes and improve functioning upon awakening.

“Delayed-On” and “No-On” Response. “Delayed-on” or “no-on” (drug-resistant off) responses to carbidopa/L-dopa can be a result of delayed gastric emptying or decreased absorption in the duodenum. Chewing a tablet or crushing it and then drinking a full glass of water, or using the orally disintegrating tablet formulation on an empty stomach, decreases gastric disintegration time and facilitates gastric emptying. Additionally, subcutaneously administered apomorphine may be used as rescue therapy from delayed-on or no-on periods. A drug-free period (“drug holiday”) has been investigated in an attempt to modify postsynaptic dopamine receptors and thus decrease unpredictable off states. Although not commonly performed because of discomfort (to the patient) and medical risks, when drug holidays are performed, it should be under close medical supervision.

Freezing. “Freezing,” or a sudden, episodic inhibition of lower-extremity motor function, may occur and will interfere with ambulation and increase the risk of falls. Patients may report that their “feet are stuck to the floor” and that they have difficulty initiating steps (start hesitation) or turns (turn hesitation). Freezing often is exacerbated by anxiety or when perceived obstacles (e.g., doorways, turnstiles) are encountered. Although changes to the antiparkinson drug regimen may be attempted, improvements are unlikely. Physiotherapy along with various specialized assistive walking devices and sensory cues are helpful.

Dyskinesias. Another complication of L-dopa therapy is “on” period dyskinesias (involuntary choreiform movements involving usually the neck, trunk, and lower/upper extremities). If patients report “shakiness,” it is important to clarify if they are referring to tremor or dyskinesias. Dyskinesias usually are associated with peak striatal dopamine levels (peak dose dyskinesia) and, simplistically, can be thought of as too much movement secondary to extension of the pharmacologic effect or too much striatal dopamine receptor stimulation. Less commonly, dyskinesias also can develop during the rise and fall of L-dopa effects (the dyskinesia-improvement-dyskinesia or diphasic pattern of response). In the case of peak-dose dyskinesias, use of lower doses of L-dopa is often beneficial. With the lowering of the L-dopa dose, dyskinesias improve but at the cost of returning parkinsonian features, thereby necessitating an increase in dosage frequency or addition of another agent to counteract the effects of using a lower L-dopa dose. Glutamate overactivity may also be involved as suggested by the antidyskinesia effect of amantadine (NMDA receptor antagonist) and the investigational drug E2007 (α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid [AMPA] receptor antagonist). For severe dyskinesias, surgery should be considered.

“Off-Period” Dystonia. In IPD, dystonias (sustained muscle contractions) occur more commonly in a distal lower extremity (e.g., the foot). In fact, clenching of the toes or involuntary turning of the foot can precede the development of IPD. Dystonias often occur in the early morning hours (as a result of waning drug levels) and improve with the first L-dopa dose of the day. Remedies for this problem include bedtime administration of sustained-release products (e.g., carbidopa/L-dopa CR, ropinirole CR, rotigotine transdermal patch), use of baclofen, or selective chemical denervation with injections of botulinum toxin.

CLINICAL CONTROVERSY

The question of when to initiate L-dopa therapy is a matter of debate. Generally, initial therapy with a non-L-dopa agent is often recommended for patients younger than 65 years of age. Proponents for initiating non-L-dopa agents first and then adding L-dopa at a later point, cite evidence suggesting that long-term L-dopa therapy is associated with an increased risk of motor complications that can be disabling and challenging to manage. Additionally, drugs such as MAO-B inhibitors and dopamine agonists provide sufficient symptom control for mild to moderate IPD. The counterargument is that L-dopa is inexpensive, more effective, and the development of motor complications is an acceptable trade-off. Age alone should not be the major deciding factor, and ultimately, individualized considerations of a patient’s disability should guide all interventions for IPD.

Monoamine Oxidase B Inhibitors

④ Two selective MAO-B type B inhibitors, rasagiline and selegiline, are available in the United States for management of IPD. The selective inhibition of MAO-B in the brain interferes with the degradation of dopamine and results in prolonged dopaminergic activity. Both drugs contain a propargylamine moiety, which is essential for conferring irreversible inhibition of MAO-B. At therapeutic doses, these agents preferentially inhibit MAO-B over MAO-A.

The most common concern with use of these agents is regarding interactions with food and other drugs. Practically speaking, at therapeutic doses, these selective MAO-B inhibitors are unlikely to induce a “cheese reaction” (transient hypertension, headache) unless excessive amounts of dietary tyramine (400 mg or greater) are ingested, unlike the nonselective MAO-A/B inhibitors, which require as little as 10 mg or less of dietary tyramine.³¹ Additionally, the potential for a hypertensive effect resulting from concomitant administration of sympathomimetic agents (e.g., ephedrine, phenylephrine, pseudoephedrine) that are substrates for MAO-B is unknown, and these medications should be taken concurrently with caution. However, the risk of a severe hypertensive episode associated with occasional administration of nonprescription sympathomimetic agents (e.g., cold products, weight-reducing agents) appears to be minimal.³²

Concomitant use of MAO-B inhibitors with meperidine and other selected analgesics is contraindicated because of a small risk of serotonin syndrome. Concomitant use of other agents that enhance serotonin levels (e.g., selective serotonin reuptake inhibitors, imipramine, clomipramine, lithium, sibutramine) is not contraindicated.

④ ⑦ Selegiline, also known as L-deprenyl, is marketed for extending L-dopa effects and is typically administered 5 mg twice daily. Selegiline is also available as an orally disintegrating tablet formulation administered 1.25 to 2.5 mg once daily. As monotherapy in early IPD, selegiline provides modest improvements in motor function.^{19,20} In more advanced IPD, the adjunctive use of selegiline can provide up to a total of 1 hour of extended on time for patients with wearing off, although the data are inconsistent.²² This inconsistent effect of conventional selegiline may be explained, in part, by poor and erratic bioavailability of the parent drug.

As an amphetamine pharmacophore, selegiline undergoes first-pass hepatic metabolism (predominantly via cytochrome P450 [CYP] 2B6 and 2C19) to end products of L-methamphetamine and L-amphetamine. Adverse effects of selegiline are minimal but can include insomnia (especially if administered at bedtime), hallucinations, and jitteriness. Selegiline also increases the peak effects of L-dopa and can worsen preexisting dyskinesias or psychiatric symptoms such as delusions. With the selegiline orally disintegrating tablet formulation, first-pass hepatic metabolism is bypassed as a

consequence of transmucosal absorption of the drug. Hence, bioavailability characteristics of the parent drug are improved and formation of amphetamine metabolites is reduced. Thus, the selegiline orally disintegrating tablet formulation may provide an improved response relative to conventional selegiline.

4 **7** Rasagiline is a second-generation, irreversible, selective MAO-B inhibitor administered at 0.5 or 1 mg once daily. Rasagiline is effective as monotherapy in early IPD and also for managing motor fluctuations in advanced IPD. In a clinical trial, patients initiated on rasagiline monotherapy early in IPD had less functional decline than did patients whose treatment was delayed for 6 months.³³ This suggests that early initiation with rasagiline (perhaps even before the onset of functional impairment) is associated with better long-term outcomes. For the management of patients with motor fluctuations, the efficacy of rasagiline appears similar to that of entacapone, offering approximately 1 hour of extra on time during the day.³⁴ Consequently, when an adjunctive agent is required for managing motor fluctuations, rasagiline is considered a first-line agent (as is entacapone).²² Overall, rasagiline is well tolerated and has an incidence of side effects similar to placebo in clinical studies. Rasagiline is metabolized by hepatic CYP1A2 to aminoindan, which is inactive and devoid of amphetamine-like properties.³¹

MAO-B inhibitors with a propargylamine molecular scaffolding have been investigated for neuroprotective properties. These agents inhibit the oxidative deamination of dopamine, which generates hydrogen peroxide and, ultimately, oxyradicals capable of damaging nigrostriatal neurons (see Fig. 61–1). Because MAO-B inhibition diverts dopamine catabolism to an alternate route that does not generate peroxide, MAO-B inhibitor therapy may spare neurons from oxidative stress. Additionally, MAO-B inhibitors have demonstrated antiapoptotic properties in laboratory experiments, further suggesting the possibility of clinical neuroprotection. A placebo-controlled study involving patients with early IPD suggests that rasagiline may provide positive disease-modifying effects when initiated early in the course of IPD, and additional studies are underway to replicate this.³⁵

CLINICAL CONTROVERSY

Great interest and considerable controversy surrounds the putative neuroprotective effects of the MAO-B inhibitors. Although preliminary findings suggest that selegiline and rasagiline delay the development of disability in patients with IPD, to date neuroprotective effects have not been clearly shown. Research is underway to address this important question.

COMT Inhibitors

7 Two COMT inhibitors, entacapone and tolcapone, have been developed to extend the effects from each dose of L-dopa and are indicated for managing wearing off.²² Both reduce the peripheral conversion of L-dopa to dopamine, thus enhancing central L-dopa bioavailability. Consequently, in the absence of L-dopa, they have no effect on IPD symptoms. For patients with wearing off, these agents can decrease off time significantly by increasing the L-dopa area under the curve by approximately 35%.³⁵ COMT inhibition is considered more effective than controlled-release carbidopa/L-dopa in providing consistent extension of L-dopa effect.²² A triple-combination product of carbidopa/L-dopa/entacapone offers convenience for some patients (i.e., fewer tablets to administer).

Tolcapone inhibits both peripheral and central COMT. Its use is limited by reports of fatal hepatotoxicity, such that strict monitoring of hepatic function, especially during the first 6 months of therapy, is required. Informed consent should also be documented to ensure that patients are aware of this serious but rare adverse

effect. Tolcapone is dosed at 100 to 200 mg three times per day. Because of the hepatotoxicity risk, tolcapone is reserved for patients with fluctuations that are not responding to other therapies. Additionally, delayed onset of diarrhea (weeks to months later) can occur in up to 5% of patients.

Entacapone has a shorter half-life than tolcapone, and 200 mg needs to be given with each dose of carbidopa/L-dopa up to a maximum of eight times per day. In clinical trials, both tolcapone and entacapone increased total daily on time by about 1 to 2 hours.^{36,37} Dopaminergic adverse effects may occur and generally are manageable by reduction of the carbidopa/L-dopa dosage. Brownish-orange urinary discoloration may occur with both agents. Unlike tolcapone, entacapone is not associated with hepatotoxicity and, if an adjunctive agent is needed for managing motor fluctuations, entacapone is considered one of the first choices.²²

Dopamine Agonists

Oral dopamine agonists fall into two pharmacologic subtypes: ergot-derived agonists (bromocriptine and pergolide) and the nonergot agonists (pramipexole, ropinirole, rotigotine). The nonergot dopamine agonists are safer than the ergot-derived agonists and are effective as monotherapy in mild-moderate IPD, and also as adjuncts to L-dopa therapy in patients with motor fluctuations.^{19,20,22} The dopamine agonists reduce the frequency of off periods and may allow reductions in L-dopa dosage. Use of bromocriptine and pergolide have fallen by the wayside for several reasons. Bromocriptine is not commonly used because of an increased risk of pulmonary fibrosis and reduced efficacy compared to the other agonists.³⁸ Pergolide use is associated with development of cardiac valve fibrosis and valvular heart disease and is no longer available.³⁹

8 Investigations comparing initial monotherapy with either L-dopa or a dopamine agonists in patients with IPD have revealed a significantly reduced risk of developing motor complications associated with dopamine agonists than with L-dopa.^{40,41} These findings have generated divergent opinions as to whether initial treatment of mild IPD should be with an oral dopamine agonist or L-dopa. Younger patients are more likely to develop motor fluctuations; consequently, dopamine agonists are preferred. Older patients are more likely to suffer intolerable side effects (e.g., hallucinations, orthostatic hypotension) from the dopamine agonists; consequently, carbidopa/L-dopa is preferred, particularly if cognitive problems or dementia is present.

Additionally, initial monotherapy with pramipexole or ropinirole is associated with a slower decline in imaging biomarkers of dopaminergic function compared with L-dopa monotherapy, suggesting neuroprotection.^{42,43} However, these neuroimaging results are inconclusive because of several issues, including concerns regarding study methodology, accuracy of imaging biomarkers in the presence of dopaminergic agents, and lack of correlation between biomarker and motor function outcomes.

Common adverse effects of dopamine agonists include nausea, confusion, hallucinations, light-headedness, lower-extremity edema, postural hypotension, sedation, and vivid dreaming. Less common but serious adverse effects include compulsive behaviors (e.g., pathologic gambling or shopping), psychosis, and sleep attacks (sudden, unexpected episodes of sleep). Hallucinations and delusion can be managed using a stepwise approach (Table 61–5) that often involves the use of an atypical antipsychotic medication, such as clozapine or quetiapine.¹⁸ The addition of a dopamine agonist to L-dopa therapy also can increase the frequency and severity of L-dopa induced dyskinesias, especially in patients with preexisting dyskinesias.

Initiation of a dopaminergic agonist is best performed by slow titration to minimize side effects. Pramipexole is initiated at a dose of 0.125 mg three times a day and increased every 5 to 7 days, as tolerated, to a maximum of 1.5 mg three times a day. Studies are

TABLE 61-5 Stepwise Approach to Management of Drug-Induced Hallucinations and Psychosis in Parkinson's Disease

- General measures such as evaluating for electrolyte disturbance (especially hypercalcemia or hyponatremia), hypoxemia, or infection (especially encephalitis, sepsis, or urinary tract infection).
- Simplify the antiparkinsonian regimen as much as possible by discontinuing or reducing the dosage of medications with the highest risk-to-benefit ratio first.^a
 - Discontinue anticholinergics, including other nonparkinsonian medications with anticholinergic activity such as antihistamines or tricyclic antidepressants.
 - Taper and discontinue amantadine.
 - Discontinue monoamine oxidase-B inhibitor.
 - Taper and discontinue dopamine agonist.
 - Consider reduction of L-dopa (especially at the end of day) and discontinuation of catechol-O-methyltransferase inhibitors.
- Consider atypical antipsychotic medication if disruptive hallucinations or psychosis persists.
 - Quetiapine 12.5–25 mg at bedtime; gradually increase by 25 mg each week if necessary, until hallucinations or psychosis improved *or*
 - Clozapine 12.5–50 mg at bedtime; gradually increase by 25 mg each week if necessary until hallucinations or psychosis improved (requires frequent monitoring for leukopenia).

^aIf dosage reduction or medication discontinuation is either infeasible or undesirable, go to step 3.

underway to investigate the efficacy of twice-daily dosing in early IPD. Ropinirole is initiated at 0.25 mg three times a day and increased by 0.25 mg three times a day on a weekly basis to a maximum of 24 mg/day. A controlled-release ropinirole formulation for once-daily administration may soon be available.⁴⁴ Rotigotine is available as a transdermal patch for once-daily administration initiated at 2 mg/day and increased by 2 mg/day on a weekly basis to a maximum of 6 mg for early IPD. The patch formulation provides stable and consistent drug levels over a 24-hour period.

Pramipexole is renally excreted with an 8- to 12-hour half-life. The initial dosage must be adjusted in renal insufficiency (0.125 mg twice daily for creatinine clearances of 35 to 59 mL/min, 0.125 mg once daily for creatinine clearances of 15 to 34 mL/min). Ropinirole has a 6-hour half-life and is metabolized by CYP1A2. Potent inhibitors (e.g., fluoroquinolone antibiotics) and inducers (e.g., cigarette smoking) of this enzyme likely will lead to alterations in ropinirole clearance. Rotigotine is a highly lipophilic agent with a half-life of approximately 5 to 7 hours. The drug has poor oral bioavailability as a consequence of extensive hepatic first-pass metabolism, but is suitable for transdermal delivery. Application sites (e.g., abdomen, hip, shoulder, upper arm, upper thigh) should be rotated to minimize development of patch dermatitis. Because the transdermal delivery system ensures continuous drug delivery and sustained rotigotine levels over a 24-hour period, overnight symptomatic control is improved.⁴⁵

Apomorphine is an injectable nonergot dopamine agonist. It is an aporphine alkaloid originally derived from morphine but lacks narcotic properties. Because of extensive hepatic first-pass metabolism, apomorphine is not suitable for oral administration and is administered subcutaneously. In some countries, apomorphine is also available for continuous subcutaneous injection with minipumps. Apomorphine should not be injected intravenously. For patients with advanced IPD who are experiencing intermittent off episodes despite optimized therapy, administration of subcutaneous apomorphine consistently and effectively triggers an “on” response within 20 minutes.²⁸ The effective dose ranges from 2 to 6 mg per injection, with most patients requiring approximately 0.06 mg/kg. Sites of injection (abdomen, upper arm, and upper thigh) should be rotated to avoid development of subcutaneous nodules. The route of apomorphine metabolism is unknown. Apomorphine elimination half-life is approximately 40 minutes, and the duration of benefit can be up to 100 minutes. These pharmacokinetic properties make apomorphine a suitable drug for intermittent, as-needed “rescue” administra-

tion. Nausea and vomiting are common side effects, and prior to the initiation of apomorphine, patients should be premedicated with the antiemetic trimethobenzamide. Other side effects include dizziness, hallucinations, injection-site irritation, orthostatic hypotension, somnolence, and yawning. As a consequence of reports of severe hypotension and syncope, apomorphine is contraindicated with drugs in the serotonin (5HT₃)-receptor blocker class, including dolasetron, granisetron, and ondansetron.

■ SURGICAL THERAPY

9 Currently, surgery should be considered as an adjunct to pharmacotherapy when patients are experiencing frequent motor fluctuations or disabling dyskinesia or tremor despite an optimized medical regimen. There are several patient-selection criteria for surgery, including a diagnosis of L-dopa-responsive IPD. Anatomic targets include the thalamus, GPi, and the subthalamic nucleus. Bilateral, chronic, high-frequency electrical stimulation of a target site, also known as deep-brain stimulation (DBS), is the preferred surgical modality.⁴⁶

In DBS surgery, a battery-powered neurostimulator (pacemaker-like device) is implanted subcutaneously below the clavicle and provides constant electrical stimulation, via electrode wires, to the targeted brain structure. Thalamic DBS is very effective for suppressing tremor in the long-term, but it does not significantly improve the other parkinsonian features (bradykinesia, rigidity, motor fluctuations, or dyskinesias). Although debatable, subthalamic nucleus DBS is favored over GPi DBS and is considered a more effective and durable surgical procedure. Subthalamic nucleus DBS is associated with improvements in tremor, rigidity, bradykinesia, motor fluctuations, and dyskinesia, as well as lowering of antiparkinsonian medications.

DBS procedures require adjustment of the electrical stimulation parameters (e.g., voltage, frequency, and pulse width) to achieve optimal control while minimizing side effects. The electrical stimulation parameters (or “electrical dosage”) are adjusted via a programmable hand-held device to meet each patient’s needs and are performed by trained individuals, including nurse practitioners, physicians, and clinical pharmacists.

Other surgical procedures that have been investigated include grafting or transplantation of human fetal mesencephalon tissue into the striatum.^{47,48} This highly experimental procedure is based on the idea that dopaminergic neurons or neuroblasts can be used to replace or “restock” dopaminergic neurons that are lost in patients with IPD.

PHARMACOECONOMIC CONSIDERATIONS

Pharmacoeconomic assessments in IPD are important. IPD places a high economic burden on society.⁴⁹ Based on an estimated 1 million cases of IPD in the United States, the direct costs associated with IPD are in the range of \$4 to \$8 billion per year. If indirect costs, such as lost productivity, are included, the economic burden of IPD significantly increases. Patient-specific factors that influence the cost of IPD include age of symptom onset; level of disability; presence of motor complications, falls, and dementia; and need for skilled nursing. As the severity and level of disability increase, so do the costs associated with IPD. Likewise, the costs of treating patients with motor complications are considerably more than the costs of treating patients without motor complications. A similar trend applies for patients with hallucinations and psychosis who incur greater costs associated with nursing home placement.

Pharmacologic treatments that allow patients to maintain high functioning or reduce the development of motor complications would likely be cost-effective. Similarly, interventions or treatment approaches that slow disease progression (e.g., neuroprotection) are also likely to be cost-effective.

TABLE 61-6 Monitoring Parkinson's Disease Therapy

1. Monitor medication administration times. Educate the patient that immediate-release carbidopa/L-dopa is absorbed best on an empty stomach but is commonly taken with food to minimize nausea. Avoid administration of conventional selegiline in the late afternoon or evening to minimize insomnia.
2. Monitor to ensure that the patient and/or caregivers understand the prescribed medication regimen. For example, catechol-*O*-methyltransferase inhibitors work by enhancing the effect of L-dopa and that the patient should not discontinue medication without notifying the clinician.
3. Monitor and inquire specifically about dose-by-dose effects of medication, including response to doses of medication and the presence of dyskinesias, wearing-off effects, dizziness, nausea, or visual hallucinations. Offer suggestions to help alleviate these or encourage the patient to discuss with their clinician.
4. Monitor and inquire about concerns that caregivers may have about the patient, such as presence of abnormal behaviors, dyskinesias, falls, hallucinations, memory problems, mood changes, and sleep disorders.
5. Monitor for nonadherence and, if present, inquire for possible reasons (e.g., dosing convenience, financial issues, adverse effects) and offer suggestions.
6. Monitor for presence of drugs that can exacerbate idiopathic Parkinson's disease motor features (e.g., D₂ receptor blockers) or if the presence of an anticholinergic agent is causing cognitive impairment.

EVALUATION OF THERAPEUTIC OUTCOMES

Table 61–6 lists the monitoring parameters for Parkinson's disease therapy. It is important to educate patients and caregivers that IPD is a neurodegenerative disease that progresses with time and that some features respond less well to pharmacotherapy (e.g., freezing, postural instability). Patients and caregivers can participate in treatment by recording medication administration times as well as the duration of on and off times that can be reviewed at each visit.

Periodic review of all medications that the patient is taking should be performed to identify use of medications (e.g., D₂-receptor blockers) that can exacerbate IPD motor features. If the patient reports memory problems, the medication profile should be screened for medications with anticholinergic properties and, if present, eliminated when possible. Assessment of the patient's general level of functioning, including activities of daily living, is important to determine when medication adjustments are needed. Screening for anxiety or depressive disorders will help to determine if antidepressant or antianxiety therapy is needed. If falling is a problem, it is important to investigate whether falls are secondary to insufficient motor control or drug side effects such as dizziness and orthostatic hypotension. The former may necessitate an increase in dose of antiparkinson agents, and the latter a reduction in drug dosage. Physical therapy is also helpful for strengthening ambulation and balance skills to minimize falls. The patient should be questioned about any difficulties with their antiparkinson medications, including presence of adverse effects. Recommendations always should be made in view of the patient's perception of the severity of symptoms and effect on quality of life.

CONCLUSIONS

1 Despite many advances in neuroscience, a universal definitive cause of IPD remains unknown, and the identification of disease-modifying (neuroprotective) therapies remains elusive. The available therapies are symptomatic and include a number of drugs for early and later stages of the disease. Pharmacotherapy can significantly improve a patient's quality of life and functional status. The goal of management remains maintaining acceptable functional control with minimal treatment emergent complications. Thoughtful consideration for choice of initial and adjunctive therapy is critical for optimizing short- and long-term outcomes.

ABBREVIATIONS

- COMT: catechol-*O*-methyl-transferase
 CR: controlled release
 DBS: deep-brain stimulation
 GABA: γ -aminobutyric acid
 GPi: globus pallidus interna
 IPD: idiopathic Parkinson's disease
 L-dopa: levodopa
 MAO: monoamine oxidase
 MPP⁺: 1-methyl-4-phenylpyridinium
 MPTP: 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine
 NMDA: *N*-methyl-D-aspartate
 SNc: substantia nigra pars compacta

TERRY J. BAUMANN AND JENNIFER STRICKLAND

KEY CONCEPTS

- 1 It is important, whenever possible, to ask patients if they have pain, to identify the source of pain, and to assess the characteristics of the pain.
- 2 Patients taking analgesics should be monitored for response and side effects, particularly sedation and constipation associated with the opioids.
- 3 Oral analgesics are preferred over other dosage forms whenever feasible, but it is important to adjust the route of administration to the needs of the patient.
- 4 Equianalgesic doses are useful as a guide when converting from one agent to another, but further dose titration usually is required to achieve treatment goals.
- 5 Doses must be individualized for each patient and administered for an adequate duration of time. Around-the-clock regimens should be considered for acute and chronic pain. As-needed regimens should be used for breakthrough pain or when acute pain displays wide variability and/or has subsided greatly.
- 6 For chronic pain that has a maladaptive inflammatory and/or neuropathic component, anticonvulsants, tricyclic antidepressants, and opioids should be considered.
- 7 Whenever possible, a multidisciplinary approach and nonpharmacologic strategies should be used.
- 8 Placebo therapy should not be used as an attempt to diagnose psychogenic pain.

Although the world is full of suffering, it is also full of the overcoming of it.

Helen Keller¹

Humans have always known and sought relief from pain.² The act of relieving pain probably is as old as the medical profession itself. Today, pain's impact on society still is great, and indeed pain complaints remain a primary reason patients seek medical advice.³

Regrettably, many healthcare providers do not receive adequate training in this area, and new information is not widely disseminated and/or understood. Clearly, pain management is enhanced when a multidisciplinary approach is applied. Thus, understanding the patho-

physiology of pain therapy and maintaining a working knowledge of individual pain regimens are important key factors in addressing pain control.

DEFINITION

An acceptable definition of pain remains an enigma. Once thought to be a punishment from the gods, the word is derived from the Latin *peone* and the Greek *poine*, meaning "penalty" or "punishment."² Aristotle considered pain a feeling and classified it as a passion of the soul, where the heart was the source or processing center of pain.² This Aristotelian concept predominated for 2,000 years, although Descartes, Galen, and Vesalius postulated that pain was a sensation in which the brain played an important role. In the 19th century, Mueller, Van Frey, and Goldscheider hypothesized the concepts of neuroreceptors, nociceptors, and sensory input.² These theories developed into the current definition of pain: "an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage."⁴ Pain often is so subjective, however, that many clinicians define pain as whatever the patient says it is. The best care is achieved when the patient comes first.⁵

EPIDEMIOLOGY

Fifty million Americans are partially or totally disabled because of pain.³ The annual cost of pain to U.S. society can be estimated to be in the billions of dollars.⁶ In 1 year, an estimated 25 million Americans will experience acute pain due to injury or surgery, and one third of Americans will experience severe chronic pain at some point in their lives.⁷ These numbers are expected to rise, as increasingly more Americans work beyond age 60 years and survive into their 80s.⁶

Unfortunately, pain often remains undertreated in hospitals, long-term care facilities, and the community. Seriously ill hospitalized patients have reported a 50% incidence of pain; 15% had extremely or moderately severe pain occurring at least 50% of the time, and 15% were dissatisfied with overall pain control.⁸ In a followup report, the authors state that pain control persists as a major problem in hospitalized patients, and some of these patients were still in pain many months after hospitalization and experienced pain even on their deathbeds.⁹ In addition, problems with inadequate use of analgesics have been reported in cancer patients residing in nursing homes.¹⁰ In the Michigan pain study, 70% of chronic pain patients claimed to have pain despite treatment, with 22% believing that treatment worsened pain.⁶

PATHOPHYSIOLOGY

The pathophysiology of pain involves a complex array of neural networks in the brain that are acted on by afferent stimuli to produce

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

the experience we know as pain. In acute pain, this modulation is short-lived, but in some situations, the changes may persist, and chronic pain develops.^{11,12}

NOCICEPTIVE PAIN

Nociceptive pain typically is classified as either somatic (arising from skin, bone, joint, muscle, or connective tissue) or visceral (arising from internal organs such as the large intestine or pancreas).¹³ Whereas somatic pain most often presents as throbbing and well localized, visceral pain can manifest as pain feeling as if it is coming from other structures (referred) or as a well-localized phenomenon.¹³ We can think of nociception in terms of stimulation, transmission, perception, modulation,¹³ and adaptive inflammation.¹²

Stimulation

The first step leading to the sensation of pain is stimulation of free nerve endings known as *nociceptors*. These receptors are found in both somatic and visceral structures. They distinguish between noxious and innocuous stimuli, and they are activated and sensitized by mechanical, thermal, and chemical impulses.¹³ The underlying mechanism of these noxious stimuli (which in and of themselves may sensitize/stimulate the receptor) may be the release of bradykinins, potassium ion (K^+), prostaglandins, histamine, leukotrienes, serotonin, and substance P (among others) that sensitize and/or activate the nociceptors.^{14,15} Receptor activation leads to action potentials that are transmitted along afferent nerve fibers to the spinal cord (Fig. 62-1).¹³

Transmission

Nociceptive transmission takes place in $A\delta$ and C-afferent nerve fibers.¹³ Stimulation of large-diameter, sparsely myelinated $A\delta$ fibers evokes sharp, well-localized pain, whereas stimulation of unmyelinated, small-diameter C fibers produces dull, aching, poorly localized pain.¹³

FIGURE 62-1. Schematic representation of nociceptive pain. (Adapted from reference 15 with permission.)

These afferent, nociceptive pain fibers synapse in various layers (laminae) of the spinal cord's dorsal horn,¹⁵ releasing a variety of neurotransmitters, including glutamate, substance P, and calcitonin gene-related peptide.¹⁶ The complex array of events that influence pain can be explained in part by the interactions between neuroreceptors and neurotransmitters that take place in this synapse. For example, by stimulating large sensory myelinated fibers (e.g., $A\beta$) that mutually connect in the dorsal horn with pain fibers, both noxious and nonnoxious stimuli can have an inhibitory effect on pain transmission (Fig. 62-1).¹⁷ Functionally, the importance of the interplay between these different fibers and various neurotransmitters and neuroreceptors is evident in the analgesic response produced by topical irritants or transcutaneous electrical nerve stimulation. These pain-initiated processes reach the brain through a complex array of at least five ascending spinal cord pathways, which include the spinothalamic tract.¹⁸ Information other than pain is also carried along these pathways. Thus, pain is influenced by many factors supplemental to nociception and precludes simple schematic representation. It is postulated that the thalamus acts as a relay station, as these pathways ascend and pass the impulses to central structures where pain can be processed further.¹³

Pain Perception

At this point in transmission, pain is thought to become a conscious experience that takes place in higher cortical structures. The brain may accommodate only a limited number of pain signals, and cognitive and behavioral functions can modify pain. Relaxation, distraction, meditation, and guided mental imagery may decrease pain by limiting the number of processed pain signals.¹³ In contrast, a change in our neurobiochemical makeup that results in states such as depression or anxiety may worsen pain.

Modulation

The body modulates pain through a number of complex processes. One, known as the *endogenous opiate system*, consists of neurotransmitters (e.g., enkephalins, dynorphins, and β -endorphins) and receptors (e.g., μ , δ , and κ) that are found throughout the central nervous system (CNS).¹⁸ Like exogenous opioids, endogenous opioids bind to opioid receptor sites and modulate the transmission of pain impulses.¹³ Other receptor types also can influence this system. Activation of N-methyl-D-aspartate (NMDA) receptors, found in the dorsal horn, can decrease the μ -receptors' responsiveness to opiates.¹⁸

The CNS also contains a highly organized descending system for control of pain transmission. This system can inhibit synaptic pain transmission at the dorsal horn and originates in the brain.¹³ Important neurotransmitters here include endogenous opioids, serotonin, norepinephrine, γ -aminobutyric acid (GABA), and neurotensin.¹³

Adaptive Inflammation

Inflammatory pain can be thought of as the body's shifting from preventing tissue damage to the promotion of healing (e.g., surgical wounds, traumatic injury). As a result of the inflammatory process, the pain threshold is reduced and the injured area becomes more sensitive to pain. This process decreases our contact with and movement of the injured area, thus promoting the progression of healing.¹² When this course of action outlives its functionality or when it is caused by diseases such as arthritis, it can move from an acute to a chronic problem (maladaptive inflammation).¹² "In response to tissue damage and inflammation, a significant alteration occurs in the chemical composition and properties of the neurons that innervate the inflamed tissues. These alterations reflect the nature and levels of the different proteins expressed by the sensory neurons. Altered production of these proteins may modify the phenotypes of the neurons, changing their transduction and transmission properties. Inflammatory pain is also associated with an increase in the excitability or responsiveness of

neurons within the CNS, referred to as *central sensitization*. This phenomenon, like peripheral sensitization, is a major cause of hypersensitivity to pain after injury.¹⁹

NEUROPATHIC PAIN/FUNCTIONAL PAIN

Neuropathic and functional pain is distinctly different from nociceptive pain in that it becomes disengaged from noxious stimuli or healing¹² and often is described in terms of chronic pain. Neuropathic pain is a result of nerve damage, whereas functional pain can be thought of as abnormal operation of the nervous system.¹² A number of neuropathic pain syndromes (e.g., postherpetic neuralgia, diabetic neuropathy) and functional pain syndromes (e.g., fibromyalgia, irritable bowel syndrome, sympathetic induced pain, tension-type headaches, and some noncardiac chest pain)¹² exist. They often are underrecognized and difficult to treat.¹³ In addition, the pain reported often is not evident by examining physical findings.¹³

The mechanism responsible for neuropathic and functional pain may be the nervous system's endogenous dynamic nature. Nerve damage or certain disease states may evoke changes seen in inflammatory pain, ectopic excitability, enhanced sensory transmission, nerve structure reorganization, and loss of modulatory pain inhibition.^{12,19} Pain circuits rewire themselves both anatomically and biochemically.¹⁶ This produces spontaneous nerve stimulation, autonomic neuronal pain stimulation, and a progressive increase in the discharge of dorsal horn neurons.^{13,16}

Clinically, patients present with spontaneous pain transmission (often described as burning, tingling, shock-like, or shooting), exaggerated painful response to normally noxious stimuli (hyperalgesia), and/or painful response to normally nonnoxious stimuli (allodynia).^{13,20} This change over time may help to explain why this type of pain often manifests long after the actual nerve-related injury or when no actual injury is identified.

CLASSIFICATION OF PAIN

ACUTE PAIN

Acute pain can be a useful physiologic process warning individuals of disease states and potentially harmful situations. Unfortunately, severe, unremitting, undertreated, acute pain, when it outlives its biologic usefulness, can produce many deleterious effects (e.g., psychological problems). Acute pain usually is nociceptive, although it can be neuropathic in nature, with a relatively strong relationship to levels of pathology.⁷ Common causes of acute pain include surgery, acute illness, trauma, labor, and medical procedures.⁷

CHRONIC PAIN

Under normal conditions, acute pain subsides quickly as the healing process decreases the pain-producing stimuli; however, in some instances, pain persists for months to years, leading to a chronic pain state with features quite different from those of acute pain (Table 62-1). This type of pain can be nociceptive, neuropathic/functional, or both.⁷ Subtypes include: pain that persists beyond the normal healing time for an acute injury (e.g., complex regional pain syndrome), pain related to a chronic disease (e.g., pain secondary to osteoarthritis), pain without an identifiable organic cause (e.g., fibromyalgia), and a fourth type that many experts believe warrants a discrete classification,⁷ pain associated with cancer.²¹

CANCER PAIN

Pain associated with potentially life-threatening conditions is often called malignant pain or simply cancer pain.⁷ This type of pain

TABLE 62-1 Characteristics of Acute and Chronic Pain

Characteristic	Acute Pain	Chronic Pain
Relief of pain	Highly desirable	Highly desirable
Dependence and tolerance to medication	Unusual	Common
Psychological component	Usually not present	Often a major problem
Organic cause	Common	Often not present
Environmental/family issues	Small	Significant
Insomnia	Unusual	Common component
Treatment goal	Cure	Functionality
Depression	Uncommon	Common

Data from Stimmel² and Jacobson and Mariano.⁶⁸

includes both chronic and acute components and often has multiple etiologies. It is pain caused by the disease itself (e.g., tumor invasion, organ obstruction), treatment (e.g., chemotherapy, radiation, surgical incisions), or diagnostic procedures (e.g., biopsy).⁷

CLINICAL PRESENTATION

Clinical presentation of pain is best addressed by proper pain assessment. A patient-oriented approach is essential, and evaluation methods should not differ from those used in other medical conditions.² Therefore, a comprehensive history and physical examination are imperative to evaluate underlying diseases and possible contributing factors.² This includes identifying the source of pain when possible.² A baseline characterization of pain can be obtained by assessing PQRST characteristics (Table 62-2).²² Attention also must be given to mental/emotional factors that alter the pain threshold. Anxiety, depression, fatigue, anger, and fear in particular are noted to lower this threshold, whereas rest, mood elevation, sympathy, diversion, and understanding raise the pain threshold.²²

Clinicians must evaluate all components of the pain experience, e.g., behavioral (part of our reaction to pain is learned),²³ cognitive (thinking processes alter pain experiences),²⁴ social (pain expression differs in accordance with social environments),²⁵ and cultural (cultural background may influence pain tolerance).²⁵ In addition, separating chronic pain from acute pain allows for improved treatment regimens. Acute pain often is localized, well described, and relieved with conventional analgesic therapy (e.g., opioids, acetaminophen, nonsteroidal antiinflammatory drugs [NSAIDs]), whereas chronic pain many times is not well recognized and is not easily treated with conventional analgesics. **2** Proper patient assessment must include an evaluation of pain management. Pain intensity, pain relief, and medication side effects (e.g., opioid-induced sedation or constipation) must be assessed and reassessed on a regular basis. The timing and regularity of this assessment will depend on the type of pain and the medications administered. Postoperative pain and acute exacerbation of cancer pain may need to be assessed hourly, whereas chronic noncancer pain may require only daily or less frequent assessment. Pain intensity assessment is vital in acute pain,

CLINICAL PRESENTATION OF PAIN

Acute**General**

- Often obvious distress (e.g., trauma)

Symptoms

- Can be described as sharp, dull, shock-like, tingling, shooting, radiating, fluctuating in intensity, and varying in location (these occur in a timely relationship with an obvious noxious stimuli)

Signs

- Hypertension, tachycardia, diaphoresis, mydriasis, and pallor, but these signs are *not diagnostic*
- In some cases there are no obvious signs
- Comorbid conditions usually not present
- Outcome of treatment generally predictable

Laboratory Tests

- Pain is always subjective
- There are *no* specific laboratory tests for pain
- Pain is best diagnosed based on patient description and history

Chronic**General**

- Can appear to have no noticeable suffering

Symptoms

- Can be described as sharp, dull, shock-like, tingling, shooting, radiating, fluctuating in intensity, and varying in location (these often occur *without* a timely relationship with an obvious noxious stimuli)
- Over time, the pain stimulus may cause symptoms that completely change (e.g., sharp to dull, obvious to vague)

Signs

- Hypertension, tachycardia, diaphoresis, mydriasis, and pallor are seldom present
- In most cases there are *NO* obvious signs
- Comorbid conditions often present (e.g., sleep problems, depression, relationship problems)
- Outcome of treatment often unpredictable

Laboratory Tests

- Pain is always subjective
- Pain is best diagnosed based on patient description and history
- There are *no* specific laboratory tests for pain; however, history and/or diagnostic proof of past trauma (e.g., computed tomography) or present disease state (e.g., autoantibodies) may be helpful in diagnosing etiology

Data from Twycross²² and the American Pain Society.²⁶

whereas functionality becomes more of an issue in chronic pain. Quality of life must be assessed on a regular basis in all patients.

The clinician must remember, however, that “pain is always subjective. Objective observations of grimacing, limping, or tachycardia may be helpful in assessing patients, but these signs are often absent in patients with chronic pain caused by structural lesions. No neurophysiological or chemical test can measure pain. The clinician must accept the patient’s report of pain.”²⁶

TREATMENT

■ NONPHARMACOLOGIC THERAPY

Stimulation Therapy

Transcutaneous electrical nerve stimulation (TENS) has been used in managing both acute and chronic pain (e.g., surgical, traumatic, low back, arthritis, neuropathy, fibromyalgia, and oral-facial pain).^{7,17} However, the studies are contradictory and fail to show any sustained pain relief. As a result, the technique has not gained widespread acceptance.

Psychological Intervention

Even though the cognitive, behavioral, and social aspects of pain are well established, psychological interventions for the treatment of acute pain are not used widely. Simple interventions (e.g., introductory information about sensations to expect after certain procedures) reduce patient distress and greatly reduce postprocedure suffering.²⁷ Other successful psychological techniques, including relaxation training, imagery, and hypnosis, have proven effective in the management of postprocedure pain and in cancer-related

pain.^{27,28} Moderate evidence demonstrates that cognitive behavioral therapy and biofeedback also may be useful nonpharmacologic tools in managing chronic pain.²⁹

■ PHARMACOLOGIC TREATMENT

Nonopioid Agents

Analgesia should be initiated with the most effective analgesic agent having the fewest side effects. Acetaminophen, acetylsalicylic acid (aspirin), and NSAIDs often are preferred over opiates in the treatment of mild-to-moderate pain (Table 62–3). These drugs (with the exception of acetaminophen) prevent formation of prostaglandins produced in response to noxious stimuli, thereby decreasing the number of pain impulses received by the CNS.²⁶ Therapeutic outcomes may be less than desired in those who do not expect “mild” analgesics to relieve pain. NSAIDs may be particularly useful in the management of cancer-related bone pain.²⁸ Studies comparing the efficacy of these agents have been inconsistent. Therefore, the choice of a particular agent often depends on availability, cost, pharmacokinetics, pharmacologic characteristics, and the side-effect profile. Because of the large interpatient variability with NSAIDs, it is considered rational therapy to switch to another member of this drug group after an adequate therapeutic trial of any single agent.

Opioid Agents

Opioids are often the next logical step in the management of acute pain and cancer-related chronic pain. They also are an effective treatment option in the management of chronic noncancer pain; however, this continues to be somewhat controversial. Many times a trial of opioids is warranted, but such a trial should not be done without a complete assessment of the pain complaint.³⁰

TABLE 62-3 Adult FDA-Approved Nonopioid Analgesics (Includes Only FDA Approved Agents for Pain)

Class and Generic Name (Brand Name)	Half-Life (h)	Usual Dosage Range (mg)	Maximal Dose (mg/day)
Salicylates			
Acetylsalicylic acid ^a —aspirin (various)	0.25	325–1,000 every 4–6 h	4,000
Magnesium—anhydrous ^a (Doan's, various, various combinations of choline and magnesium are available)	Nd/Nd	304–607 every 4 h 607–934 every 6 h	3,738
Diflunisal (Dolobid, various)	8–12	500–1,000 initial 250–500 every 8–12 h	1,500
para-Aminophenol			
Acetaminophen ^a (Tylenol, various)	2–3	325–1,000 every 4–6 h	4,000 ^b
Fenamates			
Meclofenamate (various)	0.8–2.1	50–100 every 4–6 h	400
Mefenamic acid (Ponstel)	2	Initial 500 250 every 6 h (maximum 7 days)	1,000 ^c
Pyranocarboxylic acid			
Etodolac (various) (immediate release)	7.3	200–400 every 6–8 h	1,000
Acetic acid			
Diclofenac potassium (Cataflam, various)	1.9	In some patients, initial 100, 50 three times per day	150 ^d
Propionic acids			
Ibuprofen ^a (Motrin, various)	2–2.5	200–400 every 4–6 h	3,200 ^e 2,400 ^e 1,200 ^f
Fenoprofen (Nalfon, various)	3	200 every 4–6 h	3,200
Ketoprofen (various)	2	25–50 every 6–8 h	300
Naproxen (Naprosyn, Anaprox, various)	12–17	500 initial 500 every 12 h or 250 every 6–8 h	1,000 ^c
Naproxen sodium ^a (Aleve, various)	12–13	In some patients, 440 initial ^f 220 every 8–12 h ^f	660 ^f
Pyrrolizine carboxylic acid			
Ketorolac—parenteral (various)	5–6	30–60 (single IM dose only) 15–30 (single IV dose only) 15–30 every 6 h (maximum of 5 days)	30–60 15–30 60–120
Ketorolac—oral, indicated for continuation with parenteral only (various)	5–6	10 every 4–6 h (maximum of 5 days, which includes parenteral doses) In some patients, initial oral dose of 20	40
Cyclooxygenase-2 inhibitors			
Celecoxib (Celebrex)	11	Initial 400 followed by another 200 on first day, then 200 twice daily	400

^aAvailable both as an over-the-counter preparation and as a prescription drug.

^bSome experts believe 4,000 mg may be too high.

^cUp to 1,250 mg on the first day.

^dUp to 200 mg on the first day.

^eSome individuals may respond better to 3,200 mg as opposed to 2,400 mg, although well-controlled trials show no better response; consider risk versus benefits when using 3,200 mg/day.

^fOver-the-counter dose.

FDA, Food and Drug Administration; Nd, no data.

Data from American Pain Society;²⁶ Anonymous;^{44,45} and Watkins et al.⁶⁶

CLINICAL CONTROVERSY

Many clinicians believe that some chronic painful conditions (e.g., osteoarthritis) never should be treated with opioids, whereas others believe that when other modalities are not effective or seem to pose more of a risk to that particular patient than does conventional therapy (e.g., NSAIDs), then opioids are necessary.

The classification of these agents, their equianalgesic doses, relative histamine-releasing characteristics, pharmacokinetics, and dosing guidelines are outlined in Tables 62–4 and 62–5. The choice of opiate should be based on patient acceptance; analgesic effective-

ness; and pharmacokinetic, pharmacodynamic, and side-effect profiles (Tables 62–4 and 62–6).

The pharmacologic activity of opioids depends on their affinity for opiate receptors.³¹ Therapeutic activities and side effects range from those exhibited by the opiate agonists (e.g., morphine) to those seen with the opiate antagonists (e.g., naloxone). Partial agonists and antagonists (e.g., pentazocine) compete with agonists for opiate receptor sites and, depending on the inherent agonist and antagonist properties, exhibit mixed agonist–antagonist activity. Mixed agonist–antagonist agents with analgesic activity appear to exhibit selectivity for analgesic receptor sites.³¹ This may result in analgesia with fewer undesirable side effects. Efficacy and side effects also may further differ among agents because of receptor subtype variability. Specifically, research has identified multiple

TABLE 62-4 Opioid Analgesics

Class and Generic Name (Brand Name)	Chemical Source	Relative Histamine Release	Route	Equianalgesic Dose in Adults (mg)	Onset (min)/Half-Life (h)

Data from references 26, 32, 33, 43, 44, 45, and 67.

subtype μ -receptors with varied expression. This μ -receptor subtype variability may explain why some patients respond differently to certain opioids, specifically μ -receptor agonists.³²

The effects of the opioid analgesics are relatively selective, and at normal therapeutic concentrations, these agents do not affect other sensory modalities,³³ such as sensitivity to touch, sight, or hearing; however, as the dosage increases, so do the undesirable side effects (Table 62–6). Patients in severe pain may receive very high doses of opioids with no unwanted side effects, but as the pain subsides, patients may not tolerate even very low doses.³⁴ Frequently, when opioids are administered, pain is not eliminated, but its unpleasantness is decreased.³⁴ Patients report that although their pain is still present, it no longer bothers them.

Opioids share related pharmacologic attributes and exert a profound effect on the CNS and gastrointestinal tract.³³ Mood changes,

sedation, nausea, vomiting, decreased gastrointestinal motility, constipation, respiratory depression, dependence, and tolerance are evident in varying degrees with all agents. Constipation, sedation, and nausea/vomiting are the most common side effects of opioids; respiratory depression is less common.³⁵ Tolerance to side effects (except to constipation) often develops within the first week of therapy. Consideration of efficacy and side-effect profile assists in selection of the most appropriate agent.

③ The route of administration depends on individual patient needs. In patients who have oral access, the oral route is preferred. However, the onset of analgesic effects for oral medications is approximately 45 minutes, and the peak effect usually occurs 1 to 2 hours after administration.²⁶ This delay must be a consideration when immediate relief is needed in the management of acute pain. Therefore, in some scenarios, such as acute severe pain (i.e., pain

TABLE 62-5 Dosing Guidelines

Agent(s)	Doses (Titrate Up or Down Based on Patient Response)	Notes
NSAIDs/acetaminophen/aspirin	Dose to maximum before switching to another agent (see Table 62-3)	Used in mild-to-moderate pain May use in conjunction with opioid agents to decrease doses of each Regular alcohol use and high doses of acetaminophen may result in liver toxicity Care must be exercised to avoid overdose when combination products containing these agents are used
Morphine	PO 5–30 mg q 3–4 h ^a IM 5–10 mg q 3–4 h ^a IV 1–2.5 mg q 5 min prn ^a SR 15–30 mg q 12 h (may need to be q 8 h in some patients) Rectal 10–20 mg q 4 h ^a	Drug of choice in severe pain Use immediate-release product with SR product to control “breakthrough” pain in cancer patients Every-24-hour product available
Hydromorphone	PO 2–4 mg q 3–6 h ^a IM 1–4 mg q 3–6 h ^a IV 0.1–0.5 mg q 5 min prn ^a Rectal 3 mg q 6–8 h ^a	Use in severe pain More potent than morphine; otherwise, no advantages
Oxymorphone	IM 1–1.5 mg q 4–6 h ^a IV 0.5 mg initially PO immediate release 5–10 mg q 4–6 h ^a PO extended release 10–20 mg q 12 h ^a Rectal 5 mg q 4–6 h ^a	Use in severe pain No advantages over morphine Use immediate-release product with controlled-release product to control “breakthrough” pain in cancer or chronic pain patients
Levorphanol	PO 2–3 mg q 6–8 h ^a (Levo-Dromoran) PO 2–3 mg q 3–6 h ^a (Levorphanol Tartrate) IM 1–2 mg q 6–8 h ^a IV 1 mg q 3–6 h ^a	Use in severe pain Extended half-life useful in cancer patients In chronic pain, wait 3 days between dosage adjustments
Codeine	PO 15–60 mg q 4–6 h ^a IM 15–60 mg q 4–6 h ^a	Use in moderate pain Weak analgesic; use with NSAIDs, aspirin, or acetaminophen
Hydrocodone	PO 5–10 mg q 4–6 h ^a	Use in moderate/severe pain Most effective when used with NSAIDs, aspirin, or acetaminophen Only available as combination product with other ingredients for pain and/or cough
Oxycodone	PO 5–10 mg q 4–6 h ^a Controlled release 10–20 mg q 12 h	Use in moderate/severe pain Most effective when used with NSAIDs, aspirin, or acetaminophen Use immediate-release product with controlled-release product to control “breakthrough” pain in cancer or chronic pain patients
Meperidine	IM 50–150 mg q 3–4 h ^a IV 5–10 mg q 5 min prn ^a	Use in severe pain Oral not recommended Do not use in renal failure May precipitate tremors, myoclonus, and seizures Monoamine oxidase inhibitors can induce hyperpyrexia and/or seizures or opioid overdose symptoms
Fentanyl	IV 25–50 mcg/h IM 50–100 mcg q 1–2 h ^a Transdermal 25 mcg/h q 72 h Transmucosal (Actiq Lozenge) 200 mcg may repeat × 1, 30 min after first dose is started, then titrate Transmucosal (Fentora Buccal Tablet) 100 mcg, may repeat × 1, 30 min after first dose is started, then titrate Iontophoretic transdermal system 40 mcg per activation	Used in severe pain Do not use transdermal in acute pain Transmucosal for “breakthrough” cancer pain in patients already receiving or tolerant to opioids Iontophoretic transdermal system used for acute pain and can be reactivated every 10 min
Methadone	PO 2.5–10 mg q 3–4 h (acute) ^a IM 2.5–10 mg q 8–12 h (acute) ^a (more frequent dosing may be needed during initial titration) PO 5–20 mg q 6–8 h (chronic) ^a	Effective in severe chronic pain Sedation can be major problem Some chronic pain patients can be dosed every 12 h Equianalgesic dose of methadone when compared with other opioids will decrease progressively the higher the previous opioid dose
Propoxyphene	PO 100 mg q 4 h ^a (napsylate) PO 65 mg q 4 h ^a (HCl) (maximum 600 mg daily of napsylate, 390 mg HCl)	Use in moderate pain Weak analgesic; most effective when used with NSAIDs, aspirin, or acetaminophen This drug is not recommended in the elderly Will cause carbamazepine levels to increase 100 mg of napsylate salt = 65 mg of HCl salt
Pentazocine	PO 50–100 mg q 3–4 h ^b (maximum 600 mg daily)	Third-line agent for moderate-to-severe pain May precipitate withdrawal in opiate-dependent patients Parenteral doses not recommended
Butorphanol	IM 1–4 mg q 3–4 h ^b IV 0.5–2 mg q 3–4 h ^b Intranasal 1 mg (1 spray) q 3–4 h ^b If inadequate relief after initial spray, may repeat in other nostril × 1 in 60–90 min Max 2 sprays (one per nostril) q 3–4 h ^b	Third-line agent for moderate-to-severe pain May precipitate withdrawal in opiate-dependent patients

(continued)

TABLE 62-5 Dosing Guidelines (continued)

Agent(s)	Doses (Titrate Up or Down Based on Patient Response)	Notes
Nalbuphine	IM/IV 10 mg q 3–6 h ^b (maximum 20 mg dose, 160 mg daily)	Second-line agent for moderate-to-severe pain May precipitate withdrawal in opiate-dependent patients
Buprenorphine	IM 0.3 mg q 6 h ^b Slow IV 0.3 mg q 6 h ^b May repeat $\times 1$, 30–60 min after initial dose	Second-line agent for moderate-to-severe pain May precipitate withdrawal in opiate-dependent patients Naloxone may not be effective in reversing respiratory depression
Naloxone	IV 0.4–2 mg	When reversing opiate side effects in patients needing analgesia, dilute and titrate (0.1–0.2 mg q 2–3 min) so as not to reverse analgesia
Tramadol	PO 50–100 mg q 4–6 h ^a If rapid onset not required, start 25 mg/day and titrate over several days Extended release PO 100 mg q 24 h	Maximum dose for nonextended-release, 400 mg/24 h; maximum for extended release, 300 mg/24 h Decrease dose in patient with renal impairment and in the elderly

^aMay start with an around-the-clock regimen and switch to prn if/when the painful signal subsides or is episodic.

^bMay reach a ceiling analgesic effect.

IM, intramuscular; IV, intravenous; NSAID, nonsteroidal antiinflammatory drug; PO, oral; prn, as needed; SR, sustained release.

Data from American Pain Society;²⁶ Gutstein and Akil;³³ and Anonymous.^{44,45}

crisis) or when the patient is unable to take oral medications, alternative routes of therapy (e.g., intravenous) may be preferred. **4** The opioids differ greatly in equianalgesic dose (Table 62–4), which should be used only as a guide because the nature of pain makes it necessary to individualize pain regimens. True opioid allergies are rare, but Table 62–4 also can be used when treating a patient who is allergic to opiates. Most reactions to opioids, such as itching or rash, are due to the associated histamine release and mast cell degranulation, not to a true allergic or immunoglobulin-E (IgE) response. Although caution is always advised, a decrease in potential cross-sensitivity exists when moving from one opioid structural class to another. The classes are phenanthrenes (morphine-like agonists), phenylpiperidines (meperidine-like agonists), and diphenylheptanes (methadone-like agonists). When considering cross-sensitivity, the mixed agonist–antagonist class acts much like the morphine-like agonists.³⁶ Reactions due to histamine release may be reduced by choosing agents shown to have less effect on histamine release. Morphine has been associated with the greatest histamine release, whereas agents such as oxycodone and fentanyl typically cause fewer histamine-related reactions (see Table 62–4).

2 5 In the initial stages of acute pain, analgesics should be given around the clock. This should commence after administering a typical starting dose and titrating up or down, depending on the patient's degree of pain and demonstrated side effects (e.g., sedation).²⁶ As-needed schedules often produce wide swings in analgesic plasma concentrations that create wide swings in pain and sedation. This may initiate a vicious cycle where increasing amounts of pain medications are needed for relief. **5** As the painful state subsides

and the need for medication decreases, as-needed schedules may be appropriate. As-needed schedules also may be useful in patients who present with pain that is intermittent or sporadic in nature (Fig. 62–2). The management of chronic pain is also best accomplished by around-the-clock administration schedules that inhibit serum analgesic concentrations from falling below the point at which a patient experiences the suffering of pain. As-needed schedules are to be used in conjunction with around-the-clock regimens and are used when patients experience breakthrough pain.

Continuous intravenous and subcutaneous methods of opioid infusion are effective for some postoperative pain, but the probability of unwanted side effects is high.²⁶ An alternative method is patient-controlled analgesia (PCA). With this technique, patients can self-administer a preset dose of an intravenous opioid via a pump electronically interfaced with a timing device. Compared to traditional as-needed opioid dosing, PCA yields better pain control, improved patient satisfaction, and relatively few differences in side effects.³⁷

Administration of opiates directly into the CNS (e.g., epidural and intrathecal/subarachnoid routes) has shown considerable promise in the control of acute, chronic noncancer, and cancer pain (Table 62–7)^{13,38,39} and is common in both large and small institutions throughout the United States. Because of reports of marked sedation, respiratory depression, pruritus, nausea, vomiting, urinary retention, and hypotension,⁴⁰ these methods of analgesia require careful monitoring and are best used by experienced practitioners. Respiratory depression is of concern and can occur within the first half hour or manifest as late as 12 hours after a single dose of epidural morphine.⁴⁰ Naloxone is used to antagonize this effect, but continuous infusion may be required.⁴⁰ Analgesia and side effects are evident at lower doses when the opioids are administered intrathecally instead of epidurally. Intrathecally, single morphine doses of 0.1 to 0.3 mg are common, whereas epidurally, doses of 1 to 6 mg are the norm.³⁸ These intrathecal and epidural opioids often are administered on a continuous-infusion and/or patient-controlled basis, and, when given simultaneously with intrathecal or epidural local anesthetics such as bupivacaine, they have been proven safe and effective.⁴¹ All agents administered directly into the CNS should be preservative-free.

Tolerance, Dependence, Addiction, and Pseudoaddiction

A barrier that consistently causes clinicians to misjudge and mistreat pain is the misunderstanding of opioid tolerance, physical dependence, addiction, and pseudoaddiction. “Tolerance is the diminution of drug effect over time as a consequence of exposure to the drug.”⁴² It develops at different rates and with tremendous patient variability. However, with stable disease, opioid use often stabilizes, and tolerance does not lead to addiction.⁴² “Physical dependence is defined by

TABLE 62-6 Major Adverse Effects of the Opioid Analgesic

Effect	Manifestation
Mood changes	Dysphoria, euphoria
Somnolence	Lethargy, drowsiness, apathy, inability to concentrate
Stimulation of chemoreceptor trigger zone	Nausea, vomiting
Respiratory depression	Decreased respiratory rate
Decreased gastrointestinal motility	Constipation
Increase in sphincter tone	Biliary spasm, urinary retention (varies among agents)
Histamine release	Urticaria, pruritus, rarely exacerbation of asthma (varies among agents)
Tolerance	Larger doses for same effect
Dependence	Withdrawal symptoms upon abrupt discontinuation

Data from Stimmel;² Miyoshi and Leckband;³¹ and Reisine and Pasternak.³⁴

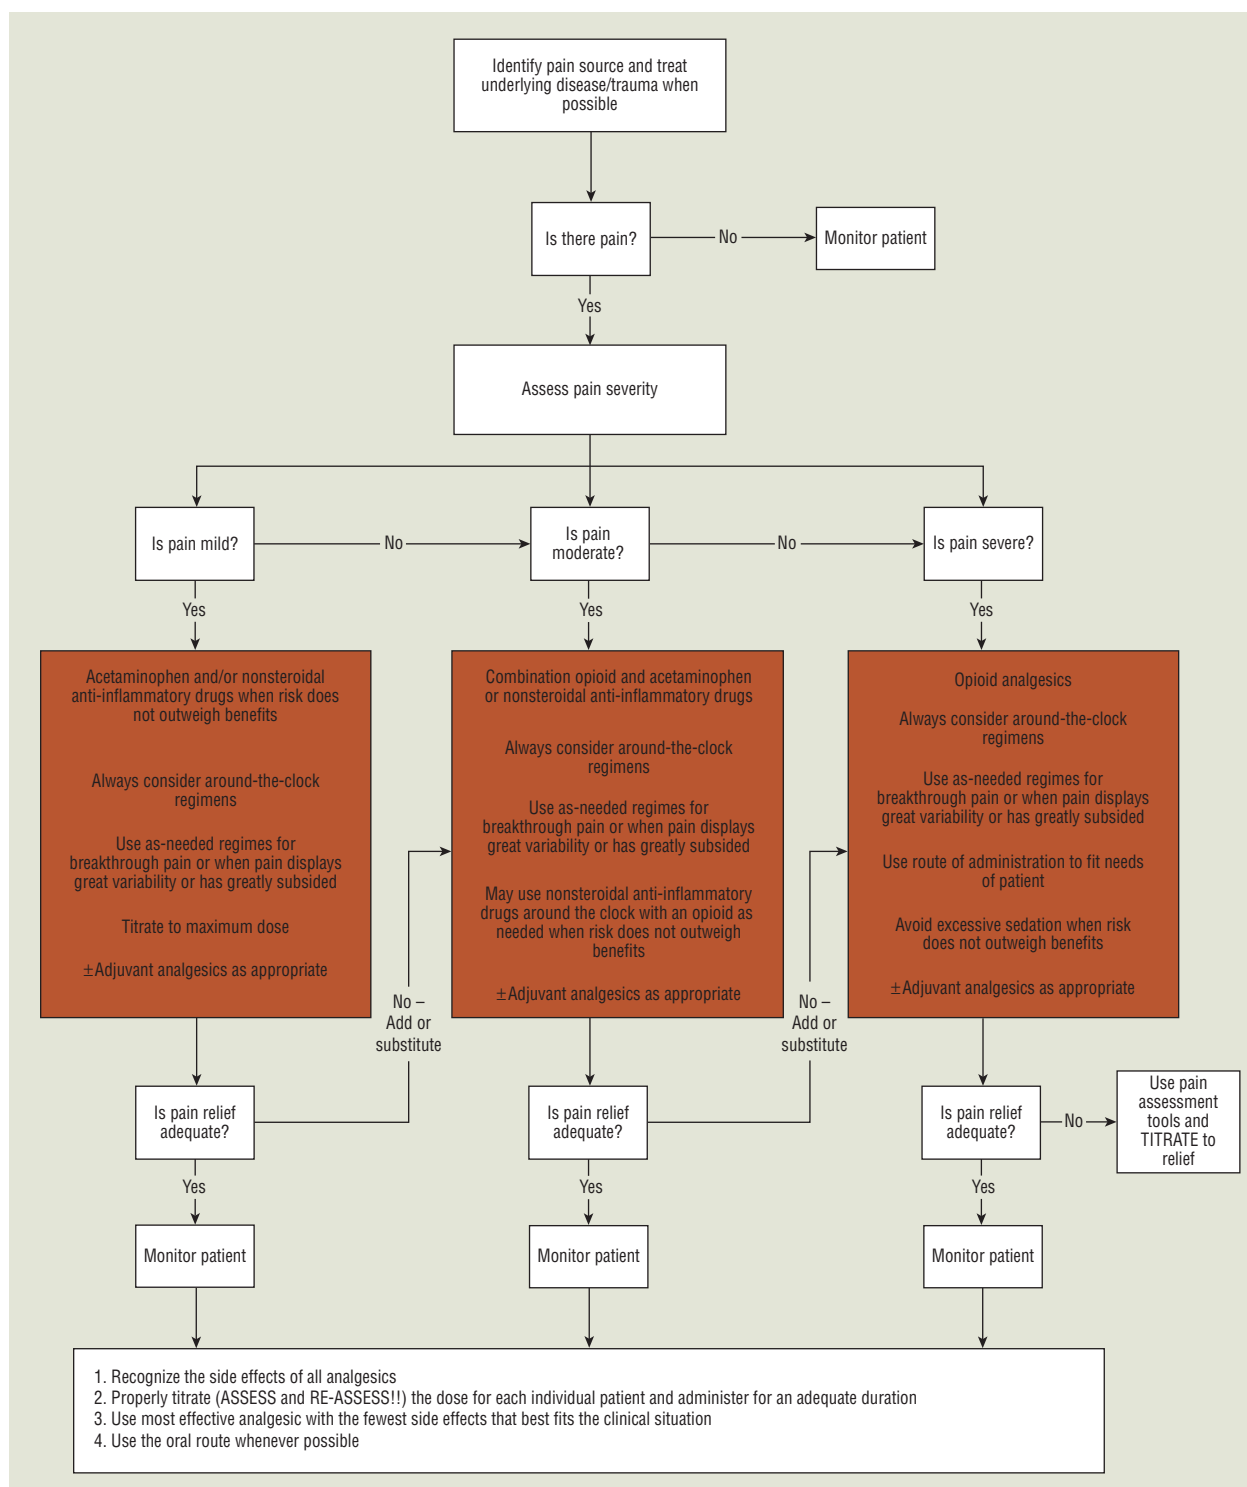

FIGURE 62-2. Algorithm for acute pain. (Data modified from Omnicare, Inc., Acute Pain Pathway.)

the occurrence of an abstinence syndrome following administration of an antagonist drug or abrupt dose reduction or discontinuation.²⁴² Clinicians must understand that physical dependence and tolerance are not equivalent to addiction; however, with chronic opioid use, they are likely to develop.²⁶ “Addiction is best defined as a behavioral pattern characterized as loss of control over drug use, compulsive drug use, and continued use of a drug despite harm.”⁴² When opioids are being used, these behaviors must be evaluated continually, but extreme caution is advised when using the term *addiction* because of its many negative connotations, which can lead to a compromised clinician–patient relationship and ineffective pain control.^{26,42} In

addition, clinicians must be aware that an individual’s behaviors may suggest addiction, when in reality the behaviors noted are a reflection of unrelieved pain or pseudoaddiction.²⁶ The incidence of addiction varies depending on the patient population. In patients with no history of addiction, the risk of addiction is relatively small. “Drug exposure appears to be only one etiologic factor in the development of addiction, and genetics, social, and psychologic factors may be more significant determinants.”⁷

Morphine and Congeners Despite the availability of several newer agents, morphine remains the prototype opiate analgesic. As

TABLE 62-7 Intraspinal Opioids

Agent	Single Dose (mg)	Onset of Pain Relief (min)	Duration of Pain Relief (h)	Continual Infusion Dose (mg/h)

Fentanyl	0.005–0.025	5	3–6	—

Data from American Pain Society²⁶ and Ready.³⁸

new opioid and nonopioid compounds are developed, their efficacy and side-effect profiles are compared against morphine as the standard. Many clinicians consider morphine the first-line agent when treating moderate-to-severe pain. Morphine can be given parenterally, orally, or rectally.

Side effects can be numerous, particularly when morphine is first initiated or when doses are significantly increased. Morphine causes nausea and vomiting through direct stimulation of the chemoreceptor trigger zone.³³ Opioid-induced nausea is observed most frequently after the initial dose and often subsides with subsequent doses.⁴³ Although euphoria and dysphoria have been reported, morphine's unpleasant effects are more prominent when administered to patients not experiencing pain.³³ As doses of morphine are increased, the respiratory center becomes less responsive to carbon dioxide, causing progressive respiratory depression. This effect is less pronounced in patients being treated for severe or chronic pain. Respiratory depression often manifests as a decrease in respiratory rate (although minute volume and tidal volume also are affected) and is further compounded because the cough reflex is also depressed. Morphine-induced respiratory depression can be reversed by pure opioid antagonists, such as naloxone.³⁴ In patients with underlying pulmonary dysfunction, caution must be used as these patients are already using compensatory breathing mechanisms and are at risk for further respiratory compromise.³⁴ Caution is also urged when combining opiate analgesics with alcohol or other CNS depressants because this combination is potentially harmful and possibly lethal.

Therapeutic doses of morphine have minimal effects on blood pressure, cardiac rate, or cardiac rhythm when patients are supine; however, morphine does produce venous and arteriolar vessel dilation, and orthostatic hypotension may result. Hypovolemic patients are more susceptible to morphine-induced cardiovascular changes (e.g., decreases in blood pressure).³⁴ Because morphine prompts a decrease in myocardial oxygen demand in ischemic cardiac patients, it is often considered the drug of choice when using opioids to treat pain associated with myocardial infarction.

Morphine decreases the propulsive contractions of the gastrointestinal tract and reduces biliary and pancreatic secretions,³⁴ resulting in constipation. Morphine-induced spasms of the sphincter of Oddi have been observed.³⁴ However, the clinical significance of such an occurrence is unclear. Urinary retention is another potential side effect of morphine; tolerance develops to this effect over time.³⁴ Morphine-induced histamine release often manifests as pruritus, and although not seen often, it may exacerbate bronchospasm in patients with a history of asthma.³⁴ Therapeutic doses of morphine do not directly affect cerebral circulation, but drug-induced respiratory depression can increase intracranial pressure. Thus, caution is advised in head trauma patients who are not ventilated because morphine may exaggerate this pressure³⁴ and cloud the neurologic examination results.

Morphine is metabolized to two important metabolites, morphine-3-glucuronide (M3G) and morphine-6-glucuronide (M6G). One metabolite, M6G, contributes to analgesia, whereas the other, M3G, may contribute to side effects if allowed to accumulate. The metabolites are renally cleared and can accumulate in patients with renal impairment, contributing to greater side effects.³³

Hydromorphone is more potent, has better oral absorption characteristics, and is more soluble than morphine, but its overall pharmacologic profile parallels that of morphine. Some clinicians believe hydromorphone is associated with fewer side effects, especially pruritus, compared to other opioids. However, the research is limited and does not conclusively demonstrate a difference in side effects between morphine and hydromorphone. Oxycodone can be administered orally, rectally, and by injection. Although extended-release and immediate-release oral products have become available, making oxycodone useful in chronic and acute pain, it offers no pharmacologic advantage over morphine. Levorphanol has an extended half-life, but its overall therapeutic effects are similar to the other agents in this class.

Codeine is a commonly used opiate in the treatment of mild-to-moderate pain. It often is combined with other analgesic products (e.g., acetaminophen). Unfortunately, it has the same propensity to produce side effects as morphine and may produce more nausea and constipation.²⁶ Hydrocodone is another commonly prescribed opiate and is available for pain only in combination products with other analgesic agents (e.g., acetaminophen, ibuprofen). Its pharmacologic properties are similar to those of morphine. Oxycodone is a useful oral analgesic for moderate-to-severe pain. This is especially true when the product is used in combination with nonopioids. Although oxycodone shares basic morphine characteristics, the availability of an immediate-release and controlled-release oral dosage form also makes it very useful in persistent pain as well as acute pain.

Meperidine and Congeners (Phenylpiperidines) The prototype phenylpiperidine, meperidine, has a pharmacologic profile comparable with that of morphine; however, it is not as potent and has a shorter analgesic duration. This necessitates larger doses that often must be administered more frequently for satisfactory pain relief. Meperidine is metabolized to the toxic metabolite normeperidine, which can cause CNS excitability, manifested as tremor, muscle twitching, and possible seizures.³³ Normeperidine is renally cleared, so the risk of accumulation and toxicity is greatest in patients with renal dysfunction or the elderly.⁴⁴ The combination of monoamine oxidase inhibitors and meperidine should not be used because this mixture can produce severe respiratory depression or excitation, delirium, hyperpyrexia, and convulsions.³⁴ Meperidine is not recommended for long-term use because of its relatively short duration of action and the CNS hyperirritability of normeperidine.²⁸ Meperidine offers no analgesic advantage over morphine, has greater toxicity, and should be limited in use. In particular, its use should be avoided in patients at greatest risk for toxicity (e.g., elderly, patients with renal dysfunction).

Fentanyl is a synthetic opioid structurally related to meperidine that is used often in anesthesiology as an adjunct to general anesthesia.⁴⁴ This agent is more potent, more lipophilic, and shorter acting than meperidine (Table 62-4). It can be administered parenterally, transmucosally, and transdermally. The fentanyl patch may provide a more convenient dosing alternative in patients on stable regimens. The transdermal patch can provide analgesia for up to 72 hours, but takes 12 to 24 hours for full onset and up to 6 days to reach steady state after dose adjustments. Therefore, the transdermal patch should be limited to patients with chronic pain; it is not appropriate for the management of acute pain.⁴⁵ A fentanyl lozenge and a buccal dosage form also are available for treatment of breakthrough cancer pain.⁴⁵ Caution should be used when fentanyl is administered to patients who have a very small body habitus, always starting with the

smallest expected effective dose and carefully titrating to effect. Most recently an iontophoretic patient controlled transdermal system has been developed for use in acute postoperative pain.⁴⁵

Methadone and Congeners Methadone has gained considerable popularity because of its oral efficacy, extended duration of action, and low cost. Although methadone is effective in acute pain,⁴⁵ it has gained particular prominence in treating cancer pain³⁹ and has increasingly been used in the management of chronic noncancer pain.⁴⁶ This despite the fact that, with repeated doses, the analgesic duration of action is prolonged,⁴⁵ resulting in an unpredictable half-life, possible excessive sedation, and difficulty in titration. Properties unique to methadone, compared with other opioids, include the D-isomer's ability to antagonize NMDA receptors, agonist effects at κ - and δ -opioid receptors, and blockade of serotonin and norepinephrine reuptake.^{46–49} These properties may prove useful in the treatment of neuropathic and chronic pain or in patients with a maladaptive inflammatory component to their pain. The equianalgesic dose of methadone may decrease with higher doses of the previous opioid,⁴⁷ complicating conversions from other opioids to methadone.

CLINICAL CONTROVERSY

Some clinicians believe that methadone should be tried before other opioids in many chronic pain conditions where an opioid is warranted because they believe that neuropathic pain is often a component. Other clinicians believe that sustained-released morphine or oxycodone are better first choices.

Propoxyphene usually is used in combination with acetaminophen for treatment of moderate pain. Propoxyphene is metabolized to norpropoxyphene, a potentially toxic metabolite.²⁶ Elderly patients and those with renal dysfunction are at greatest risk for toxicity; therefore, propoxyphene use is discouraged in these patients.^{26,50}

Opioid Agonist–Antagonist Derivatives

Analgesic agents that stimulate the analgesic portion of opioid receptors while blocking or having no effect on the toxicity portion would be considered ideal. The agonist–antagonist derivatives were developed with this in mind. The analgesic class produces analgesia and has a ceiling effect on respiratory depression.³¹ These agents also have a lower abuse potential than does morphine, but psychotomimetic responses (e.g., hallucinations and dysphoria, as seen with pentazocine), a ceiling analgesic effect, and a propensity to initiate withdrawal in opioid-dependent populations³¹ have diminished their widespread clinical use.

Opioid Antagonists

The pure opioid antagonist naloxone binds competitively to opioid receptors but does not produce an analgesic or opioid side-effect

response. Therefore, it is used most often to reverse the toxic effects of agonist- and agonist–antagonist-derived opioids.

Central Analgesic

Tramadol has two basic modes of action: μ -opiate receptor binding and inhibition of norepinephrine and serotonin reuptake. It is indicated for the relief of moderate to moderately severe pain.⁵¹

Tramadol has a side-effect profile similar to that of the previously mentioned opioid analgesics (e.g., dizziness, euphoria, hallucinations, cognitive dysfunction, and constipation).⁴⁴ Tramadol alone may enhance the risk of seizures. In addition, concomitant use with serotonin reuptake inhibitors, opioids, tricyclic antidepressants, monoamine oxidase inhibitors, neuroleptics, or other drugs that can reduce the seizure threshold and use in patients with seizure disorders may increase the risk of seizures.⁵¹ Tramadol may have a place in treating patients with chronic pain, especially neuropathic pain.⁵²

Adjuvant Analgesics

Adjuvant analgesics are pharmacologic agents with individual characteristics that make them useful in the management of pain but that typically are not classified as analgesics. Examples of adjuvant analgesics include antidepressants and anticonvulsants. **6** Chronic pain that has a maladaptive inflammatory (e.g., low back pain) and/or neuropathic component (e.g., diabetic neuropathy) may require such agents (Table 62–8). Anticonvulsants (e.g., gabapentin, which may decrease neuronal excitability), tricyclic antidepressants, serotonin and norepinephrine reuptake inhibitor antidepressants (which block the reuptake of serotonin and norepinephrine, thus enhancing pain inhibition), and topically applied local anesthetics (which decrease nerve stimulation) all have been effective in managing chronic pain.^{53,54}

In cancer patients, bone pain can be treated with radiopharmaceuticals. Both strontium 89 and samarium Sm 153 lexidronam have been shown to provide pain relief.⁴⁵ Although antihistamines, amphetamines, and steroids have been used as adjuvant pain medications,²⁸ they have demonstrated only limited success as pain relievers.

Combination Therapy

The combination of opioid and nonopioid analgesics often results in analgesia superior to that produced by either agent alone.²⁷ This facilitates the use of lower doses and a more favorable side-effect profile, and, when needed, this approach is encouraged.

REGIONAL ANALGESIA

Regional analgesia with properly administered local anesthetics can provide relief of both acute and chronic pain (Table 62–9).⁴¹ These agents can be positioned by injection (e.g., in joints, in the epidural or intrathecal space, along nerve roots, or in a nerve plexus) or topically. Lidocaine in the form of a patch has proven effective in treating focal

TABLE 62-8 Pharmacologic Management of Chronic Noncancer Pain

Type of Pain	Nonopioids	Opioids	Other Medications	Comments
Chronic low back pain	Acetaminophen, NSAIDs	Short-term use for mild-to-moderate flare-ups	TCAs, AEDs	Acetaminophen and NSAIDs first; opioids in selected patients; AEDs or TCAs if neuropathic symptoms
Fibromyalgia	Acetaminophen, NSAIDs	Long-term use not recommended	Tramadol, TCAs; AEDs	Acetaminophen and NSAIDs considered first; tramadol may be better alternative than opioids
Neuropathic pain	Acetaminophen or NSAIDs are rarely effective	Considered first-line therapy but usually are tried after AEDs and/or TCAs, tramadol, lidocaine 5% patch	TCAs, AEDs, SNRIs, tramadol, topical (e.g., 5% lidocaine patch, capsaicin)	Gabapentin, 5% lidocaine patch, tramadol, nortriptyline, desipramine, all considered first-line agents; opioids considered first-line agents but usually are tried after above

AED, antiepileptic drug; NSAIDs, nonsteroidal antiinflammatory drugs; SNRI, serotonin–norepinephrine reuptake inhibitor; TCA, tricyclic antidepressant.

Data from references 7, 19, 53, 54, and 65.

TABLE 62-9 Local Anesthetics^a

Agent (Brand Name)	Onset (min)	Duration (h)
Esters		
Procaine (Novocain, various)	2–5	0.25–1
Chloroprocaine (Nesacaine)	6–12	0.5
Tetracaine (Pontocaine)	≤15	2–3
Amides		
Mepivacaine (Polocaine, various)	3–5	0.75–1.5
Bupivacaine (Marcaine, various)	5	2–4
Lidocaine (Xylocaine, various)	<2	0.5–1
Prilocaine (Citanest)	<2	≥1
Levobupivacaine ^b (Chirocaine)	≈10	≈8
Articaine with epinephrine ^c (Septodont)	1–6	1
Ropivacaine ^d (Naropin)	11–26	1.7–3.2

neuropathic pain.⁵⁴ Regional anesthetics relieve pain by blocking nociceptive transmission and interrupting sympathetic reflexes.⁴¹ Their lipid solubility, pK_a, percentage of un-ionized drug, drug concentration, vasodilator behavior, and amount of vasoconstrictor (commonly epinephrine) used concomitantly determine the mechanism of action.⁴¹ High plasma concentrations can cause signs of CNS excitation and depression, including dizziness, tinnitus, drowsiness, disorientation, muscle twitching, seizures, and respiratory arrest.⁴⁴ Cardiovascular effects include myocardial depression, hypotension, decreased cardiac output, heart block, bradycardia, ventricular arrhythmia, and cardiac arrest.⁴⁵ Disadvantages of such methods include the need for skillful technical application, need for frequent administration, and highly specialized followup procedures.

■ SPECIAL CONSIDERATIONS IN ACUTE PAIN

1 2 3 5 The World Health Organization (WHO) recommends a three-step ladder approach using the simplest dosage schedules and medications with the least amount of potential harm based on pain intensity ratings from mild to moderate-to-severe.²⁸ An acute pain algorithm outlining how to use these principles is given in Fig. 62–2. The importance of reassessment and titration during this process cannot be overemphasized.

■ SPECIAL CONSIDERATIONS IN CANCER PAIN

Managing the pain of cancer encompasses both acute and chronic management techniques. **7** Thus, pharmacologic treatment and psychological therapies are best combined with surgical methods, anesthetic procedures, and supportive care measures in a multidisciplinary approach to pain relief.⁵⁵ The goal is to provide patients with enough pain amelioration to tolerate diagnostic and therapeutic manipulation and permit the patient to function at a level that will allow freedom of movement and choice.²⁸ Assessment of the factors given in Table 62–2 also applies to cancer patients. Special attention must be given to continual reassessment of the painful state, adverse effects with medications, and aberrant behaviors. **5** Individualization of therapy is always required.²⁸ Supportive care, in and outside the hospital, using programs such as hospice, is one of the cancer patient's greatest allies, not only in coping with pain but also in accepting the disease. The positive effect this has on the patient cannot be overstated. Pharmacologic management is the mainstay of therapy, and a typical progression of analgesic use in oncology patients is outlined in Fig. 62–3.

■ SPECIAL CONSIDERATIONS IN CHRONIC NONCANCER PAIN

7 The numerous etiologies that produce chronic noncancer pain make treatment complex, and overall management should be multidisciplinary. As pain becomes gradually more chronic, acute symptoms such as hypertension, tachycardia, and diaphoresis become less evident, and symptoms such as depression, sleep disturbances, anxiety, irritability, work problems, and family instability tend to dominate. Patients should not be told that the pain they are feeling is “psychosomatic” or is in their head. In most cases, etiology is not as important as symptomatic relief. Evaluation objectives include establishing an accurate diagnosis, identifying iatrogenic factors, obtaining a comprehensive psychiatric and psychosocial assessment, paying special attention to family and social problems, and obtaining a description of factors that alleviate or exacerbate pain.² **8** Given these objectives, placebos should never be used to diagnose pain.²

7 In all cases of chronic noncancer pain, an integrated systematic approach (such as that often provided by pain clinics), with a strong emphasis on patient–clinician relationships, is essential. The goal is to improve or maintain the patient's level of functioning, decrease the rate of physical deterioration, decrease pain perception, improve the patient's sense of well-being, improve family and social relationships, and decrease dependency on drug therapy.² Patients and clinicians must realize that maximum effective treatment may take months or even years.

■ SPECIAL POPULATIONS

The elderly and the young are at a higher risk for undertreatment because of misunderstandings regarding the pathophysiology of their pain. **5** In addition, those living with chronic, debilitating, and life-threatening illnesses need specialized pain control and care that is palliative in nature.⁵⁶ Although care must be taken in these populations to ensure that proper individualized treatment plans follow accepted guidelines,^{56–59} the key concepts in pain management as outlined in this chapter are the guiding tenets in maximizing pain control.

PHARMACOECONOMIC CONSIDERATIONS

The *suffering* component of pain cannot be overemphasized. Most of us know how devastating pain can be to our daily lives. Swift relief from acute and cancer pain and well-planned treatment regimens in chronic nonmalignant pain will allow patients to concentrate on recovery and regaining control of their lives. Although few well-designed pharmacoeconomic studies have been performed,^{60–62} most pain clinicians believe that this approach minimizes time in the hospital and time away from work while maximizing quality of life.

EVALUATION OF THERAPEUTIC OUTCOMES

2 5 The key to treating pain effectively is consistent monitoring for effectiveness (pain relief) versus side effects (e.g., sedation) and titrating treatment accordingly. In acute pain, this often must be done several times per day (in the early stages, hourly), whereas in chronic pain this may occur daily or even weekly. The frequency of evaluation also depends on the drug, the administration route, and other therapies being used. When patients cannot be asked about their pain (e.g., coma), monitoring agitation and heart rate is appropriate. Given the subjective nature of pain, the most successful therapies involve not only frequent patient assessment but also a large degree of patient control (as with PCA). With chronic pain, tools such as the Brief Pain Inventory, Initial Pain Assessment

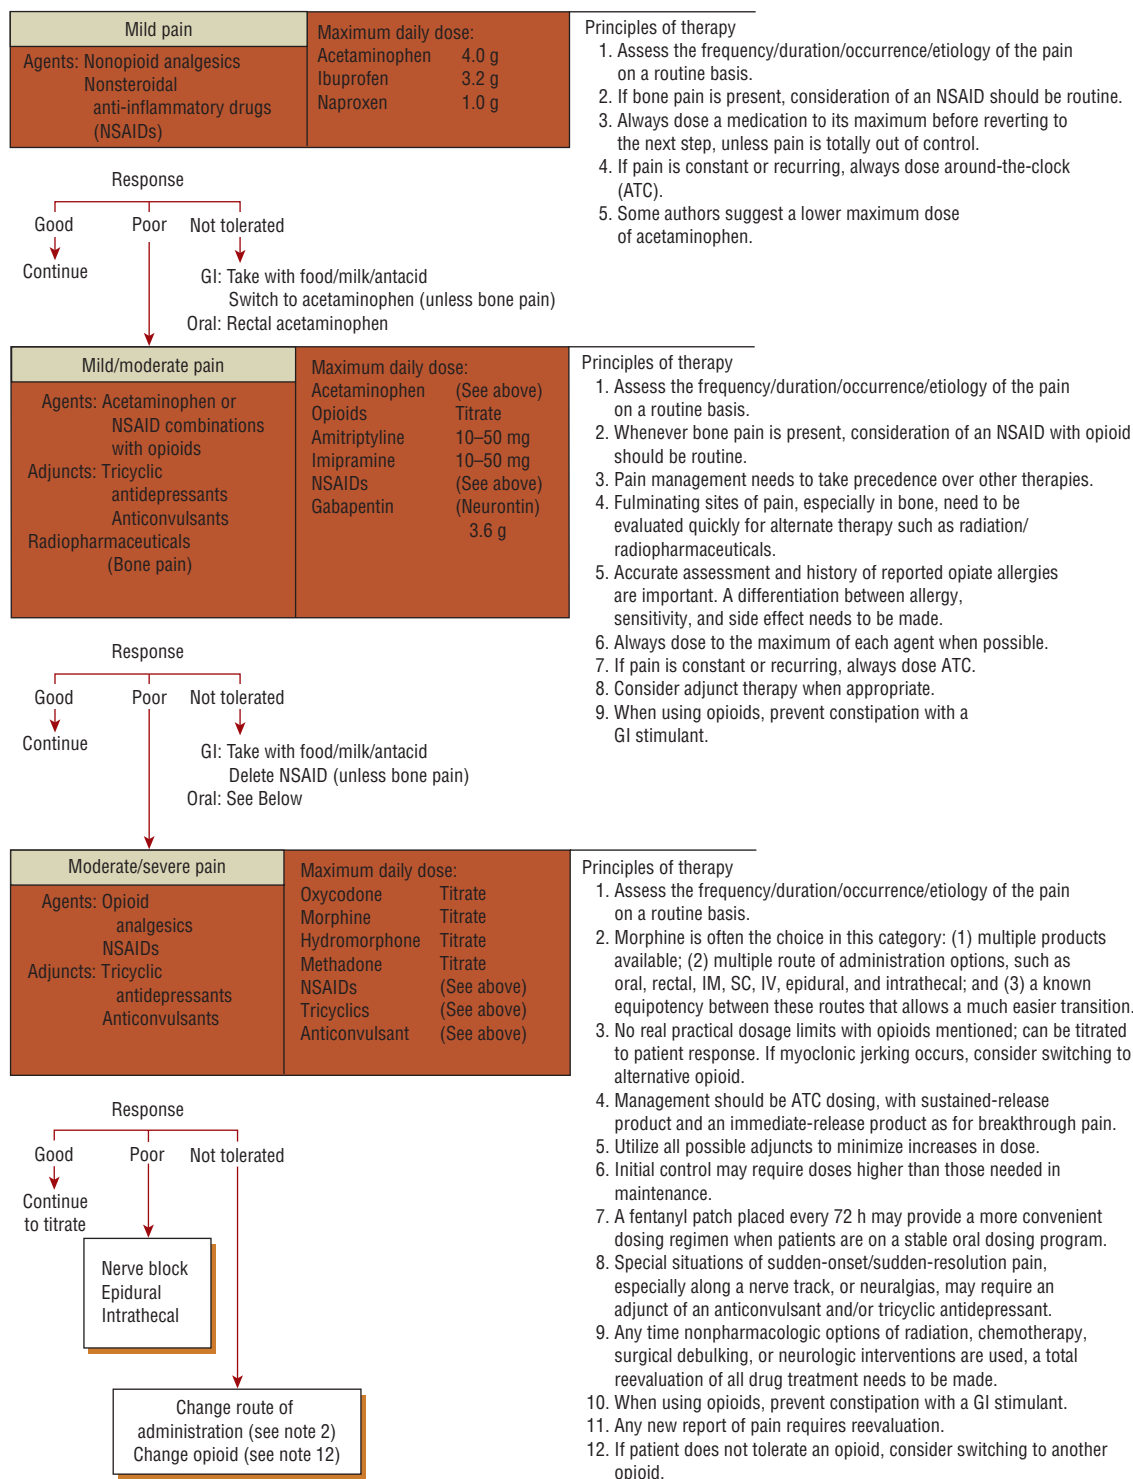

FIGURE 62-3. Algorithm for pain management in oncology patients. (Data modified from the Kaiser Permanente Algorithm for Pain Management in Patients with Advanced Malignant Disease and reference 28.)

Inventory, McGill Pain Questionnaire, or pain drawings may be helpful.⁷

② All opioids can cause constipation. The best management of constipation is prevention. Patients should be counseled on the proper intake of fluids and fiber. A stimulating laxative should be added with chronic opioid use. As noted earlier, CNS depressants (e.g., alcohol, benzodiazepines) amplify CNS depression when used with opioid analgesics, and use of these combinations should be discouraged when possible. When the combinations are used, patients should be monitored closely.

CONCLUSIONS

Poor training of healthcare practitioners in pain assessment and management, improper patient education, and inadequate communication among healthcare professionals are some of the reasons for inadequate pain relief.^{63,64} The use of an integrated approach, incorporating the expertise of many disciplines, may well be the most overlooked principle of pain pharmacotherapy. It is the responsibility of all healthcare professionals who deal with pain to work together to ensure proper management.

DEBORAH S. MINOR AND MARION R. WOFFORD

KEY CONCEPTS

- 1 Acute migraine therapies should provide consistent, rapid relief and enable the patient to resume normal activities at home, school, or work.
- 2 A stratified care approach, in which the selection of initial treatment is based on headache-related disability and symptom severity, is the preferred treatment strategy for the migraineur.
- 3 Strict adherence to maximum daily and weekly doses of anti-migraine medications is essential.
- 4 Preventive therapy should be considered in the setting of recurring migraines that produce significant disability; frequent attacks requiring symptomatic medication more than twice per week; symptomatic therapies that are ineffective, contraindicated, or produce serious side effects; and uncommon migraine variants that cause profound disruption and/or risk of neurologic injury.
- 5 The selection of an agent for migraine prophylaxis should be based on individual patient response, tolerability, convenience of the drug formulation, and comorbid conditions.
- 6 Each prophylactic medication should be given an adequate therapeutic trial (usually 2 to 3 months) to judge its efficacy.
- 7 A general wellness program and avoidance of migraine triggers should be included in the management plan.
- 8 After an effective abortive agent and dose have been identified, subsequent treatments should begin with that same regimen.

Headache is one of the most common complaints encountered by healthcare practitioners, accounting for more than 1% of visits to physicians' offices or emergency departments.¹ As one of the top 10 presenting complaints in ambulatory medical care, headache can be symptomatic of a distinct pathologic process or can occur without an underlying cause.^{1,2} In 2004, the International Headache Society (IHS) updated its classification system and diagnostic criteria for headache disorders, cranial neuralgias, and facial pain³ (Table 63–1). Designed to facilitate headache diagnosis in clinical practice and research, the IHS classification provides more precise definitions and standardized nomenclature for both the primary (tension-type, migraine, and cluster headache) and secondary (symptomatic of organic disease)

headache disorders. This chapter focuses on the management of the primary headache disorders.

Most recurrent headaches are the result of a benign chronic primary headache disorder.¹ Less often, headaches are symptomatic of a serious underlying medical condition, such as infection, cerebral hemorrhage, or brain mass lesion. The peak prevalence of tension-type and migraine headache, the most common of the primary headache disorders, occurs during the most productive years of life (20 to 55 years of age).⁴ Despite the prevalence of these disorders and their associated disability, studies indicate that most migraine and tension-type headache sufferers do not seek medical care for their headaches.^{4,5} An improved understanding of the diagnosis and pathophysiologic mechanisms of the primary headache disorders, particularly migraine, has led to the development of specific medications capable of providing rapid relief from moderate to severe attacks. However, a thorough evaluation of the headache history is essential to establish an accurate headache diagnosis and identify patients who can benefit from these newer therapeutic options.

MIGRAINE HEADACHE

EPIDEMIOLOGY

Results of the American Migraine Study II indicate that 18.2% of women and 6.5% of men in the United States experience one or more migraine headaches per year.⁶ The prevalence of migraine varies considerably by age and gender. Before the age of 12 years, migraine is more common in boys than in girls, but prevalence increases more rapidly in girls after puberty.⁴ After age 12, females are two to three times more likely than males to suffer from migraine. Gender differences in migraine prevalence have been linked to menstruation, but these differences persist beyond menopause. Prevalence is highest in both men and women between the ages of 25 and 45 years.⁷ The usual age of onset is 12 to 17 years of age for females and 5 to 11 years for males, with the incidence of migraine with aura peaking earlier in this range for both.⁷ In the American Migraine Study II, 92% of women and 89% of men with migraine reported some headache-related disability, and 53% were severely disabled or needed bed rest during an attack.⁶ A number of neurologic and psychiatric disorders, including stroke, epilepsy, major depression, and anxiety disorder, show increased comorbidity with migraine.⁴ Whether this relationship is causal or representative of a common pathophysiologic mechanism is unknown. The economic burden of migraine is substantial; however, the direct medical costs associated with migraine treatment are far exceeded by the indirect costs that result from work-related disability.⁷

ETIOLOGY AND PATHOPHYSIOLOGY

The etiologic and pathophysiologic mechanisms of migraine are not completely understood. According to the vascular hypothesis

TABLE 63-1 International Headache Society Classification System: Focus on Migraine Headache

Migraine
Migraine without aura
Migraine with aura
Typical aura with migraine headache (aura lasting less than 1 hour)
Typical aura with nonmigraine headache
Typical aura without headache
Familial hemiplegic migraine
Sporadic hemiplegic migraine
Basilar-type migraine
Childhood periodic syndromes that are commonly precursors of migraine
Cyclical vomiting (self-limiting episodic condition)
Abdominal migraine (episodic midline abdominal pain attacks lasting 1 to 72 hours)
Benign paroxysmal vertigo of childhood (brief episodic vertigo)
Retinal migraine (repeated attacks of monocular visual disturbance)
Complications of migraine
Chronic migraine (occurring on 15 or more days per month for more than 3 months)
Status migrainous (debilitating attack lasting for more than 72 hours)
Persistent aura without infarction (symptoms persisting for more than 1 week)
Migrainous infarction (aura symptoms associated with an ischemic brain lesion)
Migraine-triggered seizure
Probable migraine
Probable migraine without aura
Probable migraine with aura
Probable chronic migraine
Tension-type headache
Cluster headache and other trigeminal autonomic cephalalgias
Other primary headaches
Headache attributed to head and/or neck trauma
Headache attributed to cranial or cervical vascular disorder
Headache attributed to non-vascular intracranial disorder
Headache attributed to a substance or its withdrawal
Headache attributed to infection
Headache attributed to disorder of homeostasis
Headache or facial pain attributed to disorder of cranium, neck, eyes, ears, nose, sinuses, teeth, mouth, or other facial or cranial structures
Headache attributed to psychiatric disorder
Cranial neuralgias and central causes of facial pain
Other headache, cranial neuralgia, central or primary facial pain

Adapted with permission from Headache Classification Committee of the International Headache Society. The international classification of headache disorders, 2nd ed. Cephalalgia 2004;24(Suppl 1):1-151.

proposed by Harold Wolff in 1938, the migraine aura is caused by intracerebral arterial vasoconstriction that is followed by reactive extracranial vasodilation and associated headache.⁴ Although studies of regional blood flow in the brain do not support the vascular hypothesis, the aura phase of migraine is associated with a reduction in cerebral blood flow that begins in the occipital region and moves across the cerebral cortex at a rate of 2 to 3 mm/min.⁸ However, most clinicians now believe that the positive and negative symptoms of the migraine aura are caused by neuronal dysfunction, not ischemia. The neurologic changes of the aura parallel those that occur during cortical spreading depression, a neuronal event characterized by a wave of depressed electrical activity that advances across the brain cortex at a rate that is consistent with the spread of aura symptoms.⁸ Migraine without aura is a neurobiologic disorder.³ Migraine pain is believed to result from activity within the trigeminovascular system, a network of visceral afferent fibers that arises from the trigeminal ganglia and projects peripherally to innervate the pain-sensitive intracranial extracerebral blood vessels, dura mater, and large venous sinuses⁹ (Fig. 63-1). These fibers also project centrally, terminating in the trigeminal nucleus caudalis in the brainstem and upper cervical spinal cord, and thus

provide a pathway for nociceptive transmission from meningeal blood vessels into higher centers of the central nervous system (CNS). Activation of trigeminal sensory nerves triggers the release of vasoactive neuropeptides, including calcitonin gene-related peptide (CGRP), neurokinin A, and substance P, from perivascular axons. The released neuropeptides interact with dural blood vessels to promote vasodilation and dural plasma extravasation, resulting in neurogenic inflammation.⁸ Orthodromic conduction along trigeminovascular fibers transmits pain impulses to the trigeminal nucleus caudalis, where the information is relayed further to higher cortical pain centers. Continued afferent input can result in sensitization of these central sensory neurons, producing a hyperalgesic state that responds to previously innocuous stimuli and maintains the headache.⁸

Despite recent advances in understanding of the pathophysiology of headache pain, there is still a considerable lack of knowledge regarding the mechanisms involved in the initiation of a migraine attack. Although the exact pathophysiology of migraine needs further elucidation, new imaging techniques have provided insight into mechanisms. Previous vascular and neural theories of migraine development have merged into a combined theory of neurovascular mechanisms through evidence provided by neuroimaging. Activity within the trigeminovascular system may be regulated in part by serotonergic neurons within the brainstem. Thus the pathogenesis of migraine may be related to a defect or dysfunction in the activity of neuronal calcium channels mediating serotonin and excitatory neurotransmitter release in brainstem nuclei that modulate cerebral vascular tone and nociception.^{8,9} This dysfunction may result in vasodilation of intracranial extracerebral blood vessels and consequent activation of the trigeminovascular system. Future research might further delineate the role of the brainstem as the “migraine generator.”

Genetic factors seem to play an important role in an individual’s susceptibility to migraine attacks. Studies in monozygotic twins suggest approximately 50% heritability of migraine with a multifactorial polygenic basis.¹⁰ Although it is possible for any individual to experience a migraine attack, it is the recurrence of attacks in the migraineur that is abnormal. Attack occurrence and frequency are governed by the sensitivity of the CNS to migraine-specific triggers or environmental factors. Migraineurs appear to have a lowered threshold of response to specific environmental circumstances as a result of genetic factors that govern the balance of excitation and inhibition at various levels in the CNS.¹⁰ Thus trigger factors can be viewed as modulators of the genetic set point that predisposes to migraine headache. The hyperresponsiveness of the migrainous brain may be the result of an inherited abnormality in P/Q-type calcium channels that regulate cortical excitability through the release of serotonin and other neurotransmitters.⁴ Low levels of magnesium or dopamine, increased levels of excitatory amino acids such as glutamate, and alterations in levels of extracellular potassium also can affect the migraine threshold and initiate and propagate the phenomenon of cortical spreading depression.¹¹

Serotonin (5-hydroxytryptamine [5-HT]) has long been implicated as an important mediator of migraine headache. Specific populations of the seven subfamilies of 5-HT receptors (5-HT₁ to 5-HT₇) appear to be involved in the pathophysiology and treatment of migraine headache.⁸ Acute antimigraine drugs such as the ergot alkaloids and triptan derivatives are agonists of vascular and neuronal 5-HT₁ receptor subtypes, resulting in vasoconstriction of meningeal blood vessels and inhibition of vasoactive neuropeptide release and pain signal transmission.⁸ Drugs used for migraine prophylaxis also modulate neurotransmitter systems. These actions and benefits in migraine management are consistent with the current understanding of migraine pathophysiology and neurovascular disorders.¹²

FIGURE 63-1. The pathophysiology of migraine headache. Vasodilation of intracranial extracerebral blood vessels (possibly the result of an imbalance in the brainstem) results in the activation of the perivascular trigeminal nerves that release vasoactive neuropeptides to promote neurogenic inflammation. Central pain transmission may activate other brainstem nuclei, resulting in associated symptoms (nausea, vomiting, photophobia, phonophobia). The antimigraine effects of the 5-HT_{1B/1D} receptor agonists are highlighted at areas 1, 2, and 3. (CGRP, calcitonin gene-related peptide.) (Adapted with permission from Ferrari MD. *Migraine*. Lancet 1998;351:1043–1051. By The Lancet Ltd.)

CLINICAL PRESENTATION

The migraine attack has been divided into several phases that merit description. *Premonitory symptoms* are experienced by approximately 20% to 60% of migraineurs in the hours or days before the onset of headache.^{3,8} The previously popular terms *prodrome* and *warning symptoms* should be avoided because these are often used mistakenly to include aura.³ Premonitory symptoms vary widely among migraineurs but usually are consistent within an individual. Neurologic symptoms (e.g., phonophobia, photophobia, hyperosmia, and difficulty concentrating) are most common, but psychological (e.g., anxiety, depression, euphoria, irritability, drowsiness, hyperactivity, and restlessness), autonomic (e.g., polyuria, diarrhea, and constipation), and constitutional symptoms (e.g., stiff neck, yawning, thirst, food cravings, and anorexia) also are reported.^{4,13}

CLINICAL PRESENTATION OF MIGRAINE HEADACHE

General

- Migraine is a common, recurrent, severe headache that interferes with normal functioning. It is a primary headache disorder divided into two major subtypes, migraine without aura and migraine with aura.

Symptoms

- Migraine is characterized by recurring episodes of throbbing head pain, frequently unilateral, that when untreated can last from 4 to 72 hours. Migraine headaches can be severe and associated with nausea, vomiting, and sensitivity to light, sound, and/or movement. Not all symptoms are present at every attack.
- In the headache evaluation, diagnostic alarms should be identified. These include: acute onset of the “first” or “worst” headache ever, accelerating pattern of headache following subacute onset, onset of headache after age 50 years, headache associated with systemic illness (e.g., fever, nausea, vomiting, stiff neck, and rash), headache with focal neurologic symptoms or papille-

dema, and new-onset headache in a patient with cancer or human immunodeficiency virus (HIV) infection.

Signs

- A stable pattern, absence of daily headache, positive family history for migraine, normal neurologic examination, presence of food triggers, menstrual association, long-standing history, improvement with sleep, and subacute evolution are all signs of migraine headache. Aura can signal the migraine headache but is not required for diagnosis.

Laboratory Tests

- In selected circumstances and secondary headache presentation, serum chemistries, urine toxicology profiles, thyroid function tests, Lyme studies, and other blood tests such as a complete blood count, antinuclear antibody titer, erythrocyte sedimentation rate, and antiphospholipid antibody titer can be considered.

Diagnostic Tests

- Perform a general medical and neurologic physical examination. Check for abnormalities: vital signs (fever, hypertension), funduscopy (papilledema, hemorrhage, and exudates), palpation and auscultation of the head and neck (sinus tenderness, hardened or tender temporal arteries, trigger points, temporomandibular joint tenderness, bruits, nuchal rigidity, and cervical spine tenderness), and neurologic examination (identify abnormalities or deficits in mental status, cranial nerves, deep tendon reflexes, motor strength, coordination, gait, and cerebellar function). Consider neuroimaging studies in patients with abnormal neurologic examination findings of unknown etiology and in those with additional risk factors warranting imaging.

The migraine *aura*, a complex of positive and negative focal neurologic symptoms that precedes or accompanies an attack, is experienced by approximately 31% of migraineurs on some occa-

sions.¹⁴ The aura typically evolves over 5 to 20 minutes and lasts less than 60 minutes. Headache usually occurs within 60 minutes of the end of the aura. Occasionally, aura symptoms begin at the onset of headache or during the attack. The aura is most often visual and frequently affects half the visual field.^{3,4} Visual auras vary in their complexity and can include both positive (scintillations, photopsia, teichopsia, or fortification spectrum) and negative (scotoma, hemianopsia) features. Sensory and motor aura symptoms, such as paresthesias or numbness involving the arms and face, dysphasia or aphasia, weakness, and hemiparesis, also are reported.

Of those with migraine in the United States, 25% experience four or more severe attacks per month, 48% experience one to four severe attacks per month, and 38% experience one or fewer severe attacks per month.⁶ Migraine *headache* can occur at any time of the day or night but occurs most often in the early morning hours on awakening. Pain is usually gradual in onset, peaking in intensity over a period of minutes to hours and lasting between 4 and 72 hours in adults. Pain can occur anywhere in the face or head but most often involves the frontotemporal region. The headache is typically unilateral and throbbing or pulsating in nature; however, pain can be bilateral at onset or become generalized during the course of an attack.^{3,15} Gastrointestinal symptoms almost invariably accompany a migraine headache. During an attack, as many as 90% of migraineurs experience nausea, and emesis occurs in approximately one-third of patients.⁸ Other systemic symptoms associated with the headache phase include anorexia, food cravings, constipation, diarrhea, abdominal cramps, nasal stuffiness, blurred vision, diaphoresis, facial pallor, and localized facial, scalp, or periorbital edema. Sensory hyperacuity, manifested as photophobia, phonophobia, or osmophobia, is reported frequently. Because headache pain usually is aggravated by physical activity, most migraineurs seek a dark, quiet room for rest and relief. Impaired concentration, depression, irritability, fatigue, or anxiety often accompany the headache. Once headache pain wanes, patients may experience a *resolution phase* characterized by feeling tired, exhausted, irritable, or listless. Impaired concentration may continue, as well as scalp tenderness or mood changes. Some patients experience depression and malaise, whereas others can feel unusually refreshed or euphoric.⁸ The reader is referred to the IHS classification and recent reviews for descriptions of the classic migraine variants and other migraine subtypes^{3,4,8,16} (see also Table 63–1).

Although headaches have many potential causes, most are considered to be primary headache disorders. A comprehensive headache history is the most important element in establishing the clinical diagnosis of migraine.¹⁵ A thorough headache history always should be obtained, and information collected should include age at onset, attack frequency and timing, duration of attacks, precipitating or aggravating factors, ameliorating factors, description of neurologic symptoms, characteristics of the headache pain (quality, intensity, location, and radiation), associated signs and symptoms, treatment history, family and social history, and the impact of headaches on daily life.

Secondary headache can be identified or excluded based on the headache history, as well as the results of general medical and neurologic examinations. Diagnostic and laboratory testing also can be warranted in the setting of suspicious headache features or an abnormal examination. The routine use of neuroimaging (computed tomography or magnetic resonance imaging) generally is not indicated in patients with migraine and a normal neurologic examination, but it should be considered in patients with an unexplained abnormal neurologic examination or an atypical headache history.¹⁷ Because migraine headaches usually begin by the second or third decade of life, headaches beginning after age 50 years suggest an organic etiology such as a mass lesion, cerebrovascular disease, or temporal arteritis. Table 63–2 lists the IHS diagnostic criteria for migraine with and without aura.³

TABLE 63-2 IHS Diagnostic Criteria for Migraine

Migraine without aura
At least five attacks
Headache attack lasts 4 to 72 hours (untreated or unsuccessfully treated)
Headache has at least two of the following characteristics:
• Unilateral location
• Pulsating quality
• Moderate or severe intensity
Aggravation by or avoidance of routine physical activity (i.e., walking or climbing stairs)
During headache at least one of the following:
• Nausea, vomiting, or both
• Photophobia and phonophobia
• Not attributed to another disorder
Migraine with aura (classic migraine)
At least two attacks
Migraine aura fulfills criteria for typical aura, hemiplegic aura, or basilar-type aura
Not attributed to another disorder
Typical aura
Fully reversible visual, sensory, or speech symptoms (or any combination) but no motor weakness
Homonymous or bilateral visual symptoms including positive features (e.g., flickering lights, spot, lines) or negative features (e.g., loss of vision) or unilateral sensory symptoms including positive features (e.g., visual loss, pins and needles) or negative features (i.e., numbness), or any combination
At least one of the following:
• At least one symptom that develops gradually over a minimum of 5 minutes or different symptoms that occur in succession or both
• Each symptom lasts for at least 5 minutes and for no longer than 60 minutes
• Headache that meets criteria for migraine without aura begins during the aura or follows aura within 60 minutes

TREATMENT

Migraines

■ DESIRED OUTCOME

Clinicians who care for migraineurs must appreciate the impact of this painful and debilitating disorder on the life of the patient, the patient’s family, and the patient’s employer. Treatment strategies must address both immediate and long-term goals. 1 Acute migraine therapies should provide consistent, rapid relief and enable the patient to resume normal activities at home, school, or work. Recurrence of symptoms and treatment-related adverse effects should be minimal. Ideally, patients should be able to manage their own headaches effectively without a visit to a physician’s office or emergency room. In addition, migraineurs should take an active role in the creation of a long-term formal management plan. An individualized approach to treatment can result in a reduction in attack frequency and severity, thus minimizing headache-related disability and emotional distress and improving the patient’s quality of life. Goals of long-term and acute treatment of migraine are listed in Table 63–3.

■ GENERAL APPROACH TO TREATMENT

Nonpharmacologic and pharmacologic interventions are available for the management of migraine headache; however, drug therapy remains the mainstay of treatment for most patients. Pharmacotherapeutic management of migraine can be acute (e.g., symptomatic or abortive) or preventive (e.g., prophylactic). When choosing acute or

TABLE 63-3 Goals of Therapy in Migraine Management**Goals of long-term migraine treatment**

- Reduce migraine frequency, severity, and disability
- Reduce reliance on poorly tolerated, ineffective, or unwanted acute pharmacotherapies
- Improve quality of life
- Prevent headache
- Avoid escalation of headache medication use
- Educate and enable patients to manage their disease
- Reduce headache-related distress and psychological symptoms

Goals for acute migraine treatment

- Treat migraine attacks rapidly and consistently without recurrence
- Restore the patient's ability to function
- Minimize the use of backup and rescue medications^a
- Optimize self-care for overall management
- Be cost-effective in overall management
- Cause minimal or no adverse effects

^aRescue medications are defined as medications used at home when other treatments fail that permit the patient to get relief without a visit to the physician's office or emergency department.

Data from Silberstein¹⁷ and Aukerman et al.³²

preventive therapies, the clinician should consider the patient's response to specific medications and their tolerability, as well as coexisting illnesses that can limit treatment choices. Abortive or acute therapies can be migraine-specific (e.g., ergots and triptans) or nonspecific (e.g., analgesics, antiemetics, nonsteroidal antiinflammatory drugs [NSAIDs], and corticosteroids) and are most effective at relieving pain and associated symptoms when administered at the onset of migraine.^{8,18} (Table 63–4). **2** A stratified care approach in which the selection of initial treatment is based on headache-related disability and symptom severity is the preferred treatment strategy for the migraineur.^{17,19} Because attack severity varies in individuals, patients may be advised to use nonspecific agents for mild to moderate headache while reserving migraine-specific medications for more severe attacks. The absorption and efficacy of orally administered drugs can be compromised by the gastric stasis or nausea and vomiting that often accompany migraine.¹⁴ Pretreatment with antiemetic agents or the use of nonoral treatment (e.g., suppositories, nasal sprays, or injections) is advisable when nausea and vomiting are severe.⁸

The frequent or excessive use of acute migraine medications can result in a pattern of increasing headache frequency and drug consumption known as *medication-overuse headache* (or *rebound headache*).^{3,19} The syndrome appears to evolve as a self-sustaining headache-medication cycle in which the headache returns as the medication effect wears off, leading to the consumption of more drug for relief. The headache history often reflects the gradual onset of an atypical daily or near-daily headache with superimposed episodic migraine attacks. Medication overuse is one of the most common causes of chronic daily headache.⁴ Agents most commonly implicated in this syndrome include simple and combination analgesics, opiates, ergotamine tartrate, and triptans.^{3,17} Discontinuation of the offending agent leads to a gradual decrease in headache frequency and severity and a return of the original headache characteristics. Although detoxification usually can be accomplished on an outpatient basis, hospitalization can be necessary for the control of refractory rebound headache and other withdrawal symptoms (e.g., nausea, vomiting, asthenia, restlessness, and agitation). **3** Regulation of nociceptive systems and renewed responsiveness to therapy may not occur for 3 to 8 weeks following medication withdrawal.^{3,4} Most experts recommend limiting use of acute migraine therapies to 2 or 3 days per week to avoid the development of medication-misuse headache.^{8,17}

Preventive migraine therapies are administered on a daily basis to reduce the frequency, severity, and duration of attacks and

improve responsiveness to symptomatic migraine therapies^{17,20} (Table 63–5). **4** Preventive therapy should be considered in the setting of recurring migraines that produce significant disability despite acute therapy; frequent attacks requiring symptomatic medication more than twice per week with the risk of developing rebound headache; symptomatic therapies that are ineffective, contraindicated, or produce serious side effects; uncommon migraine variants that cause profound disruption and/or risk of permanent neurologic injury (e.g., hemiplegic migraine, basilar migraine, and migraine with prolonged aura); and patient preference to limit the number of attacks.^{17,21} Preventive therapy also may be administered preemptively or intermittently when headaches recur in a predictable pattern (e.g., exercise-induced migraine or menstrual migraine). The efficacy of the various agents used for migraine prophylaxis appears to be similar, but the quality of published data is limited for many commonly used drugs. Only propranolol, timolol, valproate, and topiramate are currently approved by the Food and Drug Administration (FDA) for the indication.^{22,23} **5** Thus the selection of an agent typically is based on its side-effect profile and the patient's comorbid conditions.²¹ **6** A therapeutic trial of 2 to 3 months is necessary to judge the efficacy of each medication, but some reduction in attack frequency can be evident by the first month of therapy.^{17,21} Drug therapy should be initiated with low doses and advanced slowly until a therapeutic effect is achieved or side effects become intolerable. Drug doses for migraine prophylaxis are often lower than those necessary for other indications.⁴ Overuse of acute headache medications will interfere with the therapeutic effects of preventive treatment.²¹ Prophylactic treatment usually is continued for at least 3 to 6 months after the frequency and severity of headaches have diminished and then is tapered gradually and discontinued. Many migraineurs experience fewer and less severe attacks for lengthy periods following discontinuation of prophylactic medications or taper to a lower dose.²¹ Figures 63–2 and 63–3 identify treatment and management algorithms for migraine headache.

■ NONPHARMACOLOGIC THERAPY

Nonpharmacologic therapy of acute migraine headache is limited but can include application of ice to the head and periods of rest or sleep, usually in a dark, quiet environment. Preventive management of migraine should begin with the identification and avoidance of factors that consistently provoke migraine attacks in susceptible individuals^{3,24,25} (Table 63–6). Changes in estrogen levels associated with menarche, menstruation, pregnancy, menopause, oral contraceptive use, and other hormone therapies can trigger, intensify, or alleviate migraine.²⁶ A headache diary that records the frequency, severity, and duration of attacks can facilitate identification of migraine triggers. **7** Patients also can benefit from adherence to a wellness program that includes regular sleep, exercise, and eating habits, smoking cessation, and limited caffeine intake. Behavioral interventions, such as relaxation therapy, biofeedback (often used in combination with relaxation therapy), and cognitive therapy, are preventive treatment options for patients who prefer nondrug therapy or when symptomatic therapies are poorly tolerated, contraindicated, or ineffective.¹⁷

CLINICAL CONTROVERSY

Patients are advised to avoid foods and even medications that are identified as migraine triggers. Despite these recommendations, convincing evidence is lacking for many commonly mentioned dietary triggers.²⁵ Keeping a headache diary can help patients identify risk factors and personal triggers.

TABLE 63-4 Acute Migraine Therapies^a

Medication	Dosage	Comments
Analgesics		
Acetaminophen	1,000 mg at onset; repeat every 4–6 hours as needed	Maximum daily dose is 4 g
Acetaminophen 250 mg/aspirin 250 mg/caffeine 65 mg	2 tablets at onset and every 6 hours	Available over-the-counter as Excedrin Migraine
Aspirin or acetaminophen with butalbital, caffeine	1–2 tablets every 4–6 hours	Limit dose to 4 tablets/day and usage to 2 days/week
Isometheptene 65 mg/dichloralphenazone 100 mg/acetaminophen 325 mg (Midrin)	2 capsules at onset; repeat 1 capsule every hour as needed	Maximum of 6 capsules/day and 20 capsules/month
Nonsteroidal antiinflammatory drugs		
Aspirin	500–1000 mg every 4–6 hours	Maximum daily dose is 4 g
Ibuprofen	200–800 mg every 6 hours	Avoid doses >2.4 g/day
Naproxen sodium	550–825 mg at onset; can repeat 220 mg in 3–4 hours	Avoid doses >1.375 g/day
Diclofenac potassium	50–100 mg at onset; can repeat 50 mg in 8 hours	Avoid doses >150 mg/day
Ergotamine tartrate		
Oral tablet (1 mg) with caffeine 100 mg	2 mg at onset; then 1–2 mg every 30 minutes as needed	Maximum dose is 6 mg/day or 10 mg/week; consider pretreatment with an antiemetic
Sublingual tablet (2 mg)		
Rectal suppository (2 mg) with caffeine 100 mg	Insert ½ to 1 suppository at onset; repeat after 1 hour as needed	Maximum dose is 4 mg/day or 10 mg/week; consider pretreatment with an antiemetic
Dihydroergotamine		
Injection 1 mg/mL	0.25–1 mg at onset IM or subcutaneous; repeat every hour as needed	Maximum dose is 3 mg/day or 6 mg/week
Nasal spray	One spray (0.5 mg) in each nostril at onset; repeat sequence 15 minutes later (total dose is 2 mg or 4 sprays)	Maximum dose is 3 mg/day; prime sprayer 4 times before using; do not tilt head back or inhale through nose while spraying; discard open ampules after 8 hours
Serotonin agonists (triptans)		
Sumatriptan		
Injection	6 mg subcutaneous at onset; can repeat after 1 hour if needed	Maximum daily dose is 12 mg
Oral tablets	25, 50, or 100 mg at onset; can repeat after 2 hours if needed	Optimal dose is 50–100 mg; maximum daily dose is 200 mg
Nasal spray	5, 10, or 20 mg at onset; can repeat after 2 hours if needed	Optimal dose is 20 mg; maximum daily dose is 40 mg; single-dose device delivering 5 or 20 mg; administer one spray in one nostril
Zolmitriptan		
Oral tablets	2.5 or 5 mg at onset as regular or orally disintegrating tablet; can repeat after 2 hours if needed	Optimal dose is 2.5 mg; maximum dose is 10 mg/day
Nasal spray	5 mg (one spray) at onset; can repeat after 2 hours if needed	Do not divide ODT dosage form
Naratriptan	1 or 2.5 mg at onset; can repeat after 4 hours if needed	Maximum daily dose is 10 mg/day
Rizatriptan	5 or 10 mg at onset as regular or orally disintegrating tablet; can repeat after 2 hours if needed	Optimal dose is 2.5 mg; maximum daily dose is 5 mg
Almotriptan	6.25 or 12.5 mg at onset; can repeat after 2 hours if needed	Optimal dose is 10 mg; maximum daily dose is 30 mg; onset of effect is similar with standard and orally disintegrating tablets; use 5-mg dose (15 mg/day max) in patients receiving propranolol
Frovatriptan	2.5 or 5 mg at onset; can repeat in 2 hours if needed	Optimal dose is 12.5 mg; maximum daily dose is 25 mg
Eletriptan	20 or 40 mg at onset; can repeat after 2 hours if needed	Optimal dose 2.5–5 mg; maximum daily dose is 7.5 mg (3 tablets)
Miscellaneous		
Butorphanol nasal spray	1 spray in 1 nostril (1 mg) at onset; repeat in 1 hour if needed	Maximum single dose is 40 mg; maximum daily dose is 80 mg
Metoclopramide	10 mg IV at onset	Limit to 4 sprays/day; consider use only when nonopioid therapies are ineffective or not tolerated
Prochlorperazine	10 mg IV or IM at onset	Useful for acute relief in the office or emergency department setting

ODT, orally disintegrating tablet.

^aLimit use of symptomatic medications to 2 or 3 days/week when possible to avoid medication-misuse headache.

Data from Ferrari,⁹ Silberstein et al.,¹⁸ Matchar et al.,²⁶ Aukerman et al.,³² and Tfelt et al.³⁵

■ PHARMACOLOGIC MANAGEMENT OF ACUTE MIGRAINE

CLINICAL CONTROVERSY

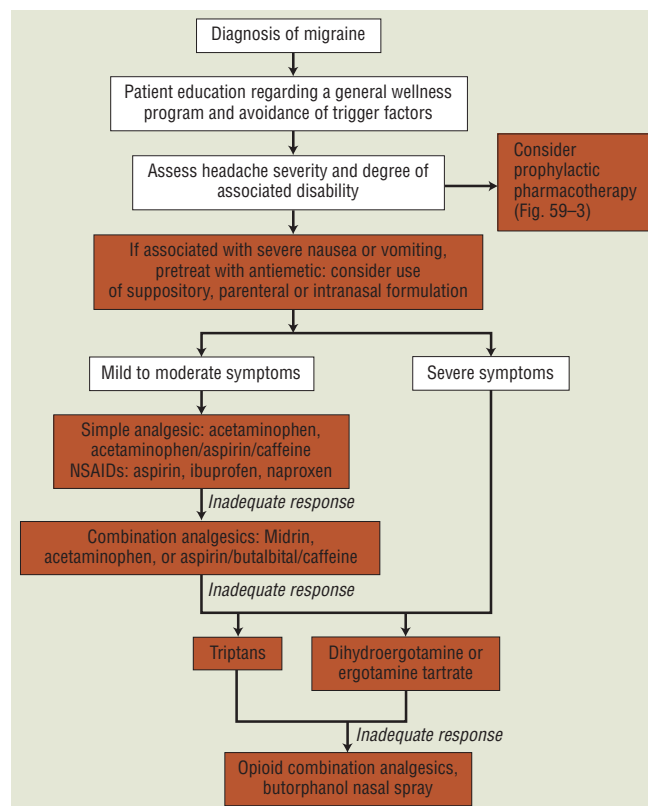

The availability of many over-the-counter drugs that were formerly prescription medications enables some migraine patients to self-medicate and delay entry into appropriate

medical management. Some clinicians feel that over-the-counter products invite patients to take a less effective step-care approach and avoid being treated according to evidence-based guidelines.²⁷

Although controversial, some clinicians argue that the efficacy and tolerability of over-the-counter medications for migraine relief are limited because of patient dissatisfaction with the route of administration, the onset of action, the completeness of pain relief, and the length of suffering and prolonged disability.²⁷

TABLE 63-5 Prophylactic Migraine Therapies

Medication	Dose
β-Adrenergic antagonists	
Atenolol	25–100 mg/day
Metoprolol ^a	50–300 mg/day in divided doses
Nadolol	80–240 mg/day
Propranolol ^{a,b}	80–240 mg/day in divided doses
Timolol ^b	20–60 mg/day in divided doses
Antidepressants	
Amisriptyline	25–150 mg at bedtime
Doxepin	10–200 mg at bedtime
Imipramine	10–200 mg at bedtime
Nortriptyline	10–150 mg at bedtime
Protriptyline	5–30 mg at bedtime
Fluoxetine	10–80 mg/day
Phenelzine ^c	15–60 mg/day in divided doses
Gapapentin	900–2,400 mg/day in divided doses
Topiramate ^b	100 mg/day in divided doses
Valproic acid/divalproex sodium ^b	500–1,500 mg/day in divided doses
Verapamil ^a	240–360 mg/day in divided doses
Methysergide ^{b,c}	2–8 mg/day in divided doses with food
Nonsteroidal antiinflammatory drugs^c	
Aspirin	1,300 mg/day in divided doses
Ketoprofen ^a	150 mg/day in divided doses
Naproxen sodium ^a	550–1,100 mg/day in divided doses
Vitamin B ₂	400 mg/day

^aSustained-release formulation available.^bFDA approved for prevention of migraine.^cDaily or prolonged use limited by potential toxicity.Compiled from Silberstein,^{8,17} Silberstein et al.,¹⁸ and Rapoport and Bigal.²²**FIGURE 63-2.** Treatment algorithm for migraine headaches.

Analgesics and NSAIDs

Simple analgesics and NSAIDs are effective medications for the management of many migraine attacks^{6,19,28} (see Table 63–4). They offer a reasonable first-line choice for treatment of mild to moderate migraine attacks or severe attacks that have been responsive in the past to similar NSAIDs or nonopiate analgesics.¹⁷ Of the NSAIDs, aspirin, ibuprofen, naproxen sodium, tolafenamic acid, and the combination of acetaminophen plus aspirin and caffeine have demonstrated the most consistent evidence of efficacy.²⁴ Evidence for other NSAIDs is either limited (only one study) or inconsistent (some positive and some negative studies).²⁸ Acetaminophen alone is not generally recommended for migraine because the scientific support is not optimal.^{8,17,28} Comparisons with other pharmacotherapeutic classes are limited.

NSAIDs appear to prevent neurogenically mediated inflammation in the trigeminovascular system through the inhibition of

prostaglandin synthesis. In general, NSAIDs with a long half-life are preferred as less frequent dosing is needed.²⁹ Metoclopramide can speed the absorption of analgesics and alleviate migraine-related nausea and vomiting.²⁵ Suppository analgesic preparations and intramuscular ketorolac are also options when nausea and vomiting are severe.¹⁸ Acute NSAID therapy is associated with gastrointestinal (e.g., dyspepsia, nausea, vomiting, and diarrhea) and CNS side effects (e.g., somnolence, dizziness). NSAIDs should be used cautiously in patients with previous ulcer disease, renal disease, or hypersensitivity to aspirin.²⁸

The over-the-counter combination of acetaminophen, aspirin, and caffeine was approved for the treatment of migraine in the United States because of its proven efficacy in relieving migraine pain and associated symptoms.²⁸ Aspirin and acetaminophen are also available in prescription combination products containing a short-acting barbiturate (butalbital) or narcotic (codeine, propoxyphene). No random-

Data from Snow et al.,²⁴ and Diamond and Cady.²⁵

ized, placebo-controlled studies support the efficacy of butalbital-containing products in the treatment of migraine. The use of butalbital-containing analgesics or narcotics should be limited because of concerns about overuse, medication-overuse headache, and withdrawal.^{8,17,28} Midrin, a combination of acetaminophen, isometheptene mucate (a sympathomimetic amine), and dichloralphenazone (a chloral hydrate derivative), has demonstrated modest benefits in placebo-controlled studies and generally is viewed as an alternative for patients with mild to moderate migraine attacks.^{17,28} Although frequent consumption of aspirin or acetaminophen alone can result in medication-overuse headache, combination analgesics appear to pose a greater risk.^{8,17}

Opiate Analgesics

Narcotic analgesic drugs (e.g., meperidine, butorphanol, oxycodone, and hydromorphone) are effective but generally should be reserved for patients with moderate to severe infrequent headaches in whom conventional therapies are contraindicated or as “rescue medication” after patients have failed to respond to conventional therapies.⁸ Frequent use of narcotic analgesics can lead to the development of dependency and rebound headache.²⁸ The intranasal formulation of butorphanol, a synthetically derived opioid agonist-antagonist, is a treatment option and alternative to frequent office or emergency department visits for injectable migraine therapies. Butorphanol is used widely despite the established risk of overuse and dependence. Opioid therapy should be supervised closely.^{17,28}

Antiemetics

Adjunctive antiemetic therapy is useful for combating the nausea and vomiting that accompany migraine headaches and the medications used to treat acute attacks (e.g., ergotamine tartrate). A single dose of an antiemetic, such as metoclopramide, chlorpromazine, or prochlorperazine, administered 15 to 30 minutes before ingestion of oral abortive migraine medications is often sufficient. Suppository preparations are available when nausea and vomiting are particularly prominent. Metoclopramide is also useful to reverse gastroparesis and improve absorption from the gastrointestinal tract during severe attacks.^{17,28}

In addition to antiemetic effects, dopamine antagonist drugs also have been used successfully as monotherapy for the treatment of

intractable headache (see Table 63–4). Prochlorperazine administered by the intravenous and intramuscular routes and intravenous metoclopramide provided more effective pain relief than placebo. Chlorpromazine also has provided relief of migraine headache comparable to that provided by intravenous metoclopramide and dihydroergotamine when administered parenterally at doses of 12.5 to 37.5 mg. Domperidone has a possible role for preemptive treatment of migraine. The precise mechanism of action for these agents is unknown. The dopamine antagonists offer an alternative to the narcotic analgesics for the treatment of refractory migraine. Drowsiness and dizziness were reported occasionally with the use of dopamine antagonists in migraineurs. Extrapyramidal side effects were reported infrequently in migraine trials.²⁸

Miscellaneous Nonspecific Medications

Corticosteroids can be considered as rescue therapy for status migrainous (a severe, continuous migraine that can last up to 1 week).^{17,28} Intravenous dexamethasone at a dose of 6 mg has been tested although there are no high-quality studies supporting the effectiveness of steroids for acute migraine.²⁸

Limited studies suggest a role for intranasal lidocaine in the treatment of acute migraine headache.^{17,28} Intranasal lidocaine, 1 to 4 drops of a 4% solution, provides rapid pain relief within 15 minutes of administration, but headache recurrence is common. Adverse effects generally are limited to local irritation of the nose or eye, an unpleasant taste, and numbness of the throat.

Preliminary investigations of intramuscular droperidol have yielded favorable results in the treatment of acute migraine headache.^{12,30} Future studies might establish a more defined role for this agent in migraine management.

Ergot Alkaloids and Derivatives

Ergotamine tartrate and dihydroergotamine are useful and can be considered for the treatment of moderate to severe migraine attacks.¹⁷ These drugs are nonselective 5-HT₁ receptor agonists that constrict intracranial blood vessels and inhibit the development of neurogenic inflammation in the trigeminovascular system.⁸ Central inhibition of the trigeminovascular pathway is also reported. These agents also display activity at α -adrenergic, β -adrenergic, and dopaminergic receptors. Venous and arterial constriction occur with therapeutic doses, but ergotamine tartrate exerts more potent arterial effects than dihydroergotamine.³¹

Ergotamine tartrate is available for oral, sublingual, and rectal administration (see Table 63–4). Oral and rectal preparations contain caffeine to enhance absorption and potentiate analgesia. Some patients respond preferentially to rectal dosing.⁸ Dosage requirements should be titrated strictly to establish an effective but subnauseating dose for future attacks. Ergotamine is most effective when administered early in the migraine attack.³¹ Despite its widespread clinical use since 1925, evidence supporting the efficacy of ergotamine tartrate in migraine is inconsistent.^{8,28}

Dihydroergotamine is available for intranasal and parenteral administration by the intramuscular, subcutaneous, and intravenous routes^{8,17} (see Table 63–4). Parenteral dihydroergotamine was viewed previously as inpatient or emergency department treatment for moderate to severe migraine, but patients can be trained to self-administer dihydroergotamine intramuscularly or subcutaneously. Clinical opinion suggests its use is relatively safe and effective when compared with other migraine therapies.^{17,28}

Nausea and vomiting (resulting from stimulation of the chemoreceptor trigger zone) are among the most common adverse effects of the ergotamine derivatives. Pretreatment with an antiemetic agent should be considered with ergotamine and intravenous dihydroergotamine therapy. Other common side effects include abdominal pain,

weakness, fatigue, paresthesias, muscle pain, diarrhea, and chest tightness. Occasionally, symptoms of severe peripheral ischemia (ergotism), including cold, numb, painful extremities, continuous paresthesias, diminished peripheral pulses, and claudication, can result from the vasoconstrictor effects of the ergot alkaloids. Gangrenous extremities, myocardial infarction, hepatic necrosis, and bowel and brain ischemia have been reported rarely.^{4,25,32} Dihydroergotamine is rarely associated with such side effects.³² Triptans and ergot derivatives should not be used within 24 hours of each other.³² Recently, reports of severe vasospasm during concomitant therapy with ergotamine and protease inhibitors have appeared in the literature.³³ These cases are attributed to inhibitory effects of the protease inhibitor on the cytochrome P450 3A4 (CYP3A4) isoenzyme and a consequent increase in ergotamine blood levels. Ergotamine derivatives are contraindicated in patients with renal or hepatic failure; coronary, cerebral, or peripheral vascular disease; uncontrolled hypertension; sepsis; and in women who are pregnant or nursing.^{4,32} Dihydroergotamine does not appear to cause rebound headache, but dosage restrictions for ergotamine tartrate should be observed strictly to prevent this complication.⁴

Serotonin Receptor Agonists (Triptans)

Introduction of the serotonin receptor agonists, or triptans, represented a significant advance in migraine pharmacotherapy. The first member of this class, sumatriptan, and the second-generation agents zolmitriptan, naratriptan, rizatriptan, almotriptan, frovatriptan, and eletriptan are selective agonists of the 5-HT_{1B} and 5-HT_{1D} receptors. Relief of migraine headache is the result of three key actions: normalization of dilated intracranial arteries through enhanced vasoconstriction, peripheral neuronal inhibition, and inhibition of transmission through second-order neurons of the trigeminocervical complex.^{9,14,34} These agents also display varying affinity for 5-HT_{1A}, 5-HT_{1E}, and 5-HT_{1F} receptors. The triptans are appropriate first-line therapy for patients with moderate to severe migraine and are used for rescue therapy when nonspecific medications are ineffective.^{17,18}

Sumatriptan, the most extensively studied antimigraine therapy, is available for subcutaneous, oral, and intranasal administration.³⁴ Subcutaneous sumatriptan is consistently superior to placebo in alleviating migraine headache and associated symptoms, with relief reported in 71% of patients at 1 hour (43% pain-free) and 79% at 2 hours (60% pain-free) in a meta-analysis of placebo-controlled studies.^{9,35} In addition to enhanced efficacy, subcutaneous sumatriptan has a more rapid onset of action (10 minutes) when compared with the oral formulation (30 minutes).^{18,35} The subcutaneous injection is packaged as an autoinjector device for self-administration by patients. Intranasal sumatriptan provides a faster onset of effect (15 minutes) than the oral formulation and produces similar rates of response (relief in 61% of patients at 2 hours) in placebo-controlled studies.³⁵ Approximately 30% to 40% of patients who respond to sumatriptan experience headache recurrence within 24 hours.³⁵ This has been attributed to the drug's short half-life, but recurrence is a problem with most acute migraine therapies.^{9,35} A second dose given at the time of recurrence usually is effective.

The second-generation triptans appear to offer an improved pharmacokinetic and pharmacodynamic profile compared with oral sumatriptan.^{34–36} These agents have higher oral bioavailability and longer half-lives than oral sumatriptan, which theoretically could improve within-patient treatment consistency and reduce headache recurrence^{14,29,34–37} (Table 63–7). Despite the fact that oral absorption can be delayed during migraine attacks, most patients prefer oral formulations, and these account for 80% of all triptan prescriptions.³⁸

Results of placebo-controlled studies with each of the second-generation agents reveal somewhat comparable 2-hour response rates. Direct comparative clinical trials are necessary to determine their relative efficacy, but these are available for only a few of the

TABLE 63-7 Pharmacokinetic Characteristics of Triptans

Drug	Half-Life (hours)	Time to Maximal Concentration (t_{max})	Bioavailability (%)	Elimination
Almotriptan	3–4	1.4–3.8 hours	70	MAO-A, CYP3A4, CYP2D6
Eletriptan	5	1.4–2.8 hours	50	CYP3A4
Frovatriptan	25	2–4 hours	24–30	CYP1A2
Naratriptan	5–6	2–3 hours	63–74	CYP450 (various isoenzymes)
Rizatriptan	2–3		40–45	MAO-A
Oral tablets		1–1.5 hours		
Disintegrating		1.6–2.5 hours		
Sumatriptan	2			MAO-A
SC injection		12–15 minutes	97	
Oral tablets		2.5 hours	14	
Nasal spray		1–2.5 hours	17	
Zolmitriptan	3		40	CYP1A2, MAO-A
Oral		1.5 hours		
Disintegrating		3 hours		
Nasal		4 hours

Data from Goadsby et al.,¹⁴ del Rio and Silberstein,²⁹ Matthew and Loder,³⁴ Tfelt-Hansen et al.,³⁵ Deleu and Hanssens,³⁶ and Pringsheim and Gawel.³⁷

triptans. A recent meta-analysis summarizes the efficacy and tolerability of the different oral triptans across both published and unpublished studies.³⁸ At all marketed doses, the oral triptans are effective and well tolerated. Across studies for sumatriptan 100 mg, mean results were a 2-hour headache response of 59%, with 29% pain-free at 2 hours, 20% sustained pain-free, and 67% consistency. Compared with sumatriptan 100 mg, rizatriptan 10 mg showed better efficacy and consistency and similar tolerability; eletriptan 80 mg showed better efficacy, similar consistency, but lower tolerability; almotriptan 12.5 mg showed similar efficacy at 2 hours but better other results; naratriptan 2.5 mg and eletriptan 20 mg showed lower efficacy and better tolerability; and zolmitriptan 2.5 and 5 mg, eletriptan 40 mg, and rizatriptan 5 mg all showed similar results. Available data suggest lower efficacy for frovatriptan, although it has the longest half-life of the triptans.³⁸

Clinical response to the triptans can vary considerably among individual patients. Individual responses cannot be predicted, and if one triptan fails, a patient can be switched successfully to another triptan.^{8,38} 8 After an effective agent and dose have been identified, subsequent treatments should begin with that same regimen.

Side effects to the triptans are common but usually mild to moderate in nature and of short duration. Adverse effects are consistent among the class and include paresthesias, fatigue, dizziness, flushing, warm sensations, and somnolence. Local side effects are reported with the subcutaneous (minor injection-site reactions) and intranasal (taste perversion, nasal discomfort) routes. Doses that provide the best ratio of efficacy and safety are considered optimal. Up to 15% of patients receiving a triptan consistently report “chest symptoms,” including tightness, pressure, heaviness, or pain in the chest, neck, or throat.^{9,18} The mechanism of these symptoms is unknown, but a cardiac source of pain seems unlikely in most patients.^{39,40} However, all triptans are partial agonists of human 5-HT coronary artery receptors in vitro, resulting in a small but significant vasoconstrictor response.^{14,36} Adverse cardiac events are rare because 5-HT_{2A} receptors mediate most of the effects of serotonin on coronary vessels.¹⁸ Isolated cases of myocardial infarction and coronary vasospasm with ischemia have been reported, but myocardial ischemia is unlikely in patients with normal coronary vasculature.³⁶ The triptans are contraindicated in patients with a history of ischemic

heart disease (e.g., angina pectoris, Prinzmetal's angina, or previous myocardial infarction), uncontrolled hypertension, and cerebrovascular disease. Patients at risk for unrecognized coronary artery disease (e.g., postmenopausal women, men older than 40 years of age, and patients with multiple risk factors) should receive a cardiovascular assessment prior to triptan use and have their initial dose administered under medical supervision. Triptans are also contraindicated in patients with hemiplegic and basilar migraine. The triptans should not be given within 24 hours of the ergotamine derivatives. Administration of sumatriptan, rizatriptan, and zolmitriptan within 2 weeks of therapy with monoamine oxidase inhibitors is not recommended. Concomitant therapy with the selective serotonin reuptake inhibitors (SSRIs) or serotonin-norepinephrine reuptake inhibitors (SNRIs) (e.g., duloxetine, venlafaxine, and sibutramine) can be life-threatening as a result of serotonin syndrome. The potential risk of these combinations should be carefully considered and discussed with the patient.⁴¹ Frequent use of the triptans has been associated with the development of medication-misuse headache.^{14,17,28}

■ PROPHYLACTIC PHARMACOLOGIC THERAPY

β -Adrenergic Antagonists

β -Adrenergic antagonists are the most widely used drugs for migraine prophylaxis.²¹ Propranolol, nadolol, timolol, atenolol, and metoprolol have proven efficacy in controlled clinical trials, reducing the frequency of attacks by 50% in 60% to 80% of patients^{21,23} (see Table 63–5). Because the relative efficacy of the individual agents has not been established, selection of a β -blocker can be based on β -selectivity, convenience of the formulation, and tolerability. β -Blockers with intrinsic sympathomimetic activity are ineffective for migraine prophylaxis.²¹ Although their precise mechanism of antimigraine action is unknown, they may raise the migraine threshold by modulating adrenergic or serotonergic neurotransmission in cortical or subcortical pathways. β -Blockers are particularly useful in patients with comorbid anxiety, hypertension, or angina. Side effects can include drowsiness, fatigue, sleep disturbances, vivid dreams, memory disturbance, depression, impotence, bradycardia, and hypotension. β -Blockers should be used with caution in patients with congestive heart failure, peripheral vascular disease, atrioventricular conduction disturbances, asthma, depression, and diabetes. Bronchoconstrictive and hypoglycemic effects can be minimized with β_1 -selective agents.

Antidepressants

The beneficial effects of antidepressants in migraine are independent of their antidepressant activity and may be related to downregulation of central 5-HT₂ and adrenergic receptors.²¹ Amitriptyline, the most widely studied antidepressant for migraine prophylaxis, has demonstrated efficacy in placebo-controlled and comparative studies.²³ Use of other antidepressants is based primarily on clinical and anecdotal experience (see Table 63–5). Other tricyclic antidepressants (TCAs) that have been used successfully for migraine prophylaxis include doxepin, nortriptyline, protriptyline, and imipramine.^{17,21} Anticholinergic side effects are common and limit use of these agents in patients with benign prostatic hyperplasia and glaucoma. Evening doses are preferred because of associated sedation. Increased appetite and weight gain can occur. Orthostatic hypotension and cardiac toxicity (slowed atrioventricular conduction) also are reported occasionally. The more favorable side-effect profile of nortriptyline and protriptyline could prove advantageous in patients who are particularly intolerant of the anticholinergic and sedative side effects of amitriptyline.

SSRIs have not been studied extensively for the preventive treatment of migraine headaches, but clinicians have used them nonetheless.¹⁸ Fluoxetine is the most studied SSRI for migraine prevention, but definitive benefit has not been demonstrated in a rigorous clinical

study.²¹ Prospective data evaluating the other SSRIs (e.g., sertraline, paroxetine, fluvoxamine, and citalopram) are lacking.¹⁷ The SSRIs are considered to be less effective than TCAs for migraine prophylaxis but have gained favor with some clinicians as a result of their more favorable adverse-effect profile.⁴ These agents should not be considered as first- or second-line medications for the management of migraine, but they are useful in patients with comorbid depression.^{4,21} Preliminary evidence suggests a possible benefit with venlafaxine, an inhibitor of serotonin and norepinephrine reuptake.⁴² Again, the potential risk of serotonin syndrome should be considered in patients using SSRIs or SNRIs along with a triptan.⁴¹

Monoamine oxidase inhibitors (MAOIs), such as phenelzine, have been used in the management of refractory headache, but their complex adverse-effect profile limits their use to experienced prescribers.⁴² Strict adherence to a tyramine-free diet is necessary to avoid potentially life-threatening hypertensive crisis. The reader is referred to Chap. 71 for dietary and concurrent medication restrictions for patients taking MAOIs.

Anticonvulsants

Anticonvulsant medications have emerged as an important therapeutic option for the prevention of migraine headaches. The beneficial effects of these agents are likely caused by multiple mechanisms of action, including enhancement of γ -aminobutyric acid (GABA)-mediated inhibition, modulation of the excitatory neurotransmitter glutamate, and inhibition of sodium and calcium ion channel activity.⁴³ Anticonvulsants, such as divalproex sodium and topiramate, are particularly useful in migraineurs with comorbid seizures, anxiety disorder, or bipolar disorder.⁴ The efficacy of valproic acid and divalproex sodium (a 1:1 molar combination of valproate sodium and valproic acid) has been demonstrated in multiple placebo-controlled studies.²¹ Nausea and vomiting, the most common early side effects, are self-limited and appear to be less common with divalproex sodium and gradual titration of doses. Alopecia, tremor, asthenia, somnolence, and weight gain are also common complaints.^{21,44} The extended-release formulation of divalproex sodium is administered once daily and is better tolerated than the enteric-coated formulation.⁴⁴ Hepatotoxicity is the most serious side effect of valproate therapy, but the risk appears to be low in migraineurs (e.g., patients older than 10 years of age who are receiving monotherapy and have no underlying metabolic or neurologic disorder).²¹ Baseline liver function tests should be obtained, but routine followup studies are not necessary in asymptomatic adults on monotherapy. Patient evaluation is recommended every 1 to 2 months during the first 6 to 9 months of therapy. Valproate is contraindicated in pregnant women (owing to potential teratogenicity) and patients with a history of pancreatitis or chronic liver disease. Although valproate level determinations can be useful for assessing compliance and toxicity, a recent study suggests that serum levels of less than 50 mcg/mL (346 μ mol/L) (usual therapeutic level is 50 to 100 mcg/mL) can provide similar benefit to higher levels.⁴⁵

Topiramate has recently been approved for a migraine prophylaxis indication based on the results of a randomized, double-blind study that demonstrated significantly greater reductions in mean monthly migraine frequency with 100 and 200 mg topiramate daily compared with placebo.⁴⁶ Topiramate should be initiated at a low dose, 25 mg, and slowly titrated up to minimize adverse effects. Treatment-emergent adverse events associated with topiramate included paresthesia, fatigue, anorexia, diarrhea, weight loss, difficulty with memory, and nausea. Kidney stones, acute myopia and acute angle-closure glaucoma, and oligohidrosis have been reported infrequently with topiramate use.⁴⁷

A recent study suggests that gabapentin also may be an effective agent for migraine prevention in patients achieving a daily dose of 2400 mg.^{21,48} Somnolence, dizziness, and asthenia were the most

commonly reported adverse events. Preliminary studies suggest a possible role for other anticonvulsants, including tiagabine, levetiracetam, and zonisamide; however, further clinical studies are needed to confirm their usefulness in migraine prophylaxis.^{22,47,49}

Calcium Channel Blockers

The calcium channel blockers generally are considered second- or third-line options for preventive treatment when other drugs with established clinical benefit are ineffective or contraindicated.¹⁸ Verapamil is the most widely used calcium channel blocker for preventive treatment, but it provided only modest benefit in decreasing the frequency of attacks in two placebo-controlled studies.⁴ The therapeutic effect of verapamil may not be noted for up to 8 weeks after initiation of therapy.⁴² Side effects of verapamil can include constipation, hypotension, bradycardia, atrioventricular block, and exacerbation of congestive heart failure. Evaluations of nifedipine, nimodipine, diltiazem, and nicardipine have yielded equivocal results.²¹

Methysergide

The semisynthetic ergot alkaloid methysergide is a potent 5-HT₂ receptor antagonist that appears to stabilize serotonergic neurotransmission in the trigeminovascular system to block the development of neurogenic inflammation.²⁸ Although methysergide is an effective preventive medication, its utility is limited by the rare (1 in 5,000 patients) development of retroperitoneal, endocardial, and pulmonary fibrosis during long-term administration.⁴ Consequently, a medication-free interval of 4 weeks is recommended following each 6-month treatment period.²⁸ The dosage should be tapered over a 1-week period to prevent rebound headaches. Monitoring for fibrotic complications should include periodic auscultation of the heart, as well as yearly chest roentgenography, echocardiography, and abdominal magnetic resonance imaging.²¹ Methysergide is best tolerated when taken with meals. In addition to gastrointestinal intolerance, muscle aching, leg cramps, claudication, weight gain, and hallucinations are also reported with its use. It is contraindicated in pregnancy, peripheral vascular disorders, coronary artery disease, severe hypertension, thrombophlebitis or cellulitis of the legs, peptic ulcer disease, liver or renal dysfunction, and valvular heart disease.⁸ Peripheral vasospasm and severe claudication have been reported occasionally in patients without a prior history of vascular disease. Methysergide is reserved for patients with refractory headaches that do not respond to other preventive therapies.

NSAIDs

NSAIDs are modestly effective for reducing the frequency, severity, and duration of migraine attacks, but potential gastrointestinal and renal toxicity can limit the daily or prolonged use of these agents.^{21,23} Consequently, NSAIDs have been used intermittently to prevent headaches that recur in a predictable pattern, such as menstrual migraine. Administration of NSAIDs in the perimenstrual period can be beneficial in women with true menstrual migraine. NSAIDs should be initiated 1 to 2 days prior to the expected onset of headache and continued during the period of vulnerability.⁴ Prostaglandin production can be enhanced in women with menstrual migraine, and the preventive mechanism of NSAIDs is thought to involve inhibition of prostaglandin synthesis.⁴ If long-term NSAID therapy is initiated, monitoring of renal function and occult blood loss is necessary.

Miscellaneous Prophylactic Agents

A double-blind, placebo-controlled study demonstrated the efficacy of riboflavin (vitamin B₂) 400 mg daily in migraine prophylaxis. Riboflavin was associated with 50% or greater improvement in attack frequency in 59% of patients.⁴⁷ More recently, localized injections of

botulinum toxin type A have reduced the frequency, severity, and disability associated with migraine headaches significantly in three small double-blind, placebo-controlled trials.⁵⁰ The angiotensin-converting enzyme inhibitor lisinopril and the angiotensin II receptor blocker candesartan provided effective migraine prophylaxis in recent double-blind, placebo-controlled, crossover studies of these agents.^{51,52} Further research is needed to establish the safety and efficacy of the herbal medication feverfew (*Tanacetum parthenium*) because studies to date have yielded conflicting results.⁴ Authors of a recent double-blind, placebo-controlled study concluded that petasites, an extract from the plant *Petasites hybridus*, may be an effective preventive treatment for migraine.⁴⁹ Further study is needed to determine the clinical utility and comparative efficacy of these agents for the prophylactic management of migraine.

PHARMACOECONOMIC CONSIDERATIONS

Although migraine is widely recognized as a disease that exacts an enormous toll on the sufferer, the direct and indirect costs associated with migraine headache impose a substantial burden on society as well. The direct medical costs associated with clinic visits for headache and migraine diagnosis and treatment are substantial, exceeding \$1 billion per year.¹⁴ Migraine also results in high use of emergency rooms and urgent care centers.⁷ Headache accounts for one-third of all over-the-counter analgesic use in the United States, and gross sales from triptans alone total more than \$1 billion per year. The indirect costs of the illness related to work absenteeism, decreased productivity, and impairment greatly exceed the direct cost of medical care.^{7,53} The estimated indirect cost of migraine-related disability for American employers, the most important determinant of the economic impact of migraine, is approximately \$13 billion each year.^{7,53}

According to the American Migraine Study II, only 48% of those surveyed with clear symptoms of migraine were diagnosed by a physician.^{5,6} Although 96% of severe migraine sufferers take some medication for their headaches, only 41% of those with moderate to severe headache-related disability take prescription medication.^{5,6} Because many migraineurs who receive inadequate care experience substantial levels of pain and disability, improvement in migraine diagnosis, care, and treatment potentially could result in lower direct and indirect costs of the disease.

Education of headache patients regarding required behavior changes and effective use of acute and prophylactic pharmacotherapy can be time-consuming, but it is also extremely cost-effective. Oversight can lead to decreased efficacy of medications resulting in repeat dosing and polypharmacy, decreased compliance, increased emergency department use, increased “doctor shopping,” and, perhaps, increased use of expensive diagnostic procedures and inpatient services. Recent studies demonstrate that effective migraine treatment can reduce the functional disability and productivity loss associated with a migraine attack.^{5,25,34} Patients with stratified care targeted to their needs had higher headache response rates, shorter disability times, less health service utilization, and less loss of productivity.²⁵

SUMMARY

Acute and preventive pharmacotherapy for migraine should be individualized based on the individual patient response, tolerability of the available agents, and presence of comorbid conditions. Migraine management should be individualized on the basis of the patient's clinical presentation and medical history. Analgesics and NSAIDs can be considered the drugs of choice for infrequent mild to moderate attacks. The triptans or dihydroergotamine can be used as secondary agents if initial therapies prove ineffective or as first-line therapy in moderate to severe migraine headache. Abortive

therapy should be instituted early in the course of the attack to optimize efficacy and minimize migraine-related pain and disability. Preventive therapy should be considered in the setting of recurring migraines that produce significant disability, frequent attacks requiring symptomatic medication more than twice per week, symptomatic therapies that are ineffective, contraindicated, or produce serious side effects, and uncommon migraine variants that cause profound disruption and/or risk of neurologic injury. Efficacy of a prescribed prophylactic regimen should be reassessed periodically. A prolonged headache-free interval could allow for gradual dosage reduction and discontinuation of therapy.

TENSION-TYPE HEADACHE

EPIDEMIOLOGY

Tension-type headache is the most common type of primary headache, with an estimated 1-year prevalence of 63% in men and 86% in women.² First onset of tension-type headache typically is early in life (younger than age 20 in 40% of patients), and prevalence peaks between the ages of 20 and 50 years.^{2,4} It is more common among women in adulthood, with a female-to-male ratio of 5:4.² The mean frequency of attacks is 2.9 days per month, with most sufferers experiencing fewer than one attack per month.⁴ The prevalence of chronic tension-type headache (defined as greater than or equal to 180 headache days per year) is estimated at 2% to 3%.⁴ Although an estimated 60% of tension-type headache sufferers experience some degree of functional impairment during their attacks, less than 15% of patients seek medical attention for their headaches.^{4,2}

PATHOPHYSIOLOGY

Although tension-type headache is the most common type of headache, it is the least studied of the primary headache disorders, and there is limited understanding of key pathophysiologic concepts.⁵⁴ Some practitioners theorize that migraine and tension-type headaches represent a continuum of headache severity within the same entity.⁵⁵ However, more recently, tension-type headache has been recognized as a distinct disorder. The pain of episodic tension-type headache is thought to originate from myofascial factors and peripheral sensitization of nociceptors. Central mechanisms also are involved.⁵⁴ Mental stress, nonphysiologic motor stress, a local myofascial release of irritants or a combination of these may be the initiating stimulus. Following activation of supraspinal pain perception structures, a self-limiting headache results in most individuals owing to central modulation of the incoming peripheral stimuli.⁵⁴ Chronic tension-type headache can evolve from episodic tension-type headache in predisposed individuals owing to a disturbance of central nociceptive processing and subsequent sensitization of the CNS.⁵⁴ It is likely that other pathophysiologic mechanisms also contribute to the development of tension-type headache.

CLINICAL PRESENTATION

Premonitory symptoms and aura are absent with tension-type headache. The pain usually is mild to moderate in intensity and often is described as a dull, nonpulsatile tightness or pressure.^{3,4} Bilateral pain is most common, but the location can vary (frontal and temporal pain are most common; occipital and parietal regions also may be affected).³ The pain is classically described as having a “hatband” pattern. Associated symptoms generally are absent, but mild photophobia or phonophobia may be reported. The disability associated with tension-type headache typically is minor in comparison with migraine headache, and routine physical activity does not affect headache severity.^{3,4} Palpation of the pericranial or cervical muscles can

reveal tender spots or localized nodules in some patients.³ Tension-type headache is classified as either episodic (infrequent or frequent) or chronic based on the frequency and duration of the attacks.⁴

TREATMENT

Tension-Type Headaches

■ GENERAL APPROACH TO TREATMENT

The vast majority of episodic tension-type headache sufferers self-medicate with over-the-counter medications and do not consult a healthcare professional. Although pharmacologic and nonpharmacologic treatments are available, simple analgesics and NSAIDs are the mainstay of acute therapy. Most agents used for tension-type headache have not been studied in controlled clinical trials.⁵⁶

■ NONPHARMACOLOGIC THERAPY

Psychophysiologic therapy and physical therapy have been used in the management of tension-type headache. Psychophysiologic therapy can consist of reassurance and counseling, stress management, relaxation training, and biofeedback. Relaxation training and biofeedback training (alone or in combination) can result in a 50% reduction in headache activity.⁴ Evidence supporting physical therapeutic options, such as heat or cold packs, ultrasound, electrical nerve stimulation, stretching, exercise, massage, acupuncture, manipulations, ergonomic instruction, and trigger point injections or occipital nerve blocks, is somewhat inconsistent.⁴ However, patients can benefit from selected modalities (e.g., massage) during an acute episode of tension-type headache.

■ PHARMACOLOGIC THERAPY

Simple analgesics (alone or in combination with caffeine) and NSAIDs are effective for the acute treatment of mild to moderate tension-type headache. Acetaminophen, aspirin, ibuprofen, naproxen, ketoprofen, indomethacin, and ketorolac have demonstrated efficacy in placebo-controlled and comparative studies.⁴ Failure of over-the-counter agents can warrant therapy with prescription drugs. High-dose NSAIDs and the combination of aspirin or acetaminophen with butalbital or, rarely, codeine are effective options. Use of butalbital and codeine combinations should be avoided when possible owing to the high potential for overuse and dependency. As with migraine headache, acute medication should be taken for episodic tension-type headache no more than 2 days per week to prevent the development of chronic tension-type headache.^{4,57} There is no evidence to support the efficacy of muscle relaxants in the management of episodic tension-type headache.^{2,4,56} Preventive treatment should be considered if headache frequency (more than two per week), duration (greater than 3–4 hours), or severity results in medication overuse or substantial disability. The principles of preventive treatment for tension-type headache are similar to those for migraine headache. TCAs are prescribed most often for prophylaxis, but other drugs also can be selected after consideration of comorbid medical conditions and respective side-effect profiles.⁴ Injection of botulinum toxin into pericranial muscles has demonstrated efficacy in the prophylaxis of chronic tension-type headache in two recently published placebo-controlled studies.⁵⁶

CLUSTER HEADACHE

EPIDEMIOLOGY

Cluster headache, the most severe of the primary headache disorders, is characterized by attacks of severe, unilateral head pain that

occur in series lasting for weeks or months (i.e., cluster periods) separated by remission periods usually lasting months or years.^{3,4,58} Cluster headaches can be episodic or chronic.³ Cluster headache is relatively uncommon among the primary headache disorders, but the exact prevalence is uncertain. The prevalence varies from 56 to 401 per 100,000.⁵⁸ Men are more likely than women to have cluster headache, and onset generally occurs in those older than 20 years of age.^{4,58} Recent genetic epidemiological surveys suggest a predisposition for cluster headache can exist in certain families.^{4,58}

PATHOPHYSIOLOGY

The etiologic and pathophysiologic mechanisms of cluster headache are not completely understood. The cyclic nature of attacks implicates a pathogenesis of hypothalamic dysfunction with resulting alterations in circadian rhythms.^{4,59} Hypothalamus-regulated changes in cortisol, prolactin, testosterone, growth hormone, leuteinizing hormone, endorphin, and melatonin have been found during periods of cluster headache attack.^{59,60} Neuroimaging studies performed during acute cluster headache attacks have demonstrated activation of the ipsilateral hypothalamic gray area, implicating the thalamus as a cluster generator.⁵⁹ Significant cranial autonomic activation occurs ipsilateral to the pain, through the same pathways that are activated during migraine.⁵⁹

CLINICAL PRESENTATION

Attacks occur in cluster periods lasting 2 weeks to 3 months in most patients, followed by long pain-free intervals.^{3,4} Periods of remission average 2 years in length but have been reported to be from 2 months to 20 years in duration. Approximately 10% of patients have chronic symptoms with attacks recurring for over 1 year without remission or with remission periods of less than 1 month.^{3,61} Cluster headache attacks occur commonly at night and appear to be more common in the spring and fall.⁶¹ Attacks occur suddenly, with pain peaking quickly after onset and generally lasting 15 to 180 minutes.³ Auras are not present with cluster headaches. The pain is excruciating, penetrating, and of a boring intensity in orbital, supraorbital, and temporal unilateral locations.^{3,4,61} The headache can be accompanied by conjunctival injection, lacrimation, nasal stuffiness, rhinorrhea, eyelid edema, facial sweating, miosis/ptosis, and restlessness or agitation. During the cluster period, attacks occur from once every other day to eight times per day.^{3,4} Whereas migraine patients retreat to a quiet dark room, cluster headache patients generally sit and rock or pace about the room clutching their head.⁶¹ There is a male preponderance in cluster headache, especially in the chronic form, and lifestyle habits such as smoking and consumption of alcohol or coffee are common.⁶² Specific diagnostic criteria for cluster headaches are provided within the IHS classification system.³

TREATMENT

Cluster Headaches

As in migraine, therapy for cluster headaches involves both abortive and prophylactic therapy. Abortive therapy is directed at managing the acute attack. Prophylactic therapies are started early in the cluster period in an attempt to induce remission and can be transitional using agents not suitable for long-term or chronic use. Patients with chronic cluster headache can require prophylactic medications indefinitely.

■ ABORTIVE THERAPY

Oxygen

The standard acute treatment of cluster headache is inhalation of 100% oxygen by nonbreather facial mask at a rate of 7 to 10 L/min

for 15 to 25 minutes.^{4,60} Repeat administration can be necessary because of recurrence, as oxygen appears to merely delay, rather than abort, the attack in some patients.⁶⁰ No side effects have been reported with the use of oxygen, but caution should be used for those who smoke or have chronic obstructive pulmonary disease.

Ergotamine Derivatives

All forms of ergotamine have been used in cluster headaches, although in general, their role has been supplanted by the triptans. Intravenous dihydroergotamine results in the quickest response, and repeated administration for 3 to 7 days can break the cycle of frequent cluster headache attacks.⁶⁰ Ergotamine tartrate also has provided effective relief of cluster headache attacks when administered sublingually or rectally, but the pharmacokinetics of these preparations frequently limit their clinical utility.⁶⁰ Dosing guidelines are similar to those for migraine headache therapy.

Triptans

The quick onset of subcutaneous and intranasal triptans make them safe and effective abortive agents for cluster headaches. Subcutaneous sumatriptan (6 mg) is the most effective agent. Nasal sprays are less effective but may be better tolerated in some patients. Adverse events reported in cluster headache patients are similar to those seen in migraineurs. Orally administered triptans have limited use in cluster attacks because of their relatively slow onset of action; oral zolmitriptan (10 mg), however, was beneficial in patients with episodic cluster headache with 60% experiencing mild or no pain at 30 minutes.^{37,60}

■ PROPHYLACTIC THERAPY

Verapamil

Verapamil, the preferred calcium channel blocker for the prevention of cluster headaches, is effective in approximately 70% of patients.⁴ The beneficial effects of verapamil often appear after 1 week of therapy. A typical suggested dosage range is from 360 mg/day to 720 mg/day.⁶⁰

Lithium

Lithium carbonate is effective for episodic and chronic cluster headache attacks and can be used in combination with verapamil. A positive response is seen in up to 78% of patients with chronic cluster headache, and in up to 63% of patients with episodic cluster headache.^{4,60} The usual dose is 600 to 1,200 mg/day, with a suggested starting dose of 300 mg twice daily. Optimal plasma lithium levels for prevention of cluster headache have not been established, but trough values should not be more than 1.0 mEq/L.^{4,60}

Initial side effects are mild and include tremor, lethargy, nausea, diarrhea, and abdominal discomfort. Thyroid and renal function must be monitored during lithium therapy. Lithium should be administered with caution to patients with significant renal or cardiovascular disease, dehydration, pregnancy, or concomitant diuretic or NSAID use.^{4,60}

Ergotamine

Ergotamine can be an efficacious agent for prophylactic as well as abortive therapy of cluster headaches.⁴ A 2-mg bedtime dose is often beneficial for the prevention of nocturnal headache attacks. Daily use of 1 to 2 mg ergotamine alone or in combination with verapamil or lithium can provide effective headache prophylaxis in patients refractory to other agents with little risk of ergotism or rebound headache.^{4,60}

Methysergide

In patients unresponsive to other therapies, methysergide 4 to 8 mg/day in divided doses is usually effective in shortening the course of

cluster headaches.⁶⁰ Response to treatment usually occurs within 1 week of initiation of the drug. Response rates in patients with episodic cluster headache approach 70%, but chronic cluster headache patients receive less benefit.⁶⁰ Precautions regarding methysergide use were described earlier in this chapter (see Pharmacologic Management of Acute Migraine above).

Corticosteroids

Corticosteroids are useful for inducing remission.^{4,60} Therapy is initiated with 40 to 60 mg/day prednisone and tapered over approximately 3 weeks. Relief appears within 1 to 2 days of initiating therapy. To avoid steroid-induced complications, long-term use is not recommended. Headaches can recur when therapy is tapered or discontinued.

Miscellaneous Agents

Other therapies that have been used in the acute management of cluster headache include intranasal lidocaine, cocaine, capsaicin, and civamide. Limited studies also support the use of divalproex sodium, topiramate, nifedipine, nimodipine, melatonin, and baclofen for cluster prophylaxis. Neurosurgical intervention can be necessary for patients with chronic cluster headache that is resistant to all medical therapies.^{4,60}

EVALUATION OF THERAPEUTIC OUTCOMES

Because of the prevalence of headache disorders, clinicians need to be actively involved in patient care issues. Patients should be monitored for frequency, intensity, and duration of headaches, as well as any change in the headache pattern. To this end, migraineurs should be encouraged to keep a headache diary to document the frequency, severity, and duration of migraine attacks, as well as response to medication and potential trigger factors. Careful monitoring is essential to initiate the most appropriate pharmacotherapy, document therapeutic successes and failures, identify medication contraindications, and prevent or minimize adverse events. Patients using acute therapies should be monitored for frequency of use of prescription and over-the-counter medications to identify potential medication-misuse headache. Patient counseling is necessary to allow for proper medication use (e.g., self-injection with sumatriptan), to encourage early use of medications in the headache cycle, and to enhance patient compliance. Strict adherence to dosing guidelines should be stressed to minimize potential toxicity. Patterns of abortive medication use can be documented to establish the need for prophylactic therapy. Prophylactic therapies also should be monitored closely for adverse reactions, abortive therapy needs, adequate dosing, and compliance. Consultation with other health-care practitioners should be encouraged when changes in headache patterns or medication use occur.

CONCLUSIONS

Although headache disorders such as migraine and cluster headaches appear to occur as a result of neuronal dysfunction, the precise etiology and nature of the dysfunction are unknown. Serotonergic neurotransmission and the trigeminovascular system appear to play important roles. A careful patient workup, including patient history, physical examination, and appropriate laboratory tests, should identify most headache patients with major disease. A variety of strategies can be helpful for managing migraine, tension-type, and cluster headaches. Management of primary headache disorders is directed at suppressing acute attacks and preventing recurrences. Continuing research will better define pathophysio-

logic mechanisms and aid the search for less toxic and more efficacious pharmacologic agents.

ABBREVIATIONS

CGRP: calcitonin gene-related peptide
 CNS: central nervous system
 GABA: γ -aminobutyric acid
 5-HT: serotonin, 5-hydroxytryptamine
 FDA: Food and Drug Administration
 IHS: International Headache Society
 MAOIs: monoamine oxidase inhibitors
 NSAIDs: nonsteroidal antiinflammatory drugs
 SNRI: serotonin-norepinephrine reuptake inhibitor
 SSRI: selective serotonin reuptake inhibitor
 TCA: tricyclic antidepressant

PSYCHIATRIC DISORDERS

CHAPTER

64

Evaluation of Psychiatric Illness

PATRICIA A. MARKEN, MARK E. SCHNEIDERHAN, AND STUART MUNRO

KEY CONCEPTS

- 1 Patients with psychiatric conditions are treated in all healthcare settings. All clinicians need to develop basic skills in psychiatric assessment to best care for their patients.
- 2 The *Diagnostic and Statistical Manual of Mental Disorders, 4th Edition, Text Revision (DSM-IV-TR)* is the most widely accepted diagnostic reference. It, along with the *American Psychiatric Association Practice Guidelines for the Psychiatric Evaluation of Adults*, provides the clinician a standardized approach for the initial assessment and followup of patients with mental illness.
- 3 At times, patients suffering from mental illness are challenging to assess, as their condition can prevent them from full cooperation. A range of strategies can be used to gather the needed information while maintaining the safety and comfort of both patient and clinician.
- 4 A thorough medication history to identify all medications currently taken, as well as those previously taken, is a cornerstone of effective patient management. In addition, it must be determined whether there was an adequate trial (dose and duration) of current and prior medications for psychiatric illnesses.
- 5 A baseline mental status examination, along with a specific target symptom list, is a critical tool in monitoring response to treatment.
- 6 Several papers have been published in recent years recommending specific physical assessment and laboratory tests needed for the evaluation of patients with psychiatric conditions. Except for patients taking antipsychotics, no single standard exists, and testing is individualized based on the patient's age, medical history, current physical health, and current medication use and in consideration of the most recent expert opinion. Baseline and followup monitoring for metabolic disturbances should be instituted for all antipsychotic therapies.

OVERVIEW OF DIAGNOSTIC AND STATISTICAL MANUAL OF MENTAL DISORDERS

- 1 Patients with mental illnesses are treated by all disciplines and in all settings of healthcare and can, in fact, receive the bulk of their care from nonpsychiatrists. Hence the need for good psychiatric assessment skills is not limited to mental health specialists. Along with traditional assessments used across all medical specialties (laboratory tests, medical history, and physical examination), psychiatrists use additional strategies to manage their patients that are perhaps less objective and less familiar to the nonpsychiatrist. This chapter provides a basic overview of appropriate assessment techniques used by clinicians to develop an individualized treatment plan for psychiatric patients. Readers needing greater depth than the materials provided in this chapter are referred to other reference materials.¹⁻⁵
- 2 The *DSM-IV-TR* is the most widely accepted and most important diagnostic reference used in the care of the mentally ill. It provides a common language for practitioners to describe and diagnose psychiatric disorders.⁶ Common language is essential because there is considerable overlap of symptoms across many diagnoses. The *Diagnostic and Statistical Manual of Mental Disorders, 1st edition (DSM-I)* was introduced in 1952 and was the first manual on mental disorders to contain a description of diagnostic categories. The most recent edition, *DSM-IV-TR*, was released in 2000. The *DSM-IV-TR* uses essentially the same diagnostic criteria sets as *Diagnostic and Statistical Manual of Mental Disorders, 4th edition (DSM-IV)*.⁶ Its purpose is to correct factual errors in *DSM-IV* and update the text sections (e.g., associated features, prevalence, and differential diagnosis) with more contemporary data. A more significant rewriting of diagnostic criteria and introduction of new diagnoses will appear in *Diagnostic and Statistical Manual of Mental Disorders, 5th edition (DSM-V)*, which probably will not be available until 2011.⁶ The *DSM-IV-TR* contains many components that provide a comprehensive understanding of specific mental illnesses and assist in making an accurate diagnosis. For example, the multiaxial patient evaluation ensures that most factors that could contribute to, or complicate, the condition are considered during a patient assessment and throughout treatment planning. Axis I lists the principal psychiatric disorder, developmental disorders, or provisional diagnoses present in the patient. Mental retardation and personality

Learning objectives, review questions, and other resources can be found at
www.pharmacotherapyonline.com.

disorders are listed on Axis II. Axis III lists existing physical disorders or conditions. Axis IV lists the severity of psychosocial stressors that might have contributed to a new or recurrent mental disorder or exacerbation of an existing condition. Stressors are rated on a scale of 1 (none) to 6 (catastrophic) and can be acute (lasting less than 6 months) or enduring (lasting longer than 6 months). Examples of stressors include difficulties with interpersonal relationships, parenting, occupation, living circumstances, finances, the legal system, and health. Axis V describes the global assessment of functioning (GAF), rated on a scale from 1 (persistent danger to self or others) to 90 (minimal or absent symptoms). A GAF rating is made based on the current level of functioning and also for the highest level of functioning seen in the previous months to a year prior to the current evaluation. By documenting the baseline level of functioning, the GAF helps evaluate progress toward a patient's therapeutic goals.

DSM-IV-TR provides general information on all mental disorders recognized by the American Psychiatric Association (APA) and includes age of onset, clinical course, complications, predisposing factors, prevalence, and the differential diagnoses. The specific diagnostic criteria for each mental illness and the number of symptoms required to establish a diagnosis are also listed. The *DSM-IV-TR* also includes decision trees for differential diagnosis and a glossary of technical terms. The *Clinical Interview Using DSM-IV* is a companion publication that provides extensive information on interviewing techniques helpful in establishing a specific *DSM-IV* diagnosis.⁷

Additional information besides the *DSM-IV-TR* diagnosis is required before a comprehensive treatment plan can be developed. The *American Psychiatric Association Practice Guidelines for Psychiatric Evaluation of Adults* (2nd edition) includes a full discussion of the domains needed for a thorough clinical evaluation. It also discusses issues of privacy, appropriate setting for assessment, and evaluations in special populations.⁵

In summary, the *DSM-IV-TR* and the APA practice guidelines allow clinicians to evaluate patients in a systematic manner, thereby creating better treatment plans and a more consistent evaluation of response.

THE CLINICAL INTERVIEW

The interview should be conducted in a quiet, nonstimulating, and comfortable area where the patient and the interviewer feel at ease. The setting should be appropriate to the patient's level of acuity and the potential for risk to the patient and clinician. The interviewer should introduce himself or herself and explain what is about to happen to establish a trusting relationship. Generally, open-ended questions come first, followed by questions focused on more specific or personal data. Open-ended questions allow the patient to provide descriptions and other information in his or her own words. Even though more specific questions may then be necessary to fill in the gaps, beginning in this manner minimizes the risk of "leading" the patient. Patients can respond to specific questions and "yes" or "no" questions with answers they think the interviewer wants to hear. The interviewer must be nonjudgmental about the information offered by the patient to develop trust and rapport and to ensure completeness and accuracy of the information. Whether a clinician takes notes or just listens during the interview is an individual decision, with the primary considerations being to make an accurate record of the content of the examination and assuring that the patient is comfortable with the note taking. Table 64-1 provides examples of questions useful for gathering information during the completion of the clinical interview.

THE CHALLENGING PATIENT

3 Patient assessment can be challenging when symptoms of the condition prevent effective engagement with the clinician. Patients

TABLE 64-1 Examples of Interview Questions for Assessing Mental Illnesses

Mania

1. Do your thoughts go faster than you can say them?
 2. Have you noticed a change in the amount of sleep that you require?
 3. Have you spent a lot of money lately, and what did you spend it on?
 4. Do you have a lot of extra energy?
- (To assess hallucinations and delusions, see Schizophrenia section below.)

Depression

1. Do you cry without any reason?
 2. Do you still enjoy the same hobbies/activities that you once did?
 3. Has your weight changed recently?
 4. Have you had changes in your energy level recently?
 5. Do you have any guilty feelings?
 6. Do you find it difficult to remember phone numbers, names of friends, appointments, and so on?
- (To assess sleep and suicidal potential, see Sleep and Suicide sections below.)

Schizophrenia

Delusions

1. Do you feel that people plot against you?
2. Do you ever feel that you are watched or spied on?
3. Do you have any special abilities?
4. Does anyone ever try to mess with you or bother you?
5. Do others read your thoughts?

Hallucinations

1. Does the TV/radio ever tell you things?
2. Do you hear voices that other people don't hear?
3. What do they say? How many voices?
4. How often do they bother you?
5. Do the voices ever tell you to hurt yourself or someone else?
6. Have you ever heard your name called when there is no one there?
7. Have you ever seen anything strange that you can't explain?
8. Do you ever see things that bother you and no one else?
9. Do you want to act on what the voices say?

Thought broadcasting/insertion

1. If I stood by you could I hear your thoughts?
2. Does your head ever act like a radio?
3. Do you feel that others can put thoughts in your head?

Insight

1. What reasons did your family give you for coming here?
2. What brought you here?
3. Do you consider yourself in need of help?
4. What does your medication do for you?

Sleep

1. Tell me about your sleep.
2. How many hours do you sleep each night at present?
3. How many hours do you usually sleep at night?
4. Do you sleep all through the night?
5. Is there a reason for your waking up?
6. Do you have trouble falling asleep?
7. How do you feel when you wake up?

Suicide potential

1. Do you feel your life is worth living?
2. Do you ever think of hurting yourself?
3. Do you see things improving in the future?
4. Do you think you will try to hurt yourself now?
5. How would you do it?
6. Do you have the means to hurt yourself?

ramble if their speech patterns are circumstantial or tangential in nature, or they can ruminate as part of a depression. Patients in the manic phases of bipolar disorder may not pause as they speak (pressured speech), making it difficult for the interviewer to interject. In all cases, the interviewer can regain control by politely redirecting the patient back toward the question. Psychotic patients may be paranoid and appear guarded or frightened by the questions. The best approach is to remain calm and respectful; use shorter or close-ended questions; and only seek essential information until the patient is less paranoid. Patients can become agitated

and occasionally violent. Often violence is preceded by increased psychomotor agitation as evidenced by pacing, speaking in a loud voice, or gripping the arms of the chair. When there is concern about safety, the interviewer should avoid any behavior that could be misconstrued as threatening, such as touching or unnecessary staring, and interview the patient in the presence of another health-care provider. Both the patient and interviewer should have equal access to leave the room if either becomes too uncomfortable. If a patient becomes threatening to the interviewer, the interviewer should not hesitate to leave the room and call for help. If a patient describes suicidal thoughts, he or she should be further assessed using the questions outlined in Table 64–1, and depending on the results of further assessment be directed to the appropriate type of care, including hospitalization for patients at immediate risk of harming themselves. A suicidal patient should never be left alone. Asking a patient about suicidal thoughts will not increase the risk. The risk is greater if these questions are never asked or signs of distress are ignored. Before any conclusions are made about a patient interview, the impact of culture on the patient's presentation should be considered. Something that sounds delusional in Western culture can be the norm in others. If a clinician is unclear whether culture of origin accounts for some of the patient's symptoms, he or she should consult with a family member or someone else familiar with the cultural issues for the patient.

PSYCHIATRIC HISTORY

Both the patient's and the patient's family history of mental illness provide important information when formulating a diagnosis and treatment plan. Information should include the current and previous psychiatric diagnoses, the clinical presentation of each illness, time frame between episodes, level of functioning between episodes, length of each episode, total duration of illness, and treatment given during each episode and response to those treatments. Baseline functioning or the highest level of functioning achieved in the past few years is important because it provides a treatment goal. Information on the history of the current episode and reasons for presenting to the clinician also should be gathered. A family history should include a medication history of the immediate relatives because a family member's response to a given medication might predict an individual patient's response to that same medication.

SOCIAL HISTORY

A social history should include educational and occupational background, religion, marital status, substance-use patterns including smoking, and current living situation. By understanding a patient's living environment and social situation, strategies to foster treatment adherence, reduce stress, and increase social support can be developed. To probe this area initially, the clinician can ask patients to describe their social support network. This can be followed by more specific questions such as "To whom are you closest?" or "In whom do you confide?"

MEDICATION HISTORY

4 A thorough medication history is one of the most important contributions a clinician can make to treatment planning. The history should include medications for both psychiatric and medical conditions. It should list all medications taken by the patient, and report on how each was tolerated and the nature of the response to that drug or combination of drugs. Because most psychiatric medications have a delay in the onset of effect, it is important to determine whether an adequate trial (adequate dose and duration) was provided before the patient was deemed "nonresponsive" to that drug. If a patient has a

history of nonadherence, specific causes such as cost, complicated dosing schedules, lack of insight, and adverse effects should be investigated.

MENTAL STATUS EXAMINATION

5 The mental status examination (MSE) is a key patient assessment tool in psychiatry and is analogous to the physical examination in medicine. The MSE is completed through a direct patient interview and results in a description of current behavior, thoughts, perceptions, and functioning. The MSE provides an objective evaluation used in diagnosis, assessment of the course of the illness, and response to treatment. The MSE is combined with other components of the patient workup (history of present illness, physical examination, appropriate laboratory tests, and medical and psychiatric history) to give a full picture of the presenting problem and factors contributing to the illness. An MSE has several components.^{5,7}

Appearance and Attitude Toward Examiner

The appearance of the patient throughout the interview should be noted, including age, dress, grooming and hygiene, use of cosmetics, and facial expressions. A description of appearance also should include unusual physical characteristics and the general state of physical health. The interviewer should note whether the patient is cooperative, mute, hostile, paranoid, guarded, or withdrawn.

Activity

Changes in motor activity include overactivity, underactivity, and catatonia. Overactivity is an increase in purposeful movements or agitation and can include pacing; hand wringing; picking at clothing, skin, or hair; inability to sit still during the interview; and excessive hand gestures. Underactive patients move less than expected. Patients with rigid posture, an absence of movement, and failure to communicate can be catatonic, paranoid, or experiencing medication-induced adverse effects.

Speech and Language

The quantity, flow, and speed of speech and the amount of eye contact should be noted. The appropriateness and degree of eye contact varies significantly between cultures, and before poor eye contact is interpreted, the patient's cultural background should be considered. Speech should be assessed as to whether it proceeds logically in a goal-directed manner or whether the content is vague and poorly organized. Abnormal speech characteristics include blocking, whereby the person suddenly stops speaking without any obvious reason. Thought blocking usually occurs when a hallucination or delusion intrudes into the person's thinking or when upsetting issues are discussed. Circumstantial speech lacks a clear direction because of excess unnecessary information, but the circumstantial patient eventually will make his or her point. In tangential speech, however, the ultimate point is never made. *Perseveration* is repetition of an original answer to subsequent questions. *Flight of ideas* is overproductive, rapid speech during which the patient jumps rapidly from one idea to the next. *Mutism* is identified when the patient does not respond even though he or she is aware of the discussion.

Mood and Affect

Affect describes the patient's current emotional tone, as expressed through facial expression, body posture, and tone of voice, all of which can be objectively observed by the clinician. Mood describes more sustained feelings, which are subjectively reported by the patient. To properly evaluate a patient's mood and affect, his or her appearance and the content of speech must be considered. Change in

facial expression and the presence of tears, flushing, sweating, or tremors should be noted. Affect can be described further by its range, appropriateness, intensity, and stability. For example, in schizophrenia or depression, the affect can be flat, whereby no change in expression occurs throughout the interview. In contrast, during a manic episode, the affect is very intense and often labile. *Blunted affect* denotes that the range of emotional expression is reduced, but not absent. An example of *inappropriate affect* is when a patient laughs when he or she is depressed or cries when stating that he or she is happy. A rapidly shifting affect from one extreme to the other is described as *labile*.

Thought and Perceptual Disturbances

A variety of thought disturbances can occur in mental illness. These disturbances generally indicate the presence of psychosis or impaired reality testing. *Delusions* are fixed, false beliefs that are not based in reality or consistent with the patient's religion or culture. Delusions can be paranoid, somatic, or grandiose in nature. Delusions are often unshakable, and although the clinician can challenge the delusional thinking, one should not attempt to talk a patient out of a delusion. *Thought broadcasting* is the belief that one's thoughts are audible to others. *Hallucinations* are false sensory impressions or perceptions that occur in the absence of an external stimulus. Hallucinations can be auditory, visual, olfactory, or gustatory and can be continuous or intermittent. In contrast, *illusions* are visual misperceptions involving a misinterpretation of a real sensory stimulus. For example, a person who initially misperceives a curtain blown by the wind to be an intruder has experienced an illusion. This phenomenon is not indicative of psychiatric illness and can be seen in normal persons. Other thought disturbances are not considered to be psychotic. For example, the couplet of obsessions and compulsions can be indicative of the presence of obsessive-compulsive disorder, which is not considered to be a psychotic disorder. *Obsessions* are unwanted thoughts or ideas that intrude into a person's thinking. *Compulsions* are actions performed in response to the obsessions or to control anxiety associated with the obsession.

Neuropsychiatric Evaluation

A neuropsychiatric evaluation assesses sensorium, attention, concentration, memory, and higher cognitive functions such as orientation and abstraction. Prior to a neuropsychiatric evaluation, the clinician should document whether the patient has received medications with sedative properties, because the outcome of the examination can be altered if central nervous system depressants were recently taken.

Sensorium, or level of consciousness, refers to the alertness of the patient, and if he or she is not fully alert, the amount of stimulation needed to awaken the patient. Attention and concentration can be assessed using serial subtraction by 7s or 3s, or by having a patient spell a five-letter word backward. Language skills are assessed initially by having a patient read something aloud and silently. General intelligence can be assessed loosely by asking factual information about current news items, recent presidents, or popular television shows or sporting events. *Memory* is the ability to recall past experiences and is classified as sensory stores (which lasts seconds), short-term memory (the ability to recall newly acquired information after several minutes), working memory (i.e., immediate application of visual or auditory instructions), and long-term or remote memory (historical facts). Orientation to time, place, person, and situation assesses sensory stores and short-term memory. Asking a patient to recall three objects 5 minutes after they are learned is the definitive test for short-term memory. Patients with depression or anxiety can have deficits in short-term memory. Asking the patient to do a certain task (e.g., pick up a pen with his or her right hand and then fold a piece of paper and pass it to the examiner) can assess the patient's

working memory. Patients with cognitive deficits, such as those seen in dementias and schizophrenia, can exhibit deficits in working memory. Remote memory is assessed by asking patients to recall old facts about their lives, such as where they were born or where they went to school. Remote memory usually remains intact the longest in patients with intellectual decline, whereas the ability to create new memories is generally the first sign of a memory deficit. *Abstraction* is the ability to interpret information such as a proverb ("People in glass houses shouldn't throw stones") or identify similarities or differences between words (apple and orange). Abstraction is influenced by education, cultures and linguistic fluency; thus inability to abstract is not always a sign of a psychiatric disorder.

Insight and Judgment

Insight refers to patient awareness that he or she has a mental illness and the consequences of that illness on his or her life. Patients typically demonstrate a lack of insight when they are psychotic. Patients with poor insight are often nonadherent with prescribed medications. *Judgment* is the ability to make decisions appropriate to the situation and can be impaired in a variety of mental illnesses. Judgment can be assessed by asking patients how they would handle either their current or a hypothetical situation. Both insight and judgment can be fluid. For example, intoxicated patients can demonstrate poor insight and judgment only to improve over several hours as their blood alcohol concentration decreases.

PHYSICAL AND LABORATORY ASSESSMENT IN PSYCHIATRY

Patients who present with psychiatric symptoms need a careful medical assessment for many reasons.¹⁻³

Both medical illnesses and medications can cause the same psychiatric symptoms. The rapidity of onset of psychiatric symptoms is an important clue that a medical cause is present. Most chronic mental illnesses have a prodromal period, whereas medically-based psychiatric symptoms often have a more rapid onset of symptoms. Patients older than 40 years of age at first presentation are more likely to have a medical cause for their psychiatric symptoms because major psychiatric illnesses such as schizophrenia and bipolar disorder usually first present in adolescence or early adulthood. Family history can provide additional clues. Patients with fluctuating levels of consciousness, disorientation, memory impairment, or visual, tactile, or olfactory hallucinations, substance abuse, and serious medical conditions are more likely to have a medical basis for their presentation.

Patients with psychiatric illnesses, especially depression and anxiety disorders, will often present with only physical complaints, leading to inappropriate care for medical problems that are not present or as serious as they may appear, while the root cause is ignored. Psychotropic medications can cause or exacerbate medical conditions, such as diabetes mellitus, hyperlipidemia, or cardiac arrhythmias, necessitating an understanding of the patient's other risk factors for these conditions before medication is selected. Finally, patients with chronic psychiatric illnesses often receive inadequate healthcare and have poorly controlled medical conditions for many reasons, including their appearance or behavior prohibiting a thorough evaluation, inaccurate information from the patient secondary to impaired memory or perception, and incomplete data to make an appropriate diagnosis and treatment recommendation. A retrospective review found that patients with diabetes or hypertension and diagnoses of schizophrenia, bipolar disorder, or posttraumatic stress disorder were statistically less likely to use medical services than similar patients without these psychiatric conditions.⁸

6 General laboratory screening is useful for ruling out medical causes of psychiatric illnesses, but extensive testing is usually unneces-

sary and not cost-effective. Laboratory tests should be individualized to the age, medical/medication history, cooperativeness, and physical health of the patient. Although there is no consensus about specific laboratory tests for diagnosing or evaluating mental illness, antipsychotic therapy warrants patient monitoring for metabolic disturbances.^{2,5,9,10} Expert consensus recommends that patients starting on antipsychotic agents should be screened for symptoms of metabolic syndrome including body weight (baseline, weeks 4, 8, and 12, then every 3 months, then annually), waist and hip measurements (baseline and annually), blood pressures (baseline, week 12, and annually), and fasting serum lipids and glucose (if possible at baseline, week 12, and annually). Although a fasting blood glucose determination is preferred over a random measure, this should not be a barrier to adequate monitoring. The clinician can employ random glucose measures or glycosylated hemoglobin A_{1c} if there is difficulty obtaining fasting serum levels. Inadequate lipid monitoring continues to be reported among patients with schizophrenia on second-generation antipsychotics; therefore, lipids should be assessed even if fasting specimens are not available because high-density lipoprotein cholesterol (HDL) levels are a direct measure to identify metabolic abnormalities.^{9–12}

A complete physical examination, along with a detailed medical and medication history, vital signs, weight and body mass index, a pregnancy test when indicated, and routine blood chemistry are commonly part of the workup of persons with mental illness. In most cases a physical examination should be chaperoned. Clinicians will want diagnostic tests to evaluate the relative safety of specific medications (e.g., renal status when using lithium or an electrocardiogram when using a tricyclic antidepressant such as amitriptyline or an antipsychotic such as ziprasidone or clozapine) or when baseline information is needed to help document future adverse effects from medications (e.g., lithium-induced hypothyroidism, clozapine-induced leukopenia, antipsychotic-induced diabetes mellitus). Serum concentration monitoring for selected medications (lithium, valproic acid, carbamazepine) is also helpful in increasing probability of response while minimizing adverse effects. Urine drug screens and blood alcohol tests play an important role in identifying the contribution of substances of abuse to the presenting symptoms.

Additional testing can include an electroencephalogram to evaluate for the presence of seizure activity or other neurologic conditions, computed tomography or magnetic resonance imaging to detect structural abnormalities, sedimentation rate and antinuclear antibodies for autoimmune disorders, a human immunodeficiency virus test, thyroid function tests, or vitamin B₁₂ and folate concentrations for anemias.²

The identification of biologic markers as diagnostic tools and predictors or indicators of drug response is of great interest but currently of little clinical usefulness. The most promising is the dexamethasone suppression test, proposed to be a marker for endogenous melancholic depression. However, its lack of sensitivity and specificity has limited its usefulness as a routine screening tool during a workup for depression.²

In summary, a range of assessments aid the clinician in making an accurate diagnosis and identifying underlying or potential drug-related problems. The MSE is the cornerstone of the psychiatric workup, although selective medical tests, a good medical, psychiatric, and medication history, and a thorough physical examination are also important.

PSYCHIATRIC RATING SCALES

Psychiatric rating scales are useful tools to provide an objective way of measuring subjective data (e.g., feelings, thoughts, and perceptions) and to diagnose specific disorders. As there are so many types of scales to choose from, the rater needs training and experience to select and use the most appropriate scale. Rating scales are used in a

variety of settings, including research and patient care, and can serve an administrative purpose such as quality control.⁴

Drawbacks to the more frequent use of rating scales include the substantial time commitment for staff to administer the tests and the inability of some patients to tolerate these interviews, especially patients who are severely paranoid or agitated. In addition, repeated ratings are usually necessary to objectively describe longitudinal changes over a defined treatment period as opposed to a snapshot of a complex clinical situation.

Some rating scales are self-administered and do not require a staff member to collect the data; thus they require minimal resources to administer. Patients can be unable to self-administer a questionnaire for a variety of reasons, including literacy and severity of symptoms.

In contrast to symptom-based rating scales (e.g., Brief Psychiatric Rating Scale [BPRS] or Hamilton Depression [HAMD] scale), global rating scales such as the Clinical Global Impression (CGI) scale assess the overall severity of illness based on a rater's clinical experience.¹³ In general, these rating scales measure the presence or severity of symptoms and can assist in the diagnostic formulation.

Rating scales are also available to measure adverse side effects from psychiatric medications. Specific adverse side-effect measures can be used for specific categories of medications. Table 64–2 provides a summary of the most common rating scales used to assess and quantify the presence and severity of adverse effects.¹⁴

Sensitivity, specificity, reliability, and validity are important considerations when selecting a rating scale. *Sensitivity* refers to a test's ability to detect a symptom or illness, given that the symptom or illness is present. *Specificity* refers to a test's ability to determine that a symptom or illness is absent given that the person does not have the illness.

Reliability is the extent to which the score on the scale reflects the hypothetical "true" score and how much interference occurs from outside influences.¹⁵ Reliability is reported by the correlation coefficient, which represents a chance correlation (zero) or perfect correlation (one). Rating scales with reliability correlation coefficients of less than 0.7 are usually considered unreliable for clinical studies. Interrater reliability—agreement in rating scores among clinicians—is important to achieve when multiple clinicians rate the same patient or population. Interrater reliability is established by having all raters independently rate individual patients at the same time to determine the correlation of their scores.

Validity, in contrast, is the ability of a scale to measure what it was designed to measure. Various validity tests are performed on a rating scale to ensure that the scale assesses the appropriate aspects of the illness (content validity), the correlation with diagnoses or clinical change (concurrent validity), and the extent to which the scale measures symptom traits in contrast to a specific symptom (construct validity).

Psychiatric rating scales should not be confused with psychological tests such as neuropsychologic and intellectual assessments and are best used as only one part of a comprehensive diagnostic plan. Tables 64–3, 64–4, and 64–5 describe commonly used patient-rated and clinician-rated scales for a variety of disease states.^{16–21}

SYSTEMATIC MEASUREMENT OF COGNITIVE FUNCTION

Neuropsychiatric rating scales provide specific information such as the rate of change and severity of cognitive decline or improvement. They are useful in situations in which repeated measurements of a patient's mental status are needed because they allow the clinician to determine response to an intervention (e.g., medication) in a more systematic manner. In addition, some cognitive function measures are useful screens for Alzheimer's disease and other causes of cognitive decline. A number of cognitive rating scales are available, the most common being the Mini Mental Status Examination (MMSE).

TABLE 64-2 Adverse Effects Measures

Rating Scale	Type	Scoring	Comments
Systematic Assessment for Treatment of Emergent Events-General Inquiry (SAFTEE-GI)	Structured interview and global assessment	Summary scores of number of events, average severity, and impairment.	5–10 minutes to complete. Baseline and weekly evaluations. Easy to administer. The specific reported information might be more useful than an overall summary score.
MED Watch	Global assessment	No scoring involved.	Minutes to complete. The one-page form requires a narrative description of the problem or adverse reaction. Online submission: www.fda.gov/medwatch/ .
Abnormal Involuntary Movement Scale (AIMS)	Tardive dyskinesia assessment	12-item, 5-point severity scale. Items 1–4 orofacial movement; 5–7 extremity and truncal movement; 8–10 global severity; 11 and 12 problems with teeth or dentures (yes or no).	5–10 minutes to complete. Commonly used in most clinical settings for dyskinesia assessment. Requires training and clinical experience to make diagnosis. Diagnostic criteria: at least 3 months of antipsychotic treatment. Mild severity score (2) in two discrete areas or moderate severity (3) in one area (i.e., orofacial).
Dyskinesia Identification System: Condensed User Scale (DISCUS)	Tardive dyskinesia assessment	15-item, 5-point severity scale. Items 1, 2 face; 3 eyes; 4, 5 oral; 6–9 lingual; 10, 11 head/neck/trunk; 12, 13 upper limb; 14, 15 lower limb.	10–15 minutes to complete. More descriptive criteria for scoring severity than the AIMS. Scoring based on three dimensions: frequency, detectability, and intensity. A flow chart is provided in the user's manual to assign an item score.
Rating Scale for Extrapyramidal Side Effects (Simpson-Angus EPS Scale)	Drug-induced Parkinson and dystonia assessments	10-item, 5-point anchored severity scale. Mean score is obtained by adding all scores and dividing by 10. A mean score of 0.3 is the upper limit for no EPS.	10 minutes to complete. Item domains include gait, arm dropping, shoulder shaking, elbow rigidity, wrist rigidity, leg pendulousness, head dropping, glabella tap, tremor, and salivation. Requires training and practice to administer.
Barnes Akathisia Scale (BAS)	Drug-induced akathisia	4 items including three 4-point anchored severity scored items and a 5-point global rating score item. Total score of 12 possible.	10 minutes to complete. Items 1–3 (objective akathisia, subjective awareness of restlessness, and subjective distress related to restlessness). Diagnostic criteria: requires both objective and subjective ratings of at least 1 in either two subjective items. Pseudoakathisia is suggested with a positive objective rating, but no subjective score is noted.

EPS, extrapyramidal symptoms.

Data from Schooler and Chengappa¹⁴ and Guy.¹³

The MMSE is a structured interview that globally assesses many cognitive domains including orientation, visuospatial organization, memory, and reasoning to determine an overall score of cognitive function. The maximum score is 30, and a score of 23 or less is indicative of cognitive impairment. The MMSE takes 5 to 10 minutes to administer and is used routinely in the clinical setting.²⁰ Other examples of cognitive rating scales include the information memory concentration (IMC) test, the dementia rating scale, and the clock drawing and Alzheimer's Disease Assessment Scale.^{22–25}

Most of the rating scales involve a structured interview that requires clinician training to ensure accurate administration. Noise and distraction can affect the patient's performance ability; therefore the interview should be conducted in a quiet area with adequate lighting. The interviewer should speak slowly and clearly to the patient when providing instructions or asking questions.

PSYCHOLOGIC TESTING

Although most clinicians do not administer psychologic testing, they can use the results to evaluate the role of medication in

relationship to the diagnosis. Psychologic testing alone cannot establish a firm diagnosis but can be a useful diagnostic tool when coupled with clinical judgment. Types of psychologic testing include personality tests (e.g., Rorschach, Minnesota Multiphasic Personality Inventory-2 [MMPI-2]), intelligence tests (e.g., Wechsler Adult Intelligence Scale-Revised, Wechsler Intelligence Scale for Children-Revised), and neuropsychologic tests (e.g., Bender Visual Motor Gestalt Test).³

CONCLUSIONS

Patient assessment is the basis from which a pharmaceutical care plan evolves. Problem identification and therapeutic monitoring cannot occur until a thorough assessment is complete. The initial assessment is also the basis for evaluating response to therapy throughout the course of treatment. Psychiatric assessment requires sensitivity and good listening skills on the part of the clinician because it is based primarily on a subjective interview and not objective tests. With careful data collection, clinicians can make substantial contributions to care that improve patient outcomes.

TABLE 64-3 Schizophrenia Rating Scales

Rating Scale	Type	Scoring	Comments
Brief Psychiatric Rating Scale (BPRS)	Clinician-rated	18 items, 7-point severity scale: score ≥ 38 indicates moderate severity	The anchored BPRS provides descriptions of each severity rating to increase the interrater reliability. The BPRS has four clusters of symptoms: thinking disturbance, anxious depression, withdrawal-retardation, and hostility-suspiciousness.
Scale for Assessment of Negative Symptoms (SANS)	Clinician-rated	30 items, 6-point severity scale: 0 = normal; 5 = severe	Measures degree of affect, avolition, anhedonia, and attention.
Positive and Negative Syndrome Scale (PANSS)	Clinician-rated	30-item scale, 7-point severity scale	Based on the 18-item brief psychiatric rating scale.
Clinical Global Impression (CGI) Scale	Observational	Severity of illness 7-point rating scale. Global improvement 7-point rating scale. Efficacy index: 1–4 marked improvement; 5–8 moderate; 9–12 minimal; 13–16 unchanged/worse	Observational rating scale to compare severity of illness compared to other similar patients and measures improvement from baseline. The efficacy index measures therapeutic effect and side effects to determine the score.

TABLE 64-4 Depression Rating Scales

Rating Scale	Type	Scoring	Comments
Hamilton Depression Scale (HAMD)	Clinician-rated	17-item scale; <6 = normal mood; 17–25 = mild depression; >25 = severe depression	Used to screen patients for drug studies and to determine severity of symptoms, treatment outcome and is the standard to compare other depression rating scales.
Montgomery-Asberg Depression Rating Scale (MADRS)	Clinician-rated	10-item, 7-point scale. For each item: 0 = no symptoms; 6 = severe symptoms	Differentiates between all the intermediate grades of depression. Decreases bias in patients with other medical illness and increased somatization.
Beck Depression Inventory (BDI)	Patient-rated	21-item scale; 0–9 = normal; 10–15 = mild depression; 16–19 = mild-moderate; 20–29 = moderate-severe; 30–63 = severe depression	The standard for self-rating scales and an objective measure of change in symptoms as a result of treatment.
Zung Self-Rating Depression Scale (ZSDS)	Patient-rated	20-item scale, 4-point severity; <50 normal; 50–59 minimal-mild; 60–69 moderate-marked; ≥70 severe depression	Severity rated by frequency of occurrence of symptoms. May not be as sensitive in measuring changes in severity of symptoms.

TABLE 64-5 Anxiety Rating Scales

Rating Scale	Type	Scoring	Comments
Hamilton Anxiety Scale (HAM-A or HAM-AS or HAMRS)	Clinician-rated	14 items, 5-point scales; scores of ≥18–20 for moderate anxiety	Consists of subscales to measure somatic and psychic anxiety.
Self-Rating Anxiety Scale (Zung SAS)	Patient-rated	20-item scale; 4-point intensity ratings	Correlates to the clinician-rated Anxiety Status Inventory (ASI); however, there is little information on the validity of either test.
Sheehan Panic and Anticipatory Anxiety Scale (SPAAS)	Patient- and clinician-rated	3-part scale	Measures panic attacks, anticipatory anxiety, and limited symptom attacks.
Yale-Brown Obsessive-Compulsive Scale (YBOCS)	Clinician-rated	Semistructured interview	Consists of several clusters of obsessions and compulsions. Used to assess change in treatment studies.

JULIE ANN DOPHEIDE, JANE TRAN TESORO, AND MICHAEL MALKIN

KEY CONCEPTS

- 1 Inattention and impulsivity caused by attention-deficit/hyperactivity disorder (ADHD) begins before age 7 years and can continue into adolescence and adulthood, often requiring ongoing drug treatment.
- 2 Stimulants are first-line treatment for ADHD, atomoxetine and bupropion are second-line, tricyclic antidepressants (TCAs) are third-line, and clonidine or guanfacine are considered fourth-line or as adjuncts to stimulants.
- 3 Coexisting disorders or symptoms such as anxiety, mood, or behavior dysregulation have an impact on drug selection for ADHD and can necessitate the use of additional agents.
- 4 Tourette's disorder presents with both motor and vocal tics, which are present during childhood, plateau during adolescence, and can continue during adulthood with a fluctuating course.
- 5 The decision to medicate patients with Tourette's disorder is based on the degree of concern perceived by the patient, symptom severity, and comorbid disorders.
- 6 Individuals with Tourette's disorder are particularly sensitive to medication side effects, so medication dosing must be individualized carefully, and close monitoring is essential.
- 7 Nondrug approaches to enuresis management, such as behavioral interventions or using bed-wetting alarms, are preferred because of lasting cure rates and avoidance of drug side effects.
- 8 Desmopressin tablets are preferred over TCAs because of better safety and tolerability. Both desmopressin and TCAs have a rapid onset of effect (1–2 weeks), however relapse on drug discontinuation is high.

All neuropsychiatric disorders can first present during childhood.¹ ADHD, Tourette's disorder, and enuresis are the focus of this chapter because, by definition, the onset of symptoms explicitly occurs during childhood.

Treating children with psychotropic drugs requires a very different approach than treating adults. Children undergo neurologic, physiologic, and psychosocial changes throughout development. Age-related pharmacodynamic and pharmacokinetic differences can alter drug disposition and response. Well-defined diagnostic criteria guide

drug selection;¹ however, comorbid disorders present treatment challenges.^{2,3} Children may not be able to articulate symptom response or adverse effects of a medication. Psychotropic drug treatment of children is intended to control symptoms or behaviors that impair learning and development.⁴

The psychiatric assessment of a child requires obtaining information from the child, parents, caregivers, and teachers.

ATTENTION-DEFICIT/HYPERACTIVITY DISORDER

CLINICAL PRESENTATION AND EPIDEMIOLOGY

A diagnosis of ADHD should be considered whenever a child presents with developmentally inappropriate inattention, impulsivity, and/or hyperactivity. Symptom presence and severity vary with the situation. It is unusual for a child to display signs of the disorder in all settings or even in the same setting at all times.¹

1 The onset of ADHD is typically by the age of 3 years and must occur by age 7 years, although the disorder may not require professional attention until the child enters school. ADHD occurs in 3% to 10% of children worldwide and is estimated to be present in 4% of adults.^{5,6} In the United States, four boys are diagnosed with ADHD for every girl. This difference is likely because of higher rates of oppositional defiant disorder and conduct disorder in boys, compared with girls, thus referrals for assessment are higher for boys. Symptoms can persist lifelong for both sexes, but hyperactivity is much less prominent in adolescence and adulthood.⁴⁻⁸

It is critical to clarify the diagnosis of ADHD in individuals with these symptoms. Inattention and distractibility can be symptoms of an anxiety, mood, or psychotic disorder.^{2,3,9} In some cases, other disorders coexist with ADHD; learning deficiencies and conduct or oppositional disorders are common comorbid conditions.^{3,7,9} The presence of multiple comorbid conditions, particularly conduct or mood disorder, can increase the likelihood of ADHD chronicity into adulthood.^{3,6}

Prescriptions for ADHD medication are increasing in all age groups. As of March 2006, two million prescriptions for ADHD were dispensed monthly for children and adolescents in the United States; this compares to one million ADHD prescriptions dispensed to adults. From January to June 2005, methylphenidate was the most prescribed ADHD medication (47%), amphetamine products were second (33.4%), and atomoxetine was the third (16.4%) most prescribed ADHD agent.¹⁰

CLINICAL PRESENTATION OF ADHD

General

- Onset of symptoms must be before 7 years of age

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

Symptoms

- Six or more of the symptoms must be present for 6 months; significant impairment must be seen in two or more settings (e.g., home and school); symptoms must be documented by parent, teacher, and clinician.
- **Inattention**
 - Often fails to give close attention to details or makes careless mistakes in schoolwork or other activities
 - Often has difficulty sustaining attention in activities
 - Often has difficulty organizing tasks and activities
 - Avoids tasks that require sustained mental effort
 - Often does not seem to listen when spoken to directly
 - Often does not follow through on instructions and fails to finish schoolwork, chores, or duties in the workplace
 - Is easily distracted by extraneous stimuli
 - Is often forgetful in daily activities
 - Loses things necessary for activities
- **Hyperactivity and Impulsivity**
 - Often fidgets with hands or feet or squirms in seat
 - Often leaves seat when remaining seated is expected
 - Often runs about or climbs excessively at inappropriate times
 - Often has difficulty playing quietly
 - Often interrupts or intrudes on others

Adapted with permission from reference American Psychiatric Association.¹

ETIOLOGY AND PATHOPHYSIOLOGY

ADHD is a clinical diagnosis with multiple heterogeneous causes.^{4,6,9} Both genetic and nongenetic factors are involved. First-degree relatives of an individual with ADHD have a four- to eightfold increased chance of developing ADHD compared to the general population; monozygotic twins have up to a 90% concordance rate for ADHD.^{6,9,11} Children with fetal alcohol syndrome, lead poisoning, and meningitis have a higher incidence of ADHD symptomatology.^{4,9} ADHD is associated with a variety of environmental risks including obstetric adversity, maternal smoking, and adverse parent-child relationships.^{6,11} Dietary causes are unlikely.^{4,6}

Although brain studies show no definitive pathophysiologic markers of ADHD, the prefrontal cortex, basal ganglia, and caudate volumes are consistently reported as smaller.^{6,12} Individuals with ADHD are twice as likely to display a defective seven-repeat allele of the type 4 dopamine (D₄) receptor gene (DRD4), which has been related to a deficiency in translating the dopaminergic signal to the second messenger system.^{6,13,14} Norepinephrine (NE) and epinephrine are agonists at this receptor as well. A genetic variation in the presynaptic

dopaminergic transport protein, also known as DAT1, has been linked to ADHD risk and to response to methylphenidate and atomoxetine.^{13,14} Clinical implications of these findings are being studied.^{6,14}

A prevailing pathophysiologic explanation for ADHD symptoms involves deficits in prefrontal cortex-mediated executive brain function also known as *response inhibition*. Children with ADHD are unable to control their behavior, resist distractions, and develop an awareness of space and time.^{2,6} A dysregulation of arousal in front subcortical pathways has also been proposed. Children with ADHD display insufficient alertness during dull and repetitive tasks, alternating with overarousal.⁶

Effective treatments modulate dopamine (DA) and norepinephrine (NE) to improve executive functioning and regulate arousal for improved performance. The clinical response associated with stimulants is not paradoxical and is not diagnostic for ADHD because stimulants can increase attention, decrease motor activity, and improve learning tasks in those with subclinical ADHD or in individuals with such problems from other sources (e.g., fatigue).^{4,13}

TREATMENT

Attention-Deficit/Hyperactivity Disorder

■ STIMULANTS

2 3 Stimulants are considered first-line therapy in most cases of ADHD; however, comorbid conditions have an impact on the drug selection process, calling for a careful, systematic approach. Pharmacotherapy should be considered whenever a thorough diagnostic assessment results in a diagnosis of ADHD. Several studies demonstrate the superiority of stimulants compared with behavioral interventions in alleviating core symptoms of ADHD.^{5,15} However, stimulants have not been shown to reliably improve social and academic functioning; therefore multimodal treatment, individualized to the specific needs of the child and family, is crucial for overall positive therapeutic outcome.^{4,16–18} Table 65–1 describes behavioral interventions for ADHD. Multimodal treatment includes parent training, family therapy, classroom interventions, and contingency management (e.g., rewards for good behavior).^{4,17,18} Figure 65–1 provides an algorithm for drug selection in the treatment of ADHD.

Stimulants (e.g., methylphenidate, dextmethylphenidate, mixed amphetamine salts, and dextroamphetamine) are the most effective drug treatment options, with efficacy ranging from 70% to 96% in trials using wide dosage ranges.^{5,16,19}

Despite knowledge of the effects of stimulants on neurotransmitter activity, how these drugs affect the primary symptoms of ADHD is unclear. Methylphenidate and amphetamines block DA and NE reuptake; amphetamines also increase catecholamine release.¹³ Both drugs inhibit monoamine oxidase (MAO), amphetamines, more potently

TABLE 65-1 Behavioral Interventions for ADHD		
Technique	Description	Example
Positive reinforcement	Providing rewards or privileges contingent on the child's performance	Child completes an assignment and is permitted to play on the computer
Time-out	Removing access to positive reinforcement contingent on performance of unwanted or problem behavior	Child hits sibling impulsively and is required to sit for 5 minutes in the corner of the room
Response cost	Withdrawing rewards or privileges contingent on the performance of unwanted or problem behavior	Child loses free-time privileges for not completing homework
Token economy	Combining positive reinforcement and response cost. The child earns rewards and privileges contingent on performing desired behaviors and loses the rewards and privileges based on undesirable behavior.	Child earns stars for completing assignments and loses stars for getting out of seat. The child cashes in the sum of stars at the end of the week for a prize.

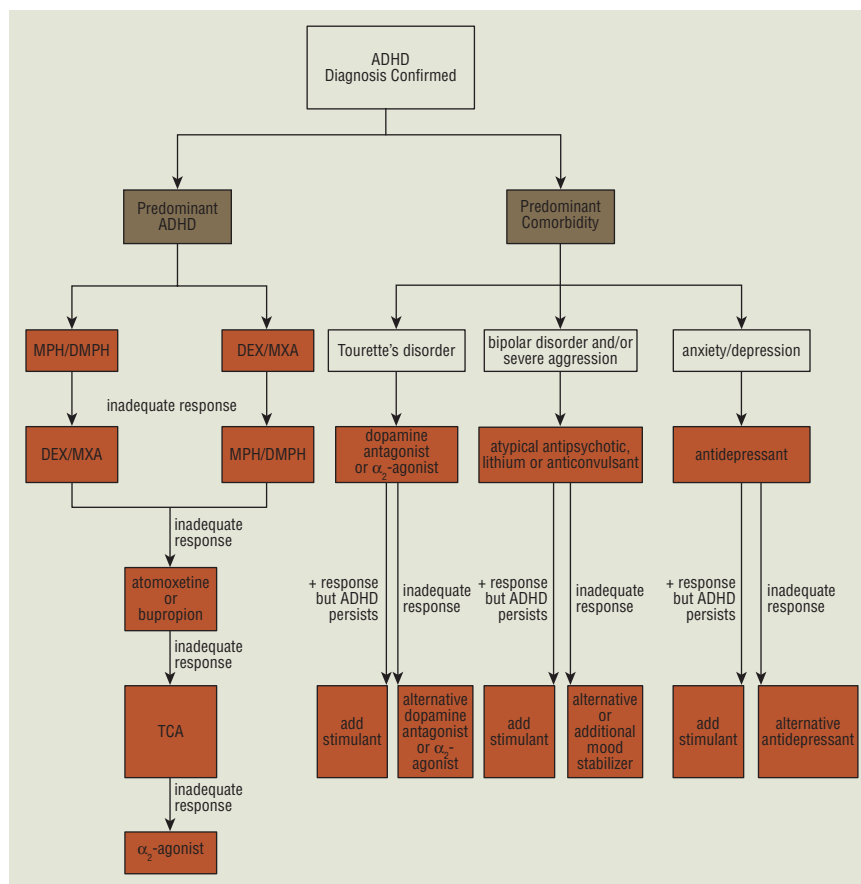

FIGURE 65-1. Algorithm for management of ADHD. Treat predominant disorder first, reassess, and consider alternative or adjunct medications for optimal symptom control. (ADHD, attention-deficit/hyperactivity disorder; DEX, dextroamphetamine; DMPH, dexamethylphenidate; MPH, methylphenidate; MXA, mixed amphetamine salts; TCA, tricyclic antidepressant.) (Data from Prince,⁵ Pliszka et al.,⁷ Lopez,¹⁹ Caballero and Nahata,³⁰ Kowatch and DelBello,³² Dopheide,³⁶ Muller-Vahl,⁴⁵ and Jimenez-Jimenez.⁴⁶)

than methylphenidate.¹³ Because different stimulants work through slightly different mechanisms, lack of response to one chemical class of stimulant (e.g., methylphenidate or dexamethylphenidate) does not preclude response to another class (e.g., dextroamphetamine or mixed amphetamine salts).^{5,7,16}

Stimulant dosing should be titrated for maximum individual efficacy and minimum side effects. Table 65–2 provides initial dose and titration recommendations for stimulants based on manufacturer's recommendations and published guidelines developed by experienced clinicians.^{5,16,20}

With immediate-release stimulants, most patients require a two or three times daily dosing schedule because of the short half-lives of these drugs (2 to 4 hours for methylphenidate and dexamethylphenidate and approximately 4 to 6 hours for dextroamphetamine or mixed amphetamine salts).^{5,15,19} Drug response is maximal during the absorption phase, is evident in 15 to 30 minutes, and lasts 2 to 6 hours.^{5,16,20}

Drug delivery systems of once-daily products (amphetamine aspartate, amphetamine sulfate, dextroamphetamine sulfate, dextroamphetamine saccharate [Adderall XR]; methylphenidate [Concerta]; methylphenidate [Daytrana]; dexamethylphenidate [Focalin XR]; methylphenidate [Metadate CD]; methylphenidate [Ritalin LA]) provide 8 to 12 hours of symptom control.^{5,20} Concerta uses an oral osmotic (OROS) controlled-release delivery system, whereas other oral preparations use combinations of immediate-release and extended-release beads containing the drug.^{5,19} Concerta is a nondeformable tablet, and it should not be given to children with gastrointestinal narrowing because of the risk of obstruction. Methylphenidate transdermal system provides 12 hours of symptom control when worn for 9 hours.²⁰ Older wax-matrix sustained-release products (e.g., Ritalin SR) are less effective and infrequently used.^{5,16} When choosing between immediate-release or once-daily stimulants, the convenience of once-daily dosing must be weighed against the potential for difficulty falling asleep and risk of increased

growth suppression with once-daily or sustained-release products.^{5,9,19,21} Adolescents and adults with ADHD are also responsive to stimulants. Methylphenidate is effective in adults in doses up to 1.3 mg/kg per day.^{16,22} Lisdexamphetamine is a prodrug conjugated to an amino acid that requires cleavage during metabolism to the active dextroamphetamine. It is available in 30, 50, and 70 mg capsules and is intended to pose less abuse potential.²³

ADVERSE EFFECTS

The most common adverse effects of stimulants and their management strategies are listed in Table 65–3. Uncommon to rare but potentially serious adverse effects are discussed below.

Psychiatric

The FDA has added warnings to the labeling of all stimulants and atomoxetine. Hundreds of post-marketing reports of three broad categories of psychiatric adverse events have been associated with stimulants: (1) psychosis or mania, (2) aggression or violent behavior, (3) severe anxiety or panic attacks. All of these reactions require dose reduction or cessation of stimulant therapy and supportive treatment.²⁴

Cardiac

Twenty-five reports of sudden death in children and adults treated with stimulants (17 amphetamine, 8 methylphenidate) were reported to the FDA. Undiscovered structural cardiac defects (thin myocardial wall, valve problems) were found postmortem in 8 of 12 children taking amphetamine and 4 of 7 children taking methylphenidate.^{24,25} The risk of sudden unexplained death per 100,000 children exposed to ADHD medication in 2005 is 0.7 for dextroamphetamine/amphetamine, 1.5 with atomoxetine, and 0.2 with methylphenidate.²⁴ An FDA advisory committee determined the rate was

TABLE 65-2 Stimulant Comparison

Stimulant	Duration of Effect	Initial Dose and Available Strengths	Usual Dosing Range Maximum Dose
Methylphenidate C-II FDA approved for children >6 y old <i>Short-acting</i> Immediate release (IR) Ritalin, Methylin, generics	3–5 hours	5 mg two or three times a day; increase by 5–10 mg/day at weekly intervals; available as: 5, 10, 20 mg	5–20 mg two or three times a day; max dose: 60 mg/day
<i>Intermediate-acting</i> Ritalin SR (sustained-release) Methylphenidate SR Metadate ER (extended-release) Methylin ER	3–8 hours	SR, ER doses; corresponds to the IR dose	20–40 mg every AM or 40 mg every AM and 20 mg in the early afternoon; max dose: 60 mg/day
<i>Long-acting</i> Metadate CD 30% IR beads, 70% ER beads Ritalin LA 50% IR, 50% ER beads Concerta (oral osmotic [OROS] controlled-release delivery) ER inner compartments coated with IR methylphenidate	8–12 hours	20 mg every AM; available as: 10, 20, and 30 mg 20 mg every AM; available as: 20, 30, and 40 mg	20–40 mg every AM and 20 mg in early afternoon; max dose: 60 mg/day 20–60 mg/day, given every AM; max dose: 60 mg/day
Daytrana Methylphenidate transdermal system	12 hours when worn for 9 hours	18 mg every AM; available as 18, 27, 36, and 54 mg; 90% bioavailability of IR 10 mg (12.5 cm ²) applied to clean, dry area on hip each morning and removed after 9 hours	27–72 mg/day, given every AM; max dose: 72 mg/day 10 to 30 mg (12.5 cm ² –37.5 cm ²) Drug active for 3 hours after patch removal
Dexmethylphenidate (Focalin) C-II FDA approved for children ≥6 y old Focalin XR 50% IR, 50% ER beads	3–5 hours 8–12 hours	2.5 mg every AM or twice a day; available as: 2.5, 5, and 10 mg tablets 5 mg every AM; available as 5, 10, 20 mg capsules	5–10 mg/day given twice a day; max initial dose: 7.5 mg/day max dose: 20 mg/day 5–20 mg/day, given every AM max dose: 20 mg/day
Mixed Amphetamine Salts C-II FDA approved for children ≥3 y old <i>Short to intermediate acting</i> Mixed amphetamine generics Adderall <i>Long-acting</i> Adderall XR 50% IR beads, 50% ER beads	4–6 hours 8–12 hours	2.5 mg every AM one to two times daily dosing 10 mg every AM; available as: 10, 20, and 30 mg	10–40 mg/day (divided in two doses) 10–30 mg every AM; max dose: 30 mg/day
Dextroamphetamine C-II FDA approved for children ≥3 y old <i>Short-acting</i> Dextroamphetamine generics Dexedrine, Dextrostat <i>Intermediate-acting</i> Dexedrine Spansule	4–6 hours 3–5 hours 5–8 hours	2.5 mg every AM to two or three times daily dosing 5 mg every AM; available as: 5 and 10 mg Available as: 5-, 10-, and 15-mg spansules	5–15 mg twice a day 10–40 mg/day given twice a day 5–30 mg every day or 5–15 mg twice a day; max: 40 mg/day

C-II, schedule II, the Drug Enforcement Administration label that refers to significant abuse potential.

Data from Prince JB;⁵ Lopez FA;¹⁹ Anderson VR.²⁰

not higher than what would be expected in the general population (0.6–6 cases per 100,000 untreated children), therefore no restriction in use was recommended.^{24,25}

Growth

A review of 29 studies examining stimulant effects on growth found a height deficit of approximately 1 cm/y (0.4 in/y) during the first 1 to 3 years of continuous treatment. Dextroamphetamine studies showed more growth attenuation in the first year than methylphenidate studies or studies that combined both stimulants in a single group.²⁵ A 24-month followup study in 540 children taking methylphenidate showed a 1 cm/y growth deficit, and documented an average loss of 3 kg (6.6 lb) in weight during the first year, with an average 1.2 kg (2.6 lb) decrease in weight during the second year.²⁶ Proposed mechanisms of stimulant effects on growth include alterations in growth hormone or growth factor, decreased thyroxine secretion, and suppression of appetite leading to reduced caloric intake.^{21,27}

In most cases, children should be given a drug-free trial every year. Drug holidays are important because they provide time to reassess treatment.¹⁷ One study showed growth rebound in weight and height occurring over a 3-month period off stimulant, although another

study with shorter duration off stimulant (1 month), reported no growth rebound.^{26,27} Consideration must be given to the risks of negative effects on learning, socialization, and self-image while off-stimulant therapy when determining the frequency and duration of drug holidays. Drug dosage often varies from year to year, largely because of age-related pharmacokinetic changes. As a child develops, hepatic metabolism slows, and volume of distribution increases.

CLINICAL CONTROVERSY

The use of stimulants to treat ADHD in individuals with substance abuse disorders is controversial. A diagnosis of ADHD confers at least a twofold greater risk of adolescent and adult substance abuse.^{2,6,28} The risk is greater if conduct disorder, antisocial personality, or bipolar disorder coexists.^{3,28} **PRO:** Stimulant therapy does not increase the risk of substance abuse, and effective treatment of ADHD can facilitate functioning and reduce substance abuse. **CON:** Regardless of the benefits, there is significant misuse or diversion of stimulant medications among older adolescents and young adults, necessitating vigilance among prescribers and careful risk-versus-benefit assessment.^{28,29}

TABLE 65-3 Stimulant Adverse Effects and Their Management

Adverse Effect	Recommendation/Management Strategy
Common	
Reduced appetite, weight loss	Give high-calorie meal when stimulant effects are low (at breakfast or at bedtime), or consider cyproheptadine at bedtime
Stomach ache	Administer stimulant on a full stomach, lower dose if possible
Insomnia	Give dose earlier in the day; lower the last dose of the day or give it earlier; consider a sedating medication at bedtime (guanfacine, clonidine, melatonin, or cyproheptadine)
Headache	Divide dose; give with food; or give an analgesic (e.g., acetaminophen or ibuprofen)
Rebound symptoms	Consider longer-acting stimulant trial, atomoxetine or antidepressant
Irritability/jitteriness	Assess for comorbid condition (e.g., bipolar disorder); reduce dosage; consider mood stabilizer or atypical antipsychotic
Uncommon to rare	
Dysphoria	Reduce dosage; reassess diagnosis; consider alternative therapy
Zombie-like state	Reduce dosage or change stimulant medication
Tics or abnormal movements	Reduce dosage; consider alternative medication
Hypertension, pulse fluctuations	Reduce dosage; change medication
Hallucinations	Discontinue stimulant; reassess diagnosis; mood stabilizer and/or antipsychotic may be needed

■ NONSTIMULANTS

2 Atomoxetine, a selective norepinephrine reuptake inhibitor, is the first nonstimulant approved by the FDA for the treatment of ADHD. In contrast to the stimulants, it has no abuse potential and is not a controlled substance.³⁰ Placebo-controlled, short-term trials (6 to 12

weeks) have shown that atomoxetine is effective in reducing ADHD symptoms in children, teens, and adults, and 9-month continuation studies show ongoing benefit for responders. However, available evidence shows lower efficacy rates compared to stimulants.^{5,19}

Atomoxetine has a significantly slower onset of therapeutic effect than stimulants (2 to 4 weeks versus 1 hour with an effective stimulant dose). Atomoxetine can be taken once daily by adults or in divided doses in the morning or late afternoon by children.^{7,30} Atomoxetine is sometimes combined with a stimulant in partially responsive patients based on case series describing less late-day rebound effects and better sleep when atomoxetine is given in the evening; however, adverse effects are additive.^{5,7,19} Table 65-4 provides dosing and titration recommendations for all nonstimulant medications.

Bupropion, a monocyclic antidepressant, is a weak DA and NE reuptake inhibitor with no significant direct effect on serotonin or MAO. Its active metabolites augment noradrenergic and dopaminergic function. Investigations with bupropion in children demonstrated efficacy greater than placebo in two controlled trials and efficacy comparable with methylphenidate ($n = 15$ children) in another controlled trial.¹⁹ Advantages of bupropion include less toxicity on overdose compared with TCAs and less appetite suppression compared with stimulants. Bupropion also may be effective in adults at antidepressant doses.^{5,7,17}

Atomoxetine and bupropion are second-line alternatives to the stimulants for treatment of ADHD in children, teens, and adults. Their potential benefits relative to stimulants include reduced risk of abuse and lower potential for sleep disturbance. TCAs are third-line agents because they are the most dangerous in overdose and pose the greatest risk for cardiovascular side effects.^{7,17} Imipramine and desipramine are the most systematically studied TCAs in the treatment of ADHD, although nortriptyline is also effective.^{7,17,19} The onset of TCA clinical response occurs within the first 2 to 4 weeks.^{7,17}

Variability in dosage requirements for atomoxetine, bupropion, and TCAs can be due to interpatient variability in drug plasma concentration achieved at a given dose. All are metabolized via

TABLE 65-4 Dosing and Adverse Effect Monitoring of Nonstimulant Drugs for ADHD

Drug	Dosing Range and Titration Schedule	Adverse Effect Monitoring
Antidepressants		
Atomoxetine (Strattera)	≤70 kg: start at 0.3 to 0.5 mg/kg every AM or twice a day; max: 1.4 mg/kg per day; ≥70 kg: start at 40 mg every AM or twice a day; max: 100 mg/day	Nausea, anorexia, ↑ blood pressure, ↑ pulse, insomnia, fatigue, sedation, severe liver injury, suicidality
Bupropion (Wellbutrin, SR, XL)	50–300 mg/day; 3 mg/kg per day by end of week one; can increase to 6 mg/kg per day or maximum of 300 mg/day as tolerated	Nausea, insomnia, rash, tics; dose-related risk of seizures
Tricyclic antidepressants: imipramine, desipramine or nortriptyline	50–150 mg/day; start at 0.5–1 mg/kg per day; increase as tolerated to 2–3 mg/kg per day; max: 300 mg/day of desipramine (adults only) or 150 mg/day nortriptyline	Sedation, dizziness, constipation, heart block (check ECG), weight gain, overdose toxicity, rapid heartbeat
Antipsychotics		
Aripiprazole ^a (Abilify)	2–5 mg daily; can titrate weekly as tolerated to response (usual range: 5–20 mg/day)	Nausea, restlessness, insomnia extrapyramidal symptoms, dizziness, sedation
Haloperidol ^a (Haldol)	0.5–1 mg twice daily; can titrate every 3–4 days as tolerated to response (usual range: 0.5–5 mg/day)	Extrapyramidal symptoms, dizziness, ↑ prolactin, sedation
Olanzapine ^a (Zyprexa)	2.5–5 mg every day; can titrate every 3–4 days as tolerated to response (usual range: 7.5–15 mg/day)	Sedation, weight gain, restlessness, extrapyramidal symptoms diabetes, hyperlipidemia
Quetiapine ^a (Seroquel)	25–50 mg twice daily; can titrate every 3–4 days as tolerated to response (usual range: 200–600 mg/day)	Sedation, dizziness, weight gain, diabetes, hyperlipidemia
Risperidone ^a (Risperdal)	0.25–0.5 mg twice daily; can titrate every 3–4 days as tolerated to response, (1–4 mg/day)	Extrapyramidal symptoms, dizziness, ↑ prolactin, hepatotoxicity, weight gain
Ziprasidone ^a (Geodon)	10–20 mg twice daily; can titrate every 3–4 days as tolerated to response (usual range: 40–120 mg/day)	Diabetes, hyperlipidemia
Other		
Clonidine (Catapres)	0.05 mg two or four times daily; can increase as tolerated to 0.1–0.4 mg/day	Nausea, restlessness, insomnia extrapyramidal symptoms, sedation, QTc prolongation
Guanfacine (Tenex)	0.5 once to twice a day; can increase as tolerated to 1–4 mg/day	Sedation, dizziness, heart block (check ECG), constipation
		Same as above with potentially lower risk of sedation

ADHD, attention-deficit/hyperactivity disorder; ECG, electrocardiogram.

^aShort-term use (1–4 months) only for severe aggression associated with ADHD.

Data from Shur et al.,³³ Pappadopulus et al.,³⁴ and Correll et al.³⁵

cytochrome P450 (CYP)2D6, and bioavailability and half-life can be 4 to 8 times greater in those taking a CYP2D6 inhibitor (e.g., bupropion, fluoxetine, or paroxetine) or in poor metabolizers. For example, atomoxetine's half-life is 5 hours in extensive metabolizers and 19 hours in poor metabolizers.^{7,30} Atomoxetine and bupropion are metabolized faster in prepubertal children and twice daily dosing is optimal (even for bupropion sustained release [SR]).⁷ Once daily dosing is possible for most adolescents and adults. If tolerance develops after months of therapy, a dosage adjustment can be necessary to compensate for age-related changes in distribution and metabolism.

2 Clonidine and guanfacine are less effective alternatives to stimulant, atomoxetine, or bupropion monotherapy. They are prescribed more frequently as adjuncts to reduce disruptive behavior, control aggression, or to improve sleep.^{7,19} Clonidine and guanfacine are central α_2 -adrenergic agonists, acting both presynaptically to inhibit NE release and post-synaptically to increase blood flow in the prefrontal cortex. Increased blood flow in the prefrontal cortex has been shown to enhance working memory and executive functioning. Both interact with a multitude of neurotransmitter systems including catecholamine, indolamine, cholinergic, α_2 -receptors on parasympathetic neurons, opioid, imidazole, and amino acid systems.¹³ Guanfacine has a longer elimination half-life (12 to 18 hours) compared with clonidine (2.5 to 4 hours), and its greater selectivity for the α_{2a} -receptor, compared to clonidine, imparts less sedation.^{5,31}

3 Lithium and anticonvulsants are used increasingly to control aggression and explosive behavior in patients with a diagnosis of ADHD. Some patients actually can have childhood-onset bipolar disorder or combined ADHD-bipolar disorder.^{7,32} Lithium, valproate, and carbamazepine are effective for explosive behavior, aggression, and impulsivity, but they are not beneficial treatments for a child with the inattentive subtype of ADHD. Dosing starts in low divided doses with titration over 1 to 2 weeks to therapeutic response.^{7,32}

Conventional antipsychotics improve symptoms of hyperactivity and impulsivity but can have negative effects on learning and cognitive functioning as well as extrapyramidal side effects (e.g., dystonia and tardive dyskinesia) that limit their usefulness.⁷ The atypical antipsychotics: risperidone, olanzapine, quetiapine, ziprasidone, and aripiprazole have been used to control severe aggression in refractory cases of ADHD, particularly if conduct disorder or bipolar disorder coexists. More studies are needed to clarify their place in therapy.^{7,33–35}

If multiple drugs are started simultaneously, it is impossible to determine the impact of each drug. The predominance and urgency of symptoms guide the drug-selection process (see Fig. 65–1). For example, if a child presents as severely anxious or depressed with associated attentional problems, then an antidepressant should be initiated first with monitoring to determine if attentional symptoms improve.^{7,9,32,36} When a child presents with severe ADHD and associated anxiety or depression, a stimulant should be initiated to treat the more severe ADHD. If ADHD symptoms improve significantly but anxiety or depression persists, then an antidepressant can be added.^{7,36} Careful monitoring is needed to detect drug interactions that lead to higher drug plasma levels and increased adverse effects.^{7,36} Studies show that stimulants do not routinely make anxiety disorders worse, but they might not improve symptoms either.^{7,16,17} In children with epilepsy, methylphenidate is safe and effective; however, the child should be stabilized and seizure-free on an anticonvulsant prior to initiation of the stimulant.³⁷

The monoamine oxidase inhibitor (MAOI), tranylcypromine is effective but used infrequently because of the potential for dangerous drug and dietary interactions.^{5,13} Selegiline is a MAOI-B selective agent, which has demonstrated comparable efficacy to methylphenidate in small placebo-controlled trials. Dangerous drug and dietary interactions are less likely compared to tranylcypromine.

The risks of MAOIs outweigh benefits in children because they are unlikely to remember to adhere to dietary restrictions.⁵

Adverse Effects

Possible atomoxetine adverse effects and their management are similar to those of stimulants including psychiatric and cardiac adverse effects (see Table 65–4). Atomoxetine has been associated with less growth suppression compared to stimulants, 0.44 cm (0.17 in) over 2 years of treatment. It has a greater risk of fatigue, sedation, and dizziness compared to stimulants and bupropion. Unlike stimulants, atomoxetine labeling includes a bolded warning of potential for severe liver injury following reports in two patients. Also, it is the only FDA-approved ADHD medication with a labeled warning for new onset suicidality, 0.4% in atomoxetine treated patients versus 0% in patients receiving placebo.^{7,19,24}

Bupropion's adverse effects include nausea, which can resolve over time or with slower dosage titration, and rash, which can require discontinuation of therapy if severe (see Table 65–4). Bupropion should not be used in children with a seizure disorder or eating disorder because of unacceptable risk of seizures in these patients. Bupropion can cause or exacerbate tics.^{5,7}

Possible central nervous system (CNS) adverse effects of TCAs include dizziness, aggressiveness, excitement, nightmares, insomnia, forgetfulness, and irritability. Similar to other antidepressants, TCAs carry a warning of the risk of new-onset suicidality in pediatric patients.³⁵ TCAs should be taken throughout the week and not just on school days. TCA-withdrawal effects are severe in children and include nausea, vomiting, and diarrhea.³⁶ Signs of CNS toxicity are confusion, impaired concentration, hallucinations, and delusions.

The most common side effects of clonidine and guanfacine are dose-dependent sedation, hypotension, and constipation.¹⁹ Sedation usually subsides after 2 to 3 weeks of therapy.^{7,39} Of concern are reports of bradycardia, syncope, rebound hypertension, heart block, and sudden death.^{7,40} Four children have died on the combination of methylphenidate and clonidine; however, complicating factors make it impossible to link the drug combination directly with the cause of death.⁴⁰ Overdoses, concurrent clonidine and stimulant administration, as well as missed doses of clonidine all add to the risk of adverse cardiovascular events.^{39,40} Similar adverse-effect concerns apply to treatment with guanfacine.¹⁹

PHARMACOECONOMIC CONSIDERATIONS

A study comparing medical care use and costs between persons with and without ADHD over 9 years found that the median cost for a person with ADHD was more than double (\$4,306 vs. \$1,944; $P < 0.001$) that of someone without ADHD. Increased costs are attributed to accidental injuries, diagnostic assessments, hospital visits, and outpatient visits.⁴¹ The cost-effectiveness of drug treatment has not been assessed. Immediate-release generic methylphenidate, dextroamphetamine, and mixed amphetamine salts appear to provide the most effective and economic therapy because of relatively low drug cost. The cost of once-daily Concerta, Ritalin LA, Metadate CD, Adderall XR, Daytrana, and atomoxetine (Strattera) is approximately 2 to 4 times that of an immediate-release generic stimulant. A retrospective analysis comparing immediate-release methylphenidate use patterns with OROS methylphenidate use patterns in 5,939 patients over 34 months found that OROS methylphenidate use was associated with longer treatment periods, increased patient adherence, and fewer emergency room visits for injury, potentially decreasing overall costs.⁴²

Generic bupropion is the least expensive nonstimulant treatment. Imipramine, desipramine, clonidine, and mood stabilizers are relatively inexpensive, but ongoing electrocardiographic and blood-level monitoring can increase costs significantly.^{7,41}

EVALUATION OF THERAPEUTIC OUTCOMES

Careful documentation of baseline symptoms and complaints over a 1-month predrug period is essential to the evaluation of therapeutic and adverse outcomes. Investigation regarding family history of psychiatric disorders and cardiac disease is essential to determine risk for related adverse drug reactions and to implement appropriate monitoring.⁷ Baseline symptoms can be measured using videotapes, clinician rating scales (e.g., Child Behavioral Checklist or ADHD Rating Scale-IV), or both.⁴³ In addition, height, weight, and eating and sleeping patterns should be recorded at baseline and every 3 months.⁷

After the initiation and titration of any drug treatment, it is necessary that parents, teachers, and clinicians assess the overall functioning of the child using standardized rating scales to determine if significant therapeutic benefit justifies continuing medication.^{7,17,43} Therapeutic effects of the stimulants include decreased motor activity and impulsivity and increased attention span.^{13,15,17} This suggests that stimulants are indicated for ADHD symptoms and not for primary learning disorders. The benefits of drug therapy must outweigh the potential for adverse effects.^{7,19}

Atomoxetine and bupropion also require monitoring to detect changes in appetite, weight, and sleep patterns, as well as pulse or blood pressure. An adequate trial of atomoxetine or bupropion consists of 6 weeks at maximum tolerated doses unless response occurs at a lower dose.^{5,19,30}

When clonidine or guanfacine are given, careful clinical monitoring for fatigue, dizziness, and autonomic changes (e.g., blood pressure and pulse) is recommended.¹⁹ The American Heart Association has stated that electrocardiographic monitoring is not required for clonidine treatment in children, although many clinicians continue to assess for electrocardiogram changes.⁴⁰ When discontinuing treatment, clonidine and guanfacine should be withdrawn slowly (0.05 mg clonidine/0.5 mg guanfacine reductions every 3 days) to prevent rebound hypertension or behavioral dyscontrol.¹⁹ A therapeutic trial requires 1 to 2 months to assess therapeutic response, although increased sleep usually occurs immediately.

The effects of TCAs on the electrocardiogram should be monitored carefully. Of more concern are reports of sudden death in children taking desipramine or imipramine.^{7,36} Children and adolescents given TCAs should have pretreatment and followup electrocardiograms to assess the effects of TCA therapy on cardiac rate and rhythm.^{7,36}

CONCLUSION

The preferred first-line drug therapy for ADHD is either methylphenidate, dexamethylphenidate, mixed amphetamine salts, or dextroamphetamine. Atomoxetine or bupropion are good options for those unresponsive to or unable to tolerate stimulants. TCAs are third-line options, and α_2 -agonists are fourth-line or can be used as adjuncts to stimulants. All agents require careful cardiovascular monitoring. Mood stabilizers (e.g., lithium, divalproex, and carbamazepine) and atypical antipsychotics are adjuncts for control of aggression or comorbid bipolar disorder. Other agents require further investigation before their status in the treatment of ADHD can be fully determined.

TOURETTE'S DISORDER

EPIDEMIOLOGY AND CLINICAL PRESENTATION

Once considered rare, Tourette's disorder is present in 0.7% to 1.1% of boys and 0.4% of girls.^{44,45} The essential features of this

CNS disorder are multiple motor and vocal tics that must be present for more than 1 year before the diagnosis of Tourette's disorder is made. A tic is a sudden, rapid, recurrent, nonrhythmic, stereotyped motor movement or vocalization.^{44,45} The clinical presentation can vary from barely noticeable to debilitating, and the type of tic expressed can change over time.^{1,44,45} The median age of onset of motor tics is 6 years, with an average delay in diagnosis of 6.8 years.^{1,44,45}

4 Transient tic disorder is diagnosed if motor or vocal tics occur for less than 1 year, with chronic tic disorder diagnosed if motor or vocal tics are present for longer than 1 year.^{1,44} Tics are most prominent during childhood and can plateau or attenuate during adolescence. The early 20s frequently bring stabilization of symptoms, although exacerbations occur during adulthood with characteristic fluctuating symptom severity.^{1,44,45}

More than 90% of children with Tourette's disorder have coexisting conditions such as ADHD (75%), mood disorders (60%), obsessive-compulsive disorder (40%), other anxiety disorders, or a combination of comorbidities. Tourette's disorder itself does not cause diminished intellectual functioning; however, the severity of tics and associated illnesses can result in significant impairment in school functioning, sometimes necessitating special education classes.⁴⁴⁻⁴⁶

CLINICAL PRESENTATION OF TOURETTE'S DISORDER

General

- Onset occurs before 18 years of age

Symptoms

- Multiple motor or one or more vocal tics are present.
- Motor and vocal tics do not need to occur concurrently.
- Tics occur many times a day (usually in bouts) nearly every day or intermittently throughout a period of more than 1 year; during this period there is never a tic-free period of more than 3 consecutive months.

Motor Tics

- Eye blinking, lip licking
- Facial twitching
- Shoulder shrugging
- Squatting, twirling

Vocal Tics

- Clicks, grunts
- Barking, yelping
- Throat clearing, echolalia
- Coprolalia, palilalia

Data from American Psychiatric Association¹ with permission.

ETIOLOGY AND PATHOPHYSIOLOGY

Tourette's disorder is inherited in a complex polygenic pattern. Symptoms and severity of the disorder vary from one generation to another.⁴⁴⁻⁴⁶ The neurochemical pathophysiology involves an imbalance in the interaction of dopaminergic, serotonergic, γ -aminobutyric acid (GABA)-ergic, glutamatergic, cholinergic, noradrenergic, and opioid systems in multiple brain regions, most notably the basal ganglia and caudate nucleus. The imbalance can cause a lack of regulation of the brain's inhibitory mechanisms, resulting in tics and associated behavior disorders. This multisystem etiology best explains the success of a variety of treatments.⁴⁴⁻⁴⁶

TREATMENT

Tourette's Disorder

5 Whenever symptoms are severe enough to impair the child's ability to function, drug therapy should be initiated. Psychotherapy and behavioral treatment are useful adjuncts.^{44–46}

CLINICAL CONTROVERSY

The decision to treat Tourette's disorder with a dopamine type 2 (D_2) receptor antagonist (atypical or conventional) rather than an α_2 -agonist is controversial and can be challenging. The choice is usually based on whether high efficacy (D_2 antagonist) or milder adverse effect burden (α_2 -agonist) is more desirable in an individual patient.^{7,44–46}

Clonidine is the most widely prescribed treatment for Tourette's disorder, according to an international database of 3,500 cases, but its efficacy is not robust, and it is not more effective than DA antagonists.^{45,46} In some patients, the response is limited to improvement in attention and behavior with no changes in the frequency of tics. A clonidine trial should be initiated carefully, usually 0.025 to 0.05 mg given in the morning or divided two to three times daily with gradual titration every 4 to 7 days to the usual therapeutic dose of 0.15 to 0.25 mg/day (maximum 0.6 mg/day).^{44–46} Doses usually are divided during maintenance therapy for more continuous symptom control and to minimize adverse effects. Case reports describe a positive response from the clonidine patch as well. The onset of therapeutic effects for both tablet and patch is slow, ranging from 2 weeks to a few months.^{45,46}

Expert consensus and evidence-based treatment guidelines recommend a trial of atypical antipsychotic before considering the FDA-approved agents, haloperidol or pimozide because of established efficacy (e.g., risperidone) and a lower risk of extrapyramidal side effects.^{21,35,46}

Risperidone was significantly more effective than placebo in decreasing motor and vocal tic severity in two controlled trials.^{47,48} In parallel comparison trials, risperidone was found to be as effective as pimozide or clonidine. The dose of risperidone in these trials ranged from 0.6–6 mg/day.^{47–50} Ziprasidone showed significant efficacy versus placebo in a controlled study at an average dose of 30 mg/day titrated from a starting dose of 5 mg/day.^{51,52} An open trial with olanzapine at a mean dose of 10.9 mg/day showed a 50% reduction in global tic severity.⁵³ One open-label trial and two case reports describe positive therapeutic effects of quetiapine.⁵⁴ Aripiprazole has shown modest to robust efficacy in case series and case reports. Clozapine, a 5-hydroxytryptamine 2 (5-HT₂) antagonist with minimal dopamine type 1 (D_1)-blocking and no significant D_2 -blocking effects, was found to be ineffective with worsening of symptoms in some Tourette's patients.^{45,46}

Therapy with haloperidol or pimozide should be initiated at very low doses of 0.25 to 0.5 mg/day given at bedtime and then increased gradually. Gradual titration over 2 to 3 weeks helps minimize extrapyramidal and sedative effects while permitting careful assessment of response. Symptoms can regress within 48 to 72 hours after an effective dose is reached. Doses less than 5 mg/day are effective in controlling tics for most patients, but occasionally up to 10 or 20 mg/day are required.^{45,46} Pimozide is approximately half as potent as haloperidol, and it is considered comparable or possibly superior to haloperidol in efficacy when equivalent doses are used.^{44,45}

COMORBIDITY

Pharmacotherapy of Tourette's disorder is challenging because of the common occurrence of coexisting disorders typically requiring

medication combinations. Often the behavioral problems precede and are more disturbing than the involuntary movements, making them a treatment priority.

TOURETTE'S AND ADHD

Pharmacotherapy with stimulants increases dopaminergic and noradrenergic activity, which has the potential to aggravate or precipitate tics, although one study in 19 children over 2 years showed no worsening of tics on methylphenidate.⁵⁵ A study examined the comparative effects of methylphenidate and dextroamphetamine on tics in children and found the majority experienced improvement in ADHD symptoms with acceptable effects on tics.^{45,47} Methylphenidate was better tolerated than dextroamphetamine.

A double-blind, placebo-controlled trial compared methylphenidate or clonidine monotherapy to combination methylphenidate and clonidine in patients with ADHD and Tourette's disorder. Combination therapy demonstrated the greatest benefit in reducing symptoms of ADHD and tics ($P < 0.0001$).⁵⁶ Clonidine appeared most helpful for impulsivity and hyperactivity, whereas methylphenidate was most helpful for inattention. All treatments were well tolerated. Patients and caregivers should be aware of the risks of using stimulants in children with Tourette's disorder (see ADHD section); careful monitoring is essential.^{45,46,56}

Controlled trials of TCA therapy for comorbid ADHD and chronic tics or Tourette's disorder show significant improvement in inattentive and hyperactive/impulsive symptoms without worsening of tics.⁵⁷ In one study, both tics and symptoms of ADHD improved.⁵⁷ TCAs offer an alternative to clonidine or combined clonidine/methylphenidate therapy that can be more effective for some patients.

Clonidine or guanfacine alone are less effective alternatives to stimulants in the treatment of children with Tourette's disorder and ADHD. Guanfacine was administered to 34 children (mean age 10.4 years), with ADHD and tic disorder during an 8-week placebo-controlled trial at a dose of 1.5 to 3 mg/day. Tic severity decreased by 31% in the guanfacine group compared to 0% in the placebo group.^{31,46} There was a mean improvement of 37% on the teacher-rated ADHD scale compared to 8% improvement with placebo. Because of its similarity to clonidine, guanfacine's cardiovascular effects warrant careful clinical monitoring.^{19,40,46}

TOURETTE'S AND ANXIETY OR MOOD DISORDERS

Therapeutic trials (6 to 12 weeks) of an SSRI or clomipramine should be added to tic-specific therapy when obsessive-compulsive, anxiety, or depressive symptoms cause functional impairment in patients with Tourette's disorder.^{45,46} Careful monitoring for behavioral activation, disinhibition, and motor restlessness is essential during SSRI or clomipramine therapy, because these symptoms can indicate increased risk for suicidal behavior or a switch to mania requiring drug discontinuation.^{36,44,45}

ADJUNCTIVE OR ALTERNATIVE TREATMENTS

For those who are unresponsive, partially responsive, or unable to tolerate DA antagonists or α_2 -agonists, there are several adjuncts or alternative treatments available. A small controlled study ($n = 27$) showed metoclopramide (5–40 mg/day) improved symptoms in children and adolescents with tic disorder.⁵⁸ Another study demonstrated effectiveness and tolerability of ondansetron (8–24 mg/day) in 30 patients (ages 12 to 46 years) with Tourette's disorder.⁵⁹

Nicotine administration by gum or patch can potentiate the effects of dopamine-blocking agents in relieving tics, according to small controlled trials.^{44,45,60} ADHD symptoms can improve as well.^{45,60} The

long-term adverse effects of nicotine on overall health can limit usefulness.⁶⁰ Clonazepam, selegiline, or baclofen appear to offer promise in relieving tics and associated symptoms.^{44–46} Opioid agonists or antagonists are not effective. Botulinum toxin requires further study.^{44–46} Nonpharmacologic interventions include support groups, “habit-reversal therapy,” and even neurosurgery.^{44,45,61}

■ ADVERSE EFFECTS

For clonidine and guanfacine, the most common adverse effect is sedation. Fortunately, tolerance usually develops to this effect over days to weeks. The most potentially serious side effects are cardiovascular (see the ADHD section).^{19,40} Other α_2 -agonist side effects include dry mouth, constipation, headache, mood changes, and even a temporary worsening of tics in approximately 10% of patients.

Atypical antipsychotics (e.g., risperidone, olanzapine, quetiapine, ziprasidone, and aripiprazole) pose similar adverse effect risks in children and adolescents compared to adults (see Table 65–4).^{33,35,45,46} Available data show that children and adolescents are at higher risk for experiencing sedation, acute extrapyramidal side effects, hyperprolactinemia, withdrawal dyskinesia, and significant weight gain during treatment compared to adults. Risperidone is associated with more weight gain in youths compared to adults, and ziprasidone and aripiprazole do not seem to be as “weight neutral” in pediatric populations as in adults.^{21,35} Children taking quetiapine have shown a decrease in serum total thyroxine (T_4), although thyroid-stimulating hormone (TSH) and T_4 levels are normal suggesting a euthyroid status.^{21,35} Ziprasidone carries a risk of QTc prolongation in youth, although torsade de pointes has not been reported, and the clinical significance requires further study.^{21,33,35,51}

6 Adverse effects have been reported with haloperidol doses of 2 mg/day or greater. In one review of 24 patients treated with haloperidol for Tourette’s disorder, 66.7% discontinued treatment because of intolerable side effects (e.g., dysphoria, akathisia, nervousness, sedation, dystonia, and cognitive dulling or feeling drugged).⁶² Lowering the dose can alleviate side effects. An antiparkinsonian agent such as benztropine (at a starting dose of 0.5 mg orally twice daily) sometimes will reverse extrapyramidal side effects. Whether a patient with Tourette’s disorder is developing a new tic or tardive dyskinesia can be difficult to determine. Dosage titration of the medication and careful monitoring will assist in this clinical decision-making process.^{45,46}

Pimozide is less likely to cause extrapyramidal side effects compared to haloperidol. Anticholinergic side effects can occur in addition to drowsiness, and occasionally, anxiety will occur. Electrocardiographic changes, including T- and U-wave abnormalities and prolongation of the QTc interval, are found rarely with recommended therapeutic doses for Tourette’s disorder; however, drugs that inhibit CYP3A4 (e.g., clarithromycin or fluoxetine) should not be combined with pimozide because of the risk of excessively elevating pimozide blood levels, which can result in lethal QTc prolongation.^{7,45,46}

PHARMACOECONOMIC CONSIDERATIONS

No pharmacoeconomic studies have been published on Tourette’s disorder. Haloperidol provides the most economic drug therapy because of high efficacy and low drug cost. Pimozide and atypical antipsychotics are more expensive than generic haloperidol. Although generic clonidine is inexpensive, delayed onset of effect and significantly lower efficacy substantially increase total costs of treatment.

EVALUATION OF THERAPEUTIC OUTCOMES

Evaluating therapeutic interventions is challenging, as most patients can suppress their tics voluntarily for minutes to hours.^{44,45} Also

numerous factors such as stress, concentration, and relaxation can impact tic frequency and severity. The use of regular videotaped assessments in conjunction with standardized rating scales (Yale Global Tic Severity Scale) is helpful in objectively evaluating symptoms, side effects, and overall drug response.^{44–46}

6 Individuals with Tourette’s disorder are particularly sensitive to medication side effects, so medication dosing must be individualized with low starting doses and careful weekly titration to response, realizing that it can take 1 to 2 months for an adequate therapeutic trial. Children taking any dopamine-blocking medication should receive monitoring every 3 to 6 months for extrapyramidal effects with a standardized rating scale (e.g., Abnormal Involuntary Movement Scale [AIMS]).^{33–35} Patients given pimozide or ziprasidone should receive baseline and followup electrocardiograms.^{45,46} Additional monitoring recommendations for individuals receiving atypical antipsychotics include height, weight, body mass index (BMI), level of sedation, appetite, exercise habits, blood pressure, pulse, glucose, and lipids monthly for 3 months and every 3 months, thereafter. Morning prolactin and TSH are recommended annually or if clinical signs and symptoms warrant assessment.³⁵ Adult patients with Tourette’s disorder still can be responsive to drug treatments that were effective during childhood, although the dose and schedule can require adjustment.^{44–46}

CONCLUSION

Haloperidol, pimozide, and risperidone have the advantage of greatest efficacy and rapid onset in the treatment of Tourette’s disorder. Ziprasidone, olanzapine, quetiapine, and aripiprazole show promise; however, comparison studies with haloperidol, pimozide, or risperidone are needed to determine their relative safety and efficacy. Clonidine and guanfacine have the advantage of no extrapyramidal side effects, but they are significantly less effective and require ongoing cardiovascular monitoring. Drug treatment must be highly individualized, considering comorbid disorders, side-effect sensitivity, and drug interactions.

ENURESIS

ETIOLOGY, PATHOPHYSIOLOGY, AND CLINICAL PRESENTATION

The essential feature of enuresis is repeated involuntary or intentional voiding of urine by day or night that is not caused by a general medical condition.¹ Medical causes of inappropriate voiding (e.g., diabetes mellitus, diabetes insipidus, seizure disorders, or urinary tract infections) should be ruled out. Enuresis can be primary or secondary. Primary enuresis, the most common type, is diagnosed if the child has never established urinary continence. Secondary enuresis follows an established period (3 to 6 months) of urinary continence.

Enuresis occurs in 12% to 25 % of 4 year olds, 7% to 10% of 8 year olds, and 2% to 3% of 12 year olds with 1% to 3% continuing to experience enuresis in late teenage years.⁶³ After age 5 years, there is a 15% annual rate of spontaneous remission. The ratio of males to females with enuresis is 2:1.⁶³ Factors that predispose a child to either type of enuresis include a positive family history, institutionalization, low socioeconomic status, reduced functional bladder capacity, delayed or lax toilet training, constipation, psychologic factors, and developmental delay.⁶³ Some children with nocturnal enuresis lack the normal circadian variation in urine excretion rate, urine osmolality, and antidiuretic hormone (ADH) secretion. Nocturnal enuresis is not associated with a particular sleep stage, although children with enuresis can be more difficult to arouse.⁶³

CLINICAL PRESENTATION OF ENURESIS

General

- Patients are 5 years old or older

Symptoms

- Repeatedly voids urine into bed and/or clothes involuntarily or intentionally.
- There is either a frequency of twice weekly for at least 3 consecutive months or the presence of clinically significant distress or impairment in social, academic (occupational), or other area of functioning.

Data from American Psychiatric Association¹ with permission.

TREATMENT

Enuresis

The first step in treating a child with enuresis is to educate the family about the high frequency of the problem, dispel any misconceptions, provide emotional support, and strongly discourage punishment.

7 Teaching continence skills and various behavioral and conditioning methods remain the primary treatments for enuresis, and drug treatment remains a secondary approach.^{63–65} Simple behavioral and physical interventions such as rewarding dry nights, or lifting and waking are often used initially to control nocturnal enuresis and have been shown to work better than no treatment in reducing wet nights without any side effects or safety concerns.^{63–65} Complex interventions, such as dry-bed training and full-spectrum home training, in combination with bedwetting alarms can be tried but require time and effort. There is insufficient evidence to support complex interventions without an alarm. After 3 to 4 months of using a bed-wetting alarm, enuresis is cured in two-thirds of children.^{63–65}

Alarms are more effective than pharmacotherapy with longer lasting results, although medications work faster, within 2 weeks. Combining medications and alarms has been tried with mixed results.^{63–65} Desmopressin tablets are preferred to tricyclic antidepressants (e.g., imipramine) because of lower toxicity risk.^{66,67} Oxybutynin or tolterodine may be effective adjuncts to desmopressin in partial responders.^{66–69}

■ DESMOPRESSIN

8 Desmopressin acetate, a synthetic analog of the natural human ADH arginine vasopressin, is currently available in a nasal spray, which is no longer recommended, and a more widely used oral tablet for the treatment of nocturnal enuresis.⁶³ A rapid dissolve tablet is under study.⁷⁰ Desmopressin increases overnight urinary osmotic concentration by increasing water reabsorption and reducing the volume of urine entering the bladder.^{67,68} Desmopressin is effective in reducing the number of wet nights in 10% to 65% of children in 1 to 2 weeks, however, up to 80% relapse on discontinuation.^{63,66}

In a 6-month, randomized, controlled trial comparing desmopressin (200–400 mcg), imipramine (25 mg), and combination desmopressin (200 mcg) and oxybutynin (5 mg) in 145 enuretic children, (mean age 7.8 years), the combination produced the most rapid results, although the number of wet nights per month at 6 months was similar in the combination desmopressin/oxybutynin group (3.7 ± 5.4) compared to the desmopressin monotherapy group (4.0 ± 4.6). Both treatments were superior to imipramine (9.3 ± 8.3). The mean number of wet nights during the 2-week baseline period in all groups was 13. Tolerability was superior in the desmopressin groups compared to the imipramine group.⁶⁸

Intranasal desmopressin should not be used due to an unacceptable risk of hyponatremia that may cause seizures. Only the tablet form is FDA approved for primary nocturnal enuresis. For children 6 years of age or older, desmopressin tablet can be initiated at 200 mcg at bedtime. Approximately 1% of oral desmopressin is absorbed. Plasma concentrations reach a maximum approximately 45 minutes after administration. Effective dosages range from 200–600 mcg/day of oral desmopressin. The duration of action varies from 10–20 hours, and there is compensatory polyuria the following day when the drug wears off.^{63,66}

■ TRICYCLIC ANTIDEPRESSANTS

8 Imipramine is the most studied TCA, although desipramine, amitriptyline, and nortriptyline are also effective. Imipramine is effective 40% to 60% of the time.^{63,71} The mechanism of action of TCAs in treating enuresis is unknown.⁶³ For children 6 years of age and older, the usual starting dose is 25 mg given 30 minutes before bedtime. Doses can be increased by 25 mg weekly until response is achieved. The usual effective dosing range is 1 to 2.5 mg/kg/night, and doses should not exceed 2.5 mg/kg/night. Most children respond within the first week.⁶³

■ ADVERSE EFFECTS

Desmopressin tablets can cause transient headache, chills, dizziness, nausea, and abdominal pain. Rarely, water intoxication, hyponatremia, and subsequent tonic-clonic seizures have been reported.⁶⁶ From 1972 to 2005, there were 151 post-marketing reports of hyponatremia in children with nocturnal enuresis, of whom 145 were treated with intranasal desmopressin and 6 received tablets. When desmopressin is administered, evening fluids should be restricted one hour before and for 8 hours after drug administration. Desmopressin tablets should be stopped during acute illnesses that may lead to fluid or electrolyte imbalance. Prompt medical assessment is needed if headache, nausea, or vomiting develops, as these could be signs of hyponatremia. Concomitant medications that may lower sodium (e.g., antidepressants, oxcarbazepine) or illnesses that change hydration status (e.g., the flu) can increase the risk of hyponatremia.^{63,66}

TCA adverse effects are dose related and include sedation, dizziness, dry mouth, constipation, weight gain, and the risk of electrocardiographic changes, heart block, and lowering of the seizure threshold.³⁶

PHARMACOECONOMIC CONSIDERATIONS

No pharmacoeconomic studies on enuresis are available. The use of a bed-wetting alarm provides the highest overall cure rate, and drugs are a secondary approach. Several types of reusable bed-wetting alarms are available, ranging from \$15 to \$170 per alarm, compared to \$80 to \$100 for a 30-day supply of desmopressin.^{63,66,72} However, insurance companies commonly reimburse drug therapy, whereas most do not reimburse for alarms. The most inexpensive drug therapy is low-dose TCA; however, electrocardiographic monitoring increases overall costs.⁷¹ Therapy with desmopressin is substantially more expensive than with TCAs because of higher drug cost.

EVALUATION OF THERAPEUTIC OUTCOMES

Before treatment begins, an accurate baseline of bed-wetting frequency must be established. A 50% or greater increase in dry nights is considered a therapeutic response. For example, if baseline dry nights are 2 out of 7 days per week, and drug treatment results in 4 or more dry nights per week, the drug is considered effective. If only one more dry night per week occurs and the drug is at the low end of the dosing range, a dosage increase is needed.^{63,66,67}

At least 1 week is needed to evaluate the efficacy of TCAs, and 2 weeks can be needed for evaluation of desmopressin. If drug treat-

ment is ongoing for several months, particularly if enuresis has resolved, attempts to discontinue the drug every 3 to 6 months are recommended to assess for spontaneous remission. Slow tapering of the medication can decrease the frequency of relapse. Unfortunately, therapeutic drug efficacy does not extend beyond drug discontinuation.^{63,66,71} Drug plasma level monitoring is not established for desmopressin; and plasma level monitoring for imipramine is inconclusive, and should be recommended only for children who do not respond or poorly tolerate a dose of 2.5 mg/kg/day.⁶³

CONCLUSION

Initially, simple interventions such as lift and awaken can be implemented. A bedwetting alarm in combination with complex behavioral interventions provide lasting cures for two-thirds of children. Drug therapy has the advantage of more rapid results, but relapse is high on drug discontinuation.^{63,64,66} Desmopressin tablets are preferred over imipramine because of better tolerability and safety.^{66,67}

ABBREVIATIONS

ADH: antidiuretic hormone

ADHD: attention-deficit/hyperactivity disorder

AIMS: abnormal involuntary movement scale

BMI: body mass index

CNS: central nervous system

DA: dopamine

STEVEN C. STONER

KEY CONCEPTS

- 1 The causes of eating disorders are complex, so ongoing multidisciplinary treatment is needed to ensure a positive outcome. Although outpatient treatment is appropriate for the majority of patients, it is important to recognize the factors that indicate a need for inpatient treatment.
- 2 Careful medical and psychiatric assessments are needed at baseline to determine the severity of illness and comorbid conditions.
- 3 Nonpharmacologic treatments such as cognitive behavioral therapy, nutritional counseling, family therapy, and interpersonal psychotherapy are the cornerstone of management of anorexia nervosa (AN).
- 4 In patients with AN, one goal is to achieve and maintain a body weight within 85% of the normal weight for age and height. If the patient is malnourished, oral refeeding with the daily caloric intake starting at 1,000 to 1,600 cal/day and slowly titrating to 2,000 to 3,000 cal/day is preferred. Parenteral refeeding is a treatment of last resort.
- 5 Antidepressants are considered to be ineffective for the core symptoms of AN and are reserved for patients with mood, anxiety, and obsessional symptoms that persist after weight has improved.
- 6 Antidepressants can improve both mood and specific target symptoms in bulimia nervosa (BN), but they remain adjunctive to nonpharmacologic treatments.
- 7 Selective serotonin reuptake inhibitors are first-line agents when medications are indicated for BN. Compared to other antidepressant classes, they are preferred because of improved tolerability and safety, although superior efficacy has not been shown. The dose of fluoxetine in BN is higher (60 mg/day) than the dose usually used in depression.
- 8 An adequate drug therapy trial in BN is 4 to 8 weeks. If drug treatment fails, consider that the patient might be vomiting or using other purging methods impacting the absorption of the drug.
- 9 The optimal duration of antidepressant treatment for BN is unknown, but most clinicians continue them for 9 to 12 months in patients who respond and then reevaluate the need for ongoing medication management. The long-term course is vari-

able, but there is the potential for a fatal outcome from cardiac arrest or suicide.

- 10 Monitoring of patients with BN should include frequency and severity of binge/purge episodes, exercise patterns, use of laxatives or ipecac, mood and anxiety symptoms, eating habits, daily caloric intake, weight, and changes in laboratory abnormalities.

The eating disorders encompass several complex diseases that share a central pathologic feature of overevaluation of body shape and weight. Eating disorders arise from the interaction between environmental, societal, developmental, psychosocial, genetic, and biologic factors. It is estimated that 5 to 10 million women and 1 million men in the United States have an eating disorder. The urbanization of society, social pressure, and obsession with perfection and being thin have led to an increasing prevalence of eating disorders, with the peak onset being between 16 and 20 years of age.¹⁻⁴ AN, BN, and eating disorders not otherwise specified (EDNOS) are the primary disorders that have been identified.⁵⁻⁹

Despite an improved understanding of these disabling and potentially fatal disorders, management remains difficult, and pharmacologic intervention is a small part of a comprehensive plan that emphasizes cognitive behavioral therapy and psychotherapy.

EPIDEMIOLOGY

ANOREXIA NERVOSA

AN occurs predominantly in females (90%) and usually presents in late adolescence (median onset 17 years of age) with new cases rarely diagnosed after age 40 years. The estimated prevalence of AN in the general population is 0.3% of females; however, a subthreshold level of symptoms are estimated to affect 0.37% to 1.3% of the population.^{2,10-12} Longitudinal management of AN is difficult, even in cases where weight restoration is achieved. Rates of relapse requiring hospitalization within 1 year are estimated to exceed 30%.¹³

The promotion of the virtues of being thin through common electronic media, such as the Internet, is also a potentially negative environmental factor. Many websites inappropriately promote healthy lifestyle aspects of AN and being thin as a means of being in control, successful, and coping with life's pressures.¹⁴

BULIMIA NERVOSA

BN also occurs predominantly in females (90%) and usually presents in adolescence or early adult life.⁵ Between 1% and 4.6% of adolescent and young adult females meet the diagnostic criteria for BN.^{3,10,15,16}

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

EATING DISORDER NOT OTHERWISE SPECIFIED

EDNOS is also described in the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders*, 4th Edition, Text Revision (DSM-IV-TR).^{3,15} Its prevalence is estimated at 1% to 4.7% of the population, with up to 50% of eating disorder patients admitted to tertiary care settings having this condition.^{10,17} These individuals present with symptoms characteristic of eating disorders but do not meet specific diagnostic criteria. Two examples of EDNOS are night eating syndrome (NES) and binge eating disorder (BED).

NES is most common in obesity clinic populations, often accompanied by depressive symptoms. The syndrome is defined by early morning anorexia, hyperphagia in the evening, nighttime insomnia, and subsequent early morning awakening with nighttime ingestion of food.^{9,18,19} NES impacts an estimated 1.5% of the general population, ranging from 8.9% to 27% in obesity clinics.^{20–22} Patients with NES are reported to benefit from antidepressant therapy, most notably sertraline 50 mg to 200 mg daily.⁹

BINGE EATING DISORDER

BED continues to be classified as a research diagnosis. The diagnostic criteria for BED describe recurrent episodes of binge eating without compensatory behaviors (e.g., purging, excessive exercise, or fasting). BED typically presents later in life (older than 40 years of age), and approximately one-fourth of BED patients are male.^{17,23}

ETIOLOGY AND PATHOPHYSIOLOGY

1 The potential etiologic or exacerbating factors for eating disorders represent an array of physiologic, biochemical, developmental, genetic, psychosocial, and psychiatric phenomena. The biologic basis for eating disorders is difficult to delineate because it is unclear if the biologic changes are caused by or are a result of the aberrant eating behavior.

Abnormalities of the hypothalamic-pituitary-gonadal, hypothalamic-pituitary-adrenal, and hypothalamic-pituitary-thyroid axes are described as potential causes of AN. Amenorrhea is found in the majority of females with AN, providing support to the association with gonadotropin.¹⁶ However, symptoms related to these abnormalities do not always correct with weight normalization, suggesting a primary biologic abnormality.²³

The roles of serotonin, norepinephrine, and dopamine have been studied extensively, as these neurotransmitters have important functions in controlling eating behaviors. Dysfunctions in these systems are thought to be secondary to weight loss. Some aspects of serotonin function do remain abnormal after weight restoration, suggesting that other mechanisms are involved.^{24,25} Another molecular genetic target of study is brain-derived neurotrophic factor (BDNF), which is also being studied in disease states such as depression.²⁶

Strong genetic influences are present in AN and likely play a role in both BN and BED, independent of the presence of obesity.²⁷ Twin studies have shown concordance of approximately 55% and 35% in monozygotic twins and 5% and 30% in dizygotic twins for AN and BN, respectively. Genetic mutation studies have focused on polymorphisms of the serotonin 2A receptor, with mixed preliminary results.²³

Emphasis is also placed on social stress and psychological and developmental issues related to dysfunctional family relationships triggering abnormal eating behavior.^{3,16,17,28} Athletes are also at risk for eating disorders, especially female gymnasts, ballet dancers, figure skaters, distance runners, swimmers, male wrestlers, and body builders.²⁹

DIAGNOSTIC CRITERIA AND CLINICAL PRESENTATION

2 AN and BN occur together in approximately 30% to 64% of patients with eating disorders, and may not be distinct diagnostic entities, but rather a continuum of symptoms.^{30–32} Many patients initially present with either AN or BN and alternate from one to the other. Figure 66–1 demonstrates similar and unique features of AN and BN.

The use of purging methods is not limited to just BN. Self-induced vomiting is the most common form of purging behavior.³³ Laxative abuse is another form common in both AN and BN, used by an estimated 3% to 70% of patients.^{33–35} Although ineffective as a weight-loss strategy, laxative abuse is often used in combination with other behaviors including exercise, diuretics, enemas, and saunas. Within the diagnostic framework of AN, laxative abuse is most common in those identified with the purging subtype.³³ Psychiatric symptoms of depression, anxiety, and borderline personality disorder are also reported in those who abuse laxatives.^{33–35}

Depression, schizophrenia, obsessive-compulsive disorder (OCD), and conversion disorders should be included in the differential

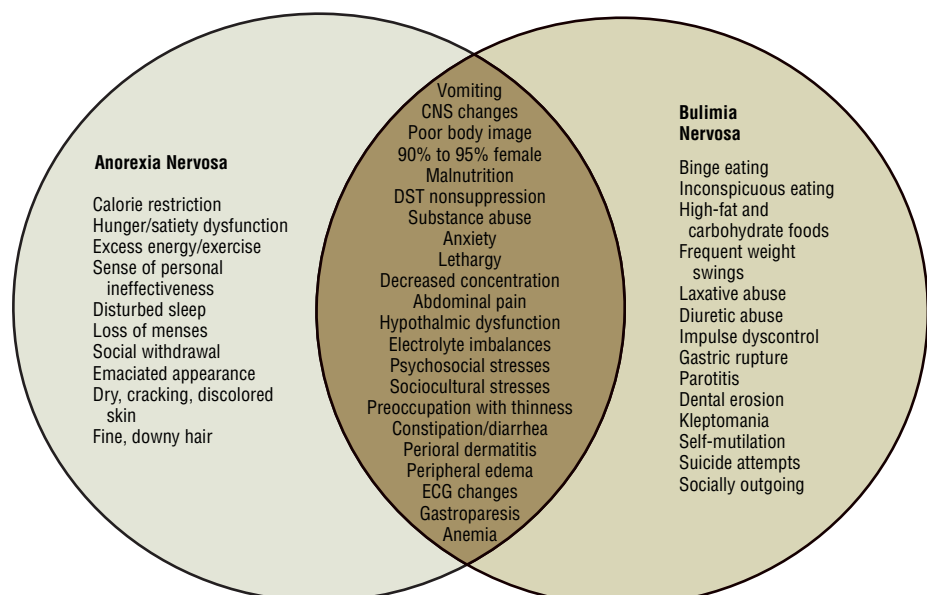

FIGURE 66-1. Signs and symptoms of anorexia nervosa and bulimia nervosa. (DST, dexamethasone suppression test; ECG, electrocardiogram.)

diagnosis of AN and BN because eating abnormalities can be a component of these illnesses. The salient difference is the overriding drive for thinness, disturbed body image, increased energy directed at losing weight, and binge eating episodes which are relatively specific for eating disorders. Most eating disorder patients experience relief of psychiatric symptoms on refeeding.¹⁷

ANOREXIA NERVOSA

The core features of AN include refusal to maintain a minimal normal body weight (e.g., greater than 85% normal body weight or body mass index greater than 17.5 kg/m²) or failure to make expected weight gains, intense fear and obsession about weight gain or being “fat,” distorted body image, and amenorrhea for at least three consecutive cycles. Patients typically lack an appreciation for the degree of weight loss experienced or are preoccupied with the idea that a part of their body is too large, despite evidence to the contrary. The DSM-IV-TR further classifies AN into restricting type (failure to engage in binge eating or purging behavior) or binge eating/purging type, in which patients regularly participate in bingeing or purging.¹⁵ The AN patient has difficulty sensing when he or she is full (satiety) and commonly complains of feeling bloated after they start eating. Patients also describe not feeling in control of various aspects of their life, particularly caloric intake. AN patients often present with features of major depression, but these symptoms should initially be considered to be secondary to starvation and not a true mood disorder.

CLINICAL PRESENTATION OF ANOREXIA NERVOSA

General

- Patients refuse to maintain body weight and have distorted perceptions about their body.

Symptoms

- Patients have obsessions and fears about eating and gaining weight.
- They complain about feeling full even when they have eaten very little food.
- Denial of symptoms and low self-esteem is the norm. They often feel ineffective and have a lack of self-control.

Signs

- Weakness, lethargy, cachexia, amenorrhea, vomiting, restricted food intake, inappropriate exercise, delayed sexual development, edema, delayed gastric emptying, constipation, bradycardia, hypotension, osteoporosis, dry cracking skin, lanugo, callus on dorsum of hand, perioral dermatitis, and erosion of dental enamel.

Laboratory Abnormalities

- Hypokalemia, hypokalemic alkalosis, hypomagnesemia, leukopenia, QT interval prolongation, ST-segment depression, U waves, hypercholesterolemia, and anemia.

Other Diagnostic Tests

- Nonspecific electroencephalograph (EEG) changes

Psychiatric comorbidity is common, as up to 75% of patients have a primary mood disorder.³⁶ There is also a link between AN and anxiety disorders, especially social phobia and OCD. The lifetime prevalence of OCD in patients with AN is reported to be as high as 25%, higher than the lifetime prevalence in the general population (2.5%).^{36,37} Avoidant and obsessive-compulsive personality disorders are also common in patients with AN.^{38,39}

CLINICAL PRESENTATION OF BULIMIA NERVOSA

General

- Patients binge eat and stop when they have abdominal pain or self-induced vomiting or are interrupted by another individual.
- They have a pattern of severe dieting followed by binge-eating episodes.
- They are concerned about their body image but do not have the drive to thinness that is characteristic of AN.

Symptoms

- Patients do not eat regular meals and do not feel satiety at the end of a meal.
- They might use laxatives for weight control.
- They have guilt, depression, and self-disparagement after binges.
- Social isolation can result from frequent bingeing.
- Chaotic and troubled personal relationships and substance abuse are common.

Signs

- Bingeing, vomiting, salivary gland inflammation, erosion of dental enamel, callus on dorsum of hand, perioral dermatitis, dental caries, parotid gland enlargement, abdominal pain, upper end of normal body weight or slightly overweight, frequent weight fluctuations, and diminished masticatory ability.

Laboratory Abnormalities

- Hypokalemia, hypochloremic metabolic acidosis, elevated serum amylase

Other Diagnostic Tests

- None

BULIMIA NERVOSA

The core feature of BN is recurrent episodes of binge eating (an excessive intake of calorie-laden food over a short period of time). Persons with BN are overly sensitive about their weight and have a distorted body image. Most have normal weight, although they might fluctuate between being underweight and overweight. Patients lack control over their eating and participate in recurrent compensatory behavior to prevent weight gain. This can include self-induced vomiting; misuse of laxatives, diuretics, enemas, or other medications; strict dieting or fasting; or excessive exercise. To meet DSM-IV-TR criteria, the binges and compensatory behaviors must occur on average at least twice weekly for 3 months. BN can further be differentiated by purging type (regularly engages in self-induced vomiting or the misuse of laxatives, diuretics, or enemas) or non-purging type (uses other inappropriate compensatory behaviors, such as fasting or excessive exercise, but doesn't engage in purging activities).¹⁵

Patients typically binge and vomit at least once daily. Caloric intake varies, but patients can consume between 5,000 and 20,000 calories during a single binge. Patients tend to consume foods that are easy to ingest, do not require much chewing or preparation, and are high in carbohydrates or fat. Binge eating is typically secretive and precipitated by a stressful event, followed by post-binge remorse. Binges typically last less than 2 hours but can last for more than 8 hours. To compensate for the excessive caloric intake, many patients fast for prolonged periods, exercise compulsively, purge, or abuse laxatives.

Psychiatric comorbidity includes depression (up to 80%), poor impulse-control, and substance abuse. Approximately 30% to 37% of bulimic patients have a personal history of substance abuse.⁴⁰ Kleptomania and borderline and avoidant personality disorders are

also frequently observed.^{38,39} Patients also commonly steal comfort items such as laxatives, candies, and clothes.¹⁶

BINGE EATING DISORDER

Patients with binge eating disorder present with recurrent episodes of bingeing without the compensatory behaviors associated with AN or BN. It is estimated that 5% to 10% of patients seeking treatment for obesity have BED. Comorbid depressive disorder is common, although the self-deprecating focus on body image is less severe than in AN or BN.^{21,37} Diagnostic criteria require that episodes of bingeing occur at least twice per week over a period of 6 months.¹⁵

MEDICAL COMPLICATIONS OF EATING DISORDERS

The potential medical complications that exist with the presence of eating disorders involve multiple organ systems. The type of medical complication encountered has been shown to be dependent on the type and frequency of the eating disorder behavior. Cardiac complications are of concern and can include wasted cardiac muscle, orthostatic hypotension, decreased cardiac output, arrhythmia, and QTc interval prolongation.⁴¹ During caloric restoration there is a risk for developing a potentially fatal collapse of the cardiovascular system known as *refeeding syndrome*. This risk is reduced by the gradual versus rapid reintroduction of calories.

Metabolic (metabolic acidosis or alkalosis) and electrolyte disturbances (e.g., hypokalemia, hypomagnesemia, hypocalcemia) along with dehydration are often seen. Elevations in bicarbonate levels during periods of hypokalemia can be an indication that the patient is inducing vomiting or using dietary weight-loss medications. Non-anion-gap acidosis has also been reported with the abuse of laxative agents. Additionally, both acute and chronic renal failure has been reported.

Gastrointestinal, oropharyngeal, and dental complications are frequent along with general complaints of lethargy and fatigue.

Hormonal changes related to the hypothalamic-pituitary-gonadal axis resulting from starvation are seen. These abnormalities include effects on estradiol, the gonadotropins (e.g., luteinizing hormone,

follicle-stimulating hormone, and gonadotropin-releasing hormone), thyroid function, adrenal function, and growth hormone.^{16,41} Specific to female athletes is the *female athlete triad*, defined by the development of irregular menses, osteoporosis, and disordered eating.^{41,42} Osteopenia, osteoporosis, and infertility are potential long-term complications of suppressed estrogen. The restoration of weight, specifically in AN, reverses the bone loss, although estrogen supplementation does not appear to be effective. In all cases, the preferred method to address these issues is the normalization of nutrition. The impact on female fertility is not well studied, although the ability to carry a pregnancy to term or to give birth to a child of average birth weight appears reduced.

Chronic starvation can contribute to brain atrophy. Decreases in white matter and cerebrospinal fluid volumes return to normal after a healthy weight is achieved, but gray matter loss can continue to persist.^{17,43,44} A thorough physical and laboratory evaluation, as described in Table 66-1, is needed to determine the severity of medical complications.^{15,28,45}

TREATMENT

Eating Disorders

■ DESIRED OUTCOMES

The goals for patients with eating disorders are to reduce distorted body image; restore and maintain healthy body weight; establish normal eating patterns; improve psychologic, psychosocial, and physical problems; resolve contributory family problems; enhance compliance; and prevent relapse.¹⁷ Specific to BED is the additional goal of weight loss.

■ ANOREXIA NERVOSA

The long-term prognosis of AN patients is not clear, as studies focus only on patients receiving treatment. The course of AN most commonly consists of a single episode with subsequent return to normal weight, although patients can still experience issues with disturbed body image, disordered eating, and other psychiatric problems.¹⁷ Some patients experience an unremitting course leading to death, whereas others suffer episodically. It is estimated that less than 50% of AN patients recover, and 20% remain chronically ill despite weight normalization, return of menses, and improved eating behaviors.⁴⁶ The prognosis is more favorable with longer followup care and younger age of onset, whereas a poorer prognosis is associated with chronic illness, lower initial weight, poor family relationships, obsessive-compulsive personality symptoms, and the presence of BN or purging behavior.^{23,46-48} Long-term followup shows that more than 5% to 10% of AN patients die, most often the result of cardiac arrest or suicide.^{15,46}

■ BULIMIA NERVOSA

The prognosis of BN, although not well studied, appears to be better than AN patients. Patients with milder presenting symptoms who are treated as outpatients tend to do better, whereas patients with electrolyte imbalances, esophagitis, dental caries, and salivary gland enlargement have a more complicated course.¹⁶ A 6-year followup study of patients who received intensive treatment found that 60% had a "good" response.⁴⁷ It is important to note that even in cases in which patients respond, they continue to exhibit symptoms that wax and wane. Total absence of symptoms is an uncommon outcome, and residual symptoms predispose the patient to relapse. The actual definition of recovery varies, as once-a-month binge/purge episodes are considered by some to be recovery if their episodes were previously more frequent, whereas others consider a patient recovered only when complete absence of these behaviors occurs.⁴⁸

TABLE 66-1 Physical and Laboratory Assessment of Eating Disorders

Evaluation	Target Symptoms
Pulse	Bradycardia
Blood pressure	Hypotension, orthostasis
Height/weight	Underweight for size and age/body mass index
Respiratory rate	Rapid if heart failure occurs during refeeding
Temperature	Hypothermia, cold intolerance
Electrocardiogram	ST depression, flat T waves, U waves, increased QT interval, atrioventricular block
Gastrointestinal	Hypoactive bowel sounds, gastritis, abdominal distention
Skin	Dry, scaling, lanugo, hair loss, calluses on fingers and hands
Menses	Amenorrhea
Complete blood count	Leukopenia, anemias, thrombocytopenia
Electrolytes	Hypokalemia, hypomagnesemia, hypo- or hyperphosphatemia
pH	Metabolic alkalosis (acidosis if laxative abuse)
Amylase	Elevated, pancreatitis rare
Liver	Hypoalbuminemia, γ -glutamyl transferase if alcohol abuse
Thyroid	Low to low normal, but not true disease
Cortisol	Elevated with lack of suppression on dexamethasone suppression test
Bone density	Osteoporosis

Data from American Psychiatric Association,^{15,17} Halmi,²⁸ and National Collaborating Center for Mental Health.⁵³

■ GENERAL APPROACH TO TREATMENT

An individualized treatment plan is based on the presence and severity of specific core features of the eating disorder and comorbid medical and psychiatric conditions. Psychiatrists, physician assistants, nurses, nutrition specialists, psychologists, and pharmacists play a role in the care of these complex patients. The absence of an adequate support system of family and friends can be cause for failed treatment. A critical first step is to determine the severity of illness, as that drives both the intensity and the setting for delivery of care. Hospitalization is based on the criteria outlined in Table 66-2 and is limited to only the most severely ill patients.^{23,28,29} Medications are rarely indicated as a sole treatment for eating disorders, and many refuse medication, although they remain part of the comprehensive treatment strategy.⁴⁹⁻⁵¹ Comparative, double-blind, placebo-controlled trials are sparse with most limited by small sample sizes, ambivalent attitudes toward treatment, medical complications, and high dropout rates.⁵²

■ ANOREXIA NERVOSA

Nonpharmacologic Treatments

3 Evidence supports that nonpharmacologic treatments have the greatest likelihood of eliciting a response in AN patients.^{17,49} This includes cognitive behavioral therapy (CBT), behavioral management, interpersonal psychotherapy, nutritional counseling, and family therapy.^{17,28,53} Current guidelines suggest at least 6 months of psychotherapy.⁵³ CBT helps the patient overcome distorted thinking, including self-worth as measured by body image, feelings of being fat despite evidence to the contrary, and denial. CBT also teaches patients how to use strategies besides eating to cope. Interpersonal psychotherapy focuses on interpersonal relationships and functioning, whereas CBT provides positive reinforcement for weight gain.³⁶ The benefit of treatment based on an addiction model (12-step program) is not supported by the literature.^{17,23} Many psychiatric symptoms in an acutely ill patient, such as depression and anxiety, diminish or disappear with weight restoration. Initial treatment is directed toward restoring a healthy weight (greater than 90% of normal weight for age-matched controls) and treating food phobias.⁵⁴ After achieving medical stability and appropriate weight, therapy can be redirected toward addressing ongoing interpersonal problems, weight maintenance, cognitive restructuring, and skill development for relapse prevention.⁵⁵ Oral refeeding, initially with liquid formulas if necessary, is the most common approach to weight restoration.

4 In severe cases, nasogastric refeeding is preferred over intravenous bolus dosing.¹⁷ Total parenteral nutrition is reserved only for the management of severely malnourished patients and if other refeeding methods fail. The decision to administer total parenteral nutrition must be made carefully, because of the potentially devastating psychologic effect on patients who do not wish to gain weight. Current clinical evidence suggests a controlled weight gain of 0.9 to 1.4 kg (2–3 lb) per week in inpatient settings and 0.2 to 0.5 kg (0.5–1 lb) per week in outpatient settings.^{15,53,56} Recommendations vary; however, it is considered acceptable for patients to begin refeeding at 1,000 to 1,600 calories per day (30–40 cal/kg per day) with slow titration upwards until they begin to demonstrate sustained weight gain.^{17,53,56} This can require the intake of an additional 3,500 to 7,000 extra calories per week.⁵³ Slow refeeding is important to minimize the risk of medical and psychologic consequences.²³

Pharmacologic Therapy

Antidepressants Although many studies examine the role of antidepressants in the treatment of AN, they often have small sample sizes and large confidence intervals.⁵⁷ Antidepressants currently have no role in the acute treatment of AN, unless there is another clinical indication present.^{17,23,49}

TABLE 66-2 Criteria for Hospitalization of Patients with Eating Disorders

- Significant weight loss of 20% or more of normal weight, particularly if weight loss has been recent and rapid, severe starvation symptoms are present, or the patient has been ill for more than 2 years
- Reduced oral intake of food (sudden and persistent)
- Medical complications (e.g., edema) and metabolic abnormalities (e.g., hypoproteinemia) from bingeing, purging, and starvation (e.g., heart rate <40 bpm or >110 bpm, blood pressure <90/60 mm Hg, glucose <60 mg/dL (3.33 mmol/L), potassium <3 mEq/L (3 mmol/L), or inability to maintain core body temperature
- Co-occurring psychiatric symptoms, notably suicidal ideation, psychotic depression, or substance abuse and dependence
- Nonresponsive to outpatient treatment (after 3–4 months) and poor motivation to recover
- Demoralization or nonfunctional family
- Denial of severity of abnormal eating behaviors
- Continuous supervision required to prevent purging (vomiting or laxative abuse)

Data from American Psychiatric Association,^{15,17} Fairburn and Harrison,²³ Halmi,²⁸ Powers,²⁹ and National Collaborating Center for Mental Health.⁵³

5 Data suggest that medication is ineffective if a patient weighs less than 85% of their expected weight, thus antidepressants should be initiated only if depression, anxiety, obsessions, or compulsions persist after the target weight is achieved.^{23,54,58} The duration of treatment when antidepressants are used in this manner is unclear, but one study showed benefit in treated patients for 1 year and current guidelines suggest 9 to 12 months of therapy.^{3,17,53} Antidepressants, along with psychotherapy, have been used to help maintain weight and prevent relapse, but data supporting this are limited.⁵⁹ Most clinicians prefer the selective serotonin reuptake inhibitor (SSRI) antidepressants because they are better tolerated and have greater cardiovascular safety than tricyclic antidepressants (TCAs) and monoamine oxidase inhibitors (MAOIs).^{17,60} Because these patients are sensitive to anticholinergic and cardiovascular effects, if TCAs or MAOIs are used, low starting doses and a slow titration toward an effective dose is appropriate. The risk of cardiotoxicity in a malnourished population must not be underestimated, and a baseline electrocardiogram (ECG) should be obtained before initiation of these agents.

Fluoxetine continues to be the most widely studied SSRI in AN. Most clinicians initiate at low doses, for example 20 mg/day, and increase to a maximum of 60 mg/day based on response and tolerability.^{56,57,59} Some clinical controversy exists regarding when antidepressant therapy should be initiated. During the starvation phases of AN, the majority of clinical trials suggest antidepressants are ineffective, and there is debate as to their effectiveness once weight restoration has occurred. Evidence from a 52-week, randomized, placebo controlled clinical trial of 93 patients with the treatment arm receiving doses from 20 mg/day to 80 mg/day showed no difference between fluoxetine and placebo for time-to-relapse.⁶¹

Antipsychotics Typical antipsychotics were the first medications used to treat AN because of their potential to reduce obsessive thoughts, paranoid ideation about weight gain, anxiety, and to promote weight gain.⁶² However, there was little improvement, and the risks outweighed the benefits. Interest in antipsychotics for acutely ill AN patients has reemerged with the introduction of the atypical agents. Most of the data are from case reports or small trials using risperidone 0.5 to 1.5 mg daily or olanzapine 2.5 to 10 mg daily.⁶³⁻⁶⁸ Improvement has been shown through weight increase and reduction of comorbid anxiety and depressive symptoms, but not all reports are favorable, and these agents require further study. Caution is urged in view of the report of increased QTc in an AN patient taking risperidone.⁶⁹ Optimal treatment duration is unknown, as most of the larger studies are less than or equal to 3 months in duration.

Miscellaneous Agents Metoclopramide can be helpful in reducing bloating, early satiety, and abdominal pain commonly found in

AN, but it does not impact weight gain.¹⁷ Low-dose, short-acting benzodiazepines (0.25 mg alprazolam or 0.5 mg lorazepam) given before meals are useful when severe anxiety limits eating.¹⁷ Estrogen replacement has been used, but restoring menses through refeeding is a preferred approach to minimize bone density loss.

CLINICAL CONTROVERSY

Clinicians continue to look for medications that are beneficial during the acute phase of AN. Recent findings from a 52-week study comparing fluoxetine to placebo in patients with anorexia nervosa after successful weight restoration found that fluoxetine did not provide any benefit in preventing relapse. Second generation antipsychotics are being used by some clinicians in acutely ill patients with severe obsessions and paranoia about eating, although the data supporting this approach are limited.

■ BULIMIA NERVOSA

Nonpharmacologic Therapy

The nondrug strategies used in BN are similar to those used with AN, and they are equally critical to success. CBT has the strongest evidence supporting its benefit in managing BN.^{18,24} Current treatment guidelines suggest that CBT should consist of 16 to 20 sessions over a 4- to 5-month period.⁵³ Interpersonal psychotherapy also plays a role and has a moderate degree of evidence to support its use.^{17,23} Nutritional counseling, planned meals, and self-monitoring can help interrupt the binge-purge cycle. Family therapy in BN patients is less critical than with AN, as these patients tend to be older. Programs using self-help and guided self-help manuals based on CBT have shown mixed results; however, when used in combination with fluoxetine, they have improved symptoms.^{28,70,71} Data supports the use of 12-step programs, but they should not be used as monotherapy.^{17,23}

Pharmacologic Therapy

6 Antidepressants Antidepressants are used in the acute and maintenance phase of BN adjunctively with nonpharmacologic approaches. A wide array of antidepressants, including TCAs, MAOIs, trazodone, serotonin-norepinephrine reuptake inhibitors (SNRIs), and SSRIs have been studied. Additionally, several reviews analyzing this body of literature have been published, although there continues to be limited placebo controlled randomized, double-blind clinical studies.^{23,49} Antidepressants are reported to reduce depression, anxiety, obsessions, impulsive behaviors such as binge eating and purging, and improve eating habits, although their impact on body dissatisfaction remains unclear. The presence of comorbid mood disorders is not necessary for an antidepressant response.^{23,72,73}

The benefit appears to be more robust in the acute phase of the illness, as relapse despite continued antidepressant use is common in patients who are in or near remission.^{23,28,51} Antidepressant response usually occurs in 6 to 8 weeks, and reduction in frequency of binge/purge behavior has been as high as 73% and as low as zero.⁴⁹ Abstinence rates (elimination of bingeing and purging behaviors) with short-term use range from zero to 68%. More data are needed to determine the long-term benefits of antidepressants for preventing relapse of BN symptoms. One trial evaluating the impact of fluoxetine versus placebo in the maintenance phase showed a better outcome in patients receiving fluoxetine 60 mg/day, although high dropout rates in both groups blurred the overall benefit.⁷⁴

7 SSRIs are the preferred agents because of their tolerability and because they have been studied in the largest number of patients. Fluoxetine is the only agent to have Food and Drug Administration

approval for BN. Tolerability is the primary criterion for selecting an antidepressant in BN because of patients' heightened sensitivity to adverse effects and lack of a clear difference in efficacy between the classes. Even though there is a suggestion that MAOIs produce the most robust effect, the risks of using these medications in impulsive patients limits their use.⁵¹ SNRIs have shown promising results; however, the data supporting their use is limited to case reports.⁷⁵ Bupropion is not used in BN patients because of the increased risk of seizures.

Before initiating pharmacologic based therapy, a careful baseline physical examination, ECG, and laboratory workup are essential. Underlying ECG changes secondary to hypokalemia or bradycardia and atrioventricular block from starvation can be present. All antidepressants can cause seizures; thus a careful risk-benefit assessment is warranted if the patient has predisposing factors such as a personal or family history of seizures, cerebrovascular disease, or alcohol or sedative-hypnotic withdrawal.

Doses in BN are in the same range as for patients with depression. Readers are referred to Chap. 71 for antidepressant dosing ranges. For fluoxetine, the higher end of the dosing range, 60 mg/day, can be necessary for response.⁷⁶ With other agents, most clinicians initially target the bottom to the middle of the dosing range and increase the dose if there is an inadequate response. Slow titration is needed to allow time to develop tolerance to adverse effects. If TCAs are used, serum concentration monitoring is recommended to ensure that absorption is not compromised by purging.

8 The time for antidepressant onset of effect in BN is unclear. In the absence of data, the definition of a therapeutic trial from the depression literature (4 to 8 weeks at a therapeutic dose) should be used. As the majority of subjects will not experience a complete remission, and there are few data on predictors of response or whether switching to another class will improve response, a clear and specific target should be stated initially.¹⁷

9 Optimal duration of treatment after response is poorly defined, although most clinicians treat for 9 months to 1 year and then reevaluate. The evidence is mixed as to whether any early benefit is sustained, hence the decision to continue treatment should be made based on both initial response and the maintenance of that benefit. If the symptoms return within a few months after antidepressant discontinuation, then the treatment might need to be reinitiated.

Table 66-3 and Fig. 66-2 describe potential guidelines for medication use in BN, but it must be noted that no evidence-based

TABLE 66-3 Guidelines for Medication Use in Bulimia Nervosa

1. Determine baseline frequency of binge and vomiting episodes, laxative abuse, obsessive thoughts, and compulsive behavior. Document weight and patient's subjective feelings of self-image. Describe a baseline level of functioning.
2. Identify comorbid psychiatric conditions (e.g., depression, anxiety disorder, substance abuse, or bipolar disorder).
3. Determine baseline physical status (especially nutritional status, electrocardiogram, and fluid status [dehydration and electrolytes]).
4. Consider whether an antidepressant should be part of a comprehensive treatment plan that includes nonpharmacologic measures, especially cognitive behavioral therapy.
5. If antidepressant is indicated, start at a low dose, and use a selective serotonin reuptake inhibitor unless there is a medical reason not to do so.
6. Monitor carefully for response, adverse effects, and compliance. Response usually is seen after 6 to 12 weeks. Response is determined by change from baseline frequency and severity of target symptoms.
7. If patient responds and response is sustained, continue treatment for 6 to 12 months, then reassess.
8. If response is poor, evaluate compliance and whether patient is vomiting medication. Ensure that the patient is receiving nonpharmacologic therapy.

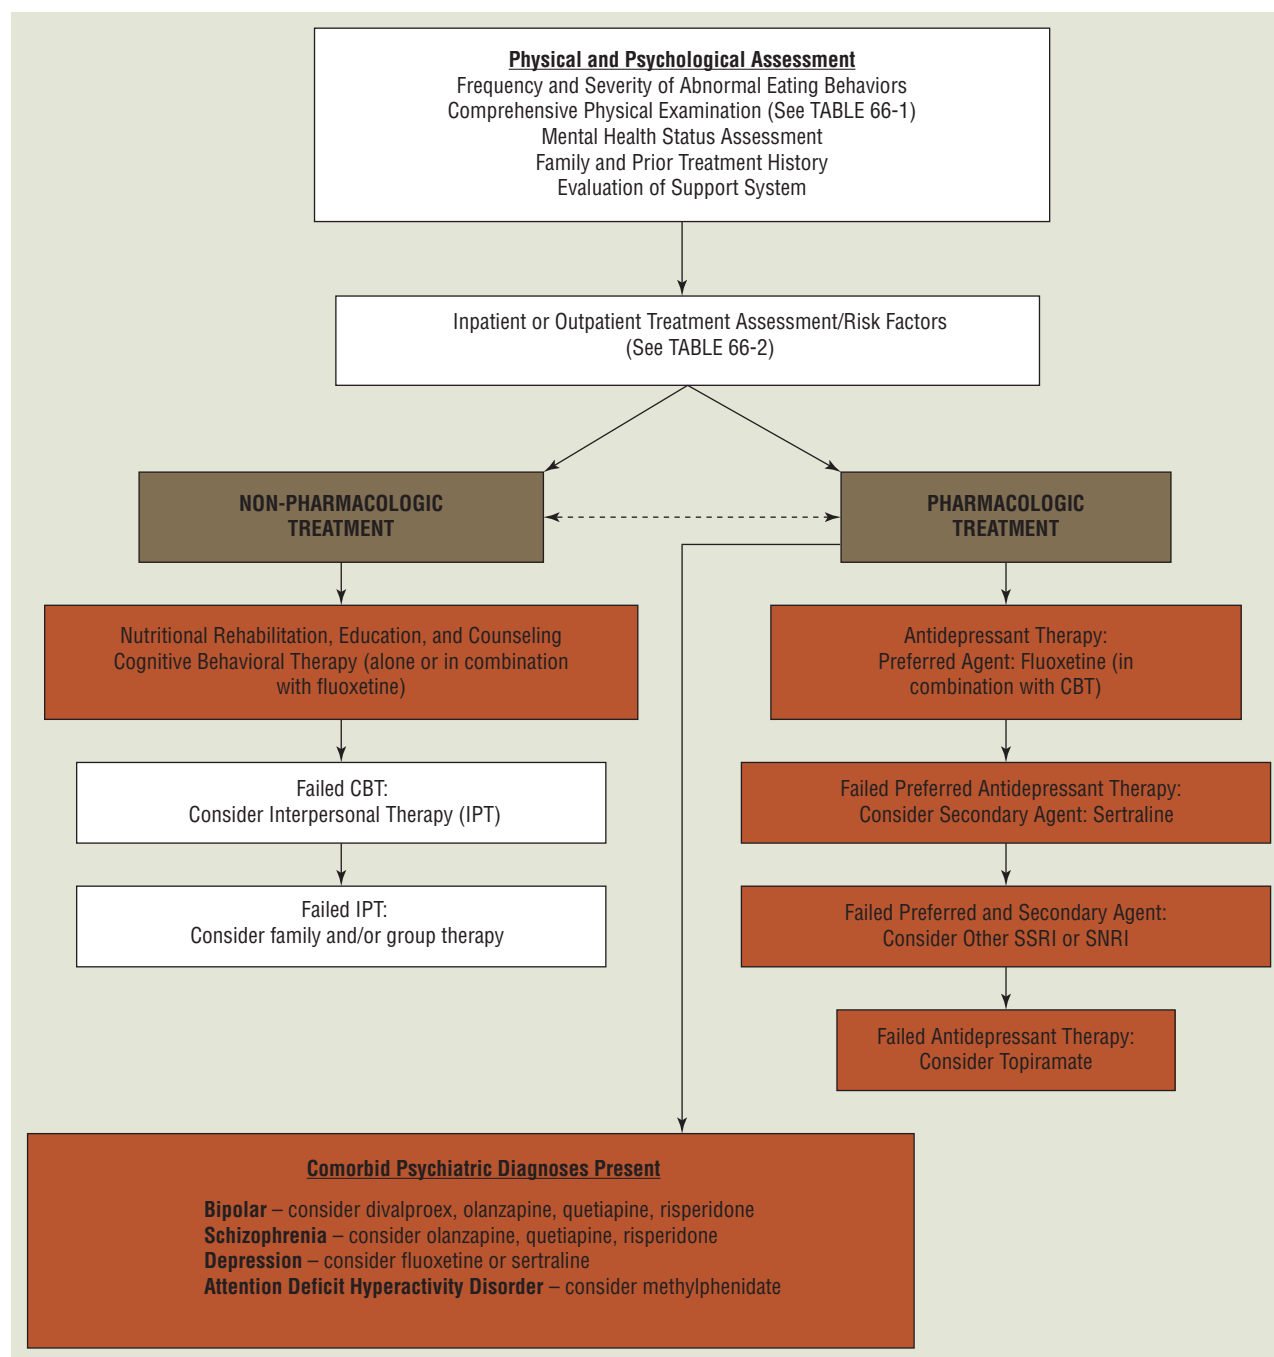

FIGURE 66-2. Bulimia nervosa treatment algorithm. (CBT, cognitive behavioral therapy; IPT, interpersonal psychotherapy; SNRI, serotonin-norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor.)

consensus for treatment has been endorsed, even with the recent guidelines, meta-analyses, and reviews of the literature.^{3,17,23,49,51,53,60}

Mood Stabilizers (Lithium and Anticonvulsants) Because of the lack of evidence demonstrating their benefit, lithium and anticonvulsants are reserved for BN patients with a comorbid bipolar affective disorder.^{17,77} Target serum concentrations and doses are similar to those used for patients with seizure or mood disorders. Lithium must be used cautiously, as fluid shifts related to purging and laxative abuse increase the risk of toxicity. The adverse effect of weight gain often makes mood stabilizers and anticonvulsants unacceptable to patients in the long term.

Miscellaneous Agents Low-dose benzodiazepines before meals can help reduce anxiety associated with refeeding, although long-term use is not warranted because of the risk of abuse and dependence. One double-blind trial with ondansetron has shown benefit,

but there are insufficient data to recommend a specific role for this agent.⁷⁸ Antipsychotics and appetite suppressants do not play a role in managing central BN symptoms.²³

Nonpharmacologic versus Pharmacologic Approaches

The combination of pharmacologic and nonpharmacologic measures appears to produce the best chance for a positive outcome for patients with BN.⁴⁹ Antidepressants, specifically SSRIs, are the class of choice in patients with BN, whereas other medications are reserved for patients with comorbid psychiatric conditions. Only in unusual circumstances should patients be treated with antidepressants alone. Evidence suggests the greatest benefit is during the acute phase of treatment, whereas data are mixed supporting their role in the prevention of relapse.

CLINICAL CONTROVERSY

The optimal time to continue antidepressant therapy in BN patients after a response is unclear. Some patients maintain their response, although others deteriorate and become symptomatic despite continued treatment. Most clinicians advise continuing the antidepressant for 9 to 12 months if they respond, then reevaluate the need for further treatment.

■ BINGE EATING DISORDER

Common to the other eating disorders, CBT and interpersonal psychotherapy seem to be the most effective interventions.²³ Antidepressants, anticonvulsants, and appetite suppressants are the pharmacologic agents with the greatest promise in BED, but data are limited, trials are short in duration (20 weeks or less), and the issue of sustained benefit is unclear.⁷⁹ Although reports are mixed, antidepressants have demonstrated efficacy as monotherapy at reducing binge eating and improving depressed mood during the acute phases of the illness compared to placebo, but can also be used alone or in combination with CBT to augment response.^{23,80–83} The majority of the data are with SSRIs given at antidepressant doses.⁷⁹ Topiramate 50 to 600 mg daily (a median dose 200 mg daily) has produced benefit in patients with impulse control disorder and because it promotes weight loss. Short-term data demonstrating superiority over placebo have been published, but data beyond 12-weeks' duration are lacking.⁸⁴ Sibutramine 10–15 mg/day has also demonstrated benefit in reducing weight and binge frequency in obese BED patients compared to placebo.⁸⁵ Orlistat 120 mg three times daily along with a calorie restricted diet has produced weight reduction in obese patients with BED.⁸⁶ Zonisamide (100 to 600 mg/day) has also displayed benefit at reducing binge eating frequency and promoting weight loss.⁸⁷

In summary, the question of where BED fits on the diagnostic spectrum continues to be explored. Current literature suggests that three different types of pharmacologic agents (SSRIs, topiramate, and sibutramine) hold promise in the short term, but long-term data are lacking. As with other eating disorders, nonpharmacologic treatments are the key to a successful outcome.

PHARMACOECONOMIC CONSIDERATIONS

There are no formal evaluations of the economic impact of eating disorders on individual patients, global healthcare costs, or on indirect costs such as unemployment, premature death, or disability payments. The chronic course, severe disability, and lack of improvement in up to a third of patients suggest a significant cost impact. Clinicians should contribute to the appropriate use of resources by ensuring that medications are used in situations in which there is evidence demonstrating their benefit and that they are never used as the sole treatment modality. For example, antidepressants are started after normal weight is restored in AN patients and not to treat depressive symptoms in significantly malnourished patients. One study evaluating the relative costs of CBT alone, medication alone, or combination treatment of BN concluded that if overall effectiveness was the prime consideration, then CBT, with medication added if the response was inadequate, was the best approach. If cost-effectiveness was the basis for making treatment decisions, then antidepressants alone as a first step, followed by the addition of CBT when response was inadequate was the preferred.⁸⁸

EVALUATION OF THERAPEUTIC OUTCOMES

ANOREXIA NERVOSA

A combination of subjective and objective measures is used to assess patient response. A reduction in the frequency and severity of abnor-

mal eating habits, normalized exercise patterns and laboratory tests, and a sustained weight close to age-matched normals are key indicators of response. A diary recording exercise frequency, menses, food intake, patterns of eating, and associated feelings while eating is a useful tool to track progress, especially in the outpatient setting. Weekly weigh-ins on the same scale, preferably at a clinician's office, help monitor progress early in treatment and reduce the focus on weight and anxiety caused by the variability found among different scales. Followup laboratory tests and ECGs are not part of routine monitoring unless the patient is restricting food intake, is purging, or continues to lose weight despite treatment. Inpatients require daily assessment of weight and caloric intake, vital signs, and urine output because of the more severe nature of their illness. They also can need monitoring of bathroom privileges early in their care. A healthy weight gain of no more than 0.2 to 0.5 kg per week toward a goal of 90% to 95% of normal weight or a body mass index greater than 18.5 kg/m² is a critical sign of treatment success. A patient's use of coping skills and contingencies for dealing with stress other than manipulating food consumption also should be assessed. Antidepressants can assist in alleviation of persistent depression, anxiety, and obsessions, after weight restoration. Improvement in mood is expected to occur within 8 weeks. Patients receiving TCAs should be evaluated for dry mouth, constipation, hypotension, and sedation. Patients receiving SSRIs should be monitored for agitation, drug-induced anorexia, nausea, weight loss, and insomnia. The decision to use long-term medication must be based on specific and sustained improvement in the target symptoms, balanced against adverse effects.

BULIMIA NERVOSA

An individualized treatment and monitoring plan begins with a thorough assessment describing the baseline frequency and severity of treatment-responsive target symptoms and other associated findings. The assessment must be comprehensive, as a patient can hide their illness by shifting from one type of behavior to another (e.g., exercise to purging).

10 A comprehensive assessment includes a description of psychiatric symptoms, physical findings, frequency and severity of binge/purge episodes, laxative and ipecac use, exercise patterns, and laboratory and ECG abnormalities. Interpersonal and relationship problems should also be evaluated. Some findings indicating a more chronic course of illness, such as salivary gland inflammation or erosion of dental enamel, can take months to reverse or might never normalize, hence these are not sensitive indicators of early treatment response. Data describing a patient's baseline level of functioning and previous response to treatment should be used to set goals in the current treatment plan.

Antidepressant response usually occurs within 4 to 8 weeks after the onset of treatment. If response does not occur, binge/purge behavior should be considered as a factor potentially contributing to the malabsorption of medication. If this behavior is not present, then every attempt should be made to maximize the dose. Serum concentration monitoring, when appropriate as with TCAs, should be done periodically (every 3 to 6 months if a patient is responding and tolerating the medication, or more frequently if clinically indicated). Evaluation of previously described adverse effects also should be part of the monitoring plan. If the patient responds, they should be followed for 6 to 12 months, then reassess the need for ongoing medication. If the patient relapses on medication discontinuation, then the medication should be restarted.

Ambulatory eating disorder patients present a particular challenge to clinicians. Impulsivity associated with BN can increase the risk for suicide. Prescriptions should be limited to small supplies. In addition, pharmacists should be alert to persons who make large or frequent purchases of laxatives or ipecac syrup, as this is an indicator of possible bulimic behaviors.

CONCLUSIONS

Our understanding of the pathophysiology and symptomatology of eating disorders has improved significantly over the past several years. Medication serves an adjunctive role to a variety of psychosocial therapies in AN, whereas it plays a more central role in BN and BED treatment. By gaining a greater understanding of the underlying physiologic changes and the psychosocial complications associated with eating disorders, treatment plans can be specifically designed for an individual patient with the goal of improving their quality of life.

ACKNOWLEDGMENTS

PATRICIA W. SLATTUM, RUSSELL H. SWERDLOW, AND ANGELA MASSEY HILL

KEY CONCEPTS

- 1 Alzheimer's disease (AD) is the most common form of dementing illness, and the prevalence of AD increases with each decade of life.
- 2 The etiology of AD is unknown, and current pharmacotherapy neither cures nor arrests the pathophysiology.
- 3 Neuritic plaques and neurofibrillary tangles are the pathologic hallmarks of AD; however, the definitive cause of this disease is yet to be determined.
- 4 AD affects multiple areas of cognition and is characterized by a gradual onset with a slow, progressive decline.
- 5 A thorough physical examination (including neurologic examination), as well as laboratory and imaging studies, is required to rule out other disorders and diagnose AD before considering drug therapy.
- 6 Pharmacotherapy for AD focuses on impacting three domains: cognition, behavioral and psychiatric symptoms, and functional ability.
- 7 Nondrug therapy and social support for the patient and family are the primary treatment interventions for AD.
- 8 Cholinesterase inhibitors and memantine are used to treat cognitive symptoms of AD; other medications have been suggested to be beneficial because of their potential preventive or cognitive effects.
- 9 Appropriate management of vascular disease risk factors may reduce the risk for developing AD and may prevent the worsening of dementia in patients with AD.
- 10 A thorough behavioral assessment and plan with careful examination of environmental factors should be conducted before initiating drug therapy for behavioral symptoms.
- 11 Pharmacotherapy may reduce the total cost of treating AD by delaying cognitive decline and time to nursing home placement.

I now begin the journey that will lead me into the sunset of my life.
Ronald Reagan

Alzheimer's disease (AD), first characterized by Alois Alzheimer in 1907, is a gradually progressive dementia affecting cognition, behavior, and functional status. The exact pathophysiologic mechanisms underlying AD are not entirely known, and no cure exists.¹ Although drugs may reduce AD symptoms for a time, the disease is eventually fatal.

AD profoundly affects the family as well as the patient. The need for supervision and assistance increases until the late stages of the disease, when AD patients become totally dependent on a family member, spouse, or other caregiver for all of their basic needs. These are the all-too-common experiences of the millions of people in the United States who care for someone with AD.

EPIDEMIOLOGY

1 AD is the most common cause of dementia. AD unassociated with any other pathology accounts for 50% to 60% of cases of late-life cognitive dysfunction. The incidence increases to 80% if AD in conjunction with other pathologic lesions is considered.² Table 67-1 lists the most common types of dementia among older adults. Dementia in an individual can result from multiple etiologies. This chapter focuses exclusively on dementia of the Alzheimer's type. However, the reader is encouraged to use the nonpharmacologic approaches and management of behavioral problems outlined in this chapter as a general treatment approach for other types of dementia that may share similar features with AD.

Approximately 4.5 million Americans have AD.³ By the year 2050, 1 in 5 people will be older than age 65 years, and the number of AD patients is projected to be 13.2 million (Fig. 67-1). Most cases present in persons older than age 65 years, but approximately 5% of cases occur in persons younger than age 65 years. Onset can be as early as age 40 years, resulting in the arbitrary age classifications of early onset (ages 40 to 64 years) and late-onset (ages 65 years and older).^{4,5}

Increasing age is the greatest risk factor for AD.⁴ The prevalence of AD increases exponentially with age, affecting approximately 7% of individuals ages 65 to 74 years, 53% of those ages 75 to 84, and 40% of persons ages 85 years and older.³ Genetic inheritance is also a significant risk factor, although other factors may contribute. Factors determining age of onset and rate of progression remain largely undefined.

FIGURE 67-1. Our aging population. The percentage of U.S. population over age 65 years and the percentage with AD projected from years 2000 to 2050. (Estimates based on data from references 1 and 116.)

Survival following AD onset is estimated to be 3 to 20 years, with an average of 8 years after the onset of symptoms.⁴ Individuals with AD survive approximately half as long from the time of diagnosis as those of similar age without AD.⁴ AD is the fifth leading cause of death as a consequence of disease in the United States.² AD may not cause death directly, but it predisposes patients to sepsis, pneumonia, choking and aspiration, nutritional deficiencies, and trauma.⁶

ETIOLOGY AND GENETICS

2 The exact etiology of AD is unknown; however, several genetic and environmental causes have been explored as potential causes of AD. Dominantly inherited forms of AD account for less than 1% of cases.⁷ Almost all early onset cases of AD can be attributed to alterations on chromosomes 1, 14, or 21. The majority and most aggressive early onset cases are attributed to mutations of a gene located on chromosome 14, which produces a protein called presenilin 1.⁷ A structurally similar protein, presenilin 2, is produced by a gene on chromosome 1. Both presenilin 1 and presenilin 2 encode for membrane proteins that may be involved in amyloid precursor protein (APP) processing. Scientists have identified more than 160 mutations in presenilin genes, and these mutations appear to result in reduced activity of γ -secretase, an enzyme important in β -amyloid peptide (β AP) formation.⁷ APP is encoded on chromosome 21. Only a small number of early onset familial AD cases have been associated with mutations in the APP gene, resulting in overproduction of β AP or an increase in the proportion of β AP ending at residue 42.⁷

Genetic susceptibility to sporadic, late-onset AD is thought to be primarily linked to the apolipoprotein E (apo E) genotype.¹ Thus far, the contribution of other candidate genes appears to be minor, although AD may be a heterogeneous disease resulting from complex interactions among multiple susceptibility genes and environmental factors. The gene responsible for the production of apo E is located on chromosome 19. There are three major subtypes or alleles of apo E (e.g., apo E2, apo E3, and apo E4). Humans inherit one copy of the apo E gene from each parent. Inheritance of the apo E4 allele is believed to account for much of the genetic risk in sporadic AD. The mechanism through which apo E4 confers an increased risk is unknown, although apo E4 is associated with other factors that may contribute to AD pathology, such as abnormalities in mitochondria, cytoskeletal dysfunction, and low glucose usage.⁷ The degree of risk depends on such factors as the number of apo E4 copies, age, ethnicity, and gender.^{5,8} Overall, approximately 40% of patients with late-onset AD have at least one copy of apo E4. Individuals homozy-

gous for apo E4 are at increased risk, and as many as 90% of persons inheriting two copies of apo E4 will develop AD by age 80 years. Moreover, onset of symptoms occurs at a relatively younger age as compared to patients having zero or only one copy of apo E4 in their genotype.^{5,8} In whites, inheriting a single copy of apo E4 increases AD risk, whereas inheriting the apo E2 allele may protect against AD.^{8,9} Although inheritance of the apo E4 allele increases the risk of AD, it is not diagnostic or even essential for disease presence.

Apo E4 is the only genetic factor that is unequivocally associated with an increased risk of late-onset AD, but it has been estimated to account for less than half of the genetic contribution to AD risk.¹⁰⁻¹² This polymorphism may also be more prevalent in the white population. Because the incidence of AD is higher in other populations, AD occurs at an early age in some individuals, and AD is associated with vascular risk factors such as obesity, diabetes, and hypertension. Genetic explanatory factors continue to be investigated.^{13,14} Genetic variation at the angiotensin-converting enzyme locus may influence the risk for AD, and be linked to the risk of AD in African Americans. Angiotensin-converting enzyme activity in the cerebrospinal fluid and in the brain differs significantly between individuals with AD and healthy controls. Angiotensin-converting enzyme has also been demonstrated to inhibit β AP aggregation and plaque formation in vitro.^{15,16}

Genetic factors have been linked to both early and late-onset AD. Alterations to chromosomes 1, 14, and 21 are associated with early onset AD, whereas the presence of apo E4 alleles increases risk of developing late-onset AD. Mutations in the tau gene on chromosome 17 is associated with an abnormality in tau protein and development of the rare frontotemporal dementia.⁷ However, genetic causes of AD have been directly associated with only a small percentage of Alzheimer's patients, and the exact cause of AD remains unknown.

ENVIRONMENTAL AND OTHER FACTORS

A number of environmental factors are associated with an increased risk of AD, including age, decreased reserve capacity of the brain (reduced brain size, low educational level, and reduced mental and physical activity in late life), head injury, and risk factors for vascular disease (hypercholesterolemia, hypertension, atherosclerosis, coronary heart disease, smoking, obesity, and diabetes).^{1,4} Whether these vascular risk factors are true causal risk factors for AD contributing to AD pathology, or whether they result in cerebrovascular pathology that, in turn, contributes to the symptoms of AD, remains to be established.

The incidence of AD rises with increasing age, so that among centenarians the histopathologic and clinical changes needed to justify a diagnosis of AD probably coexist in more than 90% of these individuals.¹⁷⁻¹⁹ One oft-quoted study concluded that almost half those older than age 85 years have AD.²⁰ Recent data suggest AD may develop in individuals over the course of decades,^{21,22} suggesting that AD is a disease most people are in the process of developing throughout adulthood. The debate about whether tangle-and-plaque dementia is a distinct disease or part of aging remains unresolved. An in-depth discussion of the aging-AD controversy is not possible in this chapter; it is reviewed elsewhere.²³

PATHOPHYSIOLOGY

3 The signature lesions in AD are neuritic plaques and neurofibrillary tangles (NFTs) located in the cortical areas and medial temporal lobe structures of the brain.¹ Along with these lesions, degeneration of neurons and synapses, as well as cortical atrophy, occurs. Plaques and NFTs may also be present in other diseases, even in normal aging, but there is a much higher concentration of plaques and NFTs in patients with AD. The circumstances in which these lesions lead to

the clinical picture of AD remain unclear. Several mechanisms have been proposed to explain these changes in the brain, including β AP aggregation and deposition leading to the formation of plaques; hyperphosphorylation of tau protein leading to NFT development; inflammatory processes; dysfunction of the neurovasculature; oxidative stress; and mitochondrial dysfunction.¹

AMYLOID CASCADE HYPOTHESIS

Neuritic plaques (also termed amyloid or senile plaques) are extracellular lesions found in the brain and cerebral vasculature. Plaques from AD brains largely consist of a protein called β AP. β AP is produced via processing of a larger protein, APP. Specific APP physiologic roles are not entirely clear, but in a general sense it is felt to contribute to proper neuronal function and perhaps cerebral development.²⁴

Because plaques contain β AP and Down syndrome patients with trisomy 21 manifest both plaque pathology and presenile cognitive decline below their baseline, the role of the APP gene in AD was previously considered. In 1991, an APP gene mutation was uncovered in a family with autosomal dominant, early onset AD.²⁵ Soon after this, the amyloid cascade hypothesis was formulated. In its original form, the amyloid cascade hypothesis proposed that altered APP processing drove β AP production, β AP gave rise to plaques, plaques induced neurodegeneration, and this neuronal loss resulted in the clinical dementia syndrome typical of AD.^{26,27} While subsequent research failed to show APP mutation was a common cause of AD, the findings of other genetic and molecular research also lent support to the amyloid cascade hypothesis. Specifically, mutations in two other genes, presenilin 1 on chromosome 14 and presenilin 2 on chromosome 1, were also shown to cause variants of early onset, autosomal dominant AD.^{28,29} More recent data suggest the presenilin gene products comprise part of the γ -secretase complex that is so intimately involved in APP processing.^{30,31}

The amyloid cascade hypothesis has substantially evolved since its initial formulation. While β AP sequestered in plaques was at first proposed to represent the critical toxic species, more recent versions of the hypothesis assume β AP that is not sequestered in plaques actually drives the disease.^{32,33} Even so, the amyloid cascade hypothesis seems most applicable in cases of early onset, autosomal dominant AD. However, such cases comprise less than 1% of AD, and it is not clear whether it is reasonable to etiologically extrapolate to the late-onset form (which afflicts the vast majority of those affected). Whether individuals with late-onset AD also carry genetic variations that promote a primary β AP amyloidosis remains to be shown. If this turns out not to be the case, the possibility that amyloidosis in late-onset AD is secondary to a more upstream event will require consideration. Before this conceptual conundrum is laid to rest, however, the amyloid cascade hypothesis will likely undergo a therapy-based practical test. If treatments that efficiently reduce β AP production or remove brain β AP fail to arrest disease progression, it would argue amyloidosis is not the primary pathology in most of those with AD.

NEUROFIBRILLARY TANGLES

As β AP was being identified in plaques, other researchers showed that NFTs are commonly found in the cells of the hippocampus and cerebral cortex in persons with AD and are composed of abnormally hyperphosphorylated tau protein. Tau protein provides structural support to microtubules, the cell's transportation and skeletal support system.¹ When tau filaments undergo abnormal phosphorylation at a specific site, they cannot bind effectively to microtubules, and the microtubules collapse. Without an intact system of microtubules, the cell cannot function properly and eventually dies. The density of the NFTs correlates well with the severity of the dementia, because they are a hallmark of neuronal death.³⁴ NFTs are found in

other dementing illnesses besides AD, and may represent a common method by which various inciting factors culminate in cell death.⁸

INFLAMMATORY MEDIATORS

Inflammatory or immunologic paradigms are often viewed as a corollary of the amyloid cascade hypothesis. Certainly, brain amyloid deposition associates with local inflammatory and immunologic alterations. This line of observation led some to propose that inflammation is relevant to AD neurodegeneration.³⁵ The inflammatory/immunologic hypotheses argue that although β AP may have direct neurotoxicity, at least some of its toxicity might actually be an indirect consequence of a β AP protofibril-induced microglia activation and astrocyte recruitment. This inflammatory response may represent an attempt to clear amyloid deposition. However, it is also associated with release of cytokines, nitric oxide, and other radical species, and complement factors that can both injure neurons and promote ongoing inflammation.³⁶ Indeed, levels of multiple cytokines and chemokines are elevated in AD brains, and certain proinflammatory gene polymorphisms are reported to be associated with AD.^{36,37}

Consistent with these molecular observations are epidemiologic data suggesting that exposure to nonsteroidal antiinflammatory drugs (NSAIDs) may reduce AD risk.^{38,39} However, multiple prospective short duration trials of NSAIDs in AD prevention and of NSAIDs, steroids, and hydroxychloroquine as AD treatment have been therapeutically disappointing.^{40,41} Interestingly, the conceptual impetus for trying NSAIDs in AD has radically shifted in recent years. Rather than postulate that clinical benefits (if any are shown to exist) might derive from an antiinflammatory effect, current thinking is that any observed benefits would reflect the ability of some NSAIDs to alter APP processing away from its 42-amino-acid degradation product (β AP 42).

THE CHOLINERGIC HYPOTHESIS

Multiple neuronal pathways are destroyed in AD. Damage occurs in any nerve cell population located in or traveling through plaque-laden areas.⁸ Widespread cell destruction results in a variety of neurotransmitter deficits, with cholinergic abnormalities being the most prominent.² Loss of cholinergic activity correlates with AD severity. In late AD, the number of cholinergic neurons is reduced, and there is loss of nicotinic receptors in the hippocampus and cortex. Presynaptic nicotinic receptors control the release of acetylcholine, as well as other neurotransmitters important for memory and mood, including glutamate, serotonin, and norepinephrine.²

The discovery of vast cholinergic cell loss led to the development of a cholinergic hypothesis linked to the pathophysiology of AD. The cholinergic hypothesis targeted cholinergic cell loss as the source of memory and cognitive impairment in AD. Consequently, it was presumed that increasing cholinergic function would improve symptoms of memory loss. This approach is flawed for two reasons. First, cholinergic cell loss appears to be a secondary consequence of Alzheimer's pathology, not the disease-producing event; second, cholinergic neurons are only one of many neuronal pathways destroyed in AD. It is increasingly clear that simple addition of acetylcholine cannot compensate for the loss of neurons, receptors, and other neurotransmitters lost during the course of the illness. Thus the goal is to minimize or improve symptoms through augmentation of neurotransmission at remaining synapses.

OTHER NEUROTRANSMITTER ABNORMALITIES

Although the cholinergic system has received the most attention in AD pharmaceutical research, deficits also exist in other neuronal

pathways. For example, serotonergic neurons of the raphe nuclei and noradrenergic cells of the locus ceruleus are lost, while monoamine oxidase type B activity is increased. Monoamine oxidase type B is found predominantly in the brain and in platelets, and is responsible for metabolizing dopamine. In addition, abnormalities appear in glutamate pathways of the cortex and limbic structures, where a loss of neurons leads to a focus on excitotoxicity models as possible contributing factors to AD pathology.

Glutamate is the major excitatory neurotransmitter in the cortex and hippocampus. Many neuronal pathways essential to learning and memory use glutamate as a neurotransmitter, including the pyramidal neurons (a layer of neurons with long axons carrying information out of the cortex), hippocampus, and entorhinal cortex. Glutamate and other excitatory amino acid neurotransmitters have been implicated as potential neurotoxins in AD.⁴² If glutamate is allowed to remain in the synapse for extended periods of time, it can destroy nerve cells. Toxic effects are thought to be mediated through increased intracellular calcium and accumulation of intracellular free radicals.⁴² Dysregulated glutamate activity is thought to be one of the primary mediators of neuronal injury after stroke or acute brain injury. Although intimately involved in cell injury, the role of excitatory amino acids in AD is as yet unclear; however, blockade of *N*-methyl-D-aspartate (NMDA) receptors decreases activity of glutamate in the synapse and may lessen the degree of cellular injury in AD.

BRAIN VASCULAR DISEASE AND HIGH CHOLESTEROL

There is growing evidence of a causal association between cardiovascular disease and its risk factors, with the incidence of AD. Cardiovascular risk factors that are also risk factors for dementia include hypertension, elevated low-density lipoprotein cholesterol, low high-density lipoprotein cholesterol, and, particularly, diabetes.⁴³ Brain vascular disease may augment the cognitive impairment observed for a given amount of AD pathology in the brain. Dysfunctional blood vessels may impair nutrient delivery to neurons and reduce clearance of β AP from the brain.¹ In addition, vascular disease may accelerate amyloid deposition and increase amyloid toxicity to neurons.⁴⁴ Controlling high blood pressure is associated with reduced rate of progression of dementia.⁴⁵ Diabetes may increase the risk of dementia through factors related to “metabolic syndrome” (dyslipidemia and hypertension), effects of potentially toxic glucose metabolites on the brain and vasculature, and through insulin itself.⁴⁶ Disturbances in insulin-signaling pathways, both in the periphery and the brain, have been linked to AD. Insulin may also regulate the metabolism of β AP and tau protein.⁴⁶

Research has found multiple links between cholesterol and the occurrence of AD. Apo E is a lipoprotein that is synthesized in the liver, central nervous system, and cerebrospinal fluid. It is responsible for transporting cholesterol in the blood through the brain. It is carried by low-density lipoprotein into neurons and binds to NFTs. Apo E4 is associated with increasing deposition of β AP and is thought to act as an accelerating modulator in the course of vascular dementia. The elevated cholesterol levels in brain neurons may alter membrane functioning and result in the cascade leading to plaque formation and AD.

OTHER MECHANISMS

Other hypotheses proposed to explain AD pathogenesis include oxidative stress, mitochondrial dysfunction, and postmenopausal loss of estrogen in women. Each of these mechanisms may contribute to AD pathogenesis, but the extent of the contribution is uncertain. There is a growing body of evidence of a role for oxidative stress and

TABLE 67-2 Stages of Alzheimer’s Disease

Mild (MMSE score 26–18)	Patient has difficulty remembering recent events. Ability to manage finances, prepare food, and carry out other household activities declines. May get lost while driving. Begins to withdraw from difficult tasks and to give up hobbies. May deny memory problems.
Moderate (MMSE score 17–10)	Patient requires assistance with activities of daily living. Frequently disoriented with regard to time (date, year, season). Recall for recent events is severely impaired. May forget some details of past life and names of family and friends. Functioning may fluctuate from day to day. Patient generally denies problems. May become suspicious or tearful. Loses ability to drive safely. Agitation, paranoia, and delusions are common.
Severe (MMSE score 9–0)	Patient loses ability to speak, walk, and feed self. Incontinent of urine and feces. Requires care 24 hours a day, 7 days a week.

MMSE, Mini Mental Status Examination.
Data from Alzheimer’s Association <http://www.alz.org>;⁴ Rubin,⁷¹ Grossberg and Desai.¹¹⁸

the accumulation of free radicals in the brain of AD patients.⁴⁷ Based on epidemiologic studies, vitamin E, and possibly the combination of vitamin E and vitamin C, may prevent AD.⁴⁷ Mitochondrial dysfunction may result in disruption of energy metabolism in the neuron.¹ Estrogen is thought to be involved in promoting neuronal growth, and in preventing oxidative damage, which would benefit cells exposed to β AP.⁴⁸ Estrogen receptors are present in the brain, and are distributed in a pattern consistent with areas destroyed in AD.^{48,49} Estrogen may be important in maintaining normal cholinergic neurotransmission.⁴⁹ Estrogen may also increase NMDA receptor numbers in brain areas involved in recording new memories and prevent cell damage by acting as an antioxidant.⁴⁸ Additional mechanisms postulated for estrogen’s involvement in maintaining memory function are related to the fact that it increases cerebral blood flow and glucose use, reduces plasma levels of Apo E, and blunts stress-related glucocorticoid release. Postmenopausal loss of estrogen may, therefore, impact maintenance of memory functions.

A single common mechanism for producing AD does not exist. Regardless of the source, however, the features remain the same: degeneration of neurons in higher brain areas; accumulation of NFTs and neuritic plaques; profound destruction of cholinergic pathways; and an insidious dementia, slowly progressive until death.

CLINICAL PRESENTATION OF ALZHEIMER’S DISEASE

4 The onset of AD is almost imperceptible, without abrupt changes in cognition or function. Deficits occur progressively over time, affecting multiple areas of cognition.^{4,50} For treatment and assessment purposes, it is helpful to divide Alzheimer’s symptoms into two basic categories: cognitive symptoms and noncognitive (behavioral) symptoms.⁵⁰ Cognitive symptoms are present throughout the illness, whereas behavioral symptoms are less predictable.⁵⁰ Table 67–2 summarizes the stages of AD.

CLINICAL PRESENTATION OF ALZHEIMER’S DISEASE

General

- The patient may have vague memory complaints initially, or the patient’s significant other may report that the patient is “forgetful.” Cognitive decline is gradual over the course of illness. Behavioral disturbances may be present in moderate stages. Loss of daily function is common in advanced stages.

Symptoms*Cognitive*

- Memory loss (poor recall and losing items)
- Aphasia (circumlocution and anomia)
- Apraxia
- Agnosia
- Disorientation (impaired perception of time and unable to recognize familiar people)
- Impaired executive function

Noncognitive

- Depression, psychotic symptoms (hallucinations and delusions)
- Behavioral disturbances (physical and verbal aggression, motor hyperactivity, uncooperativeness, wandering, repetitive mannerisms and activities, and combativeness)

Functional

- Inability to care for self (dressing, bathing, toileting, and eating)

Laboratory Tests

- Rule out vitamin B₁₂ and folate deficiency
- Rule out hypothyroidism with thyroid function tests
- Blood cell counts, serum electrolytes, liver function tests

Other Diagnostic Tests

- CT or MRI scans may aid diagnosis

DIAGNOSIS

A family member often first brings memory complaints to the attention of a primary care clinician. Up to 50% of patients who meet criteria for dementia are not given a diagnosis in the primary care setting, leading some to believe that an appropriate screening tool may be helpful in aiding diagnosis and leading to earlier treatment.^{51,52} Despite the phenomenon of underdiagnosis, the United States Preventative Services Task Force concluded that there are insufficient data to recommend for or against cognitive screening for AD, because it could not be determined if the benefits outweigh the risks.⁵¹

At present the only way to definitively diagnose AD is through direct examination of brain tissue at autopsy or biopsy. Several criteria have been developed for the detection and diagnosis of dementia, including the *Diagnostic and Statistical Manual of Mental Disorders, 4th ed. Text Revision* (DSM-IV-TR) criteria,⁵³ the Agency for Healthcare Research and Quality (AHRQ) Guidelines,⁵⁴ the American Academy of Neurology Guidelines,⁵⁵ the National Institute of Neurological Disorders and Stroke (NINDS) criteria,⁵⁶ the National Institute of Neurological Communicative Disorders and Stroke (NINCDS), and the Alzheimer's Disease and Related Disorders Association (ADRDA) Criteria.⁵⁷

AD is still primarily a clinical diagnosis.⁵⁷ The patient's examination should suggest that cognitive decline from a previously higher baseline has occurred. The history should corroborate this, and further indicate cognitive decline has reached the point where changes in social or occupational functioning are present. It is possible to administer a sophisticated exam that defines cognitive domain strengths and weaknesses, and enables a neuroanatomical localization of the observed deficits. Ideally, evidence of defective retention memory (amnesia) will implicate bimesiotemporal dysfunction. Evidence of parietal cortical dysfunction (visuospatial dysfunction), dorsolateral prefrontal dysfunction (executive dys-

function), or lateral temporal dysfunction (language dysfunction) should also be present. When approached in this way, the exam can indicate a pattern of cognitive decline that is consistent with what would be expected in AD, and assist with rendering a diagnosis that is as much a diagnosis of inclusion as it is of exclusion.

Objectively defining social or occupational dysfunction can prove tricky in the older patient who may be retired, and who may also lead a socially restricted lifestyle for reasons of frailty. For such patients, the minimal requirement is to establish a change in activities of daily living. Early on, this usually involves a change in instrumental activities of daily living (handling finances, organizing medications) rather than basic activities of daily living (hygiene, dressing). Some AD subspecialists use a detailed, standardized, semistructured interview of a nonpatient informant as the most critical piece of the diagnostic evaluation.⁵⁸

Almost any medication can contribute to cognitive impairment in vulnerable individuals, but certain classes of medication are more commonly implicated. Benzodiazepines and other sedative hypnotics, anticholinergics, opioid analgesics, antipsychotics, and anticonvulsants have been associated with cognitive impairment.⁵⁹ NSAIDs, histamine H₂ receptor antagonists, digoxin, amiodarone, anti-hypertensives, and corticosteroids have been implicated in cases of delirium.⁵⁹ Because medications are a reversible cause of cognitive symptoms, medication review and management are essential.

5 For patients who meet criteria for the dementia syndrome (whether the underlying cause is ultimately felt to be AD or not), current recommendations from the American Academy of Neurology include a neuroimaging study (computed tomography or magnetic resonance imaging), as well as a serologic evaluation that includes blood cell counts, serum electrolytes, liver function tests, a test of thyroid function, and a vitamin B₁₂ level.⁵⁵ Earlier guidelines included a serologic test for syphilis, but this requirement has since been downgraded to optional. When circumstances suggest AD is not the leading entity on the differential diagnosis, other neurologic tests such as spinal fluid analysis or electroencephalogram can occasionally be justified. Neuropsychological testing is also optional, but can prove quite useful for the diagnosis of AD by helping to establish a neuroanatomical localization for the patient's cognitive deficits.

Efforts to define the role of other AD diagnostic tests are ongoing. Positron emission tomography scanning may reveal a pattern of hypometabolism typical of AD (bitemporoparietal hypometabolism), but by itself the diagnostic accuracy of positron emission tomography scanning still lags behind that of the clinical examination and history.⁶⁰ Apo E genotyping by itself is also insufficient to make or break a diagnosis of AD, but demonstrating an apo E4 allele in a suspected patient increases the specificity of the diagnosis and can help predict which patients with mild cognitive impairment are most likely to progress to a full-blown diagnosis of AD over the next several years.^{61,62} Unless the patient developed dementia prior to age 60 years and also had a parent that developed AD before age 60 years, presenilin 1 genotyping is usually not indicated.

MILD COGNITIVE IMPAIRMENT

It has long been recognized that aging individuals experience changes in cognitive function. Mild cognitive impairment constitutes a syndromic designation that categorizes patients with cognitive complaints insufficient to warrant a syndromic diagnosis of dementia. Persons diagnosed with mild cognitive impairment carry a 10% to 15% chance per year of progressing to an AD diagnosis.⁶³ A logical extension of this is that what clinicians are actually seeing in most people with mild cognitive impairment is the initial manifestation of a progressive degenerative dementia that will eventually meet AD diagnostic criteria.⁶⁴ However, it is important to note that not everyone meeting mild cognitive impairment criteria does or will have AD.

As the mild cognitive impairment designation is increasingly applied, mild cognitive impairment criteria continue to evolve.⁶⁵

TREATMENT

Alzheimer's Disease

■ DESIRED OUTCOMES

6 The primary goal of treatment in AD is to symptomatically treat cognitive difficulties and preserve patient function as long as possible. Secondary goals include treating the psychiatric and behavioral sequelae that occur as a result of the disease. Current AD treatments have not been shown to prolong life, cure AD, or halt or reverse the pathophysiologic processes of the disorder.⁶⁶

■ GENERAL TREATMENT APPROACH

Clinical trials have consistently demonstrated modest benefits of early and continuous treatment with cholinesterase inhibitors.⁶⁶ Memantine added in moderate to severe disease may also provide benefit. Following this approach allows for maximum gain and maintenance of cognition and activities of daily living. A symptomatic approach is used to treat behavioral symptoms as they arise.

Provision of education to the patient and family at the time of diagnosis, including discussion of the course of illness, realistic expectations of treatment, and the importance of legal and financial planning, are essential to appropriate treatment. Good communication skills are important to maintain a therapeutic environment and minimize stress throughout the course of illness.

■ NONPHARMACOLOGIC THERAPY

7 AD has a profound effect on both the patient and family, so appropriate treatment, both nonpharmacologic and pharmacologic, is needed. Nonmedication interventions are the current primary interventions for management of AD, and medications should be used in the context of multimodal interventions. Behavioral and psychiatric symptoms are among the most challenging and distressing symptoms of the disease and may be the determining factor in a family's decision to seek institutional care. Symptoms such as sleep disturbances, wandering, urinary incontinence, agitation, and aggression in patients with dementia are best managed using behavioral interventions rather than medications whenever possible.⁶⁷

Upon initial diagnosis, the patient and caregiver should be educated on the course of illness, prognosis, available treatments, legal decisions, and quality-of-life issues. Education, including short- and long-term programs, improves caregiver knowledge and confidence, and in some cases, delays time to nursing home placement.⁶⁸ Table 67-3 lists basic principles of care for the AD patient.

TABLE 67-3 Basic Principles of Care for the Alzheimer's Patient

- Consider vision, hearing, or other sensory impairments.
- Find optimal level of autonomy and adjust expectations for patient performance over time.
- Avoid confrontation. Remain calm, firm, and supportive if the patient becomes upset.
- Maintain a consistent, structured environment with stimulation level appropriate to the individual patient.
- Provide frequent reminders, explanations, and orientation cues. Employ guiding, demonstration, and reinforcement.
- Reduce choices, keep requests and demands of the patient simple, and avoid complex tasks that lead to frustration.
- Bring sudden declines in function and the emergence of new symptoms to professional attention.

Data from Alzheimer's Association <http://www.alz.org>.⁴ Lyketsos et al.,⁴⁴ and Rubin.⁷¹

Communication between the patient and family members is essential in order to minimize stress on everyone.

The general approach to developing nonmedication strategies for behavioral symptoms is to identify the symptom, identify causative factors, and adapt the caregiving environment to remedy the situation.⁴ Environmental triggers may include noise, glare, an insecure space, and too much background distraction, including television. Personal discomfort may also trigger behaviors, so it is important to monitor for pain, hunger, thirst, constipation, full bladder, fatigue, infections and skin irritation, comfortable temperature, fears, and frustrations.⁴ Medical comorbidity is a major source of functional and cognitive impairment in patients with AD, so general health maintenance is warranted.⁴⁴ Interventions should redirect the patient's attention rather than be confrontational and should specifically address known triggers. Creating a calm environment and removing stressors and triggers is key. Caregivers should be referred to support services such as the Alzheimer's Association for assistance in developing strategies to manage difficult behaviors.

The caregiver must be prepared to face the changes in life that will occur, and acceptance of this does not come easily. Denial on the part of the patient and rationalization on the part of the family are common. The clinician should encourage the family to address legal and financial matters and designate a durable power of attorney for execution of financial and medical decisions once the patient is incompetent. The caregiver will need to address issues such as respite services to provide time for rest, relaxation, and conduct of personal business. Caregiver stress impacts the health and quality of life of the caregiver as well as the patient. Eventually the caregiver will need to face critical questions with respect to institutionalization. This is probably the most difficult decision for the caregiver. Clinician support and referral to social services is vitally important in assisting the caregiver at that moment. The family should also be referred to local resources, such as the Alzheimer's Association, that can provide detailed information regarding support services. Table 67-4 lists some referral sources for caregivers.

Education, communication, and planning are the key nonpharmacologic components of caring for an AD patient. Preparation in the early stages of illness will lessen some of the caregiver stress as the illness progresses.

■ PHARMACOLOGIC THERAPY

Pharmacotherapy for Cognitive Symptoms

8 Table 67-5 presents a treatment algorithm for managing cognitive symptoms in AD. Cholinesterase inhibitors and NMDA-receptor

TABLE 67-5 Treatment Options for Cognitive Symptoms in Alzheimer's Disease

- In mild-moderate disease, consider therapy with a cholinesterase inhibitor.
 - Donepezil, or
 - Rivastigmine, or
 - Galantamine
- Titrate to recommended maintenance dose as tolerated.
- In moderate to severe disease, consider adding anticholinergic therapy.
 - Memantine
- Titrate to recommended maintenance dose as tolerated.
- Alternatively, consider memantine or cholinesterase inhibitor therapy alone.
- Behavioral symptoms may require additional pharmacologic approaches.

Data from Desai and Grossberg,² Lyketsos et al.,⁴⁴ and Lleó et al.⁴⁷

antagonists are indicated for treatment of AD. The latest treatment guideline recommends the use of cholinesterase inhibitors for AD, with no preference for a specific agent.^{44,69} Donepezil, rivastigmine, and galantamine are indicated in mild to moderate AD, while donepezil is also indicated in severe disease. Memantine is indicated for moderate to severe AD; current evidence does not support its use in earlier stages of the disease.⁷⁰ Additional benefit may be achieved when memantine is added to cholinesterase inhibitor therapy in moderate to severe AD.^{44,70} There is no evidence supporting combination therapy of more than one cholinesterase inhibitor.

CLINICAL CONTROVERSY

Several cholinesterase inhibitors are now available, raising the question of whether it is appropriate to switch a patient from one to another if the first is not considered effective. Theoretical differences exist in their mechanisms of action, but many clinicians feel that these differences are not clinically meaningful, and therefore that switching is not helpful. Switching is recommended if a patient is not tolerating the initial treatment. Most clinicians probably do switch to another agent, and initial data seem to indicate that some patients do respond to an alternative cholinesterase inhibitor. Usually switching is performed without a washout period and interruptions for longer than 3 weeks are not advised.⁴⁷

Disagreement exists about how to determine effectiveness of treatments for AD. Selection of qualitative versus quantitative assessment may bias a clinician's impression of response. Subtle changes are often detected only by psychometric testing rather than with routine questioning. Because no standard has been suggested to define the effectiveness of these medications, great variation exists between clinicians and the duration of treatment ranges from months to years. Realistic expectations for treatment success may include short-term improvement of symptoms and less decline in behavioral, functional, and cognitive abilities over the longer-term.⁶⁶

Unfortunately, clinical trials have failed to provide answers to key questions in treating AD patients. Information from clinical trials is insufficient to know if a cholinesterase inhibitor dose-response relationship exists, or if additional cognitive improvement may be gained by increasing to the maximum tolerated dose, rather than continuing with the usual recommended daily dosage. Guidance in extrapolating data related to changes in cognition is needed so that a reasonable duration of clinical treatment with cholinesterase inhibitors and NMDA-antagonists can be determined.

In natural disease progression studies, scores on the Alzheimer's Disease Assessment Scale—Cognition (ADAS-cog) have been shown to worsen (increase) by an average of 4 points over 6 months and 7 points over 1 year. Based on these findings, the general consensus is that a 4-point change in the ADAS-cog represents a clinically significant change. Therefore, if a pharmacotherapeutic

agent decreases the ADAS-cog by 4 points, one could think of this as having reversed progression of disease symptoms by 6 months. The usefulness of the ADAS-cog in clinical practice is limited because of the time required for administration; it is much more practical to assess changes in disease severity using the Mini Mental Status Examination (MMSE). An untreated patient has an average decline of 2 to 4 points in MMSE score per year. Consequently, successful treatment would reflect a decline of less than 2 points a year. It is reasonable to change to a different cholinesterase inhibitor if the decline in MMSE score is greater than 2 to 4 points after 1 year with the initial agent.

CLINICAL CONTROVERSY

Disagreement exists about the usefulness of current therapies for AD in advanced stages of the disease. Some clinicians believe that patients should be taken off cognitive-enhancing medications once they have reached very severe stages of AD, whereas others believe that these medications may continue to be helpful with managing psychiatric symptoms and maintaining function. Many clinicians discontinue cognitive-enhancing medications once the AD patient is bedridden and unable to perform activities of daily living.

8 Cholinesterase Inhibitors In the early 1980s, researchers began to examine means to enhance cholinergic activity in patients with AD by inhibiting the hydrolysis of acetylcholine through reversible inhibition of cholinesterase. Tacrine was the first such drug to be examined in a systematic fashion. However, tacrine is fraught with significant side effects, including hepatotoxicity, that severely limit its usefulness. For all practical purposes the use of tacrine has been replaced by the use of safer, more tolerable cholinesterase inhibitors. Newer cholinesterase inhibitors donepezil, rivastigmine, and galantamine, show similar efficacy and adverse event profiles to one another and are generally well tolerated. The most frequent adverse events associated with these agents are mild to moderate gastrointestinal symptoms (nausea, vomiting, and diarrhea).⁴⁷ Other cholinergic side effects are generally dose-related and include urinary incontinence, dizziness, headache, syncope, bradycardia, muscle weakness, salivation, and sweating. Gradual dose titration over several months can improve tolerability.⁶⁹ Abrupt discontinuation can lead to worsening cognition and behavior in some patients.⁴⁴ Concurrent use of anticholinergic medications with cholinesterase inhibitors should be avoided.

Table 67-6 summarizes the clinical pharmacology of the cholinesterase inhibitors. The mechanism of action differs slightly between drugs in this class.⁷¹ Donepezil specifically and reversibly inhibits acetylcholinesterase. Rivastigmine inhibits both butyrylcholinesterase and acetylcholinesterase. Galantamine is a selective, competitive, reversible acetylcholinesterase inhibitor and also enhances the action of acetylcholine on nicotinic receptors. The clinical relevance of these differences is unknown. Choice of cholinesterase inhibitor therapy for an individual patient is based on ease of use, patient preference, cost, and safety issues such as potential for drug interactions.⁴⁴

8 Anticholinergic Therapy Memantine is the only NMDA-antagonist currently available. Memantine blocks glutamatergic neurotransmission by antagonizing NMDA receptors. Glutamate is an excitatory neurotransmitter in the brain implicated in long-term potentiation, a neuronal mechanism important for learning and memory.⁴⁷ By blocking NMDA receptors, excitotoxic reactions, which ultimately lead to cell death, may be prevented, although longer-term studies are needed to assess this hypothesis.^{47,70}

Memantine has been studied in patients with moderate and severe AD as monotherapy and in combination with donepezil with

Data from references 72 and 119–122.

modest favorable results on cognition and function.⁷⁰ It is currently indicated for use in AD patients with moderate to severe illness. Studies of memantine alone and in combination with cholinesterase inhibitors in mild AD performed to date have provided insufficient evidence to support an indication for mild AD.⁴

Memantine has 100% bioavailability regardless of administration with or without food. Protein binding is low. Memantine is not metabolized by the liver and does not inhibit cytochrome P450. Memantine is primarily excreted unchanged in the urine. The half-life ranges from 60 to 80 hours.⁴⁷

Overall, memantine has been well tolerated in clinical trials. The most common adverse events associated with memantine include constipation, confusion, dizziness, headache, hallucinations, coughing, and hypertension.⁷³

Memantine is likely to be used as monotherapy and also in combination with cholinesterase inhibitors in patients with moderate to severe AD. Memantine should be initiated at 5 mg once a day and increased weekly by 5 mg a day to the effective dose of 10 mg twice daily.⁷³ It may be given with or without food. Dosing of 10 mg daily is recommended in patients with severe renal impairment (creatinine clearance of 5 to 29 mL/min).⁷³

Role of Combination Therapy The efficacy of all available AD treatments is limited. Currently, the best possible short-term outcome includes a symptomatic improvement over the pretreatment baseline. Because agents with different mechanisms of action are now available for the treatment of AD, the efficacy of combination therapy has been considered. In the only combination treatment trial published to date, patients receiving donepezil were randomized to receive 20 mg/day of memantine or placebo. During the 6-month course of the trial, those randomized to receive combination therapy performed better on a cognitive scale and an activities of daily living scale than those randomized to donepezil plus placebo.⁷⁴ A subsequent report concluded that with donepezil-memantine combination therapy, behavioral benefits were also demonstrable on the Neuropsychiatric Inventory.⁷⁵ It is important to note that these studies included subjects with MMSE scores of 5 to 14. Data showing donepezil-memantine combination therapy benefits in AD patients with MMSE scores above 14 are lacking.

Available data suggest treatment strategies currently under investigation will at best slow rather than arrest cognitive decline.⁷⁶ It therefore seems reasonable to predict that for the foreseeable future combination therapy will become increasingly common in AD, especially as drugs or treatments with unique mechanisms of action become available, and drugs with neuroprotective modes of action are concomitantly used with symptomatic drugs.

Effect of Current Treatments on Neurodegenerative Processes

AD is a progressive disorder. Affected individuals typically experience some degree of cognitive decline and histologic change years (if not decades) before a diagnosis is made. Therefore, the ideal treatment will be one that not only reverses symptoms by enhancing cognitive function (a symptomatic treatment), but also arrests the neurodegeneration-relevant molecular processes that underlie cognitive decline (a disease-modifying treatment).

Clinical trials for AD prompt consideration of whether positive outcomes suggest either a symptomatic or disease-modifying effect. Any rapid performance improvement on cognitive ability, activities of daily living, or behavioral end points is indicative of a symptomatic effect. All cholinesterase inhibitor agents and memantine demonstrate this pattern. On the other hand, arrest of decline or a sustained reduction in the slope of decline would argue the presence of a disease-modifying effect. It has not been possible to unequivocally demonstrate this in trials of the currently approved treatments. Definitive trials evaluating whether cholinesterase inhibitors or memantine have disease-modifying effects are difficult to perform, because doing so requires continuing a placebo arm over an extended period, well beyond demonstration of symptomatic benefit. Also, subject attrition over an extended study would complicate both intent-to-treat and observed cases analyses.

With the currently approved AD drug treatments, placebo-controlled pivotal trials were followed by open-label extension studies. Published studies have lasted as long as 5 years, and as part of these studies, decline in the treatment group was compared to “projected” placebo groups based on the placebo groups followed during the 6-month randomized phase of the efficacy study, as well as natural history cohorts from the precholinesterase inhibitor therapy era. Although analyses of this sort conclude that, for up to at least 5 years, persons receiving treatment exceed their projected nontreatment cognitive performance, no convincing evidence of a disease-modifying effect emerges.^{77–80}

Management of Brain Vascular Health

Recent guidelines for the principles of care of patients with AD support the management of vascular brain disease and its associated risk factors as part of the treatment of AD.⁴⁴ There is a growing body of evidence that brain vascular disease plays an important role in the progression of dementia. For a given level of Alzheimer’s pathology, vascular disease in the brain may add to the degree of cognitive impairment.⁴⁴ Brain vascular disease may also accelerate deposition of β AP and increase amyloid toxicity to neurons and the neural synapses.⁴⁴ Management of brain vascular disease includes monitor-

ing blood pressure, glucose, cholesterol, and homocysteine and initiation of appropriate interventions.⁴⁴ Guidelines recommend initiation of low-dose aspirin therapy in patients with AD with significant brain vascular disease.⁴⁴ Elevated homocysteine levels correlate with decreased performance on cognitive tests, but there remains insufficient evidence of a benefit of B vitamin supplementation (B₆, B₁₂, and folic acid) on cognitive function in patients with AD.⁸¹ Reducing the risk for developing brain vascular disease may also be an important strategy in reducing the risk for developing AD. The Alzheimer's Association's Maintain Your Brain campaign is designed to increase awareness of the importance of brain health as a part of healthy aging and recommends staying physically, mentally, and socially active; adopting a low-fat, low-cholesterol diet rich in dark vegetables and fruit; and managing body weight, blood pressure, cholesterol, and blood sugar to reduce the risk of heart disease, stroke, and diabetes.⁴ Appropriate management of vascular disease risk factors may reduce the risk for developing AD and may prevent the worsening of dementia in patients with AD.

Other Potential Treatment Approaches

Estrogen Estrogen replacement has been studied extensively for the treatment and prevention for AD. Most, but not all, epidemiologic studies show a lower incidence of AD in women who took estrogen replacement therapy postmenopausally. Results from these epidemiologic surveys prompted researchers to look at the use of estrogen preventively and as a treatment for cognitive decline.

Recent clinical trials have not supported the use of estrogen as a treatment for cognitive decline. Two studies evaluating the potential benefit of conjugated estrogens as a treatment for cognitive decline did not show any benefit;^{82,83} behavioral and functional outcomes were not improved either. Conflicting data exist regarding the risk of AD in women who take estrogen replacement therapy. There is clinical evidence that loss of estrogen after menopause is associated with subclinical impairment in some aspects of neuropsychological function. The Women's Health Initiative Memory Study⁸³ was designed to evaluate the incidence of dementia and mild cognitive impairment in patients taking estrogen plus progestin versus placebo. The number of probable dementia cases in the estrogen plus progestin group was almost double that of the placebo group. The estrogen-alone trial of the Women's Health Initiative was terminated because of an increased risk of stroke and the lack of a significant effect on other cardiovascular disease outcomes. The trial did, however, suggest that estrogen initiated in the late postmenopausal period does not improve global cognitive function and may even adversely affect this outcome. These studies do not support a role for estrogen in treating symptoms of AD.

Antiinflammatory Agents Epidemiologic studies suggest a protective effect against AD in patients who have taken NSAIDs.^{84–86} Treatment for less than 2 years is associated with a lower relative risk of AD; however, longer treatment duration lowered this risk further.^{85,86}

The benefits of antiinflammatory agents on cognition have been less compelling in clinical studies. Indomethacin, prednisone, and diclofenac/misoprostol administration have had no cognitive benefit in AD patients.^{87–89} Tolerability was also problematic.^{87,88} Additionally, prednisone treatment was associated with worsening behavioral symptoms,⁸⁸ and data from other patient populations suggest that prednisone may be associated with cognitive impairment.⁹⁰ Because there is a lack of compelling data and also a significant incidence of adverse effects, particularly gastritis and the possibility of gastrointestinal bleeds, NSAIDs and prednisone are not recommended for general use in the treatment or prevention of AD at the present time.

Recent attention has shifted to the potential benefit of the cyclooxygenase-2 inhibitors in light of their antiinflammatory properties. Rofecoxib has been compared to naproxen and placebo with

no demonstrated cognitive benefit after 1 year.⁹¹ Until clinical trials establish benefit of the cyclooxygenase-2 inhibitors, their general use as preventive treatment for AD cannot be recommended. Market withdrawal of rofecoxib and other safety concerns within this class may limit further study in AD.

Lipid-Lowering Agents Interest in the potential protective effects in AD patients of lipid-lowering agents, particularly the 3-hydroxy-3-methylglutaryl-coenzyme A-reductase inhibitors, is growing. Longitudinal epidemiologic studies suggest an association between elevated midlife total cholesterol levels and AD.^{92,93} Other studies note that the incidence of AD is lower in patients who have taken either a statin^{94,95} or another lipid-lowering agent,⁹⁶ but not in patients who were taking other cardiovascular medications.⁹⁵ Interestingly, pravastatin and lovastatin, but not simvastatin, were associated with a lower prevalence of AD,⁹⁵ suggesting that individual agents rather than a class effect impact AD prevalence. Although these studies have linked cholesterol levels to increased risk of AD, others have yielded conflicting results.⁹⁷

Prospective clinical trials will need to address the cognitive benefit, duration of treatment, class effect versus effectiveness of individual agents, and optimal dosing. Simvastatin has been studied in one clinical trial showing a reduction in β AP in patients with milder AD, but not in those with severe illness.⁹⁸ Mixed results were also seen in cognitive outcomes.⁹⁸ Atorvastatin is currently being studied in clinical trials. Further studies, including randomized prospective statin trials, are needed to determine cholesterol's role, if any, in the pathogenesis of AD.

Interestingly, cognitive impairment has been recognized as a rare adverse event associated with statin therapy. The extent of cognitive impairment may depend on the lipid solubility of the drug, regulating the amount of drug that is able to cross the blood–brain barrier. As simvastatin and lovastatin have the highest lipophilicity, they may be the most likely candidates to cause memory impairment.⁹⁹ More research is needed to understand the complex relationship between cholesterol, statin therapy, and cognitive functioning. For now these agents should be reserved for patients who have other indications for their use.⁴⁴

CLINICAL CONTROVERSY

The antioxidant vitamin E has been proposed as a treatment for AD because of the association of oxygen free radicals with AD, although few studies have documented benefits of treatment. Because of its potential effectiveness, tolerability, and low cost, some clinicians recommend the addition of vitamin E to other therapies for AD. Treatment guidelines from the American Psychiatric Association and the American Academy of Neurology recommend consideration of high-dose vitamin E (e.g., 1,000 international units twice daily) as a treatment option. However, recent findings suggest that vitamin E in high doses is associated with increased mortality in older people.¹⁰⁰ Many clinicians feel that there is insufficient evidence to broadly recommend this as an additive treatment.

Dietary Supplements

Vitamin E Based on pathophysiologic theories involving oxidative stress and the accumulation of free radicals in AD, significant interest has evolved regarding the use of antioxidants in the treatment of AD. Vitamin E is often recommended as adjunctive treatment for AD patients. This recommendation is based on data from the only published clinical trial to date, which evaluated the time to critical end points (i.e., death, institutionalization, loss of ability to perform activities of daily living, or severe dementia) in patients treated with

vitamin E, selegiline, the combination, or placebo.¹⁰¹ Although vitamin E and selegiline were superior to placebo, this study has been criticized because of differences in baseline cognitive severity, calling the validity of the results into question. Nonetheless, vitamin E's potential effectiveness, favorable side effect profile, and low cost have perpetuated its use as adjunctive therapy.

Evidence related to vitamin E's role in prevention of AD is mixed. Epidemiologic studies in individuals without AD have yielded conflicting results, with some studies showing delay in the onset of AD in individuals taking vitamin E supplements, but others failing to find this association.⁴⁷ Some studies have also found that dietary intake of vitamin E is associated with reduced risk while others have not.⁴⁷ A 3-year study in patients with mild cognitive impairment failed to show that vitamin E had a significant effect on slowing the progression to AD.⁴⁷

Vitamin E treatment may also be associated with risks. Side effects observed with vitamin E administration include impaired hemostasis, fatigue, nausea, diarrhea, and abdominal pain. For example, vitamin E can cause thinning of the blood if it is taken with other medications such as aspirin, ibuprofen, and/or naproxen.¹⁰¹ A recent meta-analysis found that high dose vitamin E increases mortality in older patients. In light of these findings, doses above 400 international units per day should probably be avoided in patients with AD.⁴⁴

Ginkgo Biloba Ginkgo is one of the most popular dietary supplements used in AD. Hypothesized mechanisms of action in AD include increasing blood flow, decreasing the viscosity of blood, antagonizing platelet activating factor receptors, increasing tolerance to anoxia, inhibiting monoamine oxidase, antiinfective properties, and preventing the damage of membranes caused by free radicals. Ginkgo biloba may also inhibit catecholamine-O-methyl transferase. The most important active ingredients include the flavonoids, the ginkgo flavone glycosides, and bioflavonoids. Most studies reporting benefit in patients with AD have studied a standardized extract, EGb 761, in doses of 120 mg per day for at least 4 to 6 weeks. The general recommendations are that if ginkgo biloba is used for dementia it should be used as soon as deterioration of cognitive functioning occurs. Therapeutic response may be noted in 2 to 3 weeks, but 12 weeks of consistent dosing may be needed to get a beneficial effect. It is recommended that doses of 120 to 240 mg of the standard leaf extract twice per day be used.^{102,103}

Side effects reported in studies involving EGb 761 are rare and usually mild, and may include nausea, vomiting, diarrhea, headaches, dizziness, palpitations, restlessness, and weakness. Because EGb also has a potent antiplatelet effect, it should not be used in individuals taking anticoagulant or antiplatelet therapies, and should be used cautiously in patients taking NSAIDs.^{102,103}

Even if the herbal extract is modestly effective, significant problems exist with its use. The content of herbal products is poorly standardized, and significant variation in purported active ingredient content for some herbals exists from lot to lot and between manufacturers. Until these products are better standardized and their manufacturing and stability better assured, they should be used with caution. Current practice guidelines indicate that, in general, the use of ginkgo is not recommended for AD.⁴⁴

Huperzine A Huperzine A is an alkaloid isolated from the Chinese club moss, *Huperzia serrata*. It reversibly inhibits acetylcholinesterase and is administered orally in doses of 50 to 200 mcg two to four times daily. Clinical studies suggest that huperzine A may be promising for symptomatic treatment of Alzheimer's disease, but more studies are needed to determine its particular place in therapy. In a randomized, placebo-controlled, double-blind study, 58% of patients receiving huperzine A, 200 mcg/day for 8 weeks, had improvements in memory, cognition, and behavioral function compared to 36% who received placebo.¹⁰⁴ No severe side effects were noted. In a random-

ized, double-blind, placebo-controlled multicenter study in patients with mild to moderate AD, treatment with huperzine A at doses of 400 mcg/day for 12 weeks resulted in improvement in cognition by an average of 4.6 points assessed by ADAS-cog ($P = 0.000$), 2.7 points on the MMSE, and 1.5 points on the Alzheimer's Disease Assessment Scale–noncognition ($P = 0.008$).¹⁰⁴

Although initial results suggest a potential role for huperzine A in the treatment of AD, it has not been adequately tested for this purpose. Safety issues related to long-term use and lack of careful manufacturing oversight for product purity and consistency remain a concern. Concurrent use with other available cholinesterase inhibitors should be avoided, as there is no evidence for added benefit with increasing cholinesterase inhibitor exposure beyond recommended maintenance doses, but the risk of adverse events increases with dose.

Drugs in Development

Current drug development strategies fall broadly into one of two categories. The first category includes treatments specifically designed to reduce the burden of brain β AP. The second category includes all other strategies.

To reduce brain amyloid levels, approaches to both reducing β AP production and enhancing its removal are undergoing evaluation. β AP is produced through enzymatic processing of APP by two enzyme complexes, the β - and γ -secretases. β -Secretase inhibitors are in phase II human trials. Agents that specifically inhibit γ -secretase could prove problematic from a side-effect perspective, as γ -secretase is also critical for processing Notch3, a protein of developmental importance and perhaps brain maintenance. Certain NSAIDs (ibuprofen and flurbiprofen) influence the γ -secretase but do not inhibit it outright. In general, these NSAIDs alter where γ -secretase cuts the APP protein. An enantiomer of flurbiprofen, R-flurbiprofen, recently completed a phase II human trial and is slated for a phase III efficacy trial.

Immunotherapy approaches have been studied as a way to enhance β AP removal. The most extensive investigation involved AN1792, a β AP-based vaccine. This vaccine first showed efficacy in transgenic mice that produce human β AP. In vaccinated mice, brain β AP loads were reduced, there was preservation of cognitive abilities, and the vaccine was well tolerated.¹⁰⁵ A phase II trial in humans was prematurely halted after a substantial percentage of those mounting a robust immune response to the vaccine experienced encephalitis, a potentially life-threatening brain inflammation. Individuals in this study who were vaccinated, developed a robust immune response, and did not develop encephalitis, as well as those in the trial's placebo group, received ongoing clinical followup. One-year postvaccination neuropsychological data⁷⁶ showed that subjects in both of these groups continued to decline, although trends toward lesser decline in the vaccination group were identified. Brain histopathology from vaccinated subjects who subsequently died, demonstrated clear reductions in brain parenchyma β AP.^{106–108} In summary, available clinical data are inconclusive but indicate that, over a 1-year period, activating the immune system to remove β AP does not have a robust impact on cognition. The next generation of amyloid clearance therapy is currently under development. This generation includes modifications of the active immunization approach that, hopefully, will not trigger encephalitis. Passive immunization approaches via antibody infusions are also under investigation. The use of unique β AP antibodies is being explored. The usefulness of treating AD subjects with intravenous immunoglobulin preparations, which naturally contain antibodies to β AP, is being evaluated in an open-label study.

The second category of AD treatment development includes efforts not specifically intended to reduce brain β AP levels. Neuroscientists are unraveling intracellular pathways involved in cell information processing, and drugs that can modulate these path-

ways are under development. Drugs that retard neurofibrillary tangle formation in mice expressing mutant human tau transgenes, such as valproic acid, are being tested in humans. The thiazolidinedione drugs rosiglitazone and pioglitazone, which reduce insulin resistance and which may also have antiinflammatory effects, are undergoing testing in humans with AD. One small open-label trial has involved intracranial implantation of fibroblasts engineered to produce neurotrophic factors.¹⁰⁹

Obviously, successful development of new AD treatments depends on elucidating AD's true underlying pathophysiology. If AD is a primary amyloidosis, as is postulated by the amyloid cascade hypothesis, then reducing β AP would seem a rational way to proceed with drug development. If AD is not a primary amyloidosis, then the impact anti-amyloid therapies have on the disease will be limited at best. Moreover, if AD is not a primary amyloidosis, the usefulness of β AP-overproducing transgenic animals for preclinical drug testing is called into question. Finally, at genetic and epidemiologic levels it is now possible to define several different Alzheimer's "diseases." It is not unreasonable to consider whether treatments useful in one type of AD may not benefit patients with another type.

■ PHARMACOTHERAPY OF NONCOGNITIVE SYMPTOMS

The majority of patients with AD manifest noncognitive symptoms at some point in the illness.⁶⁷ These symptoms can be roughly divided into three categories: psychotic symptoms, inappropriate or disruptive behavior, and depression. Effective management of these problems is important because behavioral symptoms are distressing to both the patient and the caregiver, necessitate increased caregiver supervision and patience, and are a leading reason for nursing home placement. In fact, presence of neuropsychiatric symptoms increases caregiver burden more than loss of cognition or self-care.

⑩ Strategies for treatment of psychotic or behavioral symptoms should include environmental interventions first, then pharmacologic interventions if warranted. The need for medications may exist when neuropsychiatric symptoms are of sufficient severity to cause significant distress to the patient or caregiver, interfere with function or cause disability, impede delivery of necessary care, or pose a danger to self or others.⁴⁴ The balance between risks of the medication and expected benefits must be acceptable to the patient or surrogate decision maker. Medications should be used cautiously, with adequate monitoring for efficacy and adverse events.

Despite the high prevalence of noncognitive symptoms in AD, little research has been conducted in these patients. Data from clinical trials of antidepressants, cholinesterase inhibitors, and antipsychotics are now emerging, but clearly more research is needed. Because of limited clinical data, treatment is primarily empiric, with side-effect profiles used as a guide in selecting the appropriate treatment. Psychotropic medications with anticholinergic effects should be avoided because they may actually worsen cognition and interfere with cholinesterase inhibitor therapy. Other side effects in the elderly include sedation, medication-induced postural instability, and extrapyramidal side effects, which can decrease the clinical usefulness of traditional psychotropic agents.

General guidelines governing therapy can be summarized as follows: use reduced doses, monitor closely, titrate dosage slowly, and document carefully. Caregivers often have erroneous expectations regarding the effects of psychotropic medications, and the anticipated benefits and risks of therapy should be clearly explained. Disruptive behaviors and delusions wax and wane with disease progression. Attempts to slowly taper and discontinue antipsychotic medication should be undertaken regularly in minimally symptomatic patients, because some patients improve on medication withdrawal.⁴⁴ Table 67-7 outlines suggested doses of medications.

TABLE 67-7 Medications Used for Noncognitive Symptoms of Dementia

Drugs	Starting Dose (mg)	Maintenance Dose in Dementia (mg/day)	Target Symptoms
Antipsychotics			Psychosis: hallucinations, delusions, suspiciousness
Haloperidol	0.25	1–3	
Olanzapine	2.5	5–10	
Quetiapine	25	100–300	Disruptive behaviors: agitation, aggression
Risperidone	0.25	0.75–2	
Ziprasidone	20	40–160	
Antidepressants			Depression: poor appetite, insomnia, hopelessness, anhedonia, withdrawal, suicidal thoughts, agitation, anxiety
Citalopram	10	10–20	
Escitalopram	5	20–40	
Fluoxetine	5	10–40	
Paroxetine	10	10–40	
Sertraline	25	75–100	
Venlafaxine	25	75–225	
Trazodone	25	75–150	
Anticonvulsants			Agitation or aggression
Carbamazepine	100	200–600	
Valproic Acid	125	500–1,000	

Data from Lleó et al.,⁴⁷ Benoit et al.,⁶⁷ and Grossberg and Desai.¹¹⁸

CLINICAL CONTROVERSY

Antipsychotic medications have been widely used to treat disruptive behaviors and psychosis in AD patients, although the evidence supporting their modest benefit for some symptoms is limited.¹¹⁰ Use of antipsychotics to treat severe neuropsychiatric symptoms in AD remains controversial. Recent studies indicate that atypical and typical antipsychotics have been associated with infrequent but serious adverse events, including a small increased risk of death.⁴⁴ These findings resulted in a Food and Drug Administration-mandated "black box warning" concerning the use of atypical antipsychotics in the treatment of AD. Careful consideration of risk versus benefit in individual patients is warranted.

Cholinesterase Inhibitors and Memantine

Clinical trials with cholinesterase inhibitors have consistently reported modest benefit in managing neuropsychiatric symptoms, although these are generally not the primary outcomes studied in the trials. In a prospective, randomized, placebo-controlled trial, donepezil significantly improved behavioral symptoms of AD for at least 3 months. Evidence suggests that galantamine and rivastigmine have similar effects.⁶⁶ Memantine shows significant behavioral benefits for at least 6 months, either alone or in combination with cholinesterase inhibitors.⁶⁶ These treatments can provide modest short-term improvement and possibly slow the development and progression of behavioral symptoms. Cholinesterase inhibitors also have a small beneficial effect on caregiver burden and active time use among caregivers of persons with AD.¹¹¹ These benefits should be considered along with cognitive benefits in treatment decisions. Long-term effects on behavior have not been demonstrated to date, and further research is needed. Cholinesterase inhibitors and memantine can be considered as first-line therapy in the early management of behavioral symptoms in AD.¹¹²

Antipsychotics

Antipsychotics are widely used in the management of neuropsychiatric symptoms in AD. There is modestly convincing evidence that

most of the atypical antipsychotics provide some benefit for particular neuropsychiatric symptoms, but these data have been insufficient to gain a Food and Drug Administration approval as an indication for the management of behavioral symptoms in AD. Based on a recent meta-analysis, only 17% to 18% of dementia patients show a treatment response to atypical antipsychotics.¹¹³ In a double-blind, placebo-controlled trial of 421 outpatients with AD and psychosis, aggression, or agitation randomized to receive olanzapine, quetiapine, risperidone, or placebo for up to 36 weeks, there were no significant differences among the treatments in time to discontinuation of treatment or improvement in the Clinical Global Impression of Change scale. The investigators concluded that adverse effects offset advantages in the efficacy of atypical antipsychotic drugs for treatment of psychosis, aggression, or agitation in patients with AD.¹¹³ Adverse events are common with atypical and typical antipsychotics in patients with AD. These adverse events associated with atypical antipsychotics include somnolence, extrapyramidal symptoms, abnormal gait, worsening cognition, cerebrovascular events, and increased risk of death.¹¹⁰ Typical antipsychotics may also be associated with a small increased risk of death, as well as more severe extrapyramidal effects and hypotension. Chapter 70 has a more detailed discussion of antipsychotic adverse events. Overall, there is a modest expectation of treatment benefit and potential for significant harm associated with antipsychotic use in patients with AD. Individual risk and benefit must be considered when initiating therapy. Diligent monitoring during treatment is essential along with frequent reassessment of continued need.

Antidepressants

Depressive symptoms are common in patients with AD, occurring in as many as 50% of patients.⁴⁷ Apathy may be even more frequent, but these symptoms may be difficult to distinguish in patients with dementia. Many trials have studied the efficacy of antidepressants in treating depression in patients with AD, but the results are conflicting. Small sample size, short duration of treatment, and differing measures of therapy outcomes limit comparison across studies and may account in part for conflicting study results.⁴⁷ Improvement in patients receiving placebo are also common. In practice, treatment with selective serotonin reuptake inhibitors (SSRIs) is initiated most commonly in patients with AD, based on side-effect profile and evidence of efficacy. Benefit has been shown with sertraline, citalopram, fluoxetine, and paroxetine,⁴⁷ although paroxetine causes more anticholinergic effects than other SSRIs. Serotonin/norepinephrine reuptake inhibitors such as venlafaxine may be an alternative.¹¹⁴ Serotonergic function may also play a role in some of the other behavioral symptoms of AD, and some studies support the use of SSRIs in the management of these behaviors, even in the absence of depression.⁷¹ Tricyclic antidepressants have efficacy similar to the SSRIs, but should generally be avoided because of their anticholinergic activity. There is little evidence for the use of trazodone to manage behavioral or depressive symptoms, but it is commonly recommended to treat insomnia in patients with AD.⁷¹

Chapter 71 has a more complete discussion of treatment of depression.

Miscellaneous Therapies

Because antipsychotic and antidepressant therapy has shown only modest efficacy and poses a risk of undesirable side effects, medications traditionally used to treat disruptive behaviors and aggression in other psychiatric and neurologic disorders have been suggested as potential alternatives. These alternatives include benzodiazepines, buspirone, selegiline, carbamazepine, and valproic acid.

Benzodiazepines, particularly oxazepam, have been used to treat anxiety, agitation, and aggression, but they generally show inferior

efficacy when compared to antipsychotics. Because benzodiazepines impair cognition, can result in disinhibition, and may increase the risk of falls in AD patients, their routine use is not advised.³⁴ “Mood stabilizer” anticonvulsants such as carbamazepine or valproic acid may be appropriate alternatives, but evidence is conflicting.¹¹² Clearly, more rigorous placebo-controlled studies are needed to determine the relative efficacy and place in therapy for these medication alternatives.

Noncognitive symptoms are often the most difficult aspect of AD for the caregiver. Selected antipsychotics and antidepressants have been useful for effective management of behavioral, psychotic, and depressive symptoms, thereby easing caregiver burden and allowing the patient to spend additional time at home. Alternative treatments are available in case initial choices are not successful. Adverse events remain an important concern in this population.

PHARMACOECONOMIC CONSIDERATIONS

The economic and social costs of AD are staggering. It is the third most expensive illness in the United States after heart disease and cancer, and the majority of medical and caregiving expenses are left to the patients’ families and to government programs (state and federal). The total national cost of AD is estimated at approximately \$100 billion annually.⁴ In 2005, annual Medicare costs were estimated at \$91 billion and Medicaid costs for institutionalized AD patients were estimated at \$21 billion.⁴ With life expectancy and the number of AD cases increasing, the cost of AD is projected to quadruple over the next 50 years.⁴ The potential financial burden of this disease on the healthcare system could reach crisis proportions in the near future unless more effective avenues are developed to provide care for these individuals, to prevent the disease from occurring, or to slow its progression.

Seventy-five percent of care for AD patients is provided by family and friends.⁴ Lifetime cost of care for AD is estimated at \$174,000.⁴ Higher levels of home care have been associated with poorer health and higher rates of emotional stress in caregivers, increasing the likelihood of placing patients in institutionalized care, which is considered the greatest financial cost in treating patients with AD.⁴ On average, the cost of yearly nursing home care is \$42,000, but exceeds \$70,000 per year in some areas of the country.⁴ Clearly, the greatest economic burden for the home-living AD patient is the time spent in caring for the patient, whereas in the nursing home the burden is the cost for others to provide care.

Economic data on the cost benefit of medications in AD are growing. Few studies provide prospective cost data from randomized controlled trials, and the data that does exist is for relatively short durations of therapy. Two clinical trials suggest that there is no benefit or disadvantage of donepezil compared to placebo in the cost of healthcare resource use.⁶⁹ There are no similar data for galantamine or rivastigmine. One cost analysis trial of memantine found that there was a trade-off between lower costs borne by the caregiver during treatment and higher drug costs borne by the patient.⁷⁰ Cost-effectiveness would be established if medications were shown to reduce the cost of care, particularly institutional care, but current randomized controlled trials have not been of sufficient duration to establish this.⁶⁹ Most estimates of cost related to AD therapy are based on pharmacoeconomic models involving extrapolation of results from short-term trials, epidemiologic data, and data on resource use in various healthcare delivery models.¹¹⁵ Each analysis employs different assumptions and incorporates different aspects of cost, making comparisons across analyses difficult. Until long-term data are available, the true cost benefit of various treatment approaches remains unknown.

⑪ Data from current pharmacoeconomic studies in AD suggest that medication therapy may reduce costs of treating this illness;

however, the true cost-effectiveness of these therapies has yet to be established. If AD treatments delay cognitive decline and time to nursing home placement, then they not only have potential economic benefit, but significant effects on the quality of life of patients and caregivers. Future studies, including prospective pharmacoeconomic trials of longer duration and more detailed cost evaluation modeling, are needed to determine the role and benefits of pharmacotherapy on AD.

EVALUATION OF THERAPEUTIC OUTCOMES

An evaluation of therapeutic outcomes in the patient with AD begins with a thorough assessment at baseline and a clear definition of therapeutic goals. Cognitive status, physical status, functional performance, mood, thought processes, and behavior all need to be evaluated before initiation of drug therapy. The clinician should interview both the patient and the caregiver to assess response to drug therapy. Because caregivers often have difficulty giving honest and frank information about their loved one's condition in the loved one's presence, it is often necessary to interview family caregivers separately. In evaluating response to cognitive agents, the clinician should ask questions about the patient's ability to perform daily functional tasks and about mood and behavior, as well as questions about memory and orientation. Objective assessments such as the MMSE for cognition assessment and the Functional Activities Questionnaire for assessment of activities of daily living, should be used to quantify changes in symptoms and function.⁵⁴

Because target symptoms of psychiatric disorders may respond differently in demented patients, a detailed list of symptoms to be treated should be documented in the pharmacotherapy plan to aid in monitoring. These could include, for example, "striking at spouse because patient believes spouse is an impostor," "verbal threats and refusal to allow clothes to be changed," and so on, as opposed to documenting vague symptoms such as "aggression" or "delusions." To make an accurate assessment of depression, multiple symptoms (e.g., sleep, appetite, and activity and interest levels) need to be assessed in addition to the patient's stated mood.

The patient should be observed carefully for potential side effects of drug therapy. The specific side effects to be monitored and the method and frequency of monitoring should be documented. Periodic assessments for drug effectiveness, side effects, compliance, need for dosage adjustment, and change in treatment should occur at least monthly. However, patients need to be treated for an adequate duration to see a therapeutic effect from a given intervention. Because the effects of cognition-enhancing medications are not great, a treatment period of several months to a year may be necessary before it can be determined whether therapy is beneficial. Cognitive effects of the drug are often noticed only as a plateauing during treatment or as deterioration following drug discontinuation. In general, cognitive agents should be continued if the patient is demonstrating no change in clinical status. However, if there is doubt, the medication can be slowly tapered and discontinued, and the patient monitored off the drug for 4 to 6 weeks to determine the need for continued therapy.

ABBREVIATIONS

AD: Alzheimer's disease
 ADAS-cog: Alzheimer's Disease Assessment Scale—Cognition
 apo E: apolipoprotein E
 APP: amyloid precursor protein
 β AP: beta-amyloid peptide
 MMSE: Mini Mental Status Examination

NFT: neurofibrillary tangle

NMDA: N-methyl-D-aspartate

NSAID: nonsteroidal antiinflammatory drug

SSRI: selective serotonin reuptake inhibitor

Substance-Related Disorders: Overview and Depressants, Stimulants, and Hallucinogens

PAUL L. DOERING AND LISA A. BOOTHBY

KEY CONCEPTS

- 1 Problems related to abuse of chemical substances can occur acutely (e.g., respiratory arrest from using heroin) or after some length of time (e.g., dependence or withdrawal from continued use of an opiate). The treatment approach is distinctly different depending on the type of problem.
- 2 Withdrawal from certain classes of drugs (e.g., benzodiazepines or barbiturates) can be life-threatening, and steps must be taken to ensure that withdrawal is gradual and that it takes place in closely supervised settings.
- 3 Although there is much research focusing on drugs to treat the underlying addictive processes, to date the successes have been few. Whereas methadone, *levo- α -acetylmethadol* (LAAM), and now buprenorphine are used for narcotic maintenance, the logical approach at present should center on prevention. Because of their knowledge of pharmacology and the actions of drugs on the body, health professionals can play a key role in education of young people on the dangers of recreational drug use.
- 4 Pharmacotherapy of substance-related disorders is most often adjunctive to other modes of therapy such as counseling and intense psychotherapy.

Abuse of alcohol, tobacco, and other drugs (ATOD) is the nation's number one health problem, according to a Robert Wood Johnson healthcare report prepared by the Institute for Health Policy, Brandeis University.¹ There are more deaths, illnesses, and disabilities from substance abuse than from any other preventable health condition. The economic cost of substance abuse to the U.S. economy each year is staggering, and it is estimated to be more than \$414 billion.¹ A heavy smoker will stay 25% longer when hospitalized than a nonsmoker, and a problem drinker will stay four times as long as a nondrinker.¹ According to the Robert Wood Johnson health report, "Without a reduction in ATOD abuse, healthcare costs cannot be curtailed effectively." Of the more than 2 million deaths each year in the United States, approximately one in four is attributable to alcohol, illicit drug, or tobacco use: 100,000 people die as a result of alcohol, 16,000 die from illicit drug use and deaths related to the acquired immune deficiency syndrome, and 430,700 from tobacco-related illnesses.

In addition, one-half to two-thirds of homicides and serious crimes involve alcohol. Nearly one-half of men arrested for homi-

cide and assault test positive for an illegal drug.¹ ATOD abuse contributes to family problems, with one in four Americans reporting that alcohol has been a cause of trouble in the family, and alcohol abuse plays a part in one of three failed marriages.¹

Since publication of the last edition of this textbook, a disturbing trend in drug abuse has continued: the use of medicinal drugs for nonmedicinal purposes. Between 1995 and 2002 there was a 163% increase in the number of emergency room visits tied to the abuse of prescription drugs, and these percentages continue to increase.² Prescription drugs now are a factor in a quarter of all overdose deaths reported in the United States. Central nervous system (CNS) agents, primarily analgesics (pain relievers), were involved in slightly less than one-half (47%) of all drug-related suicide attempts that presented to emergency departments in 2005, including both prescription and over-the-counter (OTC) formulations. More than 56% of suicide-related emergency department visits included psychotherapeutic agents (e.g., benzodiazepines or antidepressants).³

This chapter and the next focus on the problems associated with the abuse of chemical substances and the things clinicians can do to help deal with these problems.

KEY DEFINITIONS

The lack of a common vocabulary in substance abuse treatment and prevention leads to several problems. Wide arrays of terms are in common use, many without precise meaning. A number of professional disciplines are involved in research, treatment, and education regarding alcohol and other drug-related problems, and each discipline tends to use its own terminology. This lack of universal agreement on language hampers effective communication among professionals and leads to difficulties in formulating public policy and administering third-party reimbursement programs. The Liaison Committee on Pain and Addiction, a collaborative effort of the American Academy of Pain Medicine, the American Pain Society, and the American Society of Addiction Medicine has developed definitions related to the use of medications for the treatment of pain that purport to be consistent with current understanding of relevant neurobiology, pharmacology, and appropriate clinical practice. The ultimate goal of their project was to achieve acceptance and use of uniform definitions by clinicians, regulators, and the public, both nationally and internationally, to promote appropriate treatment of pain throughout the world. The definitions have been approved by each of the three collaborating organizations. The following definitions resulted from this particular consensus development committee.⁴

- *Addiction* is a primary, chronic, neurobiologic disease, with genetic, psychosocial, and environmental factors influencing its development and manifestations. It is characterized by behaviors that include one or more of the following 5Cs:

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

chronicity, impaired control over drug use, compulsive use, continued use despite harm, and craving.

- *Drug abuse* is a maladaptive pattern of substance use characterized by repeated adverse consequences related to the repeated use of the substance. Examples include failure to fulfill important obligations at work, school, or home; repeated use creating physical danger, such as driving under the influence; legal problems; and social or interpersonal problems such as arguments and fights.
- *Physical dependence* is a state of adaptation that is manifested by a drug class–specific withdrawal syndrome that can be produced by abrupt cessation, rapid dose reduction, decreasing blood level of the drug, and/or administration of an antagonist.
- *Tolerance* is a state of adaptation in which exposure to a drug induces changes that result in a diminution of one or more of the drug's effects over time.

EPIDEMIOLOGY

NATIONAL SURVEY ON DRUG USE & HEALTH

The National Survey on Drug Use and Health (NSDUH) (formerly called the National Household Survey on Drug Abuse)³ is the primary source of statistical information on the use of illegal drugs by the U.S. population. Conducted by the federal government since 1971, the survey collects data from a representative sample of the population at their place of residence.

In 2005, there were 19.7 million Americans (8.1% of the population ages 12 or older) who used illicit drugs, a rate similar to that observed for the last 4 years. An estimated 22.2 million Americans suffered from substance dependence or abuse because of drugs, alcohol, or both. The 2005 survey found that marijuana is the most commonly used illicit drug, used by 14.6 million Americans. The incidence has remained the same for the last 4 years. The second most popular category of drug use after marijuana is the nonmedical use of prescription drugs. An estimated 6.4 million people, 2.6% of the population 12 years of age or older, were current users of prescription drugs taken nonmedically. Of these, an estimated 4.7 million used narcotic pain relievers, 1.8 million used anti-anxiety medications, 1.1 million used stimulants, and 272,000 used sedatives.³

THE MONITORING THE FUTURE STUDY

Every year the Institute for Social Research of the University of Michigan conducts its Monitoring the Future Study (MTFS), supported under a series of research grants from the National Institute on Drug Abuse.⁵ The project has many purposes. Among them is to study changes in the beliefs, attitudes, and behavior of young people in the United States. This study focuses on youth because of their significant involvement in today's social changes, and most importantly because youth in a very literal sense will constitute our future society.⁵

In 2005, 50,000 eighth, tenth, and twelfth grade students in more than 400 public and private secondary schools were surveyed. Use of a number of illicit drugs showed declines in at least one grade; these include 3,4-methylenedioxy-methamphetamine (MDMA; “ecstasy”), marijuana, lysergic acid diethylamide (LSD), amphetamines, methamphetamines, steroids, androstenedione, alcohol, and cigarette smoking. Only three drugs of abuse were reported as increased in use among the teenagers surveyed in 2005; these include sedatives, oxycodone extended-release (OxyContin), and inhalants. Among twelfth graders 5% are now current daily marijuana users, down by 1% since 2003. Other interesting trends have emerged for the following drugs⁵:

- *Ecstasy*. Use of this so-called club drug continues to decline from that reported in previous years. Annual prevalence rates

in 2005 are down by one-half to two-thirds in eighth, tenth, and twelfth grade compared to 2001 data.

- *Inhalants*. Inhalants, the only class of drug that tends to be more popular among younger teens than older ones, include a wide variety of common household products that youngsters inhale or “huff” in order to get high, such as glues, solvents, butane, gasoline, and aerosols. Some 20.4% of the 2005 eighth graders, 31.7% of the tenth graders, and 40.3% of twelfth graders indicated inhalant use in the prior 12 months, making inhalants the second most widely used class of illicitly used drugs for eighth graders (after marijuana), tenth graders (after alcohol), and twelfth graders (after alcohol). The annual prevalence rate among twelfth-grade students continued to rise in 2005, most likely because of the accessibility of inhalants.
- *Prescription drugs*. Both sedatives and OxyContin abuse continues to rise among twelfth graders. Sedative abuse is at its highest rate among twelfth graders since 1980 at 7.2% in 2005. OxyContin use among twelfth graders continued to increase in 2005 to an annual prevalence of 5.5%. OxyContin use among twelfth graders has increased 40% since 2002.
- *Amphetamine and methamphetamine*. Amphetamine use has continued to decline in all three grades in 2005.

SUBSTANCE ABUSE EMERGENCIES: THE DAWN PROGRAM

Since the early 1970s, the Drug Abuse Warning Network (DAWN),⁶ an ongoing national survey of hospital emergency departments, has collected information on patients seeking hospital emergency department treatment related to their use of an illegal drug or the nonmedical use of a legal drug. DAWN serves as an early warning system to the ever-changing patterns of use of illegal drugs. These data allow healthcare professionals to be better prepared to react to medical emergencies arising from illegal drug use and to target prevention and education programs to specific drug-using groups or populations.

DAWN defines a *drug-related episode* as an emergency department visit that was induced by or related to the use of an illegal drug(s) or the nonmedical use of a legal drug for patients aged 6 to 97 years. In 2004, there were 1.3 million drug abuse–related emergency department episodes in the United States.⁶ Cocaine-related episodes constituted nearly 30% of all emergency department drug-related episodes in 2004, more than any other illicit substance measured by DAWN. No significant changes from 2004 were evident for the club drugs ecstasy (MDMA) (8,621 mentions in 2004), γ -hydroxybutyrate (GHB) (2,340 mentions), or ketamine (227 mentions). Heroin accounted for 8% (162,137 mentions) in 2004, and amphetamines and methamphetamine combined were involved in 5% of drug abuse–related emergency department episodes. When considered together, narcotic analgesics and combinations comprised 32% of emergency department episodes estimated for the United States in 2004. From 2000 to 2002, the increase for narcotic analgesics was 45% (from 82,373), and over the 8-year period from 1995 to 2002, emergency department episodes related to narcotic analgesics and combinations increased 163% (from 45,254).

ECONOMIC IMPACT OF SUBSTANCE ABUSE

Substance abuse and addiction have an enormous impact on the economy. Over the years, the Center on Addiction and Substance Abuse (CASA) at Columbia University has conducted numerous studies aimed at quantifying the costs to local, state, and federal governments and agencies. CASA reported the results⁷ of an intensive

3-year analysis of the impact of substance abuse on state budgets. They discovered that in 1998 states spent \$620 billion of their own funds to operate state government and provide public services such as education, Medicaid, child welfare, mental health, and highway safety. Of this amount, a full 13.1%—\$81.3 billion—went to dealing with the aftermath of substance abuse and addiction.⁷ This figure does not include the financial toll such abuse extracts from federal or local spending or the private costs such as lost productivity or premature death. Each American paid \$277 per year in state taxes to deal with the burden of substance abuse and addiction in their social programs and only \$10 a year for prevention and treatment. Of every dollar states spend on substance abuse, 95.8 cents goes to pay for the burden of this problem on public programs. For example, untreated substance abuse increases the cost of every state's criminal justice system; elementary and secondary schools; Medicaid; child welfare, juvenile justice and mental health systems, highways, and state payrolls. These costs totaled \$77.9 billion in 1998.⁷

The majority of the substance abuse–related diseases in the Medicaid population are linked to tobacco and illicit drugs, many related to birth complications resulting from cocaine use. More than 60 Medicare ailments are attributable to ATOD abuse. The majority of the substance abuse–related diseases in the Medicare population are associated with tobacco, which accounts for 80% of these diseases. If substance abuse and addiction do not decrease, it will cost the Medicare program alone more than \$1 trillion over the next 20 years.⁷ Needless to say, reducing the problem of substance abuse and dependence would result in tremendous savings for local, state, and federal governments and would have a net positive impact on the quality of life of our citizens.

ACUTE VERSUS CHRONIC PROBLEMS

1 Misuse of chemical substances causes problems of two types: those that occur acutely and those that arise after continued use of a drug. Acute problems are usually predictable, given the pharmacology of the drug. Acute drug intoxications usually occur at doses in excess of that normally taken. Chronic abuse of chemical substances can cause a wide array of physical, psychological, and psychiatric ailments. The substance-induced disorders discussed here mainly include intoxication and withdrawal. Psychiatric problems associated with substance abuse, including dementia, psychosis, mood disorders, and anxiety, are discussed elsewhere. Physical illnesses associated with chronic use of chemicals (e.g., alcoholic liver disease) are likewise covered in other chapters.

The essential feature of substance dependence is the continued use of the substance despite adverse substance-related problems. The criteria for substance dependence are the same for each of the drugs or drug classes, varying only to fit the unique pharmacologic properties of each drug. Patients who take prescribed drugs for appropriate medical indications and in correct doses may still show tolerance, physical dependence, and withdrawal symptoms if the drug is stopped abruptly rather than being tapered. Tolerance and physical dependence are inevitable consequences of chronic treatment with opioids and certain other drugs, but by themselves, tolerance and physical dependence do not imply “addiction.” To meet *Diagnostic and Statistical Manual of Mental Disorders, 4th edition, Text Revision (DSM-IV-TR)* criteria⁸ for the diagnosis of substance dependence, at least three of the following must be present at any time in a 12-month period:

1. Tolerance
2. Withdrawal, indicated by the appearance of the characteristic withdrawal syndrome or the use of the same or related drug to relieve or avoid withdrawal symptoms
3. Substance taken in larger amounts or over a longer period of time than was intended

4. Persistent desire or unsuccessful efforts to cut down or control substance use
5. Time spent in activities necessary to obtain the substance, use the substance, or recover from its effects
6. Social, occupational, or recreational activities given up or reduced because of substance use
7. Substance use continued despite knowledge of having a persistent or recurrent physical or psychologic problem caused or exacerbated by the substance

The characteristic feature of *substance abuse* is a maladaptive pattern of substance use indicated by repeated adverse consequences related to the repeated use of the substance. Examples include failure to fulfill important obligations at work, school, or home; repeated use in situations in which it is physically dangerous, such as driving under the influence; legal problems; and social or interpersonal problems such as arguments and fights.⁸ *Intoxication* refers to the development of a substance-specific syndrome after recent ingestion and presence in the body of a substance, and it is associated with maladaptive behavior during the waking state caused by the effect of the substance on the central nervous system (CNS). Examples include belligerence, mood lability, impaired judgment, and impaired social or occupational functioning. Evidence for recent intake of the substance can be obtained from the history, physical examination, or laboratory examination. The most common changes involve disturbances in perception, wakefulness, attention, thinking, judgment, motor behavior, and interpersonal behavior.

In addition to the previous definition, *withdrawal* can be further described as the development of a substance-specific syndrome after cessation of or reduction in intake of a substance that was used regularly by the individual to induce a state of intoxication. Withdrawal causes significant distress to the individual and is associated with impairment in social, occupational, or other areas of functioning. Withdrawal is usually associated with substance dependence. Withdrawal generally is also associated with a craving to readminister the drug to relieve the symptoms.

As with most illnesses, the course and prognosis of the disorders of substance use and dependence are variable. Untreated physical withdrawal from the CNS depressants is potentially life-threatening, but withdrawal almost always can be managed successfully with proper medical care. Getting patients who are drug dependent to stop using drugs is very difficult, and many patients return to drug use even after treatment. As many as 75% of treated, substance-dependent patients will relapse at least once. Many patients, however, are able to obtain recovery with treatment and continued care in 12-step programs such as Alcoholics Anonymous (AA) or Narcotics Anonymous (NA). Substance dependence or addiction can be viewed as a chronic illness that can be controlled successfully with treatment but cannot be cured and is associated with a high relapse rate. Without treatment, the course can progress to life-threatening severity, resulting from the effects of the drug, drug contaminants, or medical complications of use.⁸ Although an in-depth discussion of the mechanism of drug addiction is beyond the scope of this chapter, the interested reader is directed to a concise review article that presents the current understanding of the biology of drug addiction.⁹

CNS DEPRESSANTS

BENZODIAZEPINES AND OTHER SEDATIVE-HYPNOTICS

The past several years have witnessed a sharp increase in the abuse of prescription drugs. In 2005, an estimated 6.4 million persons were current users of prescription drugs for nonmedical purposes.³

Benzodiazepines are among the most popular “party drugs” both on college campuses and in the population at large. DAWN estimates show that from 1995 to 2002, increases were evident for the most frequently mentioned benzodiazepines, alprazolam (62%, from 17,082 to 27,659), clonazepam (33%, from 12,802 to 17,042), and unnamed benzodiazepines (199%, from 11,587 to 34,697).² According to DAWN, alprazolam and clonazepam are the most frequent benzodiazepines seen in emergency department visits related to pharmaceutical misuse/abuse (49,842 visits and 26,238 visits, respectively). Benzodiazepines occurring less frequently but still in substantial numbers include diazepam in 15,733 emergency department visits and lorazepam in 16,926 emergency department visits.⁶

In clinical practice, the benzodiazepines largely have replaced the short-acting barbiturates and other nonbarbiturate sedative-hypnotics. Benzodiazepines with faster onset (e.g., diazepam) tend to be preferred by the recreational drug user because they are reinforcing. Flunitrazepam emerged in the mid-1990s as an illegal drug in the United States that was predominantly abused recreationally and associated with sexual assaults.¹⁰ Medically, this benzodiazepine is used in the short-term treatment of insomnia and as a preanesthetic medication. As with other benzodiazepines, flunitrazepam is most commonly ingested orally, frequently in conjunction with alcohol or other drugs. The drug’s effects begin within 30 minutes, peak within 2 hours, and can persist for up to 8 hours or more depending on the dosage.¹⁰

PRESENTATION OF BENZODIAZEPINE INTOXICATION AND WITHDRAWAL

General

- The intoxicated patient may be in acute distress in overdoses or when benzodiazepines are combined with alcohol.
- Patients in withdrawal may also be in acute distress and should be treated with a benzodiazepine taper to prevent seizures.

Symptoms

- The patient may experience memory impairment, drowsiness, visual disturbances, confusion, and gastrointestinal disturbances. Patients may appear intoxicated, with slurred speech, poor coordination, swaying, and bloodshot eyes, with or without the odor of alcohol.^{11–14}

Signs

- Hypotension or nystagmus may be observed, and urinary retention may occur.

Laboratory Tests

- Qualitative testing to confirm presence of benzodiazepines is useful for diagnostic purposes, but quantitative plasma concentrations are usually not clinically useful.

A dramatic drop in cases of flunitrazepam abuse followed the legal reclassification of the drug as a schedule I substance in Florida in February 1997. A recent rise in alprazolam and clonazepam cases coincides with the decreased use of flunitrazepam and represents a new trend in abuse of the benzodiazepines. Alprazolam (Xanax) has become particularly popular and is known on the street by its slang names, Z-Bars, Zandy bars, footballs, and Zannies, among others. Young people will often take alprazolam or other benzodiazepines before going to the bar or dance club, ostensibly to lower the amount of alcoholic beverage needed to attain the desired level of intoxication. Unfortunately, this “pre-partying” is especially popular among women who do not like the taste of beer or find the caloric burden of drinking to be limiting. Sadly, whether taking it intentionally or being given the drug without their knowledge or consent, these women become targets for sexual predators who know that the

victim will have diminished recall of the events that take place. When a victim is unable to give precise details of what happened and when it happened, and is unable to identify the perpetrator, the chances of successful prosecution are greatly diminished.

Because all benzodiazepines have abuse and dependence liability, patients cannot be switched from one benzodiazepine to another in hopes of decreasing a pattern of drug abuse or dependence behavior. Zolpidem, a nonbenzodiazepine, nonbarbiturate sedative, has been suggested to have little liability for physical dependence, but tolerance and withdrawal have been reported in association with its use as well.¹¹ Recent reports in the lay press have linked use of zolpidem to sleep-walking, erratic driving, binge eating, and other similarly bizarre activities.

Benzodiazepines generally do not cause life-threatening respiratory depression, as do the barbiturate-like drugs.¹² Long-term use of even therapeutic doses of benzodiazepines can cause physical dependence and withdrawal symptoms after abrupt discontinuation.¹³

② Gradual tapering of dosage is also associated with less withdrawal and rebound anxiety than abrupt discontinuation. Dependence on sedative-hypnotics and benzodiazepines is summarized in Table 68–1.

Occurrence of hallucinations or seizures would indicate severe physical withdrawal. For additional information on benzodiazepine withdrawal, refer to Chap. 73.

γ-HYDROXYBUTYRATE

GHB is a chemical compound structurally similar to the inhibitory brain neurotransmitter γ-aminobutyric acid. Powdered forms of GHB were marketed in health food stores as a nutritional supplement before being removed from the retail market by the Food and Drug Administration (FDA) in 1991. At that time it was used primarily by body builders for its purported ability to increase growth hormone, but it proved to cause serious illness and death when taken in excess doses or in combination with alcohol or other drugs. Primary groups using GHB include party and nightclub attendees. Like flunitrazepam, GHB is also characterized as a date rape drug.¹⁴ Manifestations of acute GHB toxicity include coma, seizures, respiratory depression, and vomiting. Other documented effects of GHB include amnesia and hypotonia (associated with doses of 10 mg/kg of body weight), abnormal sequence of rapid eye movement (REM) and non-REM sleep (doses of 20 to 30 mg/kg), and anesthesia (doses of approximately 50 mg/kg). Doses greater than 50 mg/kg can decrease cardiac output and produce severe respiratory depression, seizure-like activity, and coma^{15,16}; coma and respiratory depression can be potentiated by concomitant use of alcohol.¹⁷ There is no antidote for GHB overdose, and treatment is restricted to nonspecific supportive care. Figure 68–1 shows a protocol recommended for treating suspected GHB overdose.

In March 2000, GHB was placed into schedule I of the Controlled Substances Act. Until recently, the majority of GHB sold on the streets was manufactured using inexpensive kits obtained over the Internet. It is mixed largely by nonchemists from recipes that can be flawed or incomplete, and finished products are often of questionable purity, and more important, unknown potency. Improper preparation of GHB can result in a mixture of GHB and sodium hydroxide that can be severely toxic because of the combined effects of the GHB and the direct caustic effects of sodium hydroxide. As there is no way to know the strength of homemade GHB, what might be a safe dose today (e.g., “one capful”) could produce a toxic dose tomorrow if a different batch is used. Fortunately, crackdowns in 1997 by the FDA, the Department of Justice, and other enforcement groups has led to decreased availability of ready-made kits on the Internet. Despite the FDA’s action, GHB remains available to consumers.

The decreased Internet availability of kits to make GHB has been accompanied by an increased availability of chemical precursors to

TABLE 68-1 Dependence on Sedative-Hypnotics

Generic Name	Common Trade Names	Oral Sedating Dose (mg)	Physical Dependence Daily Dose and Time Needed to Produce Dependence	Time Before Onset of Withdrawal (hours)	Peak Withdrawal Symptoms (days) ^a
Benzodiazepines					
Alprazolam	Xanax	0.25–8	8–16 mg × 42 days (est.)	8–24	2–3
Clorazepate	Tranxene	7.5–15	45–180 mg × 42–120 days (est.)	12–24	5–8
Diazepam	Valium	5–10	40–100 mg × 42–120 days	12–24	5–8
Flunitrazepam	Rohypnol	1–2	8–10 mg × 42 days (est.)	24–36	2–3
Barbiturates					
Amobarbital	Amytal	65–100	Same	8–12	2–5
Secobarbital	Seconal, Seco-8	100	800–2,200 mg × 35–37 days	6–12	2–3
Equal parts of secobarbital and amobarbital	Tuinal	100	Same	6–12	2–3
Pentobarbital	Nembutal	100	Same	6–12	2–3
Nonbarbiturate sedative-hypnotics					
Chloral hydrate	Noctec	250	Exact dose unknown; 12 g/day chronically has led to delirium upon sudden withdrawal	6–12	2–3
Meprobamate	Equanil, Miltown, Meprotab	400	1.6–3.2 g × 270 days	8–12	3–8

^aWithdrawal symptoms are tremor, tachycardia, diaphoresis, nausea, vomiting, elevated blood pressure, delirium, seizures, and hallucinations.

GHB as well as GHB analogs. Also available in gyms and health food stores, these substances include γ -butyrolactone (GBL) and 1,4-butanediol.¹⁷ GBL is converted in the body to GHB. Labels of marketed products can use unfamiliar synonyms to disguise the actual content. GBL is also known by the names 2(3H)-furanone dihydro, butyrolactone, 4-butyrolactone, dihydro-2(3H)-furanone,

4-butanolide, 2(3H)-furanone, dihydro, tetrahydro-2-furanone, and butyrolactone- γ .

Withdrawal resulting in severe agitation, mental status changes, elevated blood pressure, and tachycardia has been reported hours after stopping chronic use of GHB. In one case the patient admitted to substantial GHB abuse on a daily basis for 2.5 years. Previous

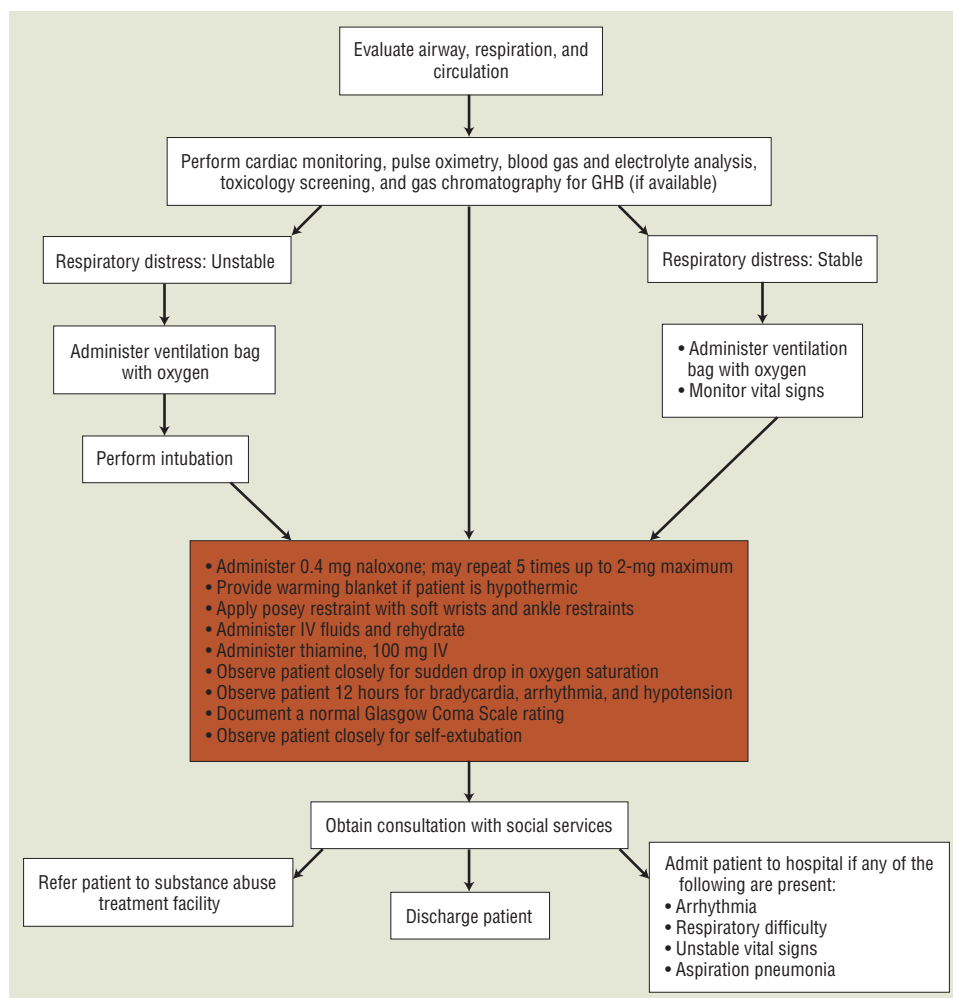

FIGURE 68-1. Protocol for treatment of suspected γ -hydroxybutyrate (GHB) overdose.

attempts at cessation reportedly resulted in diaphoresis, tremors, and agitation. The patient required 507 mg lorazepam and 120 mg diazepam over 90 hours to control agitation.¹⁸

OPIATES

Incidence and prevalence of opiate use are widely variable depending on the drug. In 2005, there were 136,000 current heroin users. Collectively, use of opiates other than heroin is far more common. An estimated 4.7 million people used narcotic pain relievers, and 3.1 million persons 12 years of age or older used what Substance Abuse and Mental Health Services Administration (SAMHSA) classified as “OxyContin” nonmedically at least once in their lifetime.¹⁹

PRESENTATION OF OPIOID INTOXICATION AND WITHDRAWAL

General

- Onset of the acute phase of withdrawal ranges from a few hours after stopping heroin to 3 to 5 days after stopping methadone. The duration of withdrawal ranges from 3 to 14 days.
- Opioid withdrawal is not fatal unless there is a concurrent medical problem of major concern.
- The presence of delirium should raise the question of concurrent withdrawal from another drug, such as alcohol, or another cause of delirium possibly secondary to drug use.

Symptoms

- During withdrawal, patients can experience piloerection, insomnia, muscle aches, and yawning. While intoxicated, patients can experience euphoria, dysphoria, apathy, sedation, or attention impairment.

Signs

- Fever, lacrimation, diaphoresis, or diarrhea may be observed during withdrawal. Motor retardation, slurred speech, and miosis may be observed during intoxication.

Laboratory Tests

- Treatment is based more on clinical presentation because plasma opioid levels may not be clinically useful.

Other Diagnostic Tests

- Arterial blood gases, pulse oximetry, and pulmonary function tests are useful to assess respiratory depression.

Many of the complications of opiate use, especially intravenous use, are related not only to the drug itself, but also to varying purity, contaminants, and techniques of administration such as dirty equipment and use of shared needles. Overdoses, anaphylactic reactions to impurities, nephrotic syndrome, septicemia, endocarditis, and acquired immune deficiency syndrome are examples.

Increased recreational use of pharmaceutical dosage forms of opiates has sparked nationwide debate on both the illegal and legal use of these drugs. OxyContin has been a target of much of this criticism. Introduced in 1995, OxyContin is a controlled-release dosage form of oxycodone that gradually releases steady amounts of narcotics for 12 hours. By crushing the OxyContin tablets, drug abusers can get the full 12-hour narcotic effect almost immediately. Snorting or injecting the crushed tablet can lead to overdose and death. Abuse of this drug has caused a nationwide discussion on whether drugs of this nature should be more closely regulated. In September 2003, a federal drug advisory panel rejected requests from members of Congress and drug enforcement officials that sales of OxyContin be severely restricted. According to testimony at the hearings, OxyContin is responsible for 500 to 1,000 deaths a year.²⁰

But, these data are refuted in a careful examination of data from an oxycodone postmortem database.²¹ Created from 1,243 solicited cases from medical examiner and coroner offices in 23 states in the United States, the database included information collected from August 27, 1999, through January 17, 2002. Researchers examined records of the 919 deaths related to oxycodone and discovered that in only 12 of the cases was OxyContin the only agent found at autopsy. The remaining victims had taken either an overdose of other oxycodone-containing drugs (for example, Percocet [oxycodone + acetaminophen]) or a combination of drugs. In fact, 97% had at least three other drugs in their systems, mostly alcohol, benzodiazepines, cocaine, antidepressants, or other narcotics such as heroin. From these data, the authors concluded that oxycodone-related deaths overwhelmingly occur in drug-abusing individuals, and rarely is OxyContin an exclusive cause of death.

Various groups have weighed in on the pros and cons of prescribing opiates for chronic pain and the debate at times is emotional. Various position statements and points of view have been expressed, but the limited space here precludes an exhaustive review of the issues. An excellent review of the appropriate use of opioid therapy for chronic pain has recently been published, and the interested reader is directed there for more information.²²

CLINICAL CONTROVERSY

There is considerable debate about the appropriate use of prescribed opiates and how this might contribute to the overuse or abuse of these same drugs for nonmedicinal purposes. Some clinicians believe that use of opiates in patients with chronic pain is inappropriate because it leads to physical dependence and addiction. Practitioners should strive to balance the therapeutic imperative that says “Always use analgesics when they are appropriate for a patient” against the regulatory imperative that says “Never use analgesics when they are inappropriate for a patient.”

CNS STIMULANTS

COCAINE

Cocaine is perhaps the most behaviorally reinforcing of all drugs of abuse. Clinicians estimate that approximately 10% of people who begin to use the drug recreationally will go on to serious, heavy use. Once having tried cocaine, an individual cannot predict or control the extent to which he or she will continue to use the drug.

The most characteristic systemic effect of cocaine is stimulation of the CNS.²³ In the CNS, cocaine appears to mediate its effects primarily by blocking reuptake of catecholamine neurotransmitters such as norepinephrine and dopamine.

PRESENTATION OF COCAINE INTOXICATION AND WITHDRAWAL

General

- In overdoses, cocaine is a central nervous system and cardiac stimulant. Cocaine-related deaths are often a result of cardiac arrest or seizures followed by respiratory arrest.

Symptoms

- Symptoms of intoxication include motor agitation, elation, euphoria, grandiosity, loquacity, hypervigilance, sweating or chills, nausea, and vomiting.
- Symptoms of withdrawal include fatigue, sleep disturbances, nightmares, depression, and changes in appetite.
- High doses of cocaine and/or prolonged use can trigger paranoia.

Signs

■ Tachycardia, mydriasis, and either elevated or lowered blood pressure may be observed with overdose. Cardiac abnormalities (e.g., arrhythmias) and respiratory depression may be observed with overdose. Bradyarrhythmias, myocardial infarction, and tremors may be observed in acute withdrawal. Prolonged cocaine snorting can result in ulceration of the mucous membranes of the nose and can damage the nasal septum enough to cause it to collapse.

Laboratory Tests

■ Qualitative drugs of abuse urine screening tests are useful, followed by confirmatory testing if necessary. Levels of the primary metabolite, benzoylecgonine, may help diagnose acute cocaine toxicity.

Other Diagnostic Tests

■ Abnormal electroencephalograms may be observed with patients in acute withdrawal.

Cocaine is absorbed rapidly from virtually all sites of application. For many years, cocaine has been administered as the hydrochloride salt form, usually by inhalation, but also by injection. In the last 15 to 18 years, as the purity of cocaine hydrochloride obtained on the street declined, many users converted the cocaine hydrochloride to cocaine base, also known as “crack” or “rock.” Smoking the drug leads to almost instant absorption and intense euphoria. Peak plasma concentrations of more than 900 ng/mL have been achieved following inhalation of cocaine base vapors, compared with concentrations of only 150 to 200 ng/mL achieved after inhalation of similar amounts of pure cocaine hydrochloride powder.²³

The high from snorting can last 15 to 30 minutes, whereas that from smoking can last 5 to 10 minutes. Increased use can reduce the period of stimulation. An appreciable tolerance to the high can be developed, and many addicts report that they seek but fail to achieve as much pleasure as they did from their first exposure. Scientific evidence suggests that the powerful neuropsychologic reinforcing property of cocaine is responsible for an individual's continued use despite harmful physical and social consequences.

Recent research has helped clarify certain patterns of cocaine use such as combining cocaine and alcohol. Such drug use would seem counterintuitive because cocaine is a CNS stimulant and alcohol a CNS depressant. In the presence of alcohol, cocaine is metabolized to cocaethylene, a longer-acting but potent psychoactive compound compared to the parent drug.²⁴ The risk of death from cocaethylene is greater than from cocaine.²⁵ The cocaine-alcohol combination is one of the most commonly identified among individuals who come to hospital emergency departments with acute substance abuse problems.

Cocaine is metabolized and eliminated rapidly. The elimination half-life of cocaine is approximately 1 hour, and the duration of effect is very short.²³ The short duration of effect provides a powerful incentive for repeated use of the drug. Many users experience intense drug use cycling, sometimes lasting days, characterized by rapidly repeating doses of cocaine until their supply is exhausted. Laboratory monkeys, given a choice between food and cocaine around the clock for 8 days, consistently choose cocaine.²⁶

Complications of cocaine use frequently involve cardiovascular events.²⁷ Cocaine is a psychotomimetic drug, sometimes even at systemically nontoxic doses. A kindling phenomenon has been described with cocaine in which neuronal function becomes altered with each dose of the drug. The psychosis is qualitatively very similar to a paranoid schizophrenic psychosis.²⁸ Although there is some controversy as to whether cocaine is associated with physical withdrawal on abrupt discontinuation, most clinicians feel that there is a characteristic syndrome of withdrawal effects, although they are not life-threatening.^{13,29}

AMPHETAMINE, METHAMPHETAMINE, AND OTHER STIMULANTS

During the 1940s the Japanese government distributed amphetamines to soldiers, sailors, and pilots, as well as to armament factory workers, to mobilize all their reserves for the war effort. Pilots routinely used the drug to remain awake and alert for long periods on long-distance bombing missions. After 1945 large quantities of the drug from looted military supplies flooded the market. In the United States in the 1950s and 1960s, legally manufactured tablets of methamphetamine were used nonmedically by college students, truck drivers, and athletes, who usually did not become severely addicted. This pattern changed drastically in the later 1960s with the increased availability of injectable methamphetamine.

There were an estimated 512,000 methamphetamine users in 2005, up from 149,000 in 1990.³ Street methamphetamine is referred to by many names, such as “speed,” “meth,” and “crank.” Methamphetamine hydrochloride, clear chunky crystals resembling ice, which can be inhaled by smoking, is referred to as “ice,” “crystal,” and “glass.”

The physiologic and psychologic effects of amphetamines and other stimulants are qualitatively similar to those of cocaine—they diminish fatigue, increase alertness, and suppress appetite. Pharmacologically, amphetamines increase the activity of catecholamine neurotransmitters (e.g., norepinephrine and dopamine) by blocking reuptake, increasing release of neurotransmitters, and inhibiting the degradative enzyme monoamine oxidase.³⁰ The longer duration of effect of methamphetamine has led to a shift away from cocaine and toward the longer-acting drug.

Methamphetamine is used orally, intranasally, rectally, by intravenous injection, and by smoking. Immediately after inhalation or intravenous injection, the methamphetamine user experiences an intense sensation, called a “rush” or “flash,” that lasts only a few minutes and is described as extremely pleasurable.

PRESENTATION OF AMPHETAMINE INTOXICATION AND WITHDRAWAL

General

- Amphetamine intoxication is an acute condition that may result in death. Pharmacotherapy may be indicated for symptomatic control of seizures.
- Patients may experience withdrawal symptoms for several days, but are usually not in acute distress. Treatment is supportive in nature. Pharmacotherapy is not effective to treat the symptoms of amphetamine withdrawal.

Symptoms

- Depression, altered mental status, drug craving, dysomnia, and fatigue are all symptoms of withdrawal.
- Amphetamine intoxication may present as increased wakefulness, increased physical activity, decreased appetite, increased respiration, hyperthermia, and euphoria. Other CNS effects include irritability, insomnia, confusion, tremors, convulsions, anxiety, paranoia, chest pain, and aggressiveness. Hyperthermia and convulsions can result in death.

Signs

- Patients with amphetamine intoxication may present with tachycardia, hypertension, or stroke.

Laboratory Tests

- A qualitative drug of abuse urine screening is used for diagnostic purposes. Confirmatory blood tests with gas chromatography or mass spectrophotometry may be used for verification.

Because methamphetamine elevates mood, people who experiment with it tend to use it with increasing frequency and in increasing doses, although this was not their original intent. The timing and intensity of the “rush” that accompanies the use of methamphetamine, which is a result of the release of high levels of dopamine in the brain, depends in part on the method of administration. Specifically, the effect is almost instantaneous when smoked or injected, whereas it takes approximately 5 minutes after snorting or 20 minutes after oral ingestion. Prolonged use of methamphetamine can result in a tolerance for the drug and increased use at higher dosage levels, creating dependence. Such continual use of the drug with little or no sleep leads to an extremely irritable and paranoid state. Discontinuing use of methamphetamine often results in a state of depression, as well as fatigue, anergia, and some types of cognitive impairment that can last from 2 days to several months.³¹

Both short- and long-term health effects have also been documented. Negative consequences of methamphetamine abuse range from anxiety and insomnia to convulsions, paranoia, and brain damage. Methamphetamine-induced caries, or “Meth mouth” is a characteristic pattern of dental decay commonly observed in patients that smoke methamphetamine.³²

In addition to the many direct effects on methamphetamine users are the indirect impacts on individuals and society. Flammable ingredients that include acetone, red phosphorous, ethyl alcohol, and lithium metal are used in methamphetamine cookers, often with disastrous results. Fires and explosions often ensue, resulting in severe burns, and uncovering laboratories to local law enforcement.³³ Children of methamphetamine abusers are at high risk of neglect and abuse, and pregnant women’s use of methamphetamine can cause growth retardation, premature birth, and developmental disorders in neonates. Within this particular group, effective treatment for methamphetamine dependence can be one of the most important strategies in reducing the spread of HIV and other associated communicable diseases.³⁴ Treatment for methamphetamine dependence is very difficult, with a low success rate.³⁴

The expanding global market is fed by an increase in clandestine manufacture of methamphetamine. Not only are there more laboratories in more countries, but their size and sophistication are also increasing. The number of clandestine methamphetamine laboratories seized nationwide by the U.S. Drug Enforcement Administration (DEA) increased from 263 in 1994 to 1,815 in 2000, a 590% increase.³⁵ In 2005, state and local police agencies seized almost 5,249 clandestine laboratories in the United States. So-called “kitchen” laboratories are still discovered, but today clandestine laboratories with 100-kilogram capacities per week are also found. Initially the clandestine manufacture of methamphetamine was based primarily in the West and Southwest. Today methamphetamine can be found in cities across the United States, although local law enforcement pressures have caused a decrease in “superlaboratories” capable of producing at least 10 pounds per production cycle.³⁵ Unfortunately, increased methamphetamine production by Mexican drug cartels has offset the decreased domestic production.

Methamphetamine is manufactured using the ephedrine or pseudoephedrine reduction method. In this process, ephedrine or pseudoephedrine is extracted from OTC cold and allergy tablets. Pharmacists should be wary of persons wishing to purchase large quantities of products containing nonprescription sympathomimetic products. As a precaution, most states have imposed restrictions on the quantities of OTC decongestants that can be purchased at one time. Many states require that pseudoephedrine-containing products be kept behind the counter as an additional precaution.

Prices for methamphetamine vary throughout different regions of the United States, ranging from \$20 to \$300 for 1 gram, \$270 to \$5,000 for 1 ounce, and \$1,600 to \$45,000 for 1 pound.³⁶

ECSTASY AND OTHER METHAMPHETAMINE ANALOGS

Several dozen analogs of amphetamine and methamphetamine are hallucinogenic. Two methamphetamine analogs of most concern are 3,4-methylenedioxymphetamine (MDA) and especially 3,4-methylenedioxymphetamine (MDMA or ecstasy). Popular among young people at all-night dance parties referred to as “raves,” these are classified among the “club drugs.” According to the MTFS data from 2005, among children aged 12 to 17, annual prevalence rates of ecstasy use are down by one-half to two-thirds since the peak observed in 2001.⁵ The vast majority of ecstasy consumed domestically is produced in Europe. It costs as little as 25 to 50 cents to manufacture an ecstasy tablet in Europe, but the street value of that same ecstasy tablet can be as high as \$40, with a tablet typically selling for between \$20 and \$30.

Patented in 1914 by Merck Pharmaceuticals, MDMA was never “legally” marketed.³⁷ MDMA is structurally similar to methamphetamine and mescaline. A mild, hallucinogenic effect is produced by stimulating the CNS. Known most commonly on the street as ecstasy, it is also called “Adam,” “X,” “X-TC,” “Stacy,” “beans,” “e,” or simply “pills.” MDMA is usually taken by mouth in tablet, capsule, or powder form, but it also can be smoked, snorted, or injected.

The effects of MDMA usually last approximately 4 to 6 hours. Users of the drug say that it produces profoundly positive feelings, empathy for others, elimination of anxiety, and extreme relaxation. MDMA is also said to suppress the need to eat, drink, or sleep, enabling users to endure 2- to 3-day parties. Consequently, MDMA use sometimes results in severe dehydration or exhaustion. MDMA generally reduces inhibitions and creates a sense of euphoria, but it also can evoke anxiety and paranoia. Heavier doses generate depression, irrationality, and psychosis. Users claim they experience feelings of closeness with others and a desire to touch them.

MDMA use can result in a variety of acute psychiatric disturbances, including panic, anxiety, depression, and paranoid thinking.³⁷ Physical symptoms include muscle tension, nausea, blurred vision, faintness, chills, and sweating. MDMA also increases the heart rate and blood pressure. Other effects include hyperthermia, dehydration, vomiting, tremors, loss of control over body movements, insomnia, convulsions, rapid eye movements, and teeth and jaw clenching.

MDMA is perceived to be a harmless drug by many of its users, based in part on the fact that the risk of death is low compared with other drugs such as heroin and cocaine. However, mounting evidence points to neurotoxic effects of MDMA, involving a complex and incompletely understood mechanism. MDMA has been clearly shown to destroy serotonin-producing neurons in animals.³⁸ Doses of MDMA that produce neurotoxicity are only two or three times more than the minimum dose needed to produce a psychotropic response.

Researchers have found that heavy MDMA users have memory problems that persist for at least 2 weeks after they have stopped using the drug.³⁹ McCann and colleagues⁴⁰ conducted a study to determine the effects of MDMA use on cognitive performance. MDMA users and controls were found to perform similarly on several cognitive tasks. However, MDMA subjects had significant performance deficits on a sustained-attention task requiring arithmetic calculations, a task requiring complex attention and incidental learning, a task requiring short-term memory, and a task of semantic recognition and verbal reasoning. MDMA users also had significant selective decreases in cerebrospinal fluid (CSF) 5-hydroxyindoleacetic acid (5-HIAA). The authors believe that their data provide further evidence that MDMA is neurotoxic to brain serotonin neurons in humans, and the behavioral data suggest that

brain serotonin injury is associated with subtle but significant cognitive deficits. Additional evidence has been accruing.⁴¹

Manufacturers of illicit drugs sometimes substitute other, potentially more dangerous substances for the one the buyer is expecting. Other suppliers produce products adulterated with chemical by-products of the incomplete synthesis of active ingredients. One such chemical, *para*-methoxyamphetamine, is a drastically more potent hyperthermic agent than MDMA.⁴² Deaths from the drug likely will increase as a result of poor-quality tablets.

PHENCYCLIDINE AND KETAMINE

Phencyclidine (PCP), commonly referred to as “angel dust” and “crystal,” was popular in the 1970s, but as its adverse effects became better known, use declined. PCP is most often a substitute for or contaminant of other drugs, and its most common pattern of use may now be unintentional. The actual extent of its use is unclear. It is often misrepresented as LSD or Δ^9 -tetrahydrocannabinol (THC). With the exception of the pharmaceutical dosage form of dronabinol, THC is virtually unavailable on the street because it is highly unstable when isolated from the marijuana plant. When used intentionally, PCP is commonly smoked with marijuana and referred to as a “crystal joint,” but it also can be taken orally or intravenously.

PCP has widely varied actions including CNS stimulation, depression, and hallucinogenic properties. Pharmacologically, it is known to block reuptake of serotonin, dopamine, and norepinephrine, but neurotransmitter antagonists do not effectively block its effects. In low doses, PCP causes sedation, ataxia, nystagmus, slurred speech, and paresthesias. At higher doses, users experience an increase in heart rate, blood pressure, temperature, diaphoresis, and muscle rigidity. At acutely toxic doses, coma and seizures can occur.⁴³

Behavioral effects of PCP range from sleep to catatonic detachment to paranoid psychosis to violent hostility. Users are sometimes amnesic for events that occur under the influence of the drug. Psychoses sometimes last for weeks. Users with a previous history of schizophrenia are especially susceptible to the psychotomimetic effects of the drug. The only truly characteristic behavioral effect of PCP use is its high unpredictability. The signs and symptoms of PCP intoxication are summarized in Table 68–2.

Ketamine, a compound chemically related to PCP, is used primarily as a veterinary anesthetic but has gained popularity recently as a recreational drug.⁴⁴ Once used extensively in human medicine, it has fallen out of favor because of “emergence delirium,” characterized by hallucinations, delirium, vivid dreams, and other psychiatric effects. This untoward effect as a medicinal agent is precisely the effect that recreational users are seeking.

Known as “special K,” “jet,” “green,” and other names on the street, ketamine is sometimes injected but can be evaporated to solid crystals, powdered, and smoked, snorted, or swallowed. Marijuana cigarettes are sometimes soaked in the ketamine solution, allowed to dry, and then smoked. Ketamine has become popular as a “rave” club drug. Side effects include significant transient increases in blood pressure and heart rate, respiratory depression, airway obstruction, apnea, muscular hypertonia, psychomotor and psychotomimetic effects, and acute dystonic reactions. Following overdose, seizures,

polyneuropathy, increased intracranial pressure, respiratory arrest, and cardiac arrest can occur.^{45,46}

The effects of a ketamine “high” usually last an hour, but they can last 4 to 6 hours, and 24 to 48 hours are generally required before the user will feel completely normal again. Effects of chronic use of ketamine can take from several months to 2 years to disappear completely. Low doses (25 to 100 mg) produce psychedelic effects quickly. Large doses can produce vomiting and convulsions and can lead to hypoxia of the brain and muscles; 1 g can cause death. Long-term effects include tolerance and possible physical and/or psychological dependence.

Since its emergence as a drug of abuse in the late 1960s, PCP has been described as one of the most dangerous of all synthetic hallucinogens. Its niche in the drug world is usually one characterized by abusers exhibiting hostile behavior that manifests itself in extremely violent episodes.^{45,46}

Despite the negative effects associated with PCP, there remains an illicit market for the drug. Illicit organizations producing and distributing PCP are still active in the United States.⁴⁷ These organizations, operating mainly in Los Angeles and to a lesser extent in Houston, supply most of the PCP available in the nation. PCP production appears to be stable, in limited quantities since 2000. The DEA considers PCP a drug of abuse that is not readily available.⁴⁷

HALLUCINOGENS

The drugs commonly classified as hallucinogens are LSD, psilocybin, dimethyltryptamine (DMT), mescaline, and other related compounds. LSD is one of the most potent mood-changing chemicals. It is manufactured from lysergic acid, which is found in ergot, a fungus that grows on rye and other grains.

Pharmacologically, LSD and related drugs stimulate both presynaptic (5-hydroxytryptamine [HT]_{1A} and 5-HT_{1B}) and postsynaptic (5-HT₂) serotonin recognition sites in the brain, which functionally can cause either agonist or antagonist effects on serotonin activity.⁴⁸ Precisely how the hallucinogens exert their effects remains unclear. LSD, often referred to as “acid,” is an extraordinarily potent compound, producing observable CNS effects at doses as low as 25 mcg.⁴⁸

LSD is sold on the street in tablets, capsules, and occasionally in liquid form. It is odorless, colorless, and tasteless and usually is taken by mouth. Often LSD is added to absorbent paper, such as blotter paper, and divided into small decorated squares, with each square representing one dose.

The DEA reports that the strength of LSD samples obtained recently from illicit sources ranges from 20 to 80 mcg of LSD per dose. This is considerably less than the levels reported during the 1960s and early 1970s, when the dosage ranged from 100 to 200 mcg or higher per unit.

The effects of LSD are unpredictable. They depend on the amount taken; the user’s personality, mood, and expectations; and the surroundings in which the drug is used. Usually the user feels the first effects of the drug 30 to 90 minutes after taking it. The physical effects include dilated pupils, higher body temperature, increased heart rate and blood pressure, sweating, loss of appetite, sleeplessness, dry mouth, and tremors.

Sensations and feelings change much more dramatically than the physical signs. The user can feel several different emotions at once or swing rapidly from one emotion to another. If taken in a large enough dose, the drug produces delusions and visual hallucinations. The user’s sense of time and self changes. Sensations can seem to “cross over,” giving the user the feeling of hearing colors and seeing sounds. These changes can be frightening and can cause panic.

Many LSD users experience flashbacks, or recurrence of certain aspects of a person’s experience, without the user having taken the drug again. A flashback occurs suddenly, often without warning,

TABLE 68-2 Signs and Symptoms of Phencyclidine Intoxication

Nystagmus	Euphoria
Increased blood pressure	Motor agitation
Tachycardia	Anxiety and emotional lability
Paresthesias	Hostility
Ataxia	Delusions
Slurred speech	Hallucinations
Muscle rigidity	

and can occur within a few days or more than a year after LSD use. Flashbacks usually occur in people who use hallucinogens chronically or have an underlying personality problem; however, otherwise healthy people who use LSD occasionally also can have flashbacks.

Most users of LSD voluntarily decrease or stop its use over time. LSD is not considered an addictive drug because it does not produce compulsive drug-seeking behavior. However, as with many of the addictive drugs, LSD use produces tolerance, so some users who take the drug repeatedly must take progressively higher doses to achieve the state of intoxication that they had achieved previously.

Psychologic symptoms of intoxication include a subjective intensification of perceptions, depersonalization, illusions, hallucinations, and synesthesias, the overflow of one sensory modality to another (colors are heard, sounds are seen). Among the hallucinogenic drugs, LSD is the most potent and long acting; it is hundreds of times more potent than both psilocybin and mescaline. DMT is inactive when ingested orally but can be smoked, inhaled, or injected. There is cross-tolerance among LSD, psilocybin, and mescaline. There is no observable physical withdrawal syndrome after abrupt discontinuation of hallucinogenic drugs.⁴⁹

Complications from hallucinogen use are primarily psychologic. Users sometimes experience prolonged episodes of panic—the so-called “bad trip.” The flashbacks noted above are common, occurring in approximately 15% of users and occurring episodically up to several years after the last exposure to the drug. Flashbacks can occur spontaneously but are also triggered by other drugs, including marijuana, and by anxiety-provoking stimuli. Contrary to a widely held notion in the 1960s and early 1970s, there is no reliable evidence that hallucinogen use causes chromosome damage or genetic defects.⁴⁸

Few LSD laboratories have ever been seized in the United States because of infrequent and irregular production cycles. In 2000, the DEA seized one LSD laboratory that was located in a converted missile silo in Kansas. This was the largest LSD laboratory seizure ever made by the DEA, and agents seized approximately 41.3 kilograms (90.86 pounds) of LSD and approximately 23.6 kilograms (51.92 pounds) of iso-LSD, a by-product of the manufacture of LSD.⁵⁰

MARIJUANA

Marijuana, referred to as “reefer,” “pot,” “grass,” or “weed,” remains the most commonly used illicit drug. In 2005, marijuana was used by nearly 75% of current illicit drug users. Of those, 54.5% used only marijuana, and 19.6% used marijuana and another illicit drug.³ According to the 2005 data, 14.6 million past month users of marijuana were reported; a similar percentage was observed in the previous 4 years. In 2005, 59.1% of the 2.1 million first-time users of marijuana were younger than 18 years of age.³ The rate of current marijuana users among youths 12 to 17 years of age decreased from 7.6% to 6.8% in 2005, a positive trend that hopefully will continue.

Most users smoke marijuana in hand-rolled cigarettes called joints, among other names; some use pipes or water pipes called bongs. Marijuana cigars called blunts have also become popular. To make blunts, users slice open cigars and replace the tobacco with marijuana, often combined with another drug, such as crack cocaine. Marijuana also is used to brew tea and is sometimes mixed into foods.⁵¹

Marijuana's effects begin immediately after the drug enters the brain and last from 1 to 3 hours. If marijuana is consumed in food or drink, the short-term effects begin more slowly, usually in 30 minutes to 1 hour, and last longer, for as long as 4 hours. Smoking marijuana deposits several times more THC into the blood than does eating or drinking the drug.⁵¹

PRESENTATION OF MARIJUANA INTOXICATION

General Symptoms

- Patients intoxicated with marijuana may experience euphoria, sensory intensification, increased appetite, apathy, hallucinations, and dry mouth. Occasionally, marijuana use produces anxiety, fear, distrust, or panic.⁵¹

Signs

- Tachycardia and conjunctival congestion may be observed in patients intoxicated with marijuana.

Laboratory Tests

- Although the duration of effect of marijuana may only be several hours, THC is detectable on toxicologic screening for up to 4 to 5 weeks, especially in chronic users.

Marijuana use impairs a person's ability to form memories, recall events, and shift attention from one thing to another.⁵² THC also disrupts coordination and balance by binding to receptors in the cerebellum and basal ganglia. Through its effects on the brain and body, marijuana intoxication can cause accidents. Studies show that approximately 6% to 11% of fatal accident victims test positive for THC. In many of these cases alcohol is detected as well.

In a study conducted by the National Highway Traffic Safety Administration, a moderate dose of marijuana alone was shown to impair driving performance; however, the effects of even a low dose of marijuana combined with alcohol were markedly greater than for either drug alone. Driving indices measured included reaction time, visual search frequency (driver checking of side streets), and the ability to perceive and/or respond to changes in the relative velocity of other vehicles.⁵³

The principal psychoactive component of marijuana is THC. Hashish, the dried resin of the top of the plant, is much more potent than the plant itself. Increasingly sophisticated growing techniques have resulted in plants of greater potency. In a recent study, the amount of Δ^9 -THC found in the samples ranged from 1.41% to 12.62% by dry weight. The average Δ^9 -THC content was 6.2%, which is almost identical to the 2002 value reported by the University of Mississippi's Potency Monitoring Project.⁵⁴

Marijuana has been used widely and is believed by many to be a relatively harmless, nonaddictive intoxicant. Chronic low doses of marijuana usually are not associated with significant physical withdrawal on abrupt discontinuation, but many chronic users exhibit compulsive drug-seeking and drug-use behaviors characteristic of addiction or dependence. Acutely, marijuana has many of the effects of alcohol—sedation, a decrease in reactivity and ability to perform complex tasks, and disinhibition. Marijuana also causes hallucinations with high enough doses. Chronic use is associated with all the risks of tobacco smoking, although marijuana smokers are commonly also tobacco smokers, and thus differentiation of effects is often difficult. Endocrine effects including amenorrhea, decreased testosterone production, and inhibition of spermatogenesis have been demonstrated. Marijuana is associated with an amotivational syndrome characterized by a behavioral pattern of apathy, dullness, impaired judgment, decreased concentration and memory, loss of interest in personal hygiene, and a general reduction of goal-directed behavior.

Marijuana smoke is irritating to the lungs. Researchers have found that the daily use of one to three marijuana joints appears to produce approximately the same lung damage and potential cancer risk as smoking five times as many cigarettes.⁵⁵ The study results suggest that the way smokers inhale marijuana, in addition to its chemical composition, increases the adverse physical effects. The study findings refute the argument that marijuana is safer than tobacco because users smoke only a few joints a day.

Clearly, there is much more work to be done before the precise health and psychologic effects of marijuana use are well understood. In fact, many of these health issues remain the subject of much debate. Undoubtedly, opinions on its risks are polarized along the lines of proponents' views on what its legal status should be. This polarization of opinion has prevented the development of any consensus on what health information the medical profession should give to patients who are users or potential users of marijuana. There is conflicting evidence about many of the effects of marijuana use. Readers are referred to an excellent article that attempts to summarize in a dispassionate way the evidence on the most probable adverse health and psychologic consequences of acute and chronic use of marijuana.⁵⁶

INHALANTS

Inhalants are a diverse group of substances that include volatile solvents, gases, and nitrites that are sniffed, snorted, huffed, or bagged to produce intoxicating effects similar to those of alcohol. These substances are found in common household products such as glues, lighter fluid, cleaning fluids, paint products, nail polish remover, gasoline, rubber glue, waxes, and varnishes. Chemicals found in these products include toluene, benzene, methanol, methylene chloride, acetone, methylethyl ketone, methylbutyl ketone, trichloroethylene, and trichloroethane. The gas used as a propellant in canned whipped cream and in small metallic containers called "whippets" (used to make whipped cream) is nitrous oxide or "laughing gas." Tiny cloth-covered ampules called "poppers" or "snappers" by abusers contain amyl nitrite, a medication used to dilate blood vessels. Butyl nitrite, sold as tape head cleaner and referred to as "rush," "locker room," or "climax," is often sniffed or huffed to get high.

The easy accessibility, low cost, legal status, and ease of transport and concealment make inhalants one of the first substances abused by children. Survey data from 2004 indicate increased inhalant use in all grades. In 2005, that increase in use continued in twelfth graders.⁵ In 2005, there were 877,000 persons aged 12 or older who had used inhalants for the first time within the last 12 months—72.3 % were younger than age 18 when they first used.³ Parents worry about alcohol, tobacco, and drug use, but can be unaware of the hazards associated with products found throughout their homes.

Inhalants can be sniffed directly from an open container or huffed from a rag soaked in the substance and held to the face. Alternatively, the open container or soaked rag can be placed in a bag where the vapors can concentrate before being inhaled. Although inhalant abusers might prefer one particular substance because of taste or

odor, a variety of substances can be used because of similar effects, availability, and cost. Once inhaled, the extensive capillary surface area of the lungs allows rapid absorption of the substance, and blood levels peak rapidly. Entry into the brain is fast, and the intoxicating effects are intense but short-lived. Intoxication is often accompanied by headache and nausea, and users can experience hallucinations and delusions. The most serious physical risk of acute use is sudden death, usually from cardiac arrhythmias. Some users die from suffocation by plastic bags that contain the solvent. With chronic use, the drugs are toxic to virtually all organ systems. Psychologic impairment; impaired pulmonary, renal, and hepatic function; neuropathies; encephalopathy; and brain damage have all been observed.⁵⁷

Inhalants depress the CNS, producing decreased respiration and blood pressure. Users report distortion in perceptions of time and space. Many users experience headaches, nausea, slurred speech, and loss of motor coordination. Mental effects can include fear, anxiety, or depression. A rash around the nose and mouth can be seen, and the abuser can start wheezing. An odor of paint or organic solvents on clothes, skin, and breath is sometimes a sign of inhalant abuse. Other indicators of inhalant abuse include slurred speech or staggering gait; red, glassy, watery eyes; and excitability or unpredictable behavior.

TREATMENT

Substance-Related Disorders

■ ACUTE DRUG INTOXICATIONS

Treatment of drug intoxication, summarized in Table 68-3, is primarily supportive. Vital functions are maintained while waiting for the drug to be eliminated. When absolutely necessary, physical restraints can be required temporarily while a diagnostic evaluation is initiated. Whenever possible, drug therapy should be avoided because psychotropic drug therapy has the potential for worsening a toxic reaction to another psychoactive agent; however, when patients are agitated, combative, assaultive, hallucinating, or delusional, drug therapy may be required. Drug therapy also may be indicated in the treatment of an acute, potentially fatal drug overdose. Toxicology screens are useful in the evaluation and treatment process, but knowledge of the metabolism of the suspected drug and its excretion patterns is important for proper interpretation of test results. When toxicology screens are desired, blood or urine should be collected immediately upon the patient's arrival.

TABLE 68-3 Pharmacologic Treatment of Substance Intoxication

Drug Class	Nonpharmacologic Therapy	Pharmacologic Therapy	Level of Evidence ^{a,b}
Benzodiazepines	Support vital functions	Flumazenil 0.2 mg/min IV initially, repeat up to 3 mg maximum	A1
Alcohol, barbiturates, and sedative-hypnotics (nonbenzodiazepines)	Support vital functions	None	B3
Opiates	Support vital functions	Naloxone 0.4–2 mg IV every 3 min	A1
Cocaine and other CNS stimulants	Monitor cardiac function	Lorazepam 2–4 mg IM every 30 min to 6 h as needed for agitation	B2
		Haloperidol 2–5 mg (or other antipsychotic agent) every 30 min to 6 h as needed for psychotic behavior	B3
Hallucinogens, marijuana, and inhalants	Reassurance; "talk-down therapy"; support vital functions	Lorazepam and/or haloperidol as above	B3
Phencyclidine	Minimize sensory input	Lorazepam and/or haloperidol as above	B3

^aStrength of recommendations, evidence to support recommendation, A, good; B, moderate; C, poor.

^bQuality of evidence: 1, evidence from more than 1 properly randomized, controlled trial; 2, evidence from more than 1 well-designed clinical trial with randomization, from cohort or case-controlled analytic studies or multiple time series; or dramatic results from uncontrolled experiments; 3, evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert communities.

Data from O'Brien,⁵⁷ Fudala et al.,⁵⁸ Smith and Seymour,⁵⁹ and Knapp et al.⁶⁰

For alcohol and barbiturate intoxication, supportive treatment is the rule. For benzodiazepine intoxication, the benzodiazepine antagonist flumazenil can be used to reverse toxic effects. However, it is not indicated in all cases of suspected drug overdose, and is specifically contraindicated in cases in which cyclic antidepressant involvement is known or suspected because of the risk of seizures. In addition, it should be used with caution in patients when benzodiazepine physical dependence is suspected because of the risks of induction of benzodiazepine withdrawal. In the case of opiate intoxication, if the patient is unconscious and respiration is depressed, the opiate antagonist naloxone can be used to revive the patient. The usual dosage for naloxone in acute opiate toxicity is 0.4 to 2 mg intravenously, given approximately every 3 minutes as necessary.⁵⁸ Although naloxone is effective in reversing opiate overdose, it also can precipitate physical withdrawal in physically dependent patients. Patients who fail to respond to a total dosage of 10 mg naloxone probably have a cause of acute intoxication other than an opiate.

Intoxication with stimulants, including cocaine, is treated pharmacologically only if the patient is overtly psychotic and agitated. Injectable benzodiazepines, usually lorazepam 2 to 4 mg intramuscularly every 30 minutes to 6 hours as necessary, can be used for agitation. As a backup to lorazepam, antipsychotic drugs can be used on a short-term basis, primarily in patients with psychotic symptoms, and usually at relatively low doses, such as haloperidol 2 to 5 mg intramuscularly every 30 minutes to 6 hours as necessary, followed by 5 to 15 mg orally per day in single or divided doses if the patient is still psychotic after initial treatment.^{28–30,59} Cardiovascular complications are treated symptomatically with antiarrhythmic agents or other interventions as necessary. Seizures generally are treated supportively. Intravenous lorazepam or diazepam can be used if seizures progress to status epilepticus.

Hallucinogen intoxication is treated in a manner similar to stimulant intoxication. Drug therapy often can be avoided because patients can respond to careful reassurance, or so-called talk-down therapy. When necessary, short-term antianxiety and/or antipsychotic drug therapy can be used, as described previously. The same approach applies to marijuana and inhalant intoxication.

PCP intoxication is more unpredictable and more difficult to treat than other psychosis-producing drugs. Most clinicians suggest that sensory input be minimized to the extent possible; thus talk-down therapy is not recommended and can, in fact, make the patient worse. If PCP intoxication is suspected, patients should be left alone in a quiet, dimly lit room. If behavior is uncontrollable, antianxiety and/or antipsychotic drug therapy can be necessary.

WITHDRAWAL

2 Treatment of drug withdrawal is the primary indication for drug therapy in substance-related disorders. Goals of drug therapy include prevention of progression of withdrawal to life-threatening severity, enabling the patient to be sufficiently comfortable and functional to participate in a behavioral treatment program, and supportive drug therapy. The clinician should remember that withdrawal is usually part of a substance dependence disorder. Patients with drug dependence generally cope with almost any stress through the use of a drug. In drug therapy for withdrawal, it is important to avoid reinforcing the patient’s drug-seeking and drug-use behavior to the extent possible. Drug withdrawal in the best of circumstances is uncomfortable. Patients must be educated to deal with the stress of withdrawal without seeking drugs. The use of drugs as needed for anxiety or insomnia should be avoided. A recent review on the management of drug and alcohol withdrawal has been published.¹³ Treatment of drug withdrawal is summarized in Table 68–4.

TABLE 68-4 Treatment of Withdrawal from Some Common Drugs of Abuse

Drug or Drug Class	Pharmacologic Therapy	Level of Evidence ^{a,b}
Benzodiazepines		
Short- to intermediate-acting	Lorazepam 2 mg three to four times a day; taper over 5–7 days	A1
Long-acting	Lorazepam 2 mg three to four times a day; taper over additional 5–7 days	A1
Barbiturates	Pentobarbital tolerance test; initial detoxification at upper limit of tolerance test; decrease dosage by 100 mg every 2–3 days	B3
Opiates	Methadone 20–80 mg orally daily; taper by 5–10 mg daily or buprenorphine 4–32 mg orally daily, or clonidine 2 mcg/kg three times a day × 7 days; taper over additional 3 days	A1 (methadone and buprenorphine) B1 (clonidine)
Mixed-substance withdrawal		
Drugs are cross-tolerant	Detoxify according to treatment for longer-acting drug used	B3
Drugs are not cross-tolerant	Detoxify from one drug while maintaining second drug (cross-tolerant drugs), then detoxify from second drug	B3
CNS stimulants	Supportive treatment only; pharmacotherapy often not used; bromocriptine 2.5 mg three times a day or higher may be used for severe craving associated with cocaine withdrawal	B2

^aStrength of recommendations, evidence to support recommendation, A, good; B, moderate; C, poor.
^bQuality of evidence: 1, evidence from more than 1 properly randomized, controlled trial; 2, evidence from more than 1 well-designed clinical trial with randomization, from cohort or case-controlled analytic studies or multiple time series; or dramatic results from uncontrolled experiments; 3, evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert communities.
Data from Hajak et al.,¹¹ O'Brien,¹² and Kosten and O'Connor.¹³

CNS DEPRESSANT WITHDRAWAL
Benzodiazepines

2 Treatment of benzodiazepine withdrawal is very similar to the treatment of alcohol withdrawal, and the same drugs and dosages can be used. The major difference in management is the length of treatment. The onset of withdrawal symptoms in patients physically dependent on the long-acting benzodiazepines can be delayed up to 7 days after discontinuation of the drug.¹² A common approach in detoxification of such patients is to initiate treatment at usual dosages (chlordiazepoxide orally 50 mg three times a day; lorazepam orally 2 mg three times a day) and to maintain the initial dosage for 5 days, with gradual tapering over an additional 5 days. Detoxification in patients physically dependent on shorter-acting benzodiazepines is similar to treatment of alcohol withdrawal. Among the benzodiazepines, alprazolam has been suggested to be more difficult to taper and discontinue than the other benzodiazepines. Whether the difficulty is related to a different patient population commonly treated with alprazolam (e.g., panic disorder) or to intrinsic differences between alprazolam and other benzodiazepines is not clear. A longer, more gradual taper of the benzodiazepine used for detoxification can be needed. With all benzodiazepines, protracted minor abstinence symptoms—such as anxiety, insomnia, irritability, sensitivity to light and sound, and muscle spasms—can remain for

several weeks in patients with a history of long exposure, even after the acute phase of benzodiazepine withdrawal is complete.

Barbiturates and Other Sedative-Hypnotic Drugs

② Although once used extensively, barbiturates and other nonbenzodiazepine sedating medications have been largely replaced by safer and more effective medications. Abuse problems with barbiturates resemble those seen with benzodiazepines in many ways. Withdrawal from barbiturates should be handled similarly to interventions for the abuse of alcohol and benzodiazepines.^{11,12}

Opiates

Opiate withdrawal syndrome is similar to a severe case of influenza.¹³ Opiate withdrawal is not life-threatening unless there is a concurrent life-threatening medical condition. Although most patients complain of symptoms of withdrawal such as cramping or insomnia, these symptoms are tolerable, and initiation of drug therapy can be avoided in many cases. Because opiate withdrawal is not life-threatening, observable signs of withdrawal, such as mydriasis, piloerector erection, diaphoresis, or diarrhea should be noted before initiation of drug therapy. Characteristic signs and symptoms of opiate withdrawal include pupillary dilatation, lacrimation, rhinorrhea, piloerection (“gooseflesh”), yawning, sneezing, anorexia, nausea, vomiting, and diarrhea. Seizures do not occur. Onset and duration of withdrawal symptoms and the time of peak occurrence depends on the half-life of the drug involved. Typically heroin withdrawal reaches a peak within 36 to 72 hours of discontinuation and can last for 7 to 10 days. For methadone, symptoms peak at 72 hours but can last for 2 weeks or more.¹²

The conventional drug therapy for opioid withdrawal has been methadone, a synthetic opiate. Recently, buprenorphine has been approved for opioid withdrawal and will be discussed in detail below. In detoxification treatment, methadone is administered in decreasing doses over a period not exceeding 30 days (short-term detoxification) or 180 days (long-term detoxification). There are many tapering schedules recommended in the literature. Most patients in withdrawal continue to complain of mild symptoms after detoxification is completed. Some patients who are unable to discontinue methadone completely or habitually return to drug use when methadone is discontinued are placed in methadone-maintenance treatment programs and receive methadone chronically.⁶⁰

Levo- α -acetylmethadol (LAAM) was approved by the FDA in 1993 as a potential alternative to methadone maintenance. LAAM forms two long-acting metabolites that allow three-times-a-week dosing.⁵⁸

Typically, opioid dependency is treated initially with detoxification, usually as an inpatient. Except in a few individuals who remain drug free, detoxification is followed by long-term maintenance therapy. In the past, opioid-dependent patients relied on methadone or LAAM, but federal restrictions limited distribution of these drugs to a small number of methadone clinics, which are not only inconvenient, but also expose patients to other drug users, and stigmatize patients if friends, family, or coworkers are aware of their trips to the clinic. There were limited provisions for take-at-home dosing of methadone or levomethadyl because of concern about the diversion of these drugs to illicit use.

In October 2003, the FDA approved two new products for treatment of opiate dependence. These products represent two new formulations of buprenorphine. The first of these formulations, Subutex, contains only buprenorphine and is intended for use at the beginning of treatment for opiate abuse. The other, Suboxone, contains both buprenorphine and the opiate antagonist naloxone, and is intended to be the formulation used in maintenance treat-

ment of opiate addiction. Naloxone has been added to Suboxone to guard against intravenous abuse of buprenorphine by individuals physically dependent on opiates.

These drugs represent the first therapy for in-office prescribing for opioid dependence under the federal Drug Addiction Treatment Act (DATA) of 2000.⁶¹ Prior to the passage of the DATA, office-based management of opioid dependence was illegal because existing federal laws prohibited physicians from prescribing narcotics for the sole purpose of maintaining a patient in a narcotic-addicted state. However, not every physician is permitted to prescribe these new drugs.

To qualify, physicians must be board certified in addiction medicine/psychiatry or hold other special credentials, and physicians are required to obtain 8 hours of authorized training before they can prescribe medications for office-based treatment of opioid dependence. They also must agree to treat no more than 30 opioid-dependent patients at any one time, and they must obtain special DEA numbers indicating that they are authorized to prescribe under the provisions of the DATA.

The two formulations of the drug have been placed into schedule III by the DEA. Each product is available in two dosage strengths, 2 mg and 8 mg. Once-daily doses are titrated to a target of 16 mg/day of buprenorphine, but the dosing range extends from 4 mg/day to 24 mg/day.

Office-based maintenance therapy is well studied for patients who are already receiving treatment.^{62–65} A recent systematic review and meta-analysis including 18 clinical trials ($n = 1,356$ patients) determined that buprenorphine was more effective than clonidine for the management of opioid withdrawal. This meta-analysis did not detect a significant difference between buprenorphine and methadone in terms of completion of treatment. Withdrawal symptoms resolved more quickly with buprenorphine, according to this systematic review.⁶⁴

In a multicenter, randomized, placebo-controlled trial,⁶² 326 opiate-addicted persons were assigned to office-based treatment with sublingual tablets consisting of buprenorphine (16 mg) in combination with naloxone (4 mg), buprenorphine alone (16 mg), or placebo given daily for 4 weeks. The primary outcome measures were the percentage of urine samples negative for opiates and the subjects' self-reported craving for opiates. Safety data were obtained on 461 opiate-addicted persons who participated in an open-label study of buprenorphine and naloxone (at daily doses of up to 24 mg and 6 mg, respectively), and another 11 persons who received this combination only during the trial. The double-blind trial was terminated early because buprenorphine and naloxone in combination and buprenorphine alone were found to have greater efficacy than placebo. The proportion of urine samples that were negative for opiates was greater in the combined-treatment and buprenorphine groups (17.8% and 20.7%, respectively) than in the placebo group (5.8%; $P < 0.001$ for both comparisons); the active-treatment groups also reported less opiate craving ($P < 0.001$ for both comparisons against placebo). Rates of adverse events were similar in the active-treatment and placebo groups. During the open-label phase, the percentage of urine samples negative for opiates ranged from 35.2% to 67.4%. Results from the open-label followup study indicated that the combined treatment was safe and well tolerated. The authors concluded that buprenorphine and naloxone in combination and buprenorphine alone are safe and reduce the use of opiates and the craving for opiates among opiate-addicted persons who receive these medications in an office-based setting.

To check to see if the prescriber is authorized to treat patients under the DATA, pharmacists can call 1-866-BUP-CSAT or send an e-mail message to info@buprenorphine.samhsa.gov. Physicians generally use Subutex during induction and give a small supply of the product directly to the patient (clinical studies used buprenorphine-

only tablets for the first 2 days). If patients present prescriptions for either agent from more than one prescriber for the same time period, a pharmacist should assume that diversion or abuse is occurring, refuse to fill the prescriptions, and notify both prescribers. Likewise, prescriptions for Subutex should be verified with prescribers, as the Suboxone formulation is preferred for long-term therapy.⁶⁵

A rapid detoxification technique has been developed that is designed to shorten detoxification by precipitating withdrawal through the administration of opioid antagonists such as naloxone hydrochloride or naltrexone.⁶⁶ This approach is thought to have the advantage of getting patients through detoxification rapidly, minimizing the risk of relapse, and initiating treatment more quickly with naltrexone maintenance combined with suitable psychosocial interventions. Ultrarapid detoxification represents a variant of this technique in which patients undergo opioid antagonist–precipitated withdrawal while under general anesthesia or heavy sedation. Although it is difficult to estimate the extent of their clinical use, these techniques are becoming increasingly available in response to increasing demand for opioid-dependence treatment services. In the United States there has been a rapid proliferation of programs offering ultrarapid detoxification, with some programs charging up to \$15,000 per treatment.⁶⁷

A meta-analysis was performed to assess the evidence for the efficacy of both rapid detoxification and ultrarapid detoxification to determine their role among the available treatment options for opioid dependence.⁶⁶ Analysis was performed on 12 studies of rapid detoxification and 9 studies of ultrarapid detoxification. The authors concluded that more research is needed using more rigorous research methods, longer-term outcomes, and comparisons with other methods of treatment for opioid dependence before these techniques can gain widespread acceptance.⁶⁶ Recently, a randomized, open label, head-to-head trial ($n = 106$) compared the efficacy of ultrarapid detoxification compared with buprenorphine-assisted rapid opioid detoxification with naltrexone induction, versus clonidine-assisted opioid detoxification with delayed naltrexone induction.⁶⁷ Outcome measures included severity of withdrawal symptoms, rates of completion of inpatient detoxification program (12 weeks), and percentage of opioid positive urine samples. Severity of withdrawal symptoms, percentage of opioid-positive urine samples, and rates of completion of treatment did not differ among the three groups. Three life-threatening adverse events occurred in the ultrarapid detoxification group.⁶⁷

CLINICAL CONTROVERSY

Ultrarapid detoxification from opiates remains somewhat controversial in terms of its efficacy, safety, and cost. Before consenting to such treatment, patients should inquire about the practitioner's previous experience with this technique, including success rates of patients remaining drug-free and also rates of complications that have occurred.

WITHDRAWAL FROM OTHER SUBSTANCES

Withdrawal from other drugs, including cocaine and other stimulants, is primarily supportive. However, pharmacotherapy recently has assumed a greater role in treating cocaine withdrawal and dependence. Bromocriptine, a dopamine antagonist at low dosages and an agonist at high dosages, is usually used in the treatment of parkinsonism and hyperprolactinemia and has been used to treat cocaine withdrawal symptoms and to reduce the craving for cocaine. Use of bromocriptine is based on the hypothesis that chronic use of cocaine causes dopamine depletion; therefore higher dosages should be used (i.e., 2.5 mg three times daily or higher). Despite initially promising pilot studies, recent evidence does not support the efficacy of bromocriptine to reduce cocaine use or craving.⁶⁸

A more likely efficacious approach is the use of the cocaine vaccine that is still in clinical trials.⁶⁹ This vaccine is an immunotherapeutic agent that treats cocaine dependence. In the presence of the vaccine, the immune system forms antibodies that prevent cocaine from crossing the blood-brain barrier, blocking access to receptor sites in the brain. Phase II clinical trials suggest the vaccine is well tolerated and effective to decrease the likelihood of cocaine use in patients that received five 400-mcg vaccinations over a 12-week period. Cocaine-specific antibodies were still present at the 6 month followup.⁷⁰

SUBSTANCE DEPENDENCE

3 The treatment of drug dependence is primarily behavioral. The patient generally is taught that complete abstinence is the only realistic alternative to a life of uncontrollable drug use and despair that ultimately will end in death, and that there is no intermediate, controllable level of drinking or use of another drug. However, complete and permanent abstinence as the sole route to recovery is controversial. There may be an extremely few individuals who can return to controllable levels of drinking alcohol, but it is impossible to predict who these individuals are; thus most treatment programs continue to advocate complete abstinence. The prospect of life without alcohol or other drugs is incomprehensible to many patients. Entry into treatment often is facilitated by some type of leverage that the drug-dependent person associates with negative consequences, such as potential loss of job, divorce, legal problems, or deteriorating physical health. Early treatment is directed at penetrating the denial of a problem that is always present. The patient must be educated as to the disease of addiction, the effects of drugs, and the permanence of the condition.

As evidenced by the approval of the two buprenorphine products, there has been a trend toward outpatient treatment for drug dependence, caused in part by cost-containment efforts. Inpatient treatment programs can cost as much as \$20,000 for a 4-week stay. When withdrawal symptoms are mild to moderate and there are no other medical indications for hospitalization, outpatient treatment can be an attractive alternative to inpatient treatment. One critical criterion for outpatient treatment is the patient's compliance with complete abstinence from the dependence-producing drug during the treatment experience.

Families must be involved in treatment. The course of the patient's illness often has a devastating effect on other family members. Severely depleted self-esteem, denial of the family member's addiction, feelings of responsibility for the family member's drug use, and other behaviors that parallel the addiction process are often present.

4 Treatment must be a lifelong process. Aftercare, or what is now being called *continued care*, should include regular and frequent treatment in some form. Most drug-dependence treatment programs embrace a treatment approach based on the twelve steps to recovery. AA is one of the most successful of all self-help groups. Associated groups include Al-Anon (a group for family members of alcoholics), NA (self-help groups based on the AA concept for users of other drugs), Overeaters Anonymous (a group for individuals with eating disorders), Gamblers Anonymous, and several other similar programs. Among chemically dependent healthcare professionals, treatment that incorporates both AA and peer-led self-help groups can be most effective.⁷¹

CONCLUSIONS

Substance use disorders remain one of the great public health issues of contemporary society. Dependence on drugs is a powerful emotional and political issue. Because we live in a chemically oriented society, everyone is affected in some way by drug abuse and drug dependence. Healthcare professionals must be particularly

vigilant for problems associated with drug use, not only for our patients, but also for ourselves.

Substance-Related Disorders: Alcohol, Nicotine, and Caffeine

PAUL L. DOERING, W. KLUGH KENNEDY, AND LISA A. BOOTHBY

KEY CONCEPTS

- 1 Alcohol, nicotine, and caffeine use impose enormous social and economic costs on society.
- 2 Alcohol abuse causes numerous chronic diseases and injuries with an inordinate amount of mortality.
- 3 Pharmacogenomics studies have identified genotypic and functional phenotypic variants that either serve to protect patients or predispose them toward alcohol dependence.
- 4 Alcohol is a central nervous system depressant that affects the central nervous system in a dose-dependent fashion.
- 5 The metabolism of alcohol is considered to follow zero-order pharmacokinetics, and this has important implications for the time course in which alcohol can exert its effects.
- 6 Benzodiazepines are the treatment of choice for alcohol withdrawal.
- 7 Disulfiram, naltrexone, and acamprosate are FDA-approved drug therapies for the treatment of alcohol dependence. The clinical usefulness of these agents to improve sustained abstinence remains controversial, and relapse is common.
- 8 More than three-quarters of smokers are nicotine dependent. Tobacco dependence is a chronic condition that requires repeated interventions.
- 9 Use of nicotine replacement therapy along with behavioral counseling doubles cessation rates.
- 10 Bupropion is efficacious alone and in combination with nicotine replacement therapy for smoking cessation.
- 11 Varenicline is efficacious for smoking cessation, although it is not first-line therapy.
- 12 Caffeine's pharmacologic actions are similar to those of other stimulant drugs. As such, abstinence from caffeine induces a distinct withdrawal syndrome that includes headache, drowsiness, and fatigue.

KEY MEDICAL TERMS

Caffeinism: *Caffeinism* is the term coined to describe the clinical syndrome produced by acute or chronic overuse of caffeine.

Euphoria: A mood state characterized by an exaggerated, superficial sense of well-being, characterized extreme happiness, sometimes more than is reasonable in a particular situation.

Intoxication: The development of a substance-specific syndrome after recent ingestion and presence in the body of a substance, and it is associated with maladaptive behavior during the waking state caused by the effect of the substance on the central nervous system.

Withdrawal: The development of a substance-specific syndrome after cessation of or reduction in intake of a substance that was used regularly by the individual to induce a state of intoxication.

1 Alcohol, nicotine, and caffeine are considered by most to be socially acceptable drugs, yet they impose an enormous social and economic cost on our society. Approximately 438,000 deaths each year are attributable to tobacco use, making tobacco the number one preventable cause of death and disease in this country.¹ The three leading causes of death attributable to smoking include lung cancer, chronic obstructive pulmonary disease, and ischemic heart disease.²

2 Approximately 12.9 million persons in the United States report current heavy use of alcohol or alcohol abuse.³ Almost one-half of these persons meet *Diagnostic and Statistical Manual of Mental Disorders, 4th edition, Text Revision (DSM-IV-TR)* criteria for alcohol dependence,⁴ and more than 700,000 persons are in treatment for alcoholism at any one time.⁵ Population-based surveys of current drinkers have found rates of 7% to 16% for alcohol abuse or dependence.⁶ The World Health Organization estimates that there are approximately 2 billion people worldwide who consume alcoholic beverages, and 76.3 million with diagnosable alcohol-use disorders.⁷ Long-term alcohol abuse often leads to chronic disease. A causal relationship between alcohol abuse and at least 60 types of chronic disease or injury have been established (e.g., esophageal cancer, liver cancer, and cirrhosis of the liver, epileptic seizures, homicide, and motor vehicle accidents) worldwide.⁷ Nationally, according to the Drug Abuse Warning Network 2002 survey, emergency department visits related to drug abuse most frequently involved alcohol, and included 31% of the observed cases.⁸

2 Worldwide, alcohol abuse leads to 1.8 million deaths annually.⁷ Nationally, an estimated 100,000 U.S. citizens die each year because of alcohol-related causes, including traffic collisions and cirrhosis of the liver.⁹ Direct and indirect health and social costs of alcoholism to the nation are estimated to be \$185 billion annually.¹⁰

Caffeine is currently the most widely used psychoactive substance in the world.¹¹ In the United States, 80% to 90% of adults regularly consume behaviorally active doses of caffeine.¹¹ Although research has shown that caffeine can cause a compulsive pattern of use, the prevalence of caffeine dependence and its clinical significance are difficult to determine.

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

The subjects of alcohol, tobacco, and caffeine abuse deserve much more attention than space permits in this chapter. Therefore the information here should serve as a brief overview of these topics, and the reader desiring more details is urged to consult one or more of the many textbooks and articles devoted to these subjects.

ALCOHOL

EPIDEMIOLOGY OF ALCOHOL USE

Roughly half (51.8%) of Americans ages 12 and older reported being current drinkers of alcohol according to the National Survey on Drug Use and Health (formerly called the National Household Survey on Drug Abuse).³ This translates to 126 million people, which is higher than the 2004 estimate of 121 million people (50.3 %). Approximately one-fifth of persons 12 years of age and older (55 million people) participated in binge drinking, defined as having five or more drinks on the same occasion, at least once in the 30 days prior to the survey. In 2005 there were 16 million heavy drinkers, meaning that they drank five or more drinks on the same occasion on at least five different days in the past month.³

THE DISEASE MODEL OF ADDICTION AS APPLIED TO ALCOHOLISM

The disease concept of addiction, using alcoholism as a model, states that addiction is a disease and that individuals who suffer from the disease do not choose to contract the disease any more than someone who suffers from heart disease or diabetes mellitus chooses to contract that illness. A *disease* is defined as “any deviation from or interruption of the normal structure or function of any part, organ, or system (or combination thereof) of the body that is manifested by a characteristic set of symptoms and signs and whose etiology, pathology, and prognosis may be known or unknown.”⁴ Alcoholism, which is discussed as a prototype, meets all the definitional criteria. Diagnostic criteria for alcoholism do not specify frequency of drinking or amount of alcohol consumed. The key determinant is whether drinking is compulsive, out of control, and consequential when one drinks.

③ It has long been recognized that alcoholism is heritable, as 50% to 60% of first-degree relatives of alcoholics become alcohol dependent themselves.¹² Past discussions have focused on whether this heritable risk is because of genetics, environment, or both. Recent research has identified several traits (or phenotypes), that attenuate one’s risk of alcohol dependence. Initially based on data from preclinical studies, pharmacogenomics studies have identified genotypic and functional phenotypic variants that either serve to protect patients, or predispose them toward alcohol dependence.¹³ Large-scale pharmacoepidemiologic studies have further elucidated the environmental risk factors that are associated with either protective effects or predisposition toward alcoholism.¹⁴ This is referred to as the “genome x” environment interaction effect. The known susceptibility genes, phenotypic characteristics, and environmental risk factors are summarized in Table 69–1.^{13–17} Further elucidation of the gene-environment interactions are needed before these data are used to (1) create alcohol abuse prevention programs that target high-risk populations, and (2) develop targeted treatments to prevent and treat alcohol dependence.¹⁸

PHARMACOLOGY AND PHARMACOKINETICS OF ALCOHOL

Alcohol as a Drug

④ Alcohol is a central nervous system (CNS) depressant that affects the CNS in a dose-dependent fashion, producing sedation that progresses to sleep, unconsciousness, coma, surgical anesthesia, and

TABLE 69-1 Genotypic, Phenotypic, and Environmental Factors That Increase Alcohol Dependence Risk

Susceptibility Genes	Phenotype	Environment
Regions on chromosomes 1 and 4 that code for the following receptors: GABA _A Serotonin 1b DRD4 Tryptophan hydroxylase Neuropeptide Y	Personality traits that include: Novelty seeking Impulsivity Aggression Depression Maximum number of alcoholic drinks consumed per day	Religious background Urban residence (vs. rural) History of sexual abuse Being single Having deceased parents
Gene that codes for: ALDH2 5HTTLPR		

ALDH2, aldehyde dehydrogenase 2; DRD4, type 4 dopamine receptor gene; GABA, gamma aminobutyric acid; 5HTTLPR, 5 hydroxytryptamine transporter.

Data from Bierut et al.,¹³ Heath et al.,¹⁴ Luo et al.,¹⁵ Boothby and Doering,¹⁶ and Krystal et al.¹⁷

finally fatal respiratory depression and cardiovascular collapse. Alcohol affects endogenous opiates and several neurotransmitter systems in the brain, including γ -aminobutyric acid (GABA), glutamine, and dopamine. Alcohol intake results in an increase in endogenous opioids,¹⁹ and this can be responsible for the euphoria experienced with alcohol consumption.

Alcohol is available in a variety of concentrations in various alcoholic beverages. There are approximately 14 g of alcohol in a 12-oz can of beer (approximately 5%), 4 oz of nonfortified wine (approximately 10% to 14%), or one shot (1.5 oz) of 80-proof whiskey (40%). Full consumption of this amount will cause an increase in blood alcohol level of approximately 20 to 25 mg/dL in a healthy 70-kg (154 lb) male, although this varies with the time frame over which the alcohol is consumed, the type of alcoholic beverage, whether food is consumed along with it, and many patient variables. The lethal dose of alcohol in humans is variable, but deaths generally occur when blood alcohol levels are greater than 400 to 500 mg/dL.²⁰

CLINICAL CONTROVERSY

Moderate alcohol consumption has been suggested in some studies to improve health. The definition of moderate consumption is narrow—one drink or less per day for females and two drinks or less per day for males. Controversy stems from the limitations of the studies that support moderate alcohol consumption. The major limitations of this research thus far are the observational study designs that cannot demonstrate cause and effect relationships between alcohol consumption and positive health benefits.^{21–24} Additional potential confounders in these studies include diet, exercise, disease states, other drug therapies known to promote or hinder cardiovascular health, and psychosocial factors such as stress management.

Pharmacokinetics

Absorption of alcohol begins in the stomach within 5 to 10 minutes of oral ingestion. The onset of clinical effects follows fairly rapidly. Peak serum concentrations of alcohol usually are achieved 30 to 90 minutes after finishing the last drink, although it is variable depending on the type of alcoholic beverage consumed, what and when the person last ate, and other factors.²⁵

More than 90% of alcohol in the plasma is metabolized in the liver by three enzyme systems that operate within the hepatocyte. The remainder is excreted by the lungs and in urine and sweat. Alcohol is metabolized to acetaldehyde by alcohol dehydrogenase in the cell. In turn, acetaldehyde is metabolized to carbon dioxide and water by the

enzyme aldehyde dehydrogenase. A second pathway for oxidation of alcohol uses catalase, an enzyme located in the peroxisomes and microsomes. The third enzyme system, the microsomal alcohol oxidase system, has a role in the oxidation of alcohol to acetaldehyde. These last two mechanisms are of lesser importance than the alcohol dehydrogenase-aldehyde dehydrogenase system.

5 The metabolism of alcohol generally is said to follow zero-order pharmacokinetics.²⁵ This can, in fact, be an oversimplification because at very high or very low concentrations of alcohol the metabolism can follow first-order pharmacokinetics.²⁶ On average, the blood alcohol concentration (BAC) is lowered from 15 to 22.2 mg/dL per hour in the nontolerant individual, assuming that the individual is in the postabsorptive state (Table 69–2). Alcohol has a volume of distribution of 0.6 to 0.8 L/kg, representing the total body water.²⁵

CLINICAL INDICATORS OF CHRONIC ALCOHOL ABUSE

The CAGE questionnaire, when correctly administered, is a tool for detecting individuals more likely to be abusing alcohol and therefore at greater risk for alcohol withdrawal. It is simple as well as sensitive and specific. CAGE is a mnemonic for four questions: (1) Do you ever feel the need to CUT DOWN on your alcohol use? (2) Have you ever been ANNOYED by others telling you that you drink too much? (3) Have you ever felt GUILTY about your drinking or something you did while drinking? (4) Do you ever have an “EYE OPENER”? A positive response to two or more of these four questions suggests an increased likelihood of alcohol abuse with a sensitivity of 43% to 94% and a specificity of 73% to 90%.²⁷ This can translate into an increased risk of alcohol withdrawal syndrome for this group. In some settings this is a useful tool to identify that subset of patients who will benefit from increased monitoring.

Alcohol Poisoning

Acute alcohol poisoning usually occurs with rapid consumption of large quantities of alcoholic beverages, because this type of drinking delivers a bolus of alcohol to the gastrointestinal (GI) tract. Normally, the user passes out before a toxic dose of alcohol can be ingested, and/

or the person vomits to rid the stomach of its toxic reservoir. With rapid drinking as described, the person may fall asleep or pass out without vomiting, allowing continued alcohol absorption from the GI tract, while the patient sleeps, until fatal BACs are achieved.

CLINICAL PRESENTATION OF ALCOHOL INTOXICATION AND WITHDRAWAL

General

- Acute alcohol detoxification and withdrawal after chronic alcohol abuse is a serious condition that can require hospitalization and adjunctive pharmacotherapy. If the BAC gets high enough, death is possible.

Symptoms

- The intoxicated patient can present with slurred speech and ataxia. The patient can be sedated or unconscious. As BACs decrease rapidly, nausea, vomiting, and hallucinations can ensue. Delirium and seizures are the most severe symptoms.

Signs

- The intoxicated patient can present with nystagmus.
- In withdrawal, the patient can present with tachycardia, diaphoresis, or hyperthermia.

Laboratory Tests

- In the emergency department, a BAC should be ordered when alcohol ingestion is suspected. Most laboratories report BAC in units of milligrams per deciliter. A whole blood alcohol level of 150 mg/dL reported in the hospital corresponds to 0.15% BAC obtained by law enforcement.
- A complete toxicologic screen to rule out the presence of other substances can be useful.

Other Diagnostic Tests

- Differentiate acute alcohol intoxication from other medical illnesses (e.g., head trauma).
- Use computed tomography (CT) on any patient with focal neurologic findings, failure to improve, new-onset seizures, or mental status out of proportion to degree of intoxication.

TABLE 69-2 Specific Effects of Alcohol Related to BAC

BAC (%) ^a	Effect
0.02–0.03	No loss of coordination, slight euphoria, and loss of shyness.
0.04–0.06	Feeling of well-being, relaxation, lower inhibitions, sensation of warmth. Euphoria. Some minor impairment of reasoning and memory, lowering of caution.
0.07–0.09	Slight impairment of balance, speech, vision, reaction time, and hearing. Euphoria. Judgment and self-control are reduced, and caution, reason, and memory are impaired. It is illegal to operate a motor vehicle in some states at this level.
0.10–0.125	Significant impairment of motor coordination and loss of good judgment. Speech can be slurred; balance, vision, reaction time, and hearing impaired. Euphoria. It is illegal to operate a motor vehicle at this level of intoxication.
0.13–0.15	Gross motor impairment and lack of physical control. Blurred vision and major loss of balance. Euphoria is reduced, and dysphoria is beginning to appear.
0.16–0.2	Dysphoria (anxiety, restlessness) predominates, nausea can appear. The drinker has the appearance of a “sloppy drunk.”
0.25	Needs assistance in walking; total mental confusion. Dysphoria with nausea and some vomiting.
0.3	Loss of consciousness.
≥ 0.4	Onset of coma, possible death caused by respiratory arrest.

BAC, blood alcohol concentration.

^aGrams of ethyl alcohol per 100 mL of whole blood.

TREATMENT

Alcohol Withdrawal

Goals for alcohol-dependent persons trying to decrease or discontinue alcohol intake include: (1) the prevention and treatment of withdrawal symptoms (including seizures and delirium tremens) and medical or psychiatric complications, (2) long-term abstinence after detoxification, and (3) entry into ongoing medical and alcohol-dependence treatment.

PHARMACOLOGIC THERAPY

6 Symptom-triggered treatment with a benzodiazepine is the current standard of care in alcohol detoxification to manage and minimize symptoms and avoid progression to the more severe stages of withdrawal. A meta-analysis was performed to provide evidence-based recommendations on the pharmacologic management of alcohol withdrawal²⁷ and delirium tremens.³² Trials comparing different benzodiazepines demonstrated that all appear similarly efficacious in reducing signs and symptoms of withdrawal.^{27,32} Lorazepam is preferred by many clinicians because it can be administered intravenously, intramuscularly, or orally with predictable results. Another consideration in the choice of benzodiazepine is their potential for abuse during recovery. Agents with rapid onset of action, such as

diazepam or alprazolam, demonstrate higher abuse potential because of their reinforcing effects. Those with slower onset of action, such as chlordiazepoxide or oxazepam, are less likely to be abused. This consideration can be relevant in an outpatient setting or for patients with a history of benzodiazepine or other substance abuse.³³

Although barbiturates are used by approximately 10% of detoxification programs in the United States, there is less evidence-based support for their use versus the benzodiazepines.³³ Clonidine, carbamazepine, vigabatrin, valproic acid, gabapentin, and topiramate can reduce symptoms of alcohol withdrawal.^{34–37}

Treatment Regimens

Symptom-Triggered Therapy With symptom-triggered therapy, medication is given only when the patient has symptoms. This approach results in treatment that is shorter, potentially avoiding oversedation and allowing the clinician to focus on specific therapy for alcohol dependence.^{27,32} A typical regimen would include lorazepam 2 mg administered every hour as needed when a structured assessment scale—such as the Clinical Institute Withdrawal Assessment—Alcohol, Revised—indicates that symptoms are moderate to severe (Table 69–3).³⁵

Fixed-Schedule Therapy Over the years, benzodiazepines given regularly at a fixed dosing interval have been used for alcohol withdrawal. The major problem with this approach is underdosing of the benzodiazepine because of the phenomenon of cross-tolerance

(see Table 69–3). Current guidelines take exception with this rigid approach, urging clinicians to allow for some degree of individualization within fixed-schedule therapy.²⁷ Patients should be monitored and given additional medication when indicated by symptoms.

Treatment of Alcohol Withdrawal Seizures

Alcohol withdrawal seizures do not require treatment with an anticonvulsant drug unless they progress to status epilepticus because seizures usually end before diazepam or another drug can be administered.^{32–34} Phenytoin, which is not cross-tolerant to alcohol, does not prevent or treat withdrawal seizures, and without an intravenous loading dose, therapeutic blood levels of phenytoin are not reached until acute withdrawal is complete. Patients experiencing seizures should be treated supportively. An increase in the dosage and slowing of the tapering schedule of the benzodiazepine used in detoxification or a single injection of a benzodiazepine can be necessary to prevent further seizure activity. Patients with a history of withdrawal seizures can be predicted to experience an especially severe withdrawal syndrome. In such patients, a higher initial dosage of a benzodiazepine and a slower tapering period of 7 to 10 days are advisable.

Treatment of Nutritional Deficits and Electrolyte Abnormalities

Fluid status should be carefully assessed, and fluid, electrolyte, and vitamin abnormalities should be corrected. Often hydration is

TABLE 69-3 Pharmacologic Agents Used in the Treatment of Alcohol Withdrawal

Drug	Dose per Day (Unless Otherwise Stated)	Indication	Monitoring	Duration of Dosing	Level of Evidence ^a
Multivitamin	1 tablet	Malnutrition	Diet	At least until eating a balanced diet at caloric goal	B3
Thiamine	50–100 mg	Deficiency	CBC, WBC, nystagmus	Empiric × 5 days. More if evidence of deficiency	B2
Crystalloid fluids (typically D5-0.45 NS with 20 mEq of KCl per liter)	50–100 mL/hr	Dehydration	Weight, electrolytes, urine output, nystagmus if dextrose	Until intake and outputs stabilize and oral intake is adequate	A3
Clonidine oral	0.05–0.3 mg	Autonomic tone rebound and hyperactivity	Shaking, tremor, sweating, blood pressure	3 days or less	B2
Clonidine transdermal	TTS-1 to TTS-3	Autonomic tone rebound and hyperactivity	Shaking, tremor, sweating, blood pressure	1 week or less. One patch only	B3
Labetalol	20 mg IV every 2 hours as needed	Hypertensive urgencies and above	Blood pressure target	Individual doses as needed	B3
Antipsychotics, haloperidol	2.5 mg to 5 mg every four hours	Agitation unresponsive to benzodiazepines, hallucinations (tactile, visual, auditory or otherwise) or delusions	Subjective response plus rating scale (CIWA-Ar or equivalent)	Individual doses as needed	B1
Antipsychotics, atypical Quetiapine Aripiprazole	25–200 mg 5–15 mg	Agitation unresponsive to benzodiazepines, hallucinations, or delusions in patients intolerant of conventional antipsychotics	Subjective response plus rating scale (CIWA-Ar or equivalent)	Individual doses as needed in addition to scheduled antipsychotic	C3
Benzodiazepines Lorazepam Chlordiazepoxide Clonazepam Diazepam	0.5–2 mg 5 mg–25 mg 0.5–2 mg 2.5–10 mg	Tremor, anxiety, diaphoresis, tachypnea, dysphoria, seizures	Subjective response plus rating scale (CIWA-Ar or equivalent)	Individual doses as needed. Underdosing is more common than overdosing	A2
Alcohol oral		Prevent withdrawal	subjective signs of withdrawal	Wide variation	C3
Alcohol IV		Prevent withdrawal	subjective signs of withdrawal	Wide variation	C3

Quality of evidence: 1, evidence from more than 1 properly randomized, controlled trial; 2, evidence from more than 1 well-designed clinical trial with randomization, from cohort or case-controlled analytic studies or multiple time series; or dramatic results from uncontrolled experiments; 3, evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert communities.

Data from Mayo-Smith,²⁶ Mayo-Smith et al.,³² and Reoux and Miller.³⁵

TABLE 69-4 Pharmacologic Agents Used in the Treatment of Alcohol Dependence

Drug	Dosage Range per Day	Indication	Monitoring	Duration of Dosing	Level of Evidence ^a
Disulfiram	250 mg–500 mg	Deterrence	Facial flushing, liver enzymes	Indefinite	B2
Acamprosate	999 mg–1,998 mg and higher (333 mg tablets)	Craving	Patient-reported craving, renal function	Indefinite	A1
Naltrexone	50 mg–100 mg	Craving	Patient-reported craving	Indefinite	A1
Mood stabilizers (e.g., lamotrigine, topiramate, carbamazepine, valproic acid)	Seizure disorder doses	Craving	Patient-reported craving, plasma drug levels	Indefinite	B2
Antidepressants (e.g., clomipramine, bupropion, doxepin, maprotiline, fluoxetine)	Depression doses	Craving, depression, anxiety	Patient-reported craving	Indefinite	B2

^aStrength of recommendations: A, B, C = good, moderate, and poor evidence to support recommendation, respectively.

Quality of evidence: 1, evidence from more than 1 properly randomized, controlled trial. 2, evidence from more than 1 well-designed clinical trial with randomization, from cohort or case-controlled analytic studies or multiple time series; or dramatic results from uncontrolled experiments. 3, evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert communities.

Data from Boothby and Doering,³⁸ Mason et al.,³⁹ Garbutt et al.,^{40,43} Morris et al.,⁴¹ Srisurapanont and Jarusuraisin,⁴² and Johnson et al.⁴⁴

unnecessary. Excessive hydration should be avoided in patients going through alcohol withdrawal because of increased vasopressin levels. Hydration can be necessary in patients with vomiting, diarrhea, increased body temperature, or severe agitation.

Alcoholics often have electrolyte imbalances because of inadequate nutrition and fluid volume related to antidiuretic hormone inhibition. Hypokalemia can be corrected with oral potassium supplementation as long as renal function is adequate. Hypophosphatemia is common but should be allowed to gradually correct with adequate nutrition if phosphorus levels are greater than 1 mg/dL. Hypomagnesemia is also common but routine magnesium replacement for alcohol withdrawal is not recommended. Only if symptoms of hypomagnesemia are present should magnesium replacement be considered.

Thiamine (vitamin B₁) is often depleted in alcoholics, particularly those with poor nutrition. Thiamine supplementation is standard therapy because it can prevent the development of the Wernicke-Korsikoff syndrome (e.g., mental confusion, eye movement disorders, and ataxia [poor motor coordination]), which may not be reversible once it develops. An initial dose of 100 mg IV or IM is commonly used. If the patient has evidence of thiamine deficiency replacement with 100 mg orally every day for 1 to 4 weeks is appropriate. Thiamine should not be continued unless there is evidence of a deficiency. Adverse effects associated with thiamine use are hypersensitivity reactions, cardiovascular effects, and CNS effects. If thiamine deficiency is suspected thiamine should always be given before dextrose administration because it is a cofactor necessary for glucose metabolism. In practice, thiamine is usually given 100 mg once daily orally, intravenously, or intramuscularly for 3 to 5 days. It is not necessary for thiamine to be continued empirically for longer than 5 days (see Table 69–3).

Other nutritional deficits can also occur with chronic alcohol abuse primarily caused by poor eating habits. A multivitamin is usually given once daily. If clotting factors are abnormal because of decreased liver function and a relative inability to produce vitamin K–dependent clotting factors, then 2.5 to 25 mg of vitamin K can also be prescribed.

Alcohol hypoglycemia usually occurs in the absence of overt liver disease, and it is more likely if the patient is fasting or exercising or is sensitive to alcohol; it is less likely if the patient is obese. The alcohol directly interferes with hepatic gluconeogenesis but not glycogenolysis. The energy required for metabolism of alcohol is diverted away from the energy needed to take up lactate and pyruvate—substrates for gluconeogenesis. So, patients who drink alcohol can become hypoglycemic once glycogen stores are depleted. Neurologic symptoms of hypoglycemia can be confused with alcohol intoxication, and in the inpatient setting, blood glucose should be monitored regularly.

Treatment Settings

Alcohol withdrawal treatment can take place in hospitals, inpatient detoxification units, or outpatient settings. Inpatient treatment can be necessary when there are coexisting acute or chronic medical (including pregnancy), surgical, or psychiatric conditions that would complicate alcohol withdrawal. Only patients with mild to moderate symptoms should be considered for outpatient treatment, and it is a good idea to have a responsible, sober person available to help the patient monitor symptoms and administer medications. Patients with a strong craving for alcohol, those concurrently using other drugs, and those with a history of seizures or delirium tremens are not good candidates for outpatient treatment. Pharmacologic agents used in the treatment of alcohol withdrawal are summarized in Table 69–3.

PHARMACOLOGIC MANAGEMENT OF ALCOHOL DEPENDENCE

7 In the United States, disulfiram, naltrexone, and acamprosate are the only three drugs that are FDA-approved for the treatment of alcohol dependence. Disulfiram acts as a deterrent to the resumption of drinking, and naltrexone is a competitive opioid antagonist that has been shown to reduce cravings for alcohol. Acamprosate is a GABA-ergic agonist that modulates alcohol cravings (Table 69–4).^{38–44} Other drugs, including nalmefene,³⁹ bupropion, various serotonergic agents (including selective serotonin reuptake inhibitors and vascular serotonin 5-HT₃ receptor antagonists), and lithium also have been used either abroad or in the United States off-label for alcohol dependence.⁴⁰

CLINICAL CONTROVERSY

The most difficult clinical problem in the treatment of alcohol related illness is helping patients remain abstinent after alcohol detoxification. Despite the availability of pharmacologic agents to decrease the craving post-acute detoxification, the usefulness of these pharmacologic agents (e.g., acamprosate, naltrexone, disulfiram) remains controversial. Acamprosate and naltrexone have been shown to be superior to nonpharmacologic therapy alone for maintenance of abstinence from alcohol; however, relapse during naltrexone and acamprosate therapy is still common. Disulfiram use has fallen out of favor. Studies have failed to prove it effective, and it is poorly tolerated. For this reason, most clinicians rarely recommend the use of disulfiram.

■ DISULFIRAM

Disulfiram deters a patient from drinking by producing an aversive reaction if the patient drinks. In the absence of alcohol, disulfiram has minimal effects. Note that although disulfiram appeared to be effective in a series of studies with a small sample size, these were largely uncontrolled.⁴⁰ Disulfiram inhibits the liver enzyme aldehyde dehydrogenase in the biochemical pathway for alcohol metabolism, allowing acetaldehyde to accumulate. The resulting increase in acetaldehyde causes severe facial flushing, throbbing headache, nausea and vomiting, chest pain, palpitations, tachycardia, weakness, dizziness, blurred vision, confusion, and hypotension. Severe reactions including myocardial infarction, congestive heart failure, cardiac arrhythmia, respiratory depression, convulsions, and death can occur, particularly in vulnerable individuals.

A rare but potentially fatal idiosyncratic hepatotoxicity can occur with disulfiram. As a result, baseline liver function tests should be obtained and the patient monitored for hepatotoxicity by monitoring for symptoms and by repeating the liver function tests at 2 weeks, 3 months, 6 months, and twice yearly thereafter. The prescriber should wait at least 24 hours after the last drink before starting disulfiram, usually at a dose of 250 mg/day. At this dose there are fewer side effects than at 500 mg, although some research suggests that higher doses are needed to reliably produce an aversive reaction if the patient drinks.⁴⁰

■ NALTREXONE

Naltrexone, an opiate antagonist that has been available in the United States since 1984 for the treatment of opioid dependence blocks the effects of exogenous opioids. In 1994 the FDA approved its use in the treatment of alcohol dependence. Naltrexone is thought to attenuate the reinforcing effects of alcohol, and those who consume alcohol while taking naltrexone report feeling less intoxicated and having less craving for alcohol.⁴¹

Short-term treatment (up to 12 weeks) with naltrexone decreases the chance of alcohol relapse by 36% versus placebo (number needed to treat seven patients to prevent one relapse).⁴² Naltrexone should not be given to patients currently dependent on opiates because it can precipitate a severe withdrawal syndrome. Naltrexone is associated with dose-related hepatotoxicity, but this generally occurs at doses higher than those recommended for treatment of alcohol dependence. Nevertheless, it is considered contraindicated in patients with hepatitis or liver failure, and liver function tests should be monitored monthly for the first 3 months and every 3 months thereafter.

Nausea is the most common side effect of naltrexone, occurring in approximately 10% of patients. Other side effects are headache, dizziness, nervousness, fatigue, insomnia, vomiting, anxiety, and somnolence. If dosed daily, naltrexone 50 mg per day is sufficient to effectively block μ -opioid receptors. A new long-acting depot formulation allows monthly administration to increase compliance and adherence. The usual effective dose is 380 mg IM each month.⁴³

■ ACAMPROSATE

Acamprosate is a glutamate modulator at the N-methyl-D-aspartate (NMDA) receptor that reduces alcohol craving. Acamprosate was approved in the United States in the summer of 2004 but has been available in Europe for many years. Patients treated with acamprosate are more successful in maintaining abstinence from alcohol versus placebo.³⁸ In addition, the combination of acamprosate and naltrexone has been shown to be more efficacious than acamprosate alone for the maintenance of abstinence from alcohol, when combined with psychosocial interventions.³⁸ Acamprosate is well tolerated, with gastrointestinal adverse effects most common. See Table

69–4 for dosing information for this and the other options used in treating alcohol dependence.

Using the limited data on serotonergic agents in the evidence-based analysis,⁴⁰ these drugs were deemed not very promising, although most studies were confounded by high rates of comorbid mood disorders.

NICOTINE

Cigarette smoking is an enormous national health problem, and as healthcare professionals, we are not doing enough to help people quit smoking. Although research has determined that brief interventions by medical professionals help patients quit smoking,⁴⁵ these interventions do not occur frequently enough in primary care settings.⁴⁶ A telephone survey of adult cigarette smokers was conducted to determine the types of smoking cessation counseling interventions they received during their physician office visits in the past year. Approximately one-half of the current smokers surveyed reported that their doctors talked with them about their smoking, less than half were advised to stop smoking, 15% were offered smoking cessation assistance in the form of education and support groups, and only 9% were prescribed drug therapies to assist smoking cessation efforts.⁴⁶ A second observational study was conducted to determine the effects of community-based academic detailing interventions on the quit rates of a sample of smokers ($n = 4295$). Detailed interventions were delivered to physicians that encouraged smoking cessation efforts with patients to comply with the National Cancer Institute and the Agency for Healthcare Quality and Research smoking intervention standards.⁴⁷ A small, significant effect was observed in a subgroup of patients residing in the intervention area.⁴⁷ Other healthcare professionals did an even poorer job, with only 22% of dentists, 24% of nurses, and 4% of pharmacists helping their patients to quit smoking.⁴⁶

EPIDEMIOLOGY OF TOBACCO USE

In 2005, an estimated 71.5 million Americans aged 12 or older were current (past month) users of a tobacco product, a prevalence rate of 30.4% for the population aged 12 or older.³ In addition, 60.5 million persons (24.9% of the population) were current cigarette smokers; 13.6 million (5.6%) smoked cigars; 7.7 million (3.2%) used smokeless tobacco; and 2.2 million (0.9%) smoked tobacco in pipes.

The rate of lifetime cigarette use among youths aged 12 to 17 has remained between 29% and 39% for every year since 1965. Although the rate increased during the 1990s from 30.3% in 1990 to 37.8% in 1999, there was a significant decline from 2001 to 2002 (from 37.3% to 33.3%). One of the national health objectives for 2010 is to reduce the prevalence of cigarette smoking among adults to less than 12%.⁴⁸

ECONOMIC IMPACT OF SMOKING

The direct medical costs associated with smoking total more than \$75 billion per year, and the costs associated with lost productivity are estimated to be \$80 billion. Approximately 14% of all Medicaid expenditures are for smoking-related illnesses. This estimate does not include the costs of smoking-related neonatal disorders.

HEALTH RISKS OF SMOKING

Each year more than 440,000 deaths, or 20% of the total deaths in the United States, are caused by smoking.⁴⁹ Cigarette smoking substantially increases the risk of (1) cardiovascular diseases such as stroke, sudden death, and heart attack; (2) nonmalignant respiratory diseases including emphysema, asthma, chronic bronchitis, and chronic obstructive pulmonary disease; (3) lung cancer; and (4) other cancers.

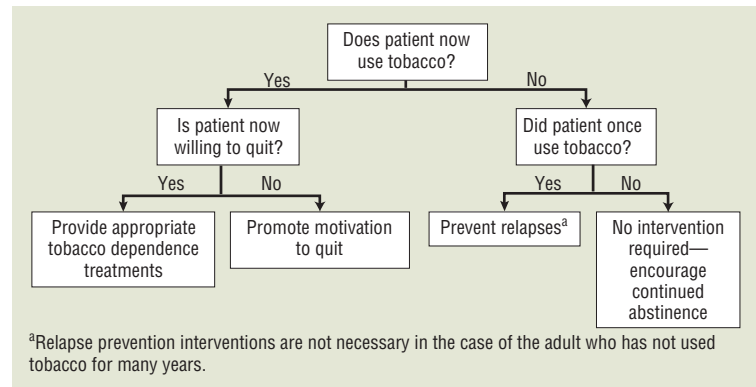

FIGURE 69-2. Algorithm for treating tobacco use.

The guideline identified a number of key findings that clinicians should use:

1. **8** Tobacco dependence is a chronic condition that often requires repeated intervention. However, effective treatments exist that can produce long-term or even permanent abstinence.
2. Because effective tobacco dependence treatments are available, every patient who uses tobacco should be offered at least one of these treatments:
 - Patients willing to try to quit tobacco use should be provided with treatments that are identified as effective in the guideline.
 - Patients unwilling to try to quit tobacco use should be provided with a brief intervention that is designed to increase their motivation to quit.
3. It is essential that clinicians and healthcare delivery systems (including administrators, insurers, and purchasers) institutionalize the consistent identification, documentation, and treatment of every tobacco user who is seen in a healthcare setting.
4. Brief tobacco dependence treatment is effective, and every patient who uses tobacco should be offered at least brief treatment.
5. There is a strong dose-response relationship between the intensity of tobacco dependence counseling and its effectiveness. Treatments involving person-to-person contact (via individual, group, or proactive telephone counseling) are consistently effective, and their effectiveness increases with treatment intensity (e.g., minutes of contact).
6. Three types of counseling and behavioral therapies were found to be especially effective and should be used with all patients who are attempting tobacco cessation:
 - Provision of practical counseling (problem-solving/skills training).
 - Provision of social support as part of treatment (intratreatment social support).
 - Help in securing social support outside treatment (extratreatment social support).
7. Numerous effective pharmacotherapies for smoking cessation now exist (Table 69–5). Except in the presence of contraindications, these should be used with all patients who are attempting to quit smoking. Five first-line pharmacotherapies were identified that reliably increase long-term smoking abstinence rates: bupropion sustained-release (SR), nicotine gum, nicotine inhaler, nicotine nasal spray, and nicotine patch.

Two second-line pharmacotherapies were identified as efficacious and can be considered by clinicians if first-line pharmacotherapies are not effective: clonidine and nortriptyline. A new drug, varenicline, was approved by the FDA in May 2006

as a smoking cessation aid. It has not yet been incorporated into Clinical Practice Guidelines.⁵⁴

8. Tobacco dependence treatments are both clinically and cost-effective relative to other medical and disease-prevention interventions. As such, insurers and purchasers should ensure all insurance plans include as a reimbursed benefit the counseling and pharmacotherapeutic treatments that are identified as effective in this guideline, as well as clinician reimbursement for providing tobacco dependence treatment just as they are reimbursed for treating other chronic conditions.

■ OTHER FACTORS IMPORTANT TO THE SUCCESS OF A SMOKING-CESSATION STRATEGY

The AHRQ expert panel emphasized the importance of the type and intensity of the contact with the counselor to the success of the intervention. When interventions last for more than 10 minutes, the increase in cessation rates is much better than when interventions do not involve contact with a professional. Group and individual counseling is more effective than no intervention in increasing abstinence rates, but self-help materials (e.g., handouts, pamphlets, and brochures) are not. Interventions are more successful when they include social support and training in general problem-solving skills, stress management, and relapse prevention.⁴⁵ The number of treatment sessions offered is also important. Providing at least four to seven sessions significantly increased cessation rates, independent of the treatment's intensity.⁵³

Comprehensive behavioral interventions are more effective in helping people quit smoking and remain abstinent, but less intensive treatments are beneficial as well. Even minimal contacts lasting less than 3 minutes and simple advice to quit are more successful in increasing cessation rates than intervention involving no contact.⁵³

9. Counseling efficacy is further augmented by the addition of nicotine-replacement products. The cessation rates of nicotine patch users are approximately double the cessation rates of smokers who receive placebos, according to a meta-analysis.⁵⁵ Although absolute quit rates have varied greatly, abstinence rates for the nicotine patch are estimated at 27% (ranging from 14% to 69%) at the end of treatment and 22% (ranging from 13% to 34%) at 6 months posttreatment.

Although comprehensive programs are most effective, few smokers (10% to 15%) seek formal assistance in quitting.⁵⁵ A healthcare professional who merely advises his or her patient to quit smoking is providing at least minimal assistance in the efforts.

■ PHARMACOLOGIC THERAPY FOR SMOKING CESSATION

All patients attempting to quit should be encouraged to use effective pharmacotherapies for smoking cessation except in the presence of

special circumstances. Long-term smoking-cessation pharmacotherapy should be considered as a strategy to reduce the likelihood of relapse. As with other chronic diseases, the most effective treatment of tobacco dependence encompasses multiple modalities. Pharmacotherapy is a vital element of a multicomponent smoking cessation program that should also always include nonpharmacologic components. The clinician should encourage all patients initiating a quit attempt to use one or a combination of efficacious pharmacotherapies, although pharmacotherapy use requires special consideration with some patient groups (e.g., those with medical contraindications, those smoking fewer than 10 cigarettes a day, pregnant or breast-feeding women, and adolescent smokers). The role of pharmacotherapy is summarized in Table 69–5.

■ NICOTINE-REPLACEMENT THERAPY

A Systematic Review of Nicotine Replacement Therapy

In 2004 a systematic review⁵⁵ of published studies was performed to determine the effectiveness of the different forms of nicotine replacement therapy (NRT; e.g., chewing gum, transdermal patches, nasal spray, inhalers, and tablets) in achieving abstinence from cigarettes or a sustained reduction in the amount smoked. The review was also designed to determine whether the effect is influenced by the clinical setting in which the smoker is recruited and treated, the dosage and form of the NRT used, or the intensity of additional advice and support offered to the smoker; to determine whether combinations of NRT are more effective than one type alone; and to determine its effectiveness compared to other pharmacotherapies.

The review was limited to randomized trials in which NRT was compared to placebo or no treatment, or where different doses of NRT were compared. The main outcome measure was abstinence from smoking after at least 6 months of followup. For each trial, researchers used the most rigorous definition of abstinence, and confirmation with biochemical markers where available. The review includes 123 studies, 103 of which included a placebo or non-

nicotine control arm. All of the commercially available forms of NRT were effective to aid smoking cessation. Use of nicotine replacement therapy doubled the odds of quitting. Higher doses of nicotine patch can produce additional small increases in quit rates compared to lower doses. Only one study directly compared NRT to another pharmacotherapy, in which bupropion was significantly more effective than nicotine patch or placebo.⁵⁵

The AHRQ guidelines recommend use of NRT in the forms of transdermal nicotine patches, nicotine gum, nicotine sprays, and nicotine inhalers.⁵³ The use of NRT is relatively safe, but it is not recommended for all smokers. Although cardiovascular disease is not an independent risk factor for acute myocardial events in patients taking NRT, NRT should be used with caution among particular cardiovascular patient groups: those in the immediate (within 2 weeks) post-myocardial infarction period, those with serious arrhythmias, and those with serious or worsening angina pectoris.⁵³

Nicotine Gum

Clinicians should offer 4-mg rather than 2-mg nicotine gum to highly dependent smokers.^{55,56} The 2-mg gum is recommended for patients smoking less than 25 cigarettes per day, whereas the 4-mg gum is recommended for patients smoking 25 or more cigarettes per day. The 2-mg nicotine gum improves long-term abstinence rates by approximately 30% to 80% as compared with placebo. Generally, the gum should be used for up to 12 weeks, no more than 24 pieces chewed per day. The dosage and duration of therapy should be tailored to meet the needs of each patient.

Nicotine gum currently is available exclusively as an over-the-counter medication and is packaged with important instructions on correct use, including chewing instructions. There is currently little evidence to suggest that combined use of the patch and gum increases abstinence beyond 24 weeks.

Gum should be chewed slowly until a peppery or minty taste emerges and then “parked” between cheek and gums to facilitate nicotine absorption through the oral mucosa. It should be chewed slowly and intermittently and parked for about 30 minutes or until the

TABLE 69-5 Pharmacologic Agents Used for Smoking Cessation

Drug	Place in Therapy	Dosage Range	Duration	Comments/Monitoring Parameters	LOE ^d
Bupropion SR ^{a,b}	First-line	Titrate up to 150 mg orally twice daily.	3 to 6 months	Patients receiving both bupropion and a nicotine patch should be monitored for hypertension.	A1
Clonidine ^{b,c}	Second-line	Titrate to response. 0.2 to 0.75 mg per day	6 to 12 months	Monitor baseline electrolyte and lipid profiles, renal function, uric acid, complete blood count, and blood pressure.	B2
Nicotine polacrilex (gum) ^a	First-line	Initial dose depends on smoking history: 2 to 4 mg every 1 to 8 hours	12 weeks (taper down over time)	Heart rate and blood pressure should be monitored periodically during nicotine replacement therapy.	A1
Nicotine inhaler ^a	First-line	24 to 64 mg per day (total daily dose)	3 to 6 months (taper down over time)	Heart rate and blood pressure should be monitored periodically during nicotine replacement therapy.	A1
Nicotine nasal spray ^a	First-line	8 to 40 mg per day (total daily dose)	14 weeks (taper down over time)	Heart rate and blood pressure should be monitored periodically during nicotine replacement therapy.	A1
Nicotine patch ^a	First-line	Initial dose depends on smoking history: 7 to 21 mg topically once daily	6 weeks (taper down over time)	Heart rate and blood pressure should be monitored periodically during nicotine replacement therapy.	A1
Nortriptyline ^{b,c}	Second-line	Titrate up to 75 to 100 mg orally daily	6 to 12 months	Dry mouth, blurred vision, and constipation are dose-dependent adverse effects.	B2
Varenicline ^b	FDA-approved in 2006	Titrate up to 1 mg orally twice daily	3 to 6 months	Monitor renal function, especially in elderly patients. Nausea, headache, insomnia are dose-dependent adverse effects.	A1

LOE, level of evidence.

^aNicotine replacement therapies can be combined with each other and/or bupropion to increase long-term abstinence rates.

^bDo not abruptly discontinue. Taper up initially, and taper off once therapy is complete.

^cClonidine and nortriptyline are not FDA-approved for smoking cessation.

^dStrength of recommendations, evidence to support recommendation: A, good; B, moderate; C, poor.

Quality of evidence: 1, evidence from more than 1 properly randomized, controlled trial; 2, evidence from more than 1 well-designed clinical trial with randomization, from cohort or case-controlled analytic studies or multiple time series; or dramatic results from uncontrolled experiments; 3, evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert communities.

Data from Goldstein et al.^{46,47} and U.S. Department of Health and Human Services.⁴⁸

taste dissipates. Acidic beverages (e.g., coffee, juices, or soft drinks) interfere with the buccal absorption of nicotine, so eating and drinking anything except water should be avoided for 15 minutes before and during chewing. Patients often do not use enough gum to get the maximum benefit: they chew too few pieces per day, and they might not use the gum for a sufficient number of weeks. Instructions to chew the gum on a fixed schedule (at least one piece every 1 to 2 hours) for at least 1 to 3 months can be more beneficial than ad libitum use.

Nicotine Patch

9 The nicotine patch approximately doubles long-term abstinence rates over those produced by placebo interventions. The nicotine patch is available both as an over-the-counter medication and as a prescription medication. Treatment of 8 weeks or less has been shown to be as efficacious as longer treatment periods. The 16- and 24-hour patches are of comparable efficacy.⁵³ Clinicians should consider individualizing treatment based on specific patient characteristics, such as previous experience with the patch, amount smoked, and degree of addiction, among others. Finally, clinicians should consider starting treatment on a lower patch dose in patients smoking 10 or fewer cigarettes per day.⁵³

At the start of each day, the patient should place a new patch on a relatively hairless location, typically between the neck and waist. There are no restrictions on activity while using the patch. Patches should be applied as soon as the patient wakes on the quit day. Patients who experience sleep disruption should remove the 24-hour patch prior to bedtime or use the 16-hour patch.

Nicotine Nasal Spray

Nicotine nasal spray more than doubles long-term abstinence rates when compared with a placebo spray. Nicotine nasal spray is available exclusively as a prescription medication. A dose of nicotine nasal spray consists of one 0.5-mg delivery to each nostril (1 mg total). Initial dosing should be one to two doses per hour, increasing as needed for symptom relief. The minimum recommended treatment is 8 doses per day, with a maximum limit of 40 doses per day (5 doses per hour). Each bottle contains approximately 100 doses. Recommended duration of therapy is 3 to 6 months. Patients should not sniff, swallow, or inhale through the nose while administering doses because this increases irritating effects. The spray is best delivered with the head tilted slightly back.⁵³

Instructing Patients in the Use of NRT

Compliance with NRT improves when the patient is presented a clear rationale for its use and a realistic expectation about the response. It should be explained to the patient that nicotine is responsible for addiction and that discontinuation of the nicotine causes craving for cigarettes, tension, irritability, sadness, problems with sleep, and difficulty concentrating. These are partly because of nicotine withdrawal. The patient should be told that using the patch results in less desire to smoke and provides an opportunity for a new nonsmoker to practice all the new nonsmoking skills without being burdened by craving. The patient should understand that with smoking, there are naturally peaks and valleys in the amount of nicotine in the bloodstream. With the patch there is a steady gradual rise in the blood nicotine concentration that levels off and remains constant for much of the day and then gradually decreases while the person is asleep. Maintaining an adequate blood level of nicotine lessens withdrawal symptoms.

A similar rationale can be used if patients are using gum. It should be emphasized that NRT is not a “magic bullet” and that the use of coping skills is essential for abstinence. The patch or the gum only buys time by reducing withdrawal symptoms and giving individuals a chance to figure out alternatives that they can use in place of smoking.⁵⁶

CLINICAL CONTROVERSY

Some clinicians are hesitant to prescribe NRT for smoking cessation during pregnancy because the safety and efficacy of NRT has not been established in controlled clinical trials in this population. This logic is somewhat counterintuitive in that continued smoking exposes the unborn child to much higher levels of nicotine and the harmful consequences of cigarette smoking during pregnancy are well documented.

Side Effects

Nicotine replacement products have relatively few side effects. Nausea and light-headedness are possible signs of nicotine overdose that warrant a reduction of the nicotine dose.

The most frequent side effect with the nicotine patch is skin irritation related to the adhesive or the medium containing nicotine and not to the nicotine itself. Approximately 50% of patients report skin irritation during the course of treatment with the patch. The patch site can be rotated to diminish this problem. The use of over-the-counter hydrocortisone cream (1%) or triamcinolone cream (0.5%) is recommended as a local treatment for patch-related skin irritations. Switching to a different brand of patch also can alleviate the problem because different products use different adhesives or media. The gum can be used instead of the patch when the skin irritation is severe. Less than 5% of patients were forced to discontinue therapy because of skin reactions.

Approximately 23% of patients using the patch report sleep disturbances, but the insomnia is hard to differentiate from the sleeplessness that often accompanies withdrawal itself, especially during the first few weeks of quitting.

More research regarding the safety and efficacy of pharmacotherapy during pregnancy is needed to define the risk-to-benefit profile of smoking cessation medications in this population.⁵⁷ Clearly, exposure of the fetus to nicotine delivered by smoking is known to be detrimental to the fetus. Because total nicotine levels are lower with NRT than smoking, if the alternative is active smoking, NRT is almost certainly safer if cessation can be achieved. Nicotine does cross the placenta, whether delivered by cigarette smoking or through nicotine replacement. Nicotine transdermal systems and inhalers are classified as FDA pregnancy risk category D, and nicotine gum is classified as FDA pregnancy category C, but there are conflicting data regarding pregnancy safety ratings of nicotine replacement products, and the pregnancy categories cannot be used in isolation from other information sources. Nicotine replacement is not contraindicated and could be appropriately used in well-selected pregnant patients.

A study⁵⁸ of women using various doses of transdermal nicotine while breast-feeding confirms that nicotine is transferred via milk to the infant. The absolute infant dose of nicotine and its metabolite cotinine decreased by about 70% while the mothers were using the 7-mg patch compared to when they were smoking or using the 21-mg patch. The use of the nicotine patch had no significant influence on milk intake by the breast-fed infant. The authors conclude that undertaking maternal smoking cessation with the nicotine patch is therefore a safer option than continued smoking. Ultimately, the choice of whether to use pharmacotherapy for smoking cessation should be made jointly by the pregnant or breast-feeding smoker and her healthcare provider.

Duration

Those who commit to quitting smoking using the nicotine patch should be told to expect a minimum of 6 to 8 weeks of treatment. Using the therapy beyond 8 weeks is not associated with better success rates.⁵³ However, some patients will experience severe withdrawal even beyond 8 weeks, and these people may need to use the patch longer.

The duration of therapy with the gum should be at least 1 to 3 months on a fixed schedule rather than when one has the urge to smoke.⁵⁵ Studies have found, however, that 15% to 20% of abstainers continue to use the gum for longer than 12 months. Patients should be encouraged to stick with the patch and/or gum for the minimally acceptable duration of treatment.

Economic and Pharmacoeconomic Considerations

Most health insurers provide coverage for the chronic illnesses caused by smoking (e.g., chronic obstructive pulmonary disease, cancer, and myocardial infarction), yet few provide coverage for treating the nicotine addiction that caused those ailments.⁵³ For each of the approximately 22 billion packs of cigarettes sold in the United States in 1999, \$3.45 was spent on medical care attributable to smoking, and \$3.73 in productivity losses were incurred, for a total cost of \$7.18 per pack.⁵⁹ Even after adding the cost of the nicotine patch to physician counseling, costs from the standpoint of a third-party payer range from \$1,441 to \$3,445 per quality-adjusted life year saved for NRT (based on 15 minutes of physician counseling and 1 to 2 months of NRT).⁵⁹ Treating tobacco dependence is particularly important economically, in that it can prevent a variety of costly chronic diseases, including heart disease, cancer, and pulmonary disease. A recent meta-analysis conducted by the Cochrane Collaboration determined that a 36% reduction in risk of death from coronary heart disease was obtained by quitting smoking. This decrease in risk is comparable, if not greater, than that obtained from lowering low-density lipoprotein (LDL) cholesterol or blood pressure lowering.⁶⁰ The failure of a health plan to cover tobacco dependence treatment could reduce the number of people seeking and receiving these services.

■ BUPROPION

10 Bupropion inhibits neuronal reuptake and potentiates the effects of norepinephrine and dopamine. Although its precise mechanism in smoking cessation is not well understood, dopamine has been associated with the rewarding effects of addictive substances. Withdrawal symptoms can be decreased by virtue of bupropion inhibition of norepinephrine uptake. The AHRQ panel concluded that sustained-release (SR) bupropion is an efficacious smoking cessation treatment that patients should be encouraged to use.⁵³ Two large multicenter studies met selection criteria and were included in the meta-analysis comparing bupropion SR with placebo. The use of bupropion SR as a part of a comprehensive smoking cessation program approximately doubles long-term abstinence rates when compared with placebo.

One study compared the effects of 100, 150, or 300 mg/day of bupropion SR or placebo for 7 weeks in 615 patients who visited the clinic each week for evaluation and counseling.⁶¹ When the study was concluded, smoking cessation rates were 19% with placebo and 28.8%, 38.6%, and 44.2% with the respective doses of the drug. The differences between the 150- and 300-mg doses and placebo were statistically significant. After 1 year, the respective rates were 12.4%, 19.6%, 22.9%, and 23.1%, indicating a fairly high rate of relapse in all groups.

Bupropion at a dose of 150 mg twice daily of sustained-release tablets was compared with the 21-mg nicotine patch separately and as combined therapy and with placebo in nearly 900 patients studied for 9 weeks. At the 10-week mark, smoking cessation had been accomplished in 20% of the placebo group, 32% of the group using the patch alone, 46% of the group using bupropion alone, and 51% of the group using combined therapy. All three active treatments were significantly better than placebo.⁶² Unlike its use as an antidepressant, no seizures occurred with bupropion in smoking cessation trials. Insomnia and dry mouth were the most frequent adverse effects. Other side effects noted in the trials were tremor, rash, and a

few anaphylactoid reactions characterized by pruritus, urticaria, angioedema, and dyspnea.⁶²

10 For smoking cessation, the manufacturer recommends a dosage of 150 mg once daily for 3 days and then twice daily for 7 to 12 weeks or longer, with or without NRT. Patients are instructed to stop smoking during the second week of treatment and are encouraged to use counseling and support services along with the medication. For maintenance therapy, consider bupropion SR 150 mg twice daily for up to 6 months.⁵³ In addition, bupropion SR appears to be effective for smokeless tobacco cessation.⁶³ Cost per quality-adjusted life-year saved after smoking cessation ranged from \$920 to \$2,150 for bupropion alone, and \$1,282 to \$2,836 for NRT plus bupropion.⁵⁹

■ SECOND-LINE MEDICATIONS

Second-line medications are pharmacotherapies for which there is evidence of efficacy for treating tobacco dependence but have a more limited role than first-line medications because (1) the FDA has not approved them for a tobacco-dependence treatment indication, and (2) there are more concerns about potential side effects than exist with first-line medications.⁵³ Second-line treatments should be considered for use on a case-by-case basis after first-line treatments have been used or considered.

Clonidine

Clonidine, a prescription drug, is an efficacious smoking cessation treatment. It can be used under a clinician's supervision as a second-line agent to treat tobacco dependence. A recent meta-analysis of six trials showed that clonidine increased smoking cessation rates by 11% (odds ratio [OR] 1.89; confidence interval [CI] 1.30 to 2.14). There was a high incidence of dose-dependent side effects, particularly dry mouth and sedation.⁶⁴ It should be noted that abrupt discontinuation of clonidine can result in symptoms such as nervousness, agitation, headache, and tremor, accompanied or followed by a rapid rise in blood pressure and elevated catecholamine levels.

Because clonidine is used primarily as an antihypertensive medication and has not been approved by the FDA as a smoking cessation medication, clinicians need to be aware of the specific warnings regarding this medication as well as its side-effect profile. Additionally, a specific dosing regimen for the use of clonidine in smoking cessation has not been established. Because of the warnings associated with clonidine discontinuation, the variability in dosages used to test this medication, and a lack of FDA approval, the guideline panel chose to recommend clonidine as a second-line agent. Doses used in various clinical cessation trials have varied significantly, from 0.15 to 0.75 mg/day orally to 0.1 to 0.2 mg/day transdermally, without a clear dose-response relation to cessation. Initial dosing typically is 0.1 mg orally twice daily or 0.1 mg/day transdermally, increasing by 0.1 mg/day each week if needed. The duration also varied across the clinical trials, ranging from 3 weeks to 12 months. Most commonly reported side effects include dry mouth, drowsiness, dizziness, sedation, and constipation. As an antihypertensive medication, clonidine can be expected to lower blood pressure in most patients. Therefore, clinicians should monitor blood pressure when using this medication.⁵³

Nortriptyline

Nortriptyline is also considered to be efficacious as a second-line agent to treat tobacco dependence. Based on limited data, the use of nortriptyline appears to increase abstinence rates compared with placebo.

Nortriptyline should be considered for smoking cessation under a clinician's direction in patients unable to use first-line medications because of contraindications or in patients who failed using first-line medications. Therapy is initiated 10 to 28 days before the quit date to allow nortriptyline to reach steady state at the target dose. Smoking

cessation trials have initiated treatment at a dose of 25 mg/day, increasing gradually to a target dose of 75 to 100 mg/day. Duration of treatment used in smoking cessation trials has been approximately 12 weeks. Most commonly reported side effects include sedation, dry mouth, blurred vision, urinary retention, light-headedness, and shaky hands.

Varenicline (Chantix)

I A new and novel aid to smoking cessation was approved by the FDA on May 10, 2006. The drug, varenicline, acts at sites in the brain affected by nicotine and may help those who wish to give up smoking in two ways: by providing some nicotine effects to ease the withdrawal symptoms and by blocking the effects of nicotine from cigarettes if they resume smoking. Specifically, varenicline is a partial agonist that binds selectively to $\alpha_4\beta_2$ -nicotinic acetylcholine receptors with a greater affinity than nicotine. When bound to the receptor, the drug blocks nicotine from binding and also evokes a response but to a lesser degree than nicotine. The stimulation of the receptor that occurs results in release of dopamine and thus provides a type of “reward” that can decrease craving and withdrawal symptoms.⁶⁵

There have been five randomized double blind placebo-controlled studies of varenicline published to date. Three of these also included a bupropion SR arm.^{66–68} In these three studies after 12 weeks of therapy, statistically higher rates of continuous smoking cessation were consistently observed for varenicline versus placebo as well as bupropion SR versus placebo. At the 12 month followup, the rates of continuous abstinence in the varenicline group remained statistically significantly different versus placebo. However, rates of continuous abstinence in the bupropion group were no longer statistically significantly different from placebo.^{66–68} For each patient who achieved continuous abstinence at the 1-year followup, 14 patients needed to be treated with varenicline for 12 weeks.

Because this drug is so new to the market, its overall place in therapy is not known at this time. It has not been compared to the nicotine products but might be a reasonable choice for those who cannot tolerate NRT or for those who have failed therapy in the past.⁶⁸

Future Treatments

Work has begun to develop a vaccine that would be used in treating nicotine addiction. One such product is called NicVAX (nicotine conjugate vaccine) and is designed to cause the immune system to produce antibodies that bind to nicotine and prevent it from entering the brain. As a result, the positive stimulus in the brain that is normally caused by nicotine is no longer present, thereby taking away the physical motivation for smoking, consequently helping people to quit.⁶⁹

CAFFEINE

Caffeine is the most widely consumed behaviorally active substance in the world.⁶³ *Caffeinism* is the term coined to describe the clinical syndrome produced by acute or chronic overuse of caffeine.⁷⁰ The syndrome usually is characterized by CNS and peripheral manifestations, most notably anxiety, psychomotor alterations, sleep disturbances, mood changes, and psychophysiologic complaints.

CLINICAL PRESENTATION OF EXCESSIVE CAFFEINE INTAKE

General

- The patient may not be in acute distress.

Symptoms

- The patient may complain of nausea, vomiting, diarrhea, and psychomotor agitation, and can appear restless, nervous, and excited.

Signs

- The patient can present with facial flushing, diuresis, and muscle twitching.
- Tachycardia or cardiac arrhythmias can also occur

Laboratory Tests

- Caffeine serum concentrations are rarely used clinically.

As many as one in five adults consume doses of caffeine generally considered large enough to cause clinical symptoms.^{71,72} Controlled double-blind studies demonstrate that caffeine has reinforcement properties in most people with a history of heavy prior use⁷³ and that this reinforcement is a function of dose and prior exposure.

Pharmacologically, the risk of developing some meaningful clinical manifestations becomes high when intake exceeds 500 mg/day. This places 20% to 30% of North Americans at risk.⁷¹ Recognizing that there are individual variations and accepting a conservative approach, these data suggest that perhaps 10% to 20% of the North American adult population probably has meaningful clinical symptoms consistent with a diagnosis of caffeinism, a prevalence rate exceeding that of most other substances of abuse.

Caffeine has been proposed as a “model of drug abuse” despite the facts that its sale is largely unrestricted and that heavy consumption of caffeine-containing beverages is not considered to be drug abuse. An exhaustive review of caffeine dependence focused on the potential for abuse of caffeine and the nature of tolerance and withdrawal.⁷² A second comprehensive review of human and animal data on coffee and caffeine consumption and caffeine dependence, withdrawal, and reinforcement also has been published.⁷¹ The information below represents a broad overview of these topics, and the reader interested in more detail is urged to consult these two reviews.^{71,72}

EPIDEMIOLOGY OF CAFFEINE USE AND ABUSE

Caffeine is used by 80% of the population of the United States,⁷⁴ and its use can be problematic for some people. In 1999 there were 108,000,000 coffee consumers in the United States spending approximately \$9.2 billion in the retail sector and \$8.7 billion in the food service sector every year.⁷⁵ The National Coffee Association found in 2001 that 52% of the adult population of the United States drinks coffee daily.⁷⁶

Average caffeine consumption in humans can range in different cultures and nations from 80 to 400 mg per person per day. In the United States caffeine consumption exceeds several billion kilograms annually. Per capita intake for the entire world’s population approximates 70 mg/day. In the United States this figure is considerably larger, at 210 to 238 mg. The majority of caffeine users progress to a pattern of frequent or daily consumption. Approximately one-fourth eventually begin consuming large quantities, exceeding 500 mg/day, and conservatively, 10% of all adults then progress to develop the syndrome of caffeinism. Mean daily consumption of caffeine in American children is surprisingly high. The Framingham Children’s Study⁷⁷ investigated the amounts of caffeine consumed each day by children between the ages of 6 and 10 years (mean 8.4 years for boys and 8.1 years for girls). Mean intake of caffeine was 16 ± 9.6 mg/day. Caffeinated soft drinks and chocolate furnished almost all of the caffeine.

Caffeine is an added ingredient in approximately 70% of soft drinks consumed in the United States.⁷⁸ Soft drink manufacturers’

justification to regulatory agencies and the public for adding caffeine to soft drinks is that caffeine is a flavoring agent. In a recent study, only 8% of a group of regular cola soft drink consumers could detect the taste effect of the caffeine concentration found in most cola soft drinks. Thus soft drinks serve as a major source of caffeine without any apparent purpose beyond its stimulant effects.⁷⁴

DIFFERENTIAL DIAGNOSIS

Caffeine intoxication is the only official diagnosis associated with caffeinism in the *DSM-IV-TR*. Caffeine-induced anxiety can manifest as restlessness, nervousness, excitement, insomnia, diuresis, flushing, gastrointestinal disturbance, muscle twitching, irritability, and jitteriness. If caffeine-induced insomnia requires specific treatment, caffeine-induced sleep disorder (*DSM-IV-TR*) is an appropriate diagnosis.^{4,70}

Because excessive caffeine consumption is so widespread, a thorough history of caffeine use should be included in the routine assessment of all new patients in primary care medical settings. In this manner, the practitioner can use the information gathered to uncover high levels of caffeine intake and then use the information to pinpoint the cause of clinical signs and symptoms typical of caffeinism. Clinical manifestations of caffeinism almost always will lessen in intensity or disappear completely within 1 to 2 weeks after removing the drug.⁴

PHARMACOLOGY OF CAFFEINE

Caffeine is rapidly and completely absorbed from the gastrointestinal tract, reaching a peak blood level within 30 to 45 minutes of oral ingestion. It easily crosses the blood-brain barrier, and levels achieved in the brain are proportional to the dose administered.

The half-life of caffeine in humans is approximately 3.5 to 5 hours. It is metabolized extensively by a complex metabolic pathway occurring primarily in the liver. Serious problems rarely result from overdoses of caffeine. In fact, the amount of caffeine needed to cause death in an average adult male is 5 to 10 g, the equivalent of 50 to 100 cups of regular brewed coffee. Thus the risk of overdose from dietary sources of caffeine is virtually nonexistent.

11 Caffeine increases the heart rate and force of contraction. It also has a strong diuretic effect. The key factor promoting caffeine use and dosage increases can be the drug's reinforcing effect on pleasure and reward centers of the brain. Caffeine's pharmacologic actions appear comparable (although less potent) in some aspects with those of other stimulants, such as amphetamines and cocaine. After years of uncertainty, it is apparent from both preclinical research and human studies that regular caffeine use does induce tolerance.

CAFFEINE DEPENDENCE

Research has shown that abstinence from caffeine induces a distinct withdrawal syndrome. Evidence for the existence of a caffeine dependence syndrome was presented by Strain and associates.⁷⁸ In a structured psychiatric interview, subjects self-identified as having problems with caffeine use were evaluated for features of a *DSM-IV-TR* diagnosis of drug dependence. Those judged as caffeine dependent manifested at least three of four criteria (i.e., tolerance, withdrawal, persistent desire, or an unsuccessful attempt to reduce consumption and persistent use despite adverse psychologic or physical consequences). Of 99 people screened, 27 were evaluated by means of a structured psychiatric interview modified for the diagnosis of caffeine dependence; 16 of those subjects (59%) met the criteria. In a second phase of the study, 11 of the 16 caffeine-dependent individuals participated in a 2-day double-blind cross-

over study of caffeine deprivation. Nine showed evidence of caffeine withdrawal during the placebo phase, a finding that validated one of the criteria for the diagnosis of dependence.

CAFFEINE WITHDRAWAL

12 The frequency of the caffeine withdrawal syndrome is not well known, but it may be common. Withdrawal can occur when individuals who previously have been consuming caffeine on a regular basis suddenly discontinue its intake.⁴ When caffeine is reintroduced, relief of withdrawal symptoms tends to occur within 30 to 60 minutes. At present, this appears to be the most effective "treatment" for the caffeine-withdrawal syndrome.

CLINICAL PRESENTATION OF CAFFEINE WITHDRAWAL

General

- The patient may be uncomfortable but is not in acute distress.

Symptoms

- The patient can experience nausea, headache, drowsiness, and fatigue. The caffeine withdrawal headache is somewhat unique, starting with a sense of fullness in the head and progressing to throbbing and diffuse pain that is made worse by movement. The maximum intensity of the pain occurs 3 to 6 hours after beginning.
- The patient can also experience difficulty concentrating and impaired psychomotor performance.

EFFECT ON SLEEP

Caffeine interferes with sleep in most nontolerant individuals.^{4,70} Once tolerance has developed, people are much less likely to self-report sleep abnormalities, or they may sense that the insomnia has disappeared altogether. To illustrate, 53% of those consuming less than 250 mg/day agreed that caffeine before bedtime would prevent sleep, compared with 43% of those consuming 250 to 749 mg/day, and only 22% of those taking 750 mg/day or more. Even though the higher-level consumers denied that caffeine interferes with their sleep, studies done in the sleep laboratory confirm that caffeine consumers do have greater sleep latency, more frequent awakenings, and altered sleep architecture, and that these effects are dose related.

TREATMENT

Caffeinism

Caffeinism is treated by reducing or discontinuing the drug. It can be necessary to wean the patient off the drug because going "cold turkey" can produce such serious symptoms that the drug must be restarted. Decaffeinated beverages can be substituted slowly for the caffeinated type. However, relapses are less likely to occur when the drug is discontinued all at once, probably because of the considerable self-discipline required to continue weaning the drug when one knows that an increase in dose will cause the symptoms to abate.

It can be possible for some individuals simply to reduce their dosage of caffeine rather than discontinue it altogether. Others can be particularly sensitive to the drug, and they may not be able to handle even reduced intake of caffeine. Patients with cardiovascular disease, especially arrhythmias, should refrain totally, as should people with prior stroke or transient ischemic attacks. Peptic ulcer patients and those with bipolar mood disorder and schizophrenia should be encouraged to avoid caffeine altogether.

An exhaustive review of recent research on coffee and its health effects has recently been published. The reader wishing more information is urged to consult this review.⁷⁹

CONCLUSIONS

Use of alcohol, tobacco, and caffeine is so commonly accepted in our society that people take notice only when their use causes serious problems. When these problems do occur, the human and economic costs are enormous. Health professionals must be committed to helping people free themselves of the addictions that can occur with these common drugs.

M. LYNN CRISMON, TAMI R. ARGO, AND PETER F. BUCKLEY

KEY CONCEPTS

- 1 The pathophysiology of schizophrenia can occur in one or more different neurotransmitter systems.
- 2 The clinical presentation of schizophrenia is characterized by positive symptoms, negative symptoms, and impairment in cognitive functioning.
- 3 Comprehensive care for individuals with schizophrenia must occur in the context of a multidisciplinary mental health care environment that offers psychotropic medication management and comprehensive psychosocial services.
- 4 A thorough patient evaluation (e.g., history, mental status examination, physical examination, and laboratory analysis) should occur to establish a diagnosis of schizophrenia and to identify potential co-occurring disorders, including substance abuse and general medical disorders.
- 5 Given that it is challenging to differentiate among antipsychotics based on efficacy, side-effect profiles become important in choosing an antipsychotic for an individual patient.
- 6 Pharmacotherapy algorithms should emphasize monotherapies with antipsychotics of optimal efficacy: side-effect ratios and progress to medications with greater side-effect risks and then to combination regimens only in the most treatment-resistant patients.
- 7 Adequate time on a given medication at a therapeutic dose is the most important variable in predicting medication response.
- 8 Long-term maintenance antipsychotic treatment is necessary for the vast majority of patients with schizophrenia to prevent relapse.
- 9 Thorough patient and family psychoeducation should occur, including education about the illness, symptoms, prognosis, medication, psychosocial treatments, and methods to improve adaptive functioning.
- 10 Pharmacotherapy decisions should be guided by systematic monitoring of patient symptoms, preferably with the use of brief symptom rating scales.

Schizophrenia is one of the most complex and challenging of psychiatric disorders. It represents a heterogeneous syndrome of disorganized and bizarre thoughts, delusions, hallucinations, inappropriate affect, and impaired psychosocial functioning. From the time that Kraepelin first described dementia praecox in 1896 until publication of the *Diagnostic and Statistical Manual of Mental Disorders, 4th edition, Text Revision (DSM-IV-TR)* in 2000, the description of this illness has continuously evolved.¹ Scientific advances that increase our knowledge of central nervous system (CNS) physiology, pathophysiology, and genetics will likely improve our understanding of schizophrenia in the future.

EPIDEMIOLOGY

According to the Epidemiologic Catchment Area Study, the U.S. lifetime prevalence of schizophrenia ranges from 0.6% to 1.9%, with an average of approximately 1%.² With only a few possible exceptions, the worldwide prevalence of schizophrenia is remarkably similar among all cultures. Schizophrenia most commonly has its onset in late adolescence or early adulthood and rarely occurs before adolescence or after the age of 40 years. Although the prevalence of schizophrenia is equal in males and females, the onset of illness tends to be earlier in males. Males most frequently have their first episode during their early twenties, whereas with females it is usually during their late twenties to early thirties.^{1,2}

ETIOLOGY

Although the etiology of schizophrenia is unknown, research has demonstrated various abnormalities in brain structure and function.³ However, these changes are not consistent among all individuals with a diagnosis of schizophrenia, and much has yet to be learned about its pathogenesis. The cause of schizophrenia is likely multifactorial; that is, multiple pathophysiologic abnormalities can play a role in producing the similar but varying clinical phenotypes we refer to as schizophrenia.

A neurodevelopmental model has been evoked as one possible explanation for the etiology of schizophrenia.⁴ This model proposes that schizophrenia has its origins in some as yet unknown in-utero disturbance, possibly occurring during the second trimester of pregnancy. Evidence for this is provided by the abnormal neuronal migration demonstrated in most studies of schizophrenic brains. This “schizophrenic lesion” can result in abnormalities in cell shape, position, symmetry, connectivity, and functionally to the development of abnormal brain circuits.^{3,4} Changes are consistent with a cell migration abnormality during the second trimester of pregnancy, and some studies associate upper respiratory infections during the second trimester of pregnancy with a higher incidence of schizophrenia.⁵ Other studies show a relationship between obstetric complica-

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

tions or neonatal hypoxia and schizophrenia. Some studies also associate low birth-weight (less than 2.5 kg [5.5 lb]) with schizophrenia.² The resulting secondary “synaptic disorganization” associated with such insults is thought not to produce overt clinical manifestations of psychosis until adolescence or early adulthood because this is the corresponding time period of neuronal maturation.

Although studies have shown decreased cortical thickness and increased ventricular size in the brains of many patients with schizophrenia, this occurs in the absence of widespread gliosis.³ Gliosis, or the proliferation of glial cells, is thought to occur as a compensatory change in degenerative diseases of the brain. One hypothesis is that obstetric complications and hypoxia, in combination with a genetic predisposition, could activate a glutamatergic cascade that results in increased neuronal pruning. It is hypothesized that this genetic predisposition may be related to genes controlling N-methyl-D-aspartate (NMDA) receptor activity. As a part of the normal neurodevelopmental process, pruning of dendrites occurs. In the normal individual, approximately 35% of the peak number of dendrites at 2 years of age are pruned by midadolescence. Some studies have shown a higher percentage of pruning in individuals with schizophrenia. Furthermore, synaptic pruning predominantly involves glutamatergic dendrites. Hypoxia or other prenatal insult can result in a decreased number of basal neurons from which to start, and glutamatergic activation can exaggerate the pruning process.⁶

Numerous studies have shown neuropsychologic abnormalities and impairment in reaching normal motor milestones and abnormal movements in young children who later develop schizophrenia.² Abnormalities in brain function occur long before the onset of psychotic symptomatology and provide empiric evidence for schizophrenia being a neurodevelopmental disorder.⁴ However, the progressive clinical deterioration in many patients suggests that this illness can also have a neurodegenerative component. This is consistent with recent brain imaging studies that show deteriorative brain changes in patients with frequent relapses.^{7,8} Schizophrenia may be neither neurodevelopmental or neurodegenerative in origin, but rather an illness exhibiting neurodegenerative propensity based on a vulnerable neurodevelopmental predisposition.^{9,10}

GENETICS

Although a specific abnormality has not been discovered, evidence suggests a genetic basis for schizophrenia. Although the risk of developing schizophrenia is 0.6% to 1.9% in the general population, the risk is approximately 10% if a first-degree relative has the illness and 3% if a second-degree relative has the illness.¹¹ If both parents have schizophrenia, the risk of producing a schizophrenic offspring increases to approximately 40%. Twin studies in dizygotic twins report that the risk of the second twin developing schizophrenia if one twin has the illness is between 12% and 14%. However, in monozygotic twins the risk increases to 48%.¹¹ Numerous adoption studies indicate that the risk for schizophrenia lies with the biologic parents, and change in the environment during the child's developmental stages does not alter this. If schizophrenia occurs in siblings, the onset of illness tends to occur at the same age in each, thus lessening the possibility of an environmental precipitant. A search for a genetic linkage in schizophrenia has been difficult, and any genetic etiologies in schizophrenia are likely heterogeneous, but present with similar phenotypes. Potential loci have been identified on chromosomes 6, 8, 13, and 22.¹¹ Beyond traditional familial and twin association studies, the study of the genetics of schizophrenia has become increasingly molecular in focus.^{3,11} Recent work has shown that polymorphism in the VAL/MET alleles of the catecholamine-O-methyl transferase gene can explain some of the frontal lobe functional deficits in a subset of individuals with schizophrenia.¹¹ Other recent studies have shown abnormalities in several genes

that code for neurodevelopment and for trophic factors.^{11–13} For example, dysbindin is a neurodevelopmental protein gene that is found on chromosome 6. Alleles associated with decreased dysbindin RNA in the dorsolateral prefrontal cortex have been reported in patients with schizophrenia and their families.¹⁴ Another recent geno-wide linkage scan of a large pedigree showed increased signal at chromosome 8p, close to the gene that encodes for neuregulin—another neurodevelopmental gene.¹⁵

PATHOPHYSIOLOGY

Computed axial tomography (CAT) scans and magnetic resonance imaging (MRI) studies show increased ventricular size, particularly in the third and lateral ventricles, in subtypes of schizophrenics. Recent studies also show a small decrease in brain size compared to matched controls. These changes appear to be consistent with brain asymmetry, the ventricular enlargement being most pronounced in the left temporal horn, and the decreased cortical size being most obvious in the left temporal lobe.^{3,7} Not only does premorbid lower hippocampal volume predict onset of symptoms in high-risk individuals, these structural changes can progress throughout the course of the illness. A reduction in medial temporal lobe volume has been reported in high-risk patients after they were scanned, indicating that some brain changes can be associated with the evolution of psychosis. In an extended analysis, high-risk subjects were compared with first-episode chronic schizophrenia and normal control groups according to hippocampal and amygdala volumes at baseline.¹⁶ No difference in MRI volumes between the high-risk subjects and normal controls were observed, irrespective of whether the at-risk patients did or did not progress to overt psychosis. First-episode schizophrenia (but not other psychosis) groups had reduced (left) hippocampal volume. The implication that these changes occur during transition is intriguing and accords well with the notion of psychosis as a biologically toxic event. Changes in hippocampal volume may correspond with impairment in neuropsychologic testing, and these patients may have poorer response to first-generation antipsychotics (FGAs).⁷ Rather than a decrease in the number of neurons in affected brain areas, a decrease in axonal and dendritic communications between cells can result in a loss of connectivity that can be important with respect to neuronal adaptivity and CNS homeostasis.³ These changes are likely consistent with the evidence for abnormal neuronal pruning.⁴

Antipsychotic effects on the brain are complex, perhaps ranging from arrest of apoptotic (*cell-death*) responses, to boosting brain neurotrophins and promoting repair/regrowth of neurons (*neurogenesis*).^{17–18} Human brain-imaging studies reveal that medications can influence brain structure in treated patients with repeated MRI brain scans.¹⁹ The clinical relevance of these findings is not yet established.

NEUROTRANSMITTER CHANGES

Four dopaminergic tracts are of primary interest. Table 70–1 outlines the origin, innervation, and primary functional activity of each tract, as well as the effects of dopamine (DA) antagonists.⁶

Evidence supports the presence of a DA-receptor defect in schizophrenia. Numerous positron emission tomography (PET) studies have shown regional brain abnormalities, including increased glucose metabolism in the caudate nucleus, and decreased blood flow and glucose metabolism in the frontal lobe and left temporal lobe.^{2,3} This can indicate dopaminergic hyperactivity in the head of the caudate nucleus and dopaminergic hypofunction in the frontotemporal regions. PET studies using Dopamine-2 (D₂)-specific ligands suggest increased densities of D₂ receptors in the head of the caudate nucleus with decreased densities in the prefrontal cortex.^{2,3} PET studies

TABLE 70-1 Dopaminergic Tracts and Effects of Dopamine Antagonists

Dopamine Tract	Origin	Innervation	Function	Dopamine Antagonist Effect
Nigrostriatal	Substantia nigra (A9 area)	Caudate nucleus Putamen	Extrapyramidal system, movement	Movement disorders
Mesolimbic	Midbrain ventral tegmentum (A10 area)	Limbic areas (e.g., amygdala, olfactory tubercle, septal nuclei), cingulate gyrus	Arousal, memory, stimulus processing, motivational behavior	Relief of psychosis
Mesocortical	Midbrain ventral tegmentum (A10 area)	Frontal and prefrontal lobe cortex	Cognition, communication, social function, response to stress	Relief of psychosis Akathisia
Tuberoinfundibular	Hypothalamus	Pituitary gland	Regulates prolactin release	Increased prolactin concentrations

assessing Dopamine-1 (D_1) function suggest that subpopulations of schizophrenics may have decreased densities of D_1 receptors in the caudate nucleus and the prefrontal cortex. Hypofrontality can be associated with lack of volition and cognitive dysfunction, core features of schizophrenia. It is unknown whether these changes represent a primary event or secondary processes related to other pathophysiologic abnormalities in schizophrenia. Because of the heterogeneity in the clinical presentation of schizophrenia, it has been suggested that the DA hypothesis can be more applicable to “neuroleptic-responsive psychosis,” with multiple different etiologies possibly being responsible for causing schizophrenia.¹⁷ Attempts have been made to develop relationships between these abnormal findings and behavioral symptoms present in schizophrenic patients. The positive symptoms are possibly more closely associated with DA-receptor hyperactivity in the mesocaudate, whereas negative symptoms and cognitive impairment are most closely related to DA-receptor hypofunction in the prefrontal cortex. Presynaptic D_1 receptors in the prefrontal cortex are thought to be involved in modulating glutamatergic activity, and this can be important with regard to working memory in individuals with schizophrenia.¹⁷

The glutamatergic system is one of the most widespread excitatory neurotransmitter systems in the brain. Alterations in its function, either hypo- or hyperactivity, can result in toxic neuronal reactions.^{2,3,17} Dopaminergic innervation from the ventral striatum decreases the limbic system’s inhibitory activity (perhaps through γ -aminobutyric acid [GABA] interneurons); thus, dopaminergic stimulation increases arousal. The corticostriatal glutamate pathways have the opposite effect, inhibiting dopaminergic function from the ventral striatum, therefore allowing the limbic system to have increased inhibitory activity. Descending glutamatergic tracts interact with dopaminergic tracts directly as well as through GABA interneurons. Glutamatergic deficiency produces symptoms similar to those of dopaminergic hyperactivity and possibly those seen in schizophrenia. The overlap between schizophrenia and substance abuse can be of importance in understanding the neurobiology of schizophrenia.²⁰ This overlap may have a genetic basis, perhaps related to core dopaminergic deficits seen both in schizophrenia and addictive disorders.²⁰ Clinical support for this comes from the fact that phencyclidine, a potent psychotomimetic, is a noncompetitive antagonist at the NMDA receptor, a major glutamate receptor. Similarly, abuse of ketamine, a veterinary anesthetic, can resemble schizophrenia. Ketamine, a competitive antagonist at glutamatergic NMDA receptors, has been shown to lead to reduction in DA- D_1 neurotransmission through glutamatergic inhibition of DA release.²¹ It is proposed that schizophrenia may involve some currently unknown in utero assault that leads to a developmental defect in NMDA receptor function—so-called NMDA hypofunction. This defect is proposed to have latent clinical expression with the psychotic manifestations from NMDA hypofunction not being seen until late adolescence or early adulthood. It has been shown that excess D_2 stimulation can impair NMDA transmission via GABAergic neurons. Thus the use of antipsychotic drugs could potentially enhance glutamatergic transmission.¹⁷

Serotonergic receptors are present on dopaminergic axons, and stimulation of these receptors decreases DA release, at least in the striatum.⁶ Although somewhat more diffuse, the distribution of serotonergic neurons is similar to that of dopaminergic neurons, thus allowing these two neurotransmitter systems to innervate the same areas. In fact, 5-hydroxytryptamine₂ (serotonin₂; 5-HT₂) receptors and D_4 receptors have been found to be colocalized in the cortex.^{3,6} Patients with schizophrenia with abnormal brain scans have higher whole-blood 5-HT concentrations, and these concentrations are correlated with increased ventricular size.²² Atypical antipsychotics with potent 5-HT₂ receptor antagonist effects reverse worsening of symptomatology induced by 5-HT agonists in patients with schizophrenia.²²

❶ Schizophrenia is a complex disorder, and multiple etiologies likely exist. Based on current knowledge, it is naive to think that any currently proposed etiology can adequately explain the genesis of this complex disease. Molecular research involving genetically determined subtle changes in G proteins, protein metabolism, and other subcellular processes can eventually identify the biologic disturbances associated with schizophrenia.^{3,7,17}

CLINICAL PRESENTATION

Schizophrenia is the most common functional psychosis, and great variability occurs in clinical presentation. Despite numerous attempts to portray a stereotype in movies and on television, the stereotypic schizophrenic essentially does not exist. Moreover, schizophrenia is not a “split personality.” It is a chronic disorder of thought and affect with the individual having a significant disturbance in interpersonal relationships and ability to function in society.

The first psychotic episode can be sudden in onset with few premorbid symptoms, or commonly can be preceded by withdrawn, suspicious, peculiar behavior (schizoid). During acute psychotic episodes, the patient loses touch with reality, and in a sense, the brain creates a false reality to replace it. Acute psychotic symptoms can include hallucinations (especially hearing voices), delusions (fixed false beliefs), and ideas of influence (beliefs that one’s actions are controlled by external influences). Thought processes are disconnected (loose associations), the patient may not be able to carry on logical conversation (alogia), and can have simultaneous contradictory thoughts (ambivalence). The patient’s affect can be flat (no emotional expression), or it can be inappropriate and labile. The patient is often withdrawn and inwardly directed (autism). Uncooperativeness, hostility, and verbal or physical aggression can be seen because of the patient’s misperception of reality. Self-care skills are impaired, and the patient is frequently dirty, unkempt, and in general has poor hygiene. Sleep and appetite are often disturbed. When the acute psychotic episode remits, the patient typically has residual features. This is an important point in differentiating schizophrenia from other psychotic disorders. Although residual symptoms and their severity vary, patients can have difficulty with anxiety management, suspiciousness, and lack of volition, motivation, insight, and judgment. Therefore, they often have difficulty living independently

in the community. Because of poor anxiety management and suspiciousness, they are frequently withdrawn socially, and have difficulty forming close relationships with others. In addition, impaired volition and motivation contribute to poor self-care skills and make it difficult for the patient with schizophrenia to maintain employment.

Patients with schizophrenia frequently experience a lack of historicity, or difficulty in learning from their experiences. They can repeatedly make the same mistakes in social conduct and situations requiring judgment. They have difficulty understanding the importance of treatment, including medications, in maintaining their ability to function in society. Therefore they tend to discontinue medications and other treatments, and this increases the risk of relapse and rehospitalization. The co-occurrence of substance abuse (predominantly alcohol or polysubstance—alcohol, cannabis, cocaine) in patients with schizophrenia is very common and is another frequent reason for relapse and hospitalization.²⁰ This effect can be caused by direct toxic effects of these drugs on the brain²¹ but is also caused by the medication nonadherence that is invariably associated with substance abuse.

Although the course of schizophrenia is variable, the long-term prognosis for many patients is poor. It is marked by intermittent acute psychotic episodes and impaired psychosocial functioning between acute episodes, with most of the deterioration in psychosocial functioning occurring within 5 years after the first psychotic episode.¹⁷ By late life, the patient can appear “burned out,” that is, the patient ceases to have acute psychotic episodes, but residual symptoms persist. However, functional skills can actually improve compared with earlier in the patient’s life. In a subpopulation of patients, probably 5% to 15%, psychotic symptoms are nearly continuous, and response to antipsychotics is poor.²³

Schizophrenia is a chronic disorder, and the patient’s history must be carefully assessed for dysfunction that has persisted for longer than 6 months. After their first episode, patients with schizophrenia rarely have a level of adaptive functioning as high as before the onset of the disorder. Table 70–2 summarizes the *DSM-IV-TR* criteria.¹

2 The *DSM-IV-TR* classifies the symptoms of schizophrenia into two categories: positive and negative. Recently greater emphasis has been placed on a third symptom category, cognitive dysfunction (Table 70–3).²³ The areas of cognition found to be abnormal in schizophrenia include attention, working memory, and executive function. Positive symptoms have traditionally attracted the most attention and are the ones most improved by antipsychotics. How-

TABLE 70-3 Schizophrenia Symptom Clusters

Positive	Negative	Cognitive
Suspiciousness	Affective flattening	Impaired attention
Unusual thought content (delusions)	Alogia	Impaired working memory
Hallucinations	Anhedonia	Impaired executive function
Conceptual disorganization	Avolition	

From American Psychiatric Association,¹ Lehman et al.,²³ and Velligan et al.¹²⁰

ever, negative symptoms and impairment in cognition are more closely associated with poor psychosocial function.

It has been suggested that symptom complexes can correlate with prognosis, cognitive functioning, structural abnormalities in the brain, and response to antipsychotic drugs. Negative symptoms and cognitive impairment can be more closely associated with prefrontal lobe dysfunction and positive symptoms with temporolimbic abnormalities. Many patients demonstrate both positive and negative symptoms. Patients with negative symptoms frequently have more antecedent cognitive dysfunction, poor premorbid adjustment, low level of educational achievement, and a poorer overall prognosis.²³

TREATMENT

Schizophrenia

■ DESIRED OUTCOME

Pharmacotherapy is the mainstay of treatment in schizophrenia, and it is impossible in most patients to implement effective psychosocial rehabilitation programs in the absence of antipsychotic treatment.²³

3 A pharmacotherapeutic treatment plan should be developed that delineates drug-related aspects of therapy. Most deterioration in psychosocial functioning occurs during the first 5 years after the initial psychotic episode, and treatment should be particularly assertive during this period.¹⁷ Explicit end points should be defined, including realistic goals for the target symptoms most likely to respond, and the relative time course for response.^{2,23} Other goals include avoiding unwanted side effects, using the minimum effective dose, emphasizing adequate time as a primary variable in determining response, and limiting augmentation medications to nonresponsive patients.

■ NONPHARMACOLOGIC THERAPY

Psychosocial rehabilitation programs oriented toward improving patients’ adaptive functioning are the mainstay of nondrug treatment for schizophrenia. These programs can include case management, psychoeducation, targeted cognitive therapy, basic living skills, social skills training, basic education, work programs, supported housing, and financial support. In particular, programs aimed at employment and housing have been the more effective interventions and are considered “best practices.” Programs that involve families in the care and life of the patient have been shown to decrease rehospitalization and improve functioning in the community. For particularly low-functioning patients, assertive intervention programs, referred to as *active community treatment* (ACT), are effective in improving patients’ functional outcomes. ACT teams are available on a 24-hour basis and work in the patient’s home and place of employment to provide comprehensive treatment, including medication, crisis intervention, daily living skills, and supported employment and housing.^{2,23} Medication treatment cannot be successful without proper attention to these other aspects of care. People with schizophrenia need comprehensive care, with coordination of services across psychiatric, addiction, medical, social, and rehabilitative services. The level of coordination in the

TABLE 70-2 DSM-IV-TR Diagnostic Criteria for Schizophrenia

- A. Characteristic symptoms: Two or more of the following, each persisting for a significant portion of at least a 1-month period:
- (1) Delusions
 - (2) Hallucinations
 - (3) Disorganized speech
 - (4) Grossly disorganized or catatonic behavior
 - (5) Negative symptoms
- Note: Only one criterion A symptom is required if delusions are bizarre or if hallucinations consist of a voice keeping a running commentary on the person’s behavior or two or more voices conversing with each other.
- B. Social/occupational dysfunction: For a significant portion of the time since onset of the disorder, one or more major areas of functioning such as work, interpersonal relations, or self-care are significantly below the level prior to onset.
- C. Duration: Continuous signs of the disorder for at least 6 months. This must include at least 1 month of symptoms fulfilling criterion A (unless successfully treated). This 6 months may include prodromal or residual symptoms.
- D. Schizoaffective or mood disorder has been excluded.
- E. Disorder is not due to a medical disorder or substance use.
- F. If a history of a pervasive developmental disorder is present, there must be symptoms of hallucinations or delusions present for at least 1 month.

United States is often insufficient, and patients become at risk to “fall through the cracks.” Recent national policy documents have called for greater coordination of care.^{24,25} Additionally, emphasis is growing on the role that the person him or herself plays in a recovery-based system of care, where the person’s lifetime aspirations and goals become the center of care, rather than symptom reduction being the primary focus. A list of psychotherapeutic approaches to the treatment of schizophrenia is given in Table 70-4.

■ PHARMACOLOGIC THERAPY

Assessment Prior to Treatment

4 The importance of initial accurate diagnostic assessment cannot be overemphasized. A thorough mental status examination, physical and neurologic examination, complete family and social history, and laboratory workup must be performed to confirm the diagnosis and exclude general medical or substance-induced causes of psychosis. Laboratory tests, biologic markers, and commonly available brain imaging techniques do not assist in diagnosis or selection of medication. A pretreatment patient workup is important in not only excluding other pathology, but in serving as a baseline for monitoring potential medication-related side effects, and should include: vital signs, complete blood count, electrolytes, hepatic function, renal function, electrocardiogram, fasting serum glucose, serum lipids, thyroid function, and urine drug screen.

■ ANTIPSYCHOTIC MEDICATION CHOICES

Second-Generation Antipsychotics

Second-generation antipsychotics (SGAs) (with the exception of clozapine) have become first-line agents in the treatment of schizophrenia.^{23,26} No absolute criterion distinguishes atypical (second-generation) from typical (traditional, conventional, or first-generation) antipsychotics, and no universally accepted definition exists for an atypical antipsychotic.²² In many respects, *second-generation antipsychotic* is a more appropriate term. Common to all definitions is the ability of the drug to produce antipsychotic response with few or no acutely occurring extrapyramidal side effects. Other attributes that have been ascribed to SGAs include enhanced efficacy, particularly for negative symptoms and cognition; absence or near absence of propensity to cause tardive dyskinesia; and lack of effect on serum prolactin.²² To date, the only approved SGA that fulfills all of these criteria is clozapine.²² Although conflicting, some evidence suggests that SGAs can have superior efficacy for the treatment of negative symptoms, cognition, and mood.^{23,26} Whether these differences are a result of differences in core efficacy or differences in side-effect profile is unknown. The major advantage of atypical antipsychotics can be their lower risk of neurologic side-effects, particularly effects on movement. Results from the Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) study indicate that olanzapine, compared with quetiapine, risperidone, ziprasidone, and the FGA perphenazine, has modest superiority in maintenance therapy when treatment persistence is the primary clinical outcome.²⁷ No significant differences were apparent among the other compared antipsychotics. However, increased metabolic adverse effects occurred with olanzapine.

Risperidone has a low incidence of EPS at low to moderate doses. The mean optimal dose in parallel, fixed-dose studies was 4 to 6 mg daily. At doses greater than 6 mg daily, risperidone’s profile is more similar to that of an FGA.²⁸ Because risperidone appears to lose its atypical profile at higher doses, the lowest possible dose should be used in treatment. This can include gradual dose titration downward if patients do not respond initially, rather than upward titration as has been the traditional approach to dosing antipsychotics.²³

Paliperidone (9-hydroxyrisperidone), the major active metabolite of risperidone, is formulated in an extended-release osmotically controlled release system. EPS-related adverse effects with paliperidone appear at a dose threshold, increasing at doses greater than 9 mg daily.^{29,30} Postmarketing pharmacovigilance studies are needed to further define the safety profile of paliperidone.

Olanzapine has a very low incidence of extrapyramidal side effects when used within the approved dose range of 10 to 20 mg daily.^{2,23} However, many patients are being treated at doses above the currently recommended limit in the approved product labeling of 20 mg/day. Quetiapine is an efficacious antipsychotic with an excellent EPS profile.^{23,31} Although contrary to efficacy studies, doses above 500 mg are often used to achieve optimal effects, with dose titration to 800 mg/day being a common occurrence. From a clinical perspective, the optimal daily quetiapine dose is unclear.

Ziprasidone 40 to 160 mg/day has efficacy similar to other SGAs, with response rates increasing at doses greater than 80 mg daily.^{2,23,32} Aripiprazole has established efficacy at 15 to 30 mg/day.^{23,33} Both aripiprazole and ziprasidone have significantly less potential to produce weight gain than other SGAs.

5 Side-effect profiles differ among atypical antipsychotics, and this information in combination with individual patient characteristics should be used in deciding which drug to use in an individual patient. Information from the algorithm (Fig. 70-1) and the adverse effects sections should be used in arriving at this decision.

First-Generation (Typical) Antipsychotics

Maintenance effectiveness studies in individuals with chronic schizophrenia do not show any major overall clinical outcome differences between using the FGA perphenazine versus SGAs. However, in first-episode schizophrenia, SGAs are often considered first-line treatments because of the risk of tardive dyskinesia with FGAs.^{23,26} This can be of particular significance in individuals with their first psychotic break, as they seem particularly susceptible to extrapyramidal side effects.

No known differences exist in efficacy between low- and high-potency FGAs. Previous patient or family history of response to an antipsychotic is helpful in the selection of an agent. Traditional dosage equivalents (expressed in “chlorpromazine equivalent dosages”—the equipotent dosage of any traditional FGA compared with 100 mg of chlorpromazine) can assist in determining the effective dosage range if the need arises to treat a patient with a different FGA. However, because SGAs differ in mechanism of action, the dose equivalents have little relevance when comparing dosages of SGAs. Table 70-5 lists antipsychotics and their usual dosage ranges.

■ PHARMACOTHERAPEUTIC ALGORITHM

6 Figure 70-1 outlines a suggested pharmacotherapeutic algorithm for schizophrenia.²⁶ Stage 1 of the treatment algorithm applies only to those patients experiencing their first episode of schizophrenia. In these patients, a majority of schizophrenia experts felt that SGAs should be used initially because of the risk of tardive dyskinesia with FGAs.²⁶ Treatment-naïve patients appear more sensitive to acutely occurring extrapyramidal side effects, and lower doses of antipsychotics should be used.²⁶ However, the tradeoff with SGAs is the increased risk of metabolic side effects, particularly weight gain with some SGAs,

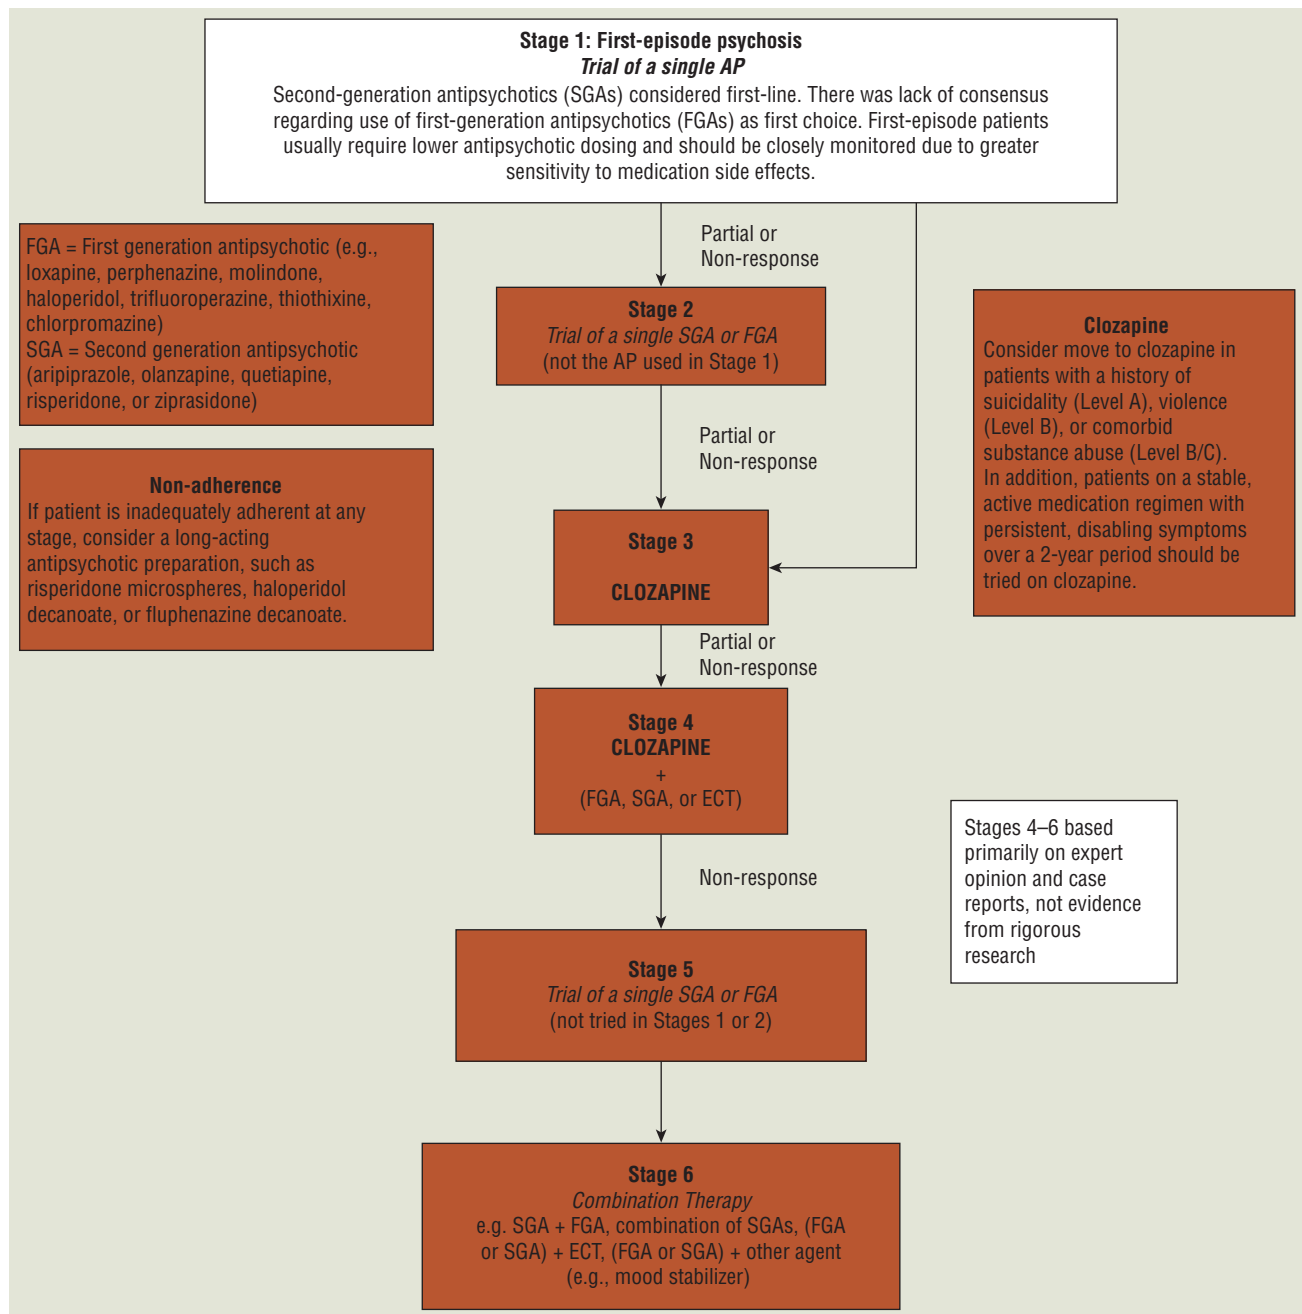

FIGURE 70-1. Patient entry into the algorithm is determined by individual patient history and clinical presentation. Only new onset patients with no history of antipsychotic treatment failure are treated at stage 1. Algorithm stages can be skipped if clinically appropriate, and one can go back stages if indicated. In general, inadequately responding patients should not remain in stages 1 or 2 longer than 12 weeks at therapeutic doses. Stage 3 can be up to 6 months. In stages 4, 5, and 6, a 12-week trial is recommended, and if there is greater than or equal to 20% improvement in positive symptoms at week 12, the medication trial warrants extension for an additional 12 weeks with dose titration as clinically warranted. The levels of evidence for algorithm recommendations are as follows: stage 1, level A for efficacy for both first-generation antipsychotics (FGAs) and second-generation antipsychotics (SGAs); level C for SGAs as first choice; stage 2, level A; stage 3, level A; stage 4, level C; stage 5, level C; stage 6, level C. Level A is supported by one or more randomized controlled trials. Level B is supported by large cohort studies, epidemiological studies, and so on. Level C is supported by case series, case reports, or expert opinion. (ECT, electroconvulsive therapy.) (This figure is copyrighted by the Texas Department of State Health Services and may be reproduced with appropriate citation of the authors and source. Algorithm updates and user manuals can be obtained at <http://www.mhmr.state.tx.us/centraloffice/medicaldirector/timasczman.pdf>. Data from Moore et al.²⁶)

especially olanzapine. Stage two applies to chronically ill patients who are newly started on antipsychotics, or it can involve a new onset patient who had inadequate clinical response at stage 1. Stage 2 recommends either FGAs or SGAs, with the exception of clozapine.²⁶

Because of safety concerns and the need for white blood cell (WBC) monitoring, it is recommended that patients be tried on one newer SGA and one other SGA or FGA as monotherapy before proceeding to a trial of clozapine (stage 3).²⁶ Clozapine has superior efficacy in decreasing suicidal behavior, and it should also be

considered as a higher treatment option in the suicidal patient.²⁶ Clozapine can also be considered earlier in treatment in patients with a history of violence or comorbid substance abuse.²⁶

Stage 4 of the treatment algorithm includes clozapine and augmentation with either a FGA, SGA, or electroconvulsive therapy (ECT).²⁶ Combination treatment at this stage is supported by limited controlled and equivocal evidence.²⁶ Treatment algorithm recommendations after stage 3 (i.e., clozapine monotherapy) are based more on anecdotal experiences and expert opinion than on empirical

TABLE 70-5 Available Antipsychotics: Doses and Dosage Forms

Generic Name	Trade Name	Traditional Equivalent Dose (mg)	Usual Dosage Range (mg/day)	Manufacturer's Maximum Dose (mg/day) ^a	Dosage Forms ^b
Traditional antipsychotics (first-generation antipsychotics)					
chlorpromazine	Thorazine	100	100–800	2,000	T,L,LC,I,C-ER,S
fluphenazine	Prolixin	2	2–20	40	T,L,LC,I,LAI

research.²⁶ In general, patients who experience poor improvement with clozapine do not respond well with other antipsychotic monotherapies (stage 5), thus one of the primary reasons that clozapine augmentation is recommended at stage 4. Stage 6 combination pharmacotherapy interventions should be implemented with time limited, careful evaluation of a patient's symptom response and discontinuation of the combination if improvement does not occur.²⁶

If partial or poor adherence contributes to inadequate clinical improvement, then long-acting or depot injectable antipsychotics should be considered.^{23,26} Risperidone microspheres is the only available long-acting injectable SGA, and long-acting FGAs include fluphenazine decanoate and haloperidol decanoate. In addition to individuals who are identified as partially adherent, some patients can elect for injections every 2 to 4 weeks instead of taking daily oral medications. A long-acting injectable antipsychotic can be substituted for an oral antipsychotic at any point in the algorithm where they are thought to be indicated.

CLINICAL CONTROVERSY

Efficacy and effectiveness studies demonstrate conflicting results with regard to the use of SGAs versus FGAs in schizophrenia. Although most studies have demonstrated a lower incidence of EPS with SGAs, weight gain is a significant trade-off adverse effect with some of the SGAs, particularly olanzapine. Tension exists between policy decision makers who are responsible for managing finite resources and clinicians who see clinical benefits of the SGAs in the patients they treat.

The use of antipsychotic combinations is controversial, as very limited evidence supports increased efficacy for combination antipsychotic treatment. Combination antipsychotics are frequently used by clinicians, and testimonies attest to clinical benefits when a second SGA is added.

PREDICTORS OF RESPONSE

Obtaining a thorough medication history is important, and previous antipsychotic treatment should help guide the selection of drug therapy, in that either a good prior response favors the use of the

same agent or a negative prior response suggests the selection of a dissimilar drug. Nonprescription and illicit drug use can influence psychiatric presentation and thus diagnosis or antipsychotic response. Amphetamines and other CNS stimulants, cocaine, corticosteroids, digitalis glycosides, indomethacin, marijuana, pentazocine, phencyclidine, and other drugs can induce psychosis in susceptible individuals or exacerbate psychosis in patients with preexisting psychiatric illness.³⁴ Patients with schizophrenia who continue to abuse alcohol or drugs usually have a poor response to medications and a poor prognosis. Alcohol, caffeine, and nicotine use potentially results in drug interactions.

Individual differences in patient response have been either proposed or identified, which can be clinically useful predictors of response.³⁵ Acute onset and short duration of illness, presence of acute stressors or precipitating factors, later age of onset, family history of affective illness, and good premorbid adjustment as reflected in stable interpersonal relationships or employment are all predictors of good response.³⁵

Although controversial, affective symptoms can correlate with an overall good response. Negative symptoms and neuropsychologic deficits related to cognition and neurologic soft signs can correlate with poor antipsychotic response.³⁵ A patient's subjective response within the first 48 hours after being administered an FGA can be associated with drug responsiveness.³⁶ An initial dysphoric response, demonstrated by stating a dislike of the medication, or feeling worse or zombie-like, combined with anxiety or akathisia-like symptoms, is associated with poor drug response, adverse effects, and nonadherence.

The importance of developing a therapeutic alliance between the patient and the clinician cannot be underestimated. Patients who form positive therapeutic alliances are more likely to be adherent with all aspects of therapy, experience a better outcome at 2 years, and require smaller antipsychotic doses.

A certain minority of patients fail to benefit from antipsychotic therapy, and their psychosocial functioning can actually worsen. Unfortunately, no accepted method is available to identify these people before treatment.³⁵ Recent evidence suggests that pharmacogenetics can play a role in predicting treatment response, both with respect to symptom improvement and with liability to develop side effects.^{37–38} However, insufficient information is available to recommend routine clinical testing.

■ INITIAL TREATMENT IN AN ACUTE PSYCHOTIC EPISODE

The goals during the first 7 days of treatment should be decreased agitation, hostility, combativeness, anxiety, tension, and aggression, and normalization of sleep and eating patterns. The usual recommendation is to initiate therapy and to titrate dose over the first few days to an average effective dose, unless the patient's physiologic status or history indicates that this dose can result in unacceptable adverse effects. Table 70-5 lists the usual dosage range, and an average dose is typically midrange. Because of increased sensitivity to side effects, particularly extrapyramidal side effects, in first-episode psychotic patients, typical dosing ranges are approximately 50% of the doses used in chronically ill individuals.²⁶ If "cheeking" of medication is suspected, liquid formulations and orally disintegrating tablets of different antipsychotics are available (see Table 70-5). If a patient has shown absolutely no improvement after 3 to 4 weeks at therapeutic doses, then an alternative antipsychotic should be considered (i.e., moving to the next treatment stage in the algorithm; see Fig. 70-1).^{20,22}

Although some clinicians believe that larger daily doses are necessary in more severely symptomatic patients, data are not available to support this practice. Some symptoms, such as agitation, tension, aggression, and increased motor activity, can respond more quickly, but side effects can be more common with higher doses. However, interindividual differences in dosage and patient response do occur. In partial but inadequate responders who are tolerating the chosen antipsychotic, it may be reasonable to titrate above usual dose ranges. However, this tactic should be time-limited (i.e., 2 to 4 weeks), and if the patient does not achieve further improvement, the dose should either be decreased, or an alternative treatment strategy tried.³⁹ In general, rapid titration of antipsychotic dosage is not indicated.³⁹ However, intramuscular antipsychotic administration (e.g., aripiprazole 5.25 to 9.75 mg IM, haloperidol 2 to 5 mg IM, olanzapine 2.5 to 10 mg IM, or ziprasidone 10 to 20 mg IM) can be used to assist in calming a severely agitated patient. Agitation can be manifested as loud, physically or verbally threatening behavior, motor hyperactivity, or physical aggression. Although this technique can assist in calming an acutely agitated psychotic patient, it does not improve the extent of or time to remission, or the length of hospitalization. If IM haloperidol is used, the occurrence of EPS can eliminate some of the advantages of using an oral SGA. If the patient is receiving an antipsychotic within the usual therapeutic range, the use of lorazepam 2 mg IM as needed in combination with the maintenance antipsychotic is a rational alternative to an injectable antipsychotic. Hypotension, respiratory depression, and CNS depression are possible when injectable lorazepam and olanzapine are used concomitantly; thus this parenteral combination is not recommended.

CLINICAL CONTROVERSY

Minimal research evidence supports the use of antipsychotic doses beyond the dose range in the Food and Drug Administration (FDA) approved product labeling. However, clinicians frequently titrate doses above the approved range, and frequently attest to symptom improvement when this is done.

■ STABILIZATION THERAPY

Improvement is usually a slow but steady process over 6 to 12 weeks or longer. During the first 2 to 3 weeks, goals should include increased socialization and improvement in self-care habits and mood. Improvement in formal thought disorder should follow and can take an additional 6 to 8 weeks to respond. Patients who are early in the course of their illness can experience a more rapid resolution

of symptoms than individuals who are more chronically ill. In general, if a patient has no improvement with treatment after 3 to 4 weeks at therapeutic doses, or has achieved only a partial decrease in positive and negative symptoms within 12 weeks at adequate doses, then the next algorithm stage should be considered. In a more chronically ill patient, symptoms can continue to improve for 3 to 6 months. During acute stabilization, usual labeled doses of SGAs are recommended (see Table 70-5); with FGAs, a range of 300 to 1,000 mg of chlorpromazine equivalents daily is recommended.^{23,26} An optimum dose of the chosen drug should be estimated in the initial treatment plan. If the patient begins to show adequate response before or at this dosage, then the patient should remain at this dosage as long as symptoms continue to improve. **7** In general, adequate time on a therapeutic antipsychotic dose is the most important factor in predicting medication response. However, if necessary, dose titration can continue within the therapeutic range every week or two as long as the patient has no side effects.

Before changing medications in a poorly responding patient, the following should be considered: Were the initial target symptoms indicative of schizophrenia or did they represent manifestations of a different diagnosis, a long-standing behavioral problem, a substance abuse disorder, or a general medical condition? Is the patient adherent with pharmacotherapy? Are the persistent symptoms poorly responsive to antipsychotics (e.g., impaired insight or judgment, or fixed delusions)? How does the patient's current status compare with response during previous exacerbations? Would this patient potentially benefit from a change to a different treatment stage (see Fig. 70-1)? Does this patient have a treatment-refractory schizophrenic illness?

The conclusion that a partially responding patient has achieved as much symptomatic improvement as possible is one that must be made with great care and after considering all possible treatment alternatives. However, treatment goals must be realistic. Medications are effective at decreasing many of the symptoms of schizophrenia (and are thus referred to as palliative), but they are not curative, and all symptoms may not abate. This being said, the treatment approach should be assertive. Although one should aim to achieve none to minimal residual positive symptoms with effective treatment, it is still unclear what a realistic goal is with regard to maximum improvement in negative symptoms.

It is important to screen patients for co-occurring mental disorders, and their presence can become more apparent during the stabilization or maintenance phases of schizophrenia treatment. Examples include substance abuse disorders, depression, obsessive-compulsive disorder, and panic disorder. As co-occurring disorders will limit symptom and functional improvement and increase the risk of relapse, it is critical that pharmacologic and nonpharmacologic interventions for the co-occurring disorder be implemented in combination with evidence-based treatment for schizophrenia.

■ MAINTENANCE TREATMENT

Maintenance drug therapy prevents relapse, as shown in numerous double-blind studies. The average relapse rate after 1 year is 18% to 32% with active drug (including some nonadherent patients) versus 60% to 80% for placebo.^{23,28,40}

After treatment of the first psychotic episode in a schizophrenic patient, medication should be continued for at least 12 months after remission.^{23,39} **8** Many schizophrenia experts recommend that patients with robust medication response be treated for at least 5 years. In chronically ill individuals, continuous or lifetime pharmacotherapy is necessary in the majority of patients to prevent relapse. This should be approached with the lowest effective dose of the antipsychotic that is likely to be tolerated by the patient.^{23,39}

Antipsychotics should be tapered slowly before discontinuation. Abrupt discontinuation of antipsychotics, especially low-potency

FGAs and clozapine, can result in withdrawal symptoms, felt to be a manifestation of rebound cholinergic outflow. Insomnia, nightmares, headaches, gastrointestinal symptoms (e.g., abdominal cramps, stomach pain, nausea, vomiting, and diarrhea), restlessness, increased salivation, and sweating are reported. When switching from one antipsychotic to another, it is often recommended to taper and discontinue the first antipsychotic over at least 1 to 2 weeks after the second antipsychotic is initiated.^{23,39} Tapering often needs to occur more slowly, especially with clozapine.^{23,39}

Long-Acting or Depot Injectable Antipsychotics

Depot or long-acting antipsychotics are recommended for patients who are unreliable in taking oral medication on a daily basis, and thus are not usually used as first-line therapy. Before a long-acting antipsychotic is initiated, it should be determined whether the patient's medication nonadherence is because of side effects. If so, an alternative medication with a more favorable side-effect profile should be considered before a long-acting injectable antipsychotic.

The patient's motivation for treatment is a major factor influencing outcome. Conversion from oral therapy to a long-acting injectable is most successful in patients who have been stabilized on oral therapy. The ideal patient for a long-acting injectable is the individual who does not like the daily reminder of oral medication or is unreliable in taking medications. Risperidone is the only SGA available as a long-acting injectable.^{26,41} Long-acting risperidone has demonstrated efficacy, with an optimum dose range likely between 25 and 50 mg given IM every 2 weeks. Doses above 50 mg every 2 weeks are not recommended, as results from one study showed no greater efficacy but more EPS.⁴¹ The pattern of adverse effects, especially low propensity to induce EPS and tardive dyskinesia, is similar to that of oral risperidone, and it appears to be well tolerated by patients.⁴¹

Conversion from an oral antipsychotic to a long-acting medication should start with stabilization on an oral dosage form of the same agent, or at least a short trial (3 to 7 days), to determine whether the patient tolerates the medication without significant side effects. Long-acting risperidone is a suspension of drug in glycolic acid-lactate copolymer microspheres that must be reconstituted before administration. The microspheres are degraded via hydrolysis with significant risperidone serum concentrations being measurable approximately 3 weeks after single-dose administration. Thus it is important that the oral antipsychotic be administered for at least 3 weeks after beginning the injections. Dose adjustments are recommended to be made no more often than once every 4 weeks.^{39,41} The recommended starting dose with the depot injection is 25 mg, and clinical experience suggests that titration to doses greater than or equal to 37.5 mg per injection may be necessary for maintenance treatment.

For fluphenazine decanoate, the simplest dosing conversion method recommends 1.2 times the oral fluphenazine daily dose for stabilized patients, rounding up to the nearest 12.5-mg interval, administered in weekly doses for the first 4 to 6 weeks; or 1.6 times the oral daily dose for more acutely ill patients.⁴² Subsequently, fluphenazine decanoate can be administered once every 2 to 3 weeks. Oral fluphenazine can be overlapped for 1 week. For haloperidol decanoate, a factor of 10 to 15 times the oral haloperidol daily dose is commonly recommended, rounding up to the nearest 50-mg interval, administered in a once-monthly dose with an oral haloperidol overlap for the first month. A more assertive conversion method recommends 20 times the oral daily dose, but dividing the injection into consecutive doses of 100 to 200 mg every 3 to 7 days until the entire amount is given.⁴³ With this method, oral medication overlap is unnecessary. The haloperidol decanoate dose is decreased by 25% at the second and third months.

Injection site reactions have been reported with the haloperidol decanoate 100 mg/mL preparation, consisting of painful pruritic

swelling at the injection site.⁴⁴ Acute EPS can be seen following injections of either fluphenazine or haloperidol decanoate. These effects are minimized with the use of risperidone microspheres. Both haloperidol and fluphenazine decanoate should be administered by a deep, "Z-tract" intramuscular method. Long-acting risperidone is injected by deep IM injection in the gluteus maximus, but Z-tracting is not necessary. An oral test dose of the medication is recommended before administering the first IM dose of the long-acting antipsychotic.

Methods to Enhance Patient Adherence

It is often a challenge for individuals with chronic illnesses to maintain high levels of medication adherence, and partial compliance is a reality in the treatment of all chronic illnesses.⁴⁵ Individuals with serious mental disorders have somewhat higher nonadherence rates than those with general medical disorders, with the following explanations provided: denial of illness, lack of insight, grandiosity or paranoia, no perceived need for medication, perceived lack of input into choice of medication or dosage, side effects, misperceived "allergies," or the number of medications prescribed or doses received daily. In fact, clinicians should expect partial compliance to be the norm with regard to medication-taking behavior. This should be approached in a nonjudgmental manner, with the clinician actively engaging the patient in care and using motivational interviewing techniques as mechanisms to enhance therapeutic alliance and patient adherence.

9 Education geared toward patients becoming more informed about their illness and the effectiveness and risks of treatment can help to increase adherence.⁴⁶ These programs should be staged so that patients initially receive basic information about their disorder and its symptoms and basic information about their medication and self-monitoring techniques. As the patient is capable of dealing with more complex information, more detailed information regarding schizophrenia, psychosocial treatments, and prognosis should be discussed. Patients and families should be taught self-monitoring techniques and when to report symptom exacerbation or medication side effects to the clinician.⁴⁶ Psychoeducation strategies should include motivational interview techniques in individual counseling as well as group activities.

Recent evidence suggests that cognitive behavioral therapy focusing on medication adherence can improve patient outcome.⁴⁷ This approach is called compliance therapy. Groups facilitated by trained individuals who have the illness can be more effective in enhancing awareness and acceptance of schizophrenia and necessary treatment than groups led only by professionals. Active involvement of family members further increases the likelihood of patient adherence with treatment. In addition to programs provided by community mental health centers, support groups operated by consumer groups such as the National Alliance on Mental Illness (NAMI) are available in most urban areas. Contact information for local NAMI chapters can be accessed at http://www.nami.org/Template.cfm?Section=Your_Local_NAMI. In the hospital, self-medication administration can reinforce the patient's perception of their active role in their own treatment. When patients miss outpatient appointments, active outreach interventions must be implemented to enhance patient engagement in treatment.^{23,46}

MANAGEMENT OF TREATMENT-RESISTANT SCHIZOPHRENIA

In general, "treatment resistant" describes a patient who has had inadequate symptom response from multiple antipsychotic trials.²³ Traditionally, treatment resistance has been defined as lack of improvement in positive symptoms, but it can be defined by poor improvement in negative symptoms, or even by medication intolerance. Between 10% and 30% of patients receive minimal symptomatic improvement after multiple FGA monotherapy trials.²³ An

additional 30% to 60% of patients have partial but inadequate improvement in symptoms or unacceptable side effects associated with antipsychotic use.^{23,26} In those patients failing two or more trials of pharmacotherapy, a treatment refractory evaluation should be performed to reexamine diagnosis, substance abuse, medication adherence, and psychosocial stressors. Targeted cognitive behavioral therapy or other psychosocial augmentation strategies should be considered.²⁶

Clozapine

Only clozapine has shown superiority over other antipsychotics in randomized clinical trials for the management of treatment-resistant schizophrenia. Most other SGAs have either not been studied in treatment-refractory patients or evaluated in small open trials. In a seminal study, clozapine was effective in approximately 30% of patients with treatment-resistant schizophrenia, compared with only 4% treated with a combination of chlorpromazine and benzotropine.⁴⁸ The criteria for treatment-resistance require two treatment failures, and includes both FGAs and SGAs. Other treatment candidates for clozapine include those patients who cannot tolerate even conservative doses of other antipsychotics.

Symptomatic improvement with clozapine in the treatment-resistant patient often occurs slowly, and as many as 60% of patients may improve if clozapine is used for up to 6 months.³⁹ This, in combination with clozapine's adverse effects profile, provides sufficient information to conclude that clozapine is not a panacea for schizophrenia. Polydipsia and hyponatremia (psychogenic water drinking) is a frequent problem among treatment-resistant patients, and clozapine reportedly decreases water drinking and increases serum sodium in such patients.⁴⁹

Because of the risk of orthostatic hypotension, clozapine is usually titrated more slowly than other antipsychotics, particularly on an outpatient basis. If a 12.5 mg test dose does not produce hypotension, then clozapine 25 mg at bedtime is recommended, increased to 25 mg twice a day after 3 days, and then increased in 25- to 50-mg/day increments every 3 days until a dose of at least 300 mg/day is reached. Because high doses are associated with significantly increased side effects, including seizures, a clozapine serum concentration is recommended before exceeding 600 mg/day. Although some clinicians add valproate when exceeding this dose to prevent the occurrence of seizures, no evidence supports this intervention.

Augmentation and Combination Strategies

Little empirical evidence exists to guide treatment decisions for patients who do not respond to clozapine.^{26,39} A small number of randomized trials have examined the efficacy of clozapine augmentation with SGAs, and the results have been inconsistent, but more negative than positive (see Fig. 70–1).²⁶ Augmentation therapy involves the addition of a nonantipsychotic drug to an antipsychotic drug in a poorly or partially responsive patient, whereas combination treatment involves using two antipsychotics simultaneously. Several guidelines should be followed regarding augmentation: (a) augmentation should be used only in inadequately responding patients; (b) augmentation agents are rarely effective for schizophrenic symptoms when used alone; (c) augmentation responders usually improve rapidly; and (d) if augmentation does not improve symptomatology, the augmenting agent should be discontinued.^{39,50}

Mood stabilizers are frequently used as an augmentation strategy. Lithium does not enhance antipsychotic effect but can improve labile affect and agitated behavior in selected patients.⁵¹ Valproic acid and carbamazepine have also been used. A large placebo-controlled trial supports faster symptom improvement, but no difference in maintenance treatment, when divalproex was used in combination with either olanzapine or risperidone.⁵² Enzyme induction with carba-

mazepine can cause a decrease in antipsychotic serum concentrations and potentially worsen psychotic symptoms in some patients. Dosing of mood stabilizers in treatment-resistant schizophrenia is similar to dosing in bipolar disorder (Chap. 72).^{23,39}

Selective serotonin reuptake inhibitors (SSRIs), particularly fluoxetine and fluvoxamine, have reasonable evidence for improving negative symptoms when used as augmentation of FGAs. Potential benefits of combining SSRIs with SGAs require more study.⁵³ Consistently positive results have been reported when using SSRIs to treat obsessive-compulsive symptoms that worsen or arise during clozapine treatment.

β -Blockers such as propranolol, pindolol, and nadolol have been reported to have an antiaggressive effect when used in a variety of psychiatric disorders, but particularly in the organic aggressive syndrome.²³ Doses are typically higher than those required for cardiovascular β -blockade, but patients should be monitored carefully for β -blocker-related side effects. Patients may need to be treated with adequate doses for 6 to 8 weeks to experience an antiaggression response.

Combining an FGA with an SGA and combining different SGAs have been suggested as intervention strategies for treatment-resistant patients. These treatments are based on the hypothesis that using antipsychotics with different mechanisms of action will result in greater efficacy than using any medication individually. Critics argue that combining an FGA with an SGA will negate the advantages of the SGA (e.g., fewer EPS). Pharmacodynamically, no clear rationale exists for explaining how combinations of antipsychotics would produce enhanced efficacy, and increased side effects, particularly increased EPS and hyperprolactinemia are possible results.⁵⁴ In general, a series of antipsychotic monotherapies, including clozapine, are preferred over antipsychotic combinations.^{26,39} However, when this fails to produce desired outcomes, a time-limited combination trial can be attempted (see Fig. 70–1, stages 4 or 6).^{23,26,29} Such antipsychotic combination treatment trials should be time limited (12 weeks) and the patient carefully evaluated with rating scales for changes in symptomatology. If no apparent improvement is observed, then one of the medications should be tapered and discontinued. However, if the patient has a partial response (greater than or equal to 20% improvement in positive symptoms) after 12 weeks with combination treatment in stages 4 or 6, medications should be titrated to doses at the upper end of the therapeutic range, and treatment should continue for an additional 12 weeks before a change in stage is considered.

■ ANTIPSYCHOTIC DRUG MECHANISMS OF ACTION

The exact mechanism of action of antipsychotics is unknown. It has been suggested that current antipsychotics be classified into three different categories: (a) typical or traditional (high D_2 antagonism and low 5-HT_{2A} antagonism); (b) atypical (moderate to high D_2 antagonism and high 5-HT_{2A} antagonism); and (c) atypical clozapine-like (low D_2 antagonism and high 5-HT_{2A} antagonism).^{55,56} With the exception of aripiprazole, all current SGAs have a greater affinity for 5-HT_{2A} receptors than D_2 receptors.

Studies of antipsychotic receptor binding in humans have used PET scans to examine neurotransmitter receptor binding at steady-state, 12 hours postdose in small numbers of individuals. At least 60% to 65% occupation of D_2 receptors is necessary to decrease positive psychotic symptoms, whereas blockade of approximately 77% or more of D_2 receptors is associated with EPS.^{55,57} FGAs are dopaminergic antagonists with high affinity for D_2 receptors. During chronic treatment with these agents, between 70% and 90% of D_2 receptors in the striatum are usually occupied. In contrast, during clozapine treatment only 38% to 47% of D_2 receptors are occupied,

even with high doses. Newer SGAs have variable D_2 binding. With low-dose risperidone (2 to 5 mg/day), D_2 binding ranges from 60% to 79%, but with doses greater than 6 mg daily, binding commonly exceeds the 77% threshold associated with the development of EPS. Risperidone 2 mg/day produces 5-HT_{2A} binding greater than 70%, and with 4 mg/day it is nearly 100%.^{55,58} The binding affinity of paliperidone to D_2 and 5-HT_{2A} receptors is yet to be characterized.

Olanzapine 10 to 20 mg/day produces D_2 binding ranging from 71% to 80%, whereas at 30 to 40 mg/day, it ranges from 83% to 88%. At 5 mg/day, 5-HT_{2A} receptors are near saturation of binding.⁵⁵ Ziprasidone has the highest 5-HT_{2A}: D_2 affinity ratio of any of the currently available antipsychotics. It is also a potent 5-HT_{1A} agonist.⁵⁹

Quetiapine has the lowest D_2 binding. At doses of 300 to 600 mg/day, D_2 binding ranges from 0% to 27%. Even at quetiapine 800 mg/day, only 30% of D_2 receptors are occupied. At these same daily doses, 45% to 90% of 5-HT_{2A} receptors are occupied. However, when quetiapine D_2 binding is examined 2 to 3 hours postdose, 58% and 64% of receptors were occupied with 400 mg and 450 mg, respectively. Transient blockade of dopamine receptors can be adequate to produce antipsychotic effect, but long-term D_2 blockade is required for production of EPS and sustained hyperprolactinemia. Low D_2 binding, and thus atypicality, can be directly associated with how rapidly the antipsychotic disassociates from the D_2 receptor.^{55,58} The availability of aripiprazole, a partial agonist at D_2 receptors, represents a further elaboration of the dopamine hypothesis of antipsychotic action.^{33,56} It is proposed that aripiprazole works as a functional partial agonist. Aripiprazole is a rather weak 5-HT_{2A} antagonist but a potent 5-HT_{1A} agonist.^{33,56} It is clear that the SGAs differ in their mechanisms of action and most likely in the manner in which they produce an atypical clinical profile.

The primary therapeutic effects of FGAs are thought to occur in the limbic system, including the ventral striatum, whereas EPS are thought to be related to DA blockade in the dorsal striatum. Tolerance often develops to the acutely occurring EPS within a few weeks, but tolerance to the antipsychotic effects appears to be less common, if not rare. 5-HT_{2A} antagonism in combination with modest D_2 blockade leads to release of dopamine in the prefrontal cortex, and this is one explanation for the decrease in negative symptoms and improvement in cognition reported with atypical antipsychotics.

Antipsychotics vary in their effects on other neurotransmitter receptor systems.^{55,56,58} Although the significance of these different mechanisms on efficacy is unclear, they do potentially explain differences in side-effect profiles. These differences in pharmacodynamic

profiles also point out that the SGAs are not all alike, and that patients obtaining an inadequate clinical response (either efficacy or side effects) with one antipsychotic can have a superior response on an alternate drug. Thus serial SGA monotherapy trials should be tried in patients receiving a suboptimal clinical response (see Fig. 70–1).

■ PHARMACOKINETICS

As a class, antipsychotics are highly lipophilic and highly bound to membranes and plasma proteins. They distribute readily into most tissues with a high blood supply and can accumulate in tissues; therefore they have large volumes of distribution.⁶⁰ Most antipsychotics are largely metabolized, primarily through the cytochrome P450 (CYP) pathways in the liver, except for ziprasidone, which is largely metabolized by aldehyde oxidase. Risperidone is metabolized through CYP2D6, and thus is susceptible to polymorphic metabolism. In particular, 30% to 35% of Africans and Asians are slow to intermediate metabolizers, in addition to approximately 7% and 2%, respectively, who are poor metabolizers.⁶¹ Thus approximately 40% of patients in these racial/ethnic groups can have increased sensitivity to side effects with drugs such as risperidone that are primarily metabolized through CYP2D6. Table 70–6 outlines the prominent metabolic pathways of selected antipsychotics.

Most antipsychotics have fairly long elimination half-lives, in the range of 20 to 40 hours, with the exception of quetiapine and ziprasidone, which have short half-lives.^{33,60} After dosage stabilization most antipsychotics can be dosed once daily. Although not systematically studied, brain receptor kinetics are different than peripheral kinetics, and it may be possible to dose these SGAs less often than their plasma kinetics would suggest. Among the SGAs, only clozapine has an established therapeutic range, with efficacy being associated with a clozapine plasma concentration greater than 250 to 350 ng/mL. A 12-hour postdose clozapine serum concentration of at least 250 ng/mL is recommended if the patient is receiving divided clozapine doses, or 350 ng/mL if the patient is being dosed once daily. Whether a potential maximum therapeutic clozapine serum concentration exists is unknown. It is likely not cost effective to routinely monitor clozapine serum concentrations in all patients. However, they should be monitored before exceeding 600 mg daily; in patients who develop unusual or severe adverse side effects; in patients who are taking concomitant medications that can cause drug interactions; in patients who have age or pathophysiologic changes suggesting a change in pharmacokinetics; or for assessment of patient adherence.^{39,40,60}

TABLE 70-6 Pharmacokinetic Parameters of Selected Antipsychotics

Drug	Bioavailability (%)	Half-Life (h)	Major Metabolic Pathways	Active Metabolites
Selected first-generation antipsychotics (FGAs)				
Chlorpromazine	10–30	8–35	FMO3, CYP3A4	7-hydroxy, others
Fluphenazine	20–50	14–24	CYP2D6	?
Fluphenazine decanoate		14.2 ± 2.2 ^d days		
Haloperidol	40–70	12–36	CYP1A2, CYP2D6, CYP3A4	Reduced haloperidol
Haloperidol decanoate		21 days		
Perphenazine	20–25	8.1–12.3	CYP2D6	7-OH-perphenazine
Second-generation antipsychotics (SGAs)				
Aripiprazole	87	48–68	CYP3A4, CYP2D6	Dehydroaripiprazole
Clozapine	12–81	11–105	CYP1A2, CYP3A4, CYP2C19	Desmethylclozapine
Olanzapine	80	20–70	CYP1A2, CYP3A4, FMO3	N-glucuronide; 2-OH-methyl; 4-N-oxide
Paliperidone ER	28	23	Renal unchanged (59%) Multiple pathways	None known
Quetiapine	9 ± 4	6.88	CYP3A4	7-OH-quetiapine
Risperidone	68	3–24	CYP2D6	9-OH-risperidone
Risperidone Consta [®]		3–6 days	CYP2D6	9-OH-risperidone
Ziprasidone	59	4–10	Aldehyde oxidase, CYP3A4	None

^aBased on multiple dose data. Single dose data indicate a β -half-life of 6–10 days.

EPS, extrapyramidal side effects; Relative side-effect risk: ±, negligible; +, low; ++, moderate; +++, moderately high; +++++, high.

^aSide effects shown are relative risk based on doses within the recommended therapeutic range.

^bIndividual patient risk varies depending on patient-specific factors.

Long-acting risperidone is a suspension of drug in glycolic acid-lactate copolymer microspheres.⁴¹ After IM injection the polymer is slowly hydrolyzed, and significant risperidone begins being released after about 3 weeks. The apparent β -phase half-life is 3 to 6 days.⁴¹ With dosing every 2 weeks, steady-state risperidone concentrations are achieved after approximately 2 months. The depot FGAs fluphenazine decanoate (also available in an enanthate salt) and haloperidol decanoate are esterified drugs formulated in sesame seed oil for deep intramuscular injection. Their absorption from the muscle and metabolism to the free base is sufficiently slow to cause absorption to be the rate-limiting step in determining their respective apparent half-lives.⁴²

ADVERSE EFFECTS

Table 70–7 presents the relative incidence of common categories of antipsychotic side effects. Side effects are discussed below with respect to organ system affected. A general approach to monitoring and assessing side effects requires prospective monitoring by clinicians, preferably using a thorough review of systems approach. Patient-oriented self-rated side-effect scales can be helpful, as many patients with schizophrenia do not readily complain of side effects.

With the variety of antipsychotics currently available, using an alternative drug should be considered in patients who complain of poorly tolerated side effects. Because medication side effects are one of the primary predictors of patient nonadherence, the clinician should take advantage of the treatment options currently available in an attempt to improve patient outcomes. As new antipsychotics become available, side effects and risks associated with different drugs should be reevaluated. As we learn more about relative side-effect risks (e.g., weight gain, glucose intolerance, QTc prolongation, acute extrapyramidal side effects, and tardive dyskinesia), it will be necessary to regularly reconsider which antipsychotics should be considered first-line treatment alternatives.

Endocrine System

DA blockade in the tuberoinfundibular tract results in increased prolactin levels, because DA is the major prolactin-inhibiting factor. Galactorrhea can occur in up to 57% of women, and menstrual irregularities or amenorrhea in up to 97%. These effects can be dose related and are more common with the use of FGAs and risperidone. Gynecomastia and galactorrhea are reported in men as well. Tolerance does not appear to develop to these effects.⁶² Switching to the SGAs olanzapine, quetiapine, ziprasidone, or aripiprazole, which have no appreciable sustained effect on prolactin, is the most reasonable treatment option.

Weight gain is frequently reported in both adults and children receiving antipsychotics.^{63,64} Although the exact mechanism is uncertain, weight gain has been associated with antihistaminic effects, antimuscarinic effects, and blockade of 5-HT_{2C} receptors. However, dietary factors and activity levels can play a significant role in this population, as does renourishment after a period of poor self-care. In particular, significant weight gain, as defined by greater than or equal to 7% of the baseline body weight, is associated with clozapine and olanzapine therapy in 40% or more of patients.^{63,65} Ziprasidone and aripiprazole both have been associated with minimal weight gain.

The clinical significance of weight gain during antipsychotic therapy is substantial. The risk of cardiovascular-related mortality is higher in individuals with schizophrenia,^{66,67} and this is further aggravated by drug-related weight gain and the high prevalence of smoking.⁶⁸ Additionally, obesity is a risk factor for diabetes mellitus.⁶⁹ Weight gain during treatment is a major reason for poor patient medication adherence, and patients commonly report weight gain as being a concern.⁷⁰

A number of pharmacologic interventions have been attempted for antipsychotic-related weight gain, but in general these should be discouraged. Switching patients to antipsychotics less likely to cause weight gain, dietary restriction, exercise, and behavior modification programs are reported to be successful in small short-term studies.⁷¹ An American Diabetes Association consensus task force recommends consideration of a change in antipsychotic if a patient gains more than 5% of baseline body weight after starting the drug.⁷²

Schizophrenic patients have a higher prevalence of type II diabetes than the nonschizophrenic population. Beyond this, antipsychotics may adversely affect glucose levels in diabetic patients. The extent to which these effects are related to drug-induced weight increase is unclear.^{65,73} Data collected from the FDA MedWatch Drug Surveillance System for clozapine, olanzapine, quetiapine, and risperidone indicate that nearly 60% of the new-onset diabetes reported occurred within the first 6 months of treatment initiation.^{74,75} New-onset diabetes has been reported during treatment with risperidone, olanzapine, quetiapine, and ziprasidone; aripiprazole has limited case reports linking its association with diabetes.^{76,77} Although data are conflicting, evidence suggests a greater risk for the development of diabetes with clozapine and olanzapine.⁷⁵ In March 2004 the FDA issued a safety alert requiring revisions in the labeling of all SGAs, that describes the increased risk of diabetes mellitus in patients taking atypical antipsychotics.⁷⁸ Given the public health significance of diabetes, clarifying the diabetogenic effect of SGAs is a major focus of current research. Moreover, designing care models and standards for managing diabetes in patients with schizophrenia is another major consideration.

CLINICAL CONTROVERSY

The relative role of individual SGAs in precipitating diabetes mellitus is controversial. Clinicians are increasingly concerned about the escalating number of new cases of diabetes mellitus being reported in patients taking SGAs. It is clear, however, that obesity is associated with an increased risk of type II diabetes mellitus; olanzapine and clozapine cause more weight gain than other SGAs.

Cardiovascular System

Orthostatic Hypotension Postural or orthostatic hypotension, defined as a greater than 20-mm Hg drop in systolic pressure, is caused by α -adrenergic blockade.⁷⁹ Associated with lower potency FGAs and SGAs (especially on intramuscular or intravenous administration), orthostatic hypotension can occur in any patient, but diabetic patients with preexisting cardiovascular disease and the elderly seem particularly predisposed. Patient education should address slow changes in posture to allow for adaptation. For most patients, tolerance to this effect occurs within 2 to 3 months. If tolerance does not occur, lower doses or a change to an antipsychotic with less α -blockade can be attempted.

Electrocardiographic Changes Among the antipsychotics, thioridazine, clozapine, and ziprasidone are most likely to cause electrocardiogram (ECG) changes. ECG changes include increased heart rate (through sinus tachycardia from anticholinergic effects, or reflex tachycardia from α -adrenergic blockade), flattened T waves, ST segment depression, and prolongation of QT and PR intervals. The most clinically important of these potential changes is prolongation of the QTc, which has been associated with ventricular arrhythmias, including torsades de pointes syndrome. Thioridazine has been shown to prolong the QTc on average approximately 20 milliseconds (msec) longer than haloperidol, risperidone, olanzapine, or quetiapine.⁶⁵ Thioridazine's effects on QTc prolongation is dose related, and has led to a black box warning in the FDA-approved product labeling. In the same study, ziprasidone prolonged the QTc approximately 10 msec longer than about one-half of the effect of thioridazine.⁶⁵ Widespread clinical use suggests that ziprasidone's effects on the ECG are not associated with clinical sequelae, unless the patient has baseline risk factors.⁶⁵ Although the precise point at which QTc prolongation becomes clinically dangerous is unclear, it has been recommended to discontinue a medication associated with QTc prolongation if the interval consistently exceeds 500 msec.

Greater caution regarding antipsychotic choice and use is necessary in the elderly, in patients with preexisting cardiac or cerebrovascular disease, and in patients taking diuretics or medications that may prolong the QTc.⁶⁵ In patients older than 50 years of age, a pretreatment ECG is recommended, as are baseline serum potassium and magnesium levels. These factors should be considered in antipsychotic selection.

Lipid Changes

Treatment with at least some SGAs and phenothiazines appears associated with elevations in serum triglycerides and cholesterol. Among the SGAs, less risk for change in serum lipid or cholesterol levels can occur with risperidone, ziprasidone, or aripiprazole.⁶⁷ In the CATIE trial, olanzapine was associated with greater and significant adverse effects on metabolic parameters, including lipids, blood glucose, and body weight versus the other study treatments, but these differences in tolerability did not affect discontinuation rates.⁸⁰

The occurrence of weight gain, diabetes, and lipid abnormalities during antipsychotic therapy is consistent with the development of metabolic syndrome (i.e., syndrome X). Metabolic syndrome con-

sists of raised triglycerides (greater than or equal to 150 mg/dL), low HDL cholesterol (less than or equal to 40 mg/dL for males, less than or equal to 50 mg/dL for females), elevated fasting glucose (greater than or equal to 100 mg/dL), blood pressure elevation (greater than or equal to 130/85 mm Hg), and weight gain (abdominal circumference greater than 102 cm [40 in] for males, greater than 88 cm [34 in] in females).⁶⁷ These abnormalities dictate an important role for general health screening and monitoring in patients with schizophrenia, and prompt intervention when such abnormalities occur. The propensity of individual antipsychotics to produce metabolic disturbances should be considered in the context of individual patient risk factors at the time of drug selection.

Autonomic Nervous System

Patients receiving antipsychotics, or antipsychotics in combination with anticholinergics, can experience anticholinergic side effects (e.g., dry mouth, constipation, tachycardia, blurred vision, inhibition or impairment of ejaculation, urinary retention, or impaired memory). This is particularly so with low-potency FGAs, and the elderly are especially sensitive to these effects. Of the SGAs, clozapine and olanzapine have moderately high rates of causing anticholinergic effects. Constipation, caused by slowed peristaltic movement and decreased intestinal fluid content, should be closely monitored and treated, especially in the elderly. Paralytic ileus and necrotizing enterocolitis can also occur.

Central Nervous System

Extrapyramidal System

Dystonia. Dystonia is a state of abnormal tonicity, sometimes described simplistically as a severe "muscle spasm."⁸¹ More accurately, they are prolonged tonic contractions, with a rapid onset, usually within 24 to 96 hours of dosage initiation or dosage increase. They can be life-threatening, as in the case of pharyngeal-laryngeal dystonias, and can contribute to patient nonadherence. Types of dystonic reactions include trismus, glossospasm, tongue protrusion, pharyngeal-laryngeal dystonia, blepharospasm, oculogyric crisis, torticollis, and retrocollis. Dystonic reactions occur primarily with FGAs. Risk factors include younger patients (especially males), the use of high-potency agents, and high dosage. The overall incidence from the 1960s through the mid-1970s ranged from 2.3% to 10%, but as higher-potency traditional antipsychotics became more widely used, the rate increased to as high as 64%.

Intramuscular or intravenous anticholinergics (Table 70–8) or benzodiazepines are the treatments of choice for dystonia. Benzotropine mesylate 2 mg or diphenhydramine 50 mg can be given intramuscularly or intravenously. Diazepam 5 to 10 mg by slow IV push or lorazepam 1 to 2 mg intramuscularly are treatment alternatives. Relief is typically seen within 15 to 20 minutes of an intramuscular injection and within 5 minutes of intravenous administration. The antipsychotic can be continued, with concomitant short-term use of oral anticholinergic agents. In general, prophylactic anticholinergic medications are not recommended routinely with all FGAs. However, prophylaxis is reasonable when using high-potency FGAs (e.g., haloperidol or fluphenazine) in young men, and in patients with a history of dystonia.⁸¹ Dystonias can also be minimized by the use of lower initial FGA doses. Anticholinergics are good choices for prophylaxis, whereas amantadine has not been proved effective for this purpose. The risk of dystonia is greatly reduced with SGAs.

Akathisia. Akathisia is defined as the inability to sit still and as being functionally motor restless. The most accurate diagnosis is made by combining subjective complaints with objective symptoms (pacing, shifting, shuffling, or tapping feet). Subjectively, patients may describe a feeling of inner restlessness or disquiet or a compulsion to move or remain in constant motion. Akathisia occurs in

TABLE 70-8 Agents Used to Treat Extrapyramidal Side Effects

Generic Name	Equivalent Dose (mg)	Daily Dosage Range (mg)
Antimuscarinics

NA, not applicable

^aInjectable dosage form can be given intramuscularly for relief of acute dystonia.^bDosage can be titrated to 12 mg/day with careful monitoring; nonlinear pharmacokinetics have been demonstrated.

20% to 40% of patients treated with high-potency FGAs.⁸¹ Akathisia is frequently accompanied by dysphoria.

Treatment with anticholinergic agents, usually considered the standard treatment for acute extrapyramidal side effects, is disappointing for akathisia, but can be helpful in patients with concomitant pseudoparkinsonism.⁸¹ Traditionally, reduction in antipsychotic dosage has been considered the best intervention; however, this might not be a realistic goal in an acutely psychotic patient. A logical alternative is to switch to an antipsychotic with a lower risk of akathisia, or an antipsychotic previously used in the patient without adverse effect. Akathisia can occasionally occur with SGAs. Quetiapine and clozapine appear to have the lowest risk of producing akathisia.³⁹

Benzodiazepines have been used for treatment of akathisia, but the high prevalence of co-occurring substance abuse in schizophrenia discourages their prescribing.⁸¹ The β-blockers (e.g., propranolol in doses up to 160 mg daily, nadolol in doses up to 80 mg daily, and metoprolol in β₂-selective doses of 100 mg daily or less) are reported as effective.⁸¹

Pseudoparkinsonism. Pseudoparkinsonism, produced by D₂ blockade in the nigrostriatum, resembles idiopathic Parkinson disease. A patient with pseudoparkinsonism can present with any of four cardinal symptoms: (1) akinesia, bradykinesia, or decreased motor activity including difficulty initiating movement, as well as extreme slowness, mask-like facial expression, micrographia, slowed speech, and decreased arm swing; (2) tremor, known as pill-rolling type, that is predominant at rest and decreases with movement, usually involving the fingers and hands, although tremors can also be seen in the arms, legs, neck, head, and chin; (3) cogwheel rigidity, seen as the patient's limbs yielding in jerky, ratchet-like fashion when passively moved by the examiner (a mild form can present as stiffness); and (4) postural abnormalities and instability manifested as stooped posture, difficulty in maintaining stability when changing body position, and a gait that ranges from slow and shuffling to festinating. Fatigue and weakness can be noted, as well as oral abnormalities including dysphagia, dysarthria, and abnormal palmarmental and glabellar reflexes. The overall incidence of pseudoparkinsonism from FGAs ranges from 15.4% to 36%, depending on the drug and dose. Akinesia alone can be seen in 59% of patients on high-potency FGAs. Other risk factors include increasing age and possibly female gender. The onset of symptoms is typically 1 to 2 weeks after initiation of antipsychotic therapy or a dose increase.

The efficacy of anticholinergic medications in alleviating or attenuating symptoms of pseudoparkinsonism is well established.⁸¹ Benzotropine's long half-life allows once- to twice-daily dosing.

Typical dosing is 1 to 2 mg twice a day up to a usual maximum dosage of 8 mg daily, although some patients will continue to respond to doses up to 12 mg. Trihexyphenidyl (2 to 5 mg three times a day), diphenhydramine (25 to 50 mg three times a day), and biperiden (2 mg three times a day) usually require thrice-daily administration. Diphenhydramine produces more sedation than the other agents. All of the anticholinergics have been abused for their euphoriant effects.⁸² Symptoms typically begin to resolve within 3 to 4 days after initiation of treatment, but a minimum of at least 2 weeks of treatment is normally required for full response. Amantadine is generally as efficacious for pseudoparkinsonism as anticholinergics, with significantly less effect on memory function.⁸¹ The need for prophylactic use of these agents against pseudoparkinsonism is less convincing than with dystonias, and is unnecessary when using SGAs.⁸¹ The long-term treatment of pseudoparkinsonism with antiparkinsonism medication is somewhat controversial, and an attempt should be made to taper and discontinue these agents 6 weeks to 3 months after symptom resolution. If symptoms reappear, then switching to an SGA should be considered. The risk of pseudoparkinsonism with SGAs is extremely low. When risperidone is used in doses greater than 6 mg/day, the risk of pseudoparkinsonism symptoms approaches that with FGAs. Quetiapine, aripiprazole, or clozapine are reasonable alternatives in a patient experiencing extrapyramidal side effects with other SGAs.^{33,39,81}

Tardive Dyskinesia. Tardive dyskinesia is a syndrome characterized by abnormal involuntary movements occurring late in onset in relation to initiation of antipsychotic therapy. Tardive dyskinesia is sometimes irreversible and continues to be a controversial issue.

The classic description of tardive dyskinesia is the buccal-lingual-masticatory (BLM) syndrome, or orofacial movements. The onset of BLM movements is usually insidious. Typically, they are the first detectable signs of tardive dyskinesia and begin with mild forward, backward, or lateral movements of the tongue. As the disorder progresses, more obvious or frank BLM movements appear, including tongue thrusting, rolling, or fly-catching movements, and chewing or lateral jaw movements. Tardive dyskinesia symptoms can interfere with the patient's ability to chew, speak, or swallow. Further complications include oral ulcerations, inability to wear dentures, and inflammation and loosening of mandibular joints. Eating difficulties and malnutrition can be primary physical complications of tardive dyskinesia. Weight loss can be seen in patients with esophageal or respiratory manifestations but not in those with truncal movements. Facial movements include frequent blinking, brow arching, grimacing, upward deviation of the eyes, and lip smacking. Involvement of the extremities sometimes occurs, with the appearance of restless choreiform (irregular spasmodic) and distal athetosis (slow, writhing movement) of limbs including twisting, spreading, flexion (bending) and extension of fingers, toe tapping, and toe dorsiflexion (upward turning). Unusual posture, hyperextension, pelvic thrusting, axial hyperkinesia (excessive muscular activity of head and trunk), ballismus (jerking or shaking), exaggerated lordosis (bending backward), rocking, and swaying are occasionally observed. Among the more common differential diagnoses are withdrawal dyskinesias occurring after short-term use of antipsychotics, spontaneous orofacial dyskinesias in the elderly, orofacial dyskinesias in the edentulous, stereotypic movements in schizophrenics, Huntington disease, and congenital torsion dystonia. Orofacial movements are reported more commonly in older patients, whereas the truncal axial movements are classically reported in young adults. Movements can worsen with stress, decrease with sedation, and disappear during sleep. Concentration on motor tasks or attempts to suppress the movements voluntarily can actually increase them.

Early signs of tardive dyskinesia can be reversible but if allowed to persist or if not detected in the early stages, they can become irreversible, even with drug discontinuation. When the antipsychotic

dose is decreased or tapered and discontinued, worsening of abnormal movements can occur, followed by possible slow improvement after months or years if the patient remains on lower doses or discontinues treatment. No standardized diagnostic criteria for tardive dyskinesia are available. Abnormal involuntary movements can be detected early through physical assessment and the use of rating scales. Available rating scales include the Abnormal Involuntary Movements Scale (AIMS) and the Dyskinesia Identification System: Condensed User Scale (DISCUS).^{81,83} Neither scale is diagnostic in itself.

Risk factors include increasing age, the occurrence of acute extrapyramidal side effects, poor antipsychotic drug response, diagnosis of organic mental disorder, diabetes mellitus, mood disorders, and possibly female gender.^{84,85} Duration of antipsychotic therapy, daily dosage, and possibly total cumulative dosage are probably the most significant risk factors. Overall morbidity and mortality are greater in tardive dyskinesia patients.

With FGAs, the reported incidence of tardive dyskinesia ranges from 0.5% to 62%.⁸⁴ In a first episode of schizophrenia, the incidence is estimated at about 5% per year, with the overall prevalence ranging from 20% to 25% with long-term treatment. Among the elderly, the overall risk of tardive dyskinesia is higher.⁸⁵ Tardive dyskinesia is not always permanent, with remission of symptoms observed in 25% of patients after 5 years of continued treatment.^{81,84,85}

The risk of tardive dyskinesia with SGAs is significantly lower. A systematic review of 11 studies with SGAs lasting 1 year or more found an overall risk of tardive dyskinesia to be approximately 0.8% per year in nonelderly (<65 years) adults and 5.3% per year in the elderly (≥65 years). For individual agents, the annual incidence rates ranged from zero to 0.5% for olanzapine to 0.6% to 0.7% for risperidone or quetiapine. To date, there are no reports of tardive dyskinesia with clozapine monotherapy.

Prevention of tardive dyskinesia is important, as treatment of the movements once they occur is difficult. One of the more compelling arguments for the first-line use of SGAs is their lower risk of tardive dyskinesia.^{26,39,86} (see Fig. 70–1). Regular neurologic examinations (AIMS or other scales) should be performed at baseline and at least quarterly to assess for early signs of tardive dyskinesia. At the first signs of tardive dyskinesia, the need for continuing antipsychotic treatment should be reassessed. In such situations, if the patient is taking an FGA and continuing treatment is indicated, the medication should be switched to an SGA.

Numerous drugs have been used in an attempt to treat tardive dyskinesia, representing various strategies affecting CNS neurotransmission. In two controlled trials lasting 22 to 52 weeks, clozapine decreased abnormal involuntary movements.^{85,87} Switching antipsychotic therapy to clozapine is a favored first-line pharmacotherapeutic strategy, particularly in patients with moderate to severe dyskinesias.^{84,85,87}

Sedation and Cognition Sedation is as an antipsychotic side effect and not an indication of therapeutic effect. Chlorpromazine, thioridazine, mesoridazine, clozapine, olanzapine, and quetiapine are most frequently implicated. Administration of most or all of the daily dosage at bedtime (depending on the drug half-life) can decrease daytime sedation and in some patients eliminate the need for hypnotic agents. Sedation occurs early in treatment and can decrease over time.⁷⁹ Oversedation can play a large role in cognitive, perceptual, and motor dysfunction. However, positive effects of medication on cognition are seen with chronic administration, evidenced by improvements in tasks involving visual-motor skills, attention to task, and working memory. Compared with FGAs, several studies have shown cognitive benefits of SGAs. Comparative effects of different SGAs on cognition are as yet unclear, but available studies suggest that different SGAs can have effects on varying cognitive domains.⁸⁹ An algorithm-driven disease manage-

ment program using SGAs as first-line treatment was shown to improve cognition over a 9-month period.⁹⁰

Seizures An increased risk of drug-induced seizures occurs in all patients treated with antipsychotics. However, this risk is greater if the following predisposing factors are present: preexisting seizure disorder, history of drug-induced seizure, abnormal electroencephalogram (EEG), and preexisting CNS pathology or head trauma. Seizures are more closely associated with the use of higher doses, rapid dosage increases, and on initiation of treatment. When an isolated seizure occurs, a dosage decrease is first recommended; anticonvulsant therapy is not recommended. Although spontaneously occurring seizures have been reported with most antipsychotics, the highest potential risk for an antipsychotic-related seizure is with clozapine or chlorpromazine. If a change in antipsychotic therapy is required because of a drug-induced seizure, risperidone, molindone, thioridazine, haloperidol, pimozide, trifluoperazine, and fluphenazine are associated with the lowest potential.⁹¹

Thermoregulation Poikilothermia, the body temperature adjusting to the ambient temperature, can be a serious side effect of antipsychotic therapy in temperature extremes.⁹² Hyperpyrexia can be a danger in hot weather or during exercise. Inhibition of sweating, a result of anticholinergic properties impairing the peripheral mechanisms of heat dissipation, can also contribute to this problem, which in its severest form can lead to heat stroke. Hypothermia is also a risk, particularly in the elderly (≥65 years) and in cold climates. All patients receiving antipsychotics should be educated about these potential problems. Thermoregulatory problems are reportedly more common with the use of low-potency FGAs and can occur with the more anticholinergic SGAs.

Neuroleptic Malignant Syndrome Neuroleptic malignant syndrome (NMS) occurs in 0.5% to 1% of patients receiving FGAs. The rate of NMS has diminished since the introduction of SGAs, and reliable current estimates of the incidence with SGAs are not available. NMS can occur more frequently in patients receiving high-potency FGAs, injectable or depot FGAs, and in patients who are dehydrated, with physical exhaustion, or organic mental disorders. Although less common than with FGAs, NMS has been reported with SGAs, including clozapine. The onset of symptoms varies from early in treatment to months later. It develops rapidly, over the course of 24 to 72 hours. NMS can occur after antipsychotic discontinuation, especially when depot agents are used. Possible mechanisms of NMS include disruption of the central thermoregulatory process or excess production of heat secondary to skeletal muscle contractions. The differential diagnosis includes heat stroke, lethal catatonia, anesthetic-associated malignant hyperthermia, anticholinergic toxicity, and monoamine oxidase inhibitor drug interactions. Cardinal signs and symptoms of NMS are body temperature exceeding 38°C (100.4°F), altered level of consciousness, autonomic dysfunction (tachycardia, labile blood pressure, diaphoresis, tachypnea, or urinary or fecal incontinence), and rigidity. Laboratory evaluation, although considered nonspecific, frequently shows leukocytosis with or without a left shift, increases in creatine kinase (CK), aspartate aminotransferase, alanine aminotransferase, lactate dehydrogenase, and myoglobinuria.⁹³

Treatment should always begin with antipsychotic discontinuation and supportive care. In many cases that alone is effective. The role of adjunctive agents is unclear, yet they are often used in clinical settings. The DA agonist bromocriptine reduces rigidity, fever, or CK in up to 94% of patients, whereas the use of another DA agonist, amantadine, has been successfully used in up to 63% of patients. Dantrolene has been used as a skeletal muscle relaxant, with effects on temperature, heart rate, respiratory rate, and CK in up to 81% of patients.⁹³ Wide recognition and rapid antipsychotic discontinuation has drastically reduced mortality from 20% 15 years ago to 4% in the mid-1990s.

Many patients with schizophrenia, despite having had NMS, will require future antipsychotic pharmacotherapy. A review of antipsychotic rechallenges suggests that the risk of rechallenge is acceptable in most patients, provided that the patient is observed for an extended period of time (2 weeks or more is suggested) without antipsychotics, that there is careful monitoring and slow dose titration, and that the patient is maintained on the lowest possible dose.⁹³ Only SGAs should be used for rechallenge following an episode of NMS.

Psychiatric Side Effects Antipsychotic-induced akathisia, akinesia, and dysphoria can have unfortunate sequelae, resulting in what has been termed “behavioral toxicity.”⁹⁶ Akinesia, characterized by “diminished spontaneity,” results in symptoms of apathy and withdrawal, often mistaken for the negative symptoms of schizophrenia; these patients can actually appear depressed on formal evaluation.

Delirium and psychosis are reported with larger doses of FGAs or combinations of anticholinergics with FGAs. Chronic confusion and disorientation can occur in the elderly as a result of antipsychotic treatment.⁹⁴ Unfortunately, the link is not always made between initiation of antipsychotic therapy, and the patient can be misdiagnosed with an organic mental disorder. This clinical presentation, called a *pseudodementia*, is easily reversible on discontinuation of the antipsychotic.

Ophthalmologic Effects Anticholinergic effects of antipsychotics or concomitant antiparkinson medications can exacerbate narrow-angle (angle closure) glaucoma. Antipsychotics with low anticholinergic effects should be used in such individuals, and they should be appropriately monitored.⁹⁵

Opaque deposits in the cornea and lens occur with chronic phenothiazine treatment, most frequently with chlorpromazine. Although visual acuity is not usually affected, periodic slit-lamp ophthalmologic examinations are frequently recommended in patients receiving long-term treatment with phenothiazines.

Because of cataract development and lenticular changes in animals, baseline and periodic eye examinations are recommended in the product labeling for patients receiving quetiapine.⁹⁶ However, clinical use of quetiapine since its marketing has not shown a significant risk of cataracts.^{39,96} Retinitis pigmentosa can result from use of thioridazine doses greater than 800 mg daily. It is caused by melanin deposits and can result in permanent visual impairment or blindness. There is no evidence that it is a function of cumulative dose.⁹⁵

Hepatic System

Cholestatic hepatocanalicular jaundice has been reported in up to 2% of patients receiving phenothiazines. Additionally, liver function test (LFT) abnormalities (elevated aminotransferases and alkaline phosphatase), often asymptomatic, were reported in up to 50% of patients.⁹⁷ If aminotransferases are greater than three times the upper limit of normal, antipsychotic therapy should be changed to a chemically unrelated antipsychotic.

Overall, LFT abnormalities are uncommon with SGAs. However, cholestatic hepatitis has been reported with risperidone,⁹⁸ and LFT abnormalities, mostly transient, have been reported with olanzapine and clozapine.⁹⁹

Genitourinary System

Urinary hesitancy and retention is reported with low-potency FGAs and with clozapine. Anticholinergic effects cause smooth muscle slowing and paralyze the detrusor muscle of the bladder, requiring greater urine volume to evoke muscle contraction. Men with benign prostatic hypertrophy are especially prone to this effect.⁹⁴

Urinary incontinence is thought to be caused by α -blockade, and among the SGAs, it appears to be particularly problematic with

clozapine. The incidence has been reported to be as high as 44%, and it can be persistent in 25% of patients.¹⁰⁰

Numerous different mechanisms have been suggested to cause sexual dysfunction, including dopaminergic blockade, hyperprolactinemia, histaminergic blockade (sedation), anticholinergic effects, and α -adrenergic blockade. This area is inadequately studied, and multiple mechanisms are likely responsible for producing sexual dysfunction. Unmedicated individuals with schizophrenia report decreased libido. Most but not all studies have shown a relationship between hyperprolactinemia and sexual dysfunction, including decreased libido, erectile dysfunction, difficulty achieving orgasm, and ejaculatory abnormalities. Although risperidone produces at least as much sexual dysfunction as FGAs, other SGAs, which have weak effects on prolactin or are “prolactin-sparing,” produce less sexual dysfunction. It is unclear whether hyperprolactinemia directly impairs sexual functioning, reflects high dopaminergic blockade from risperidone and FGAs, or is associated with other mechanisms of producing sexual dysfunction. Patients experiencing sexual dysfunction with FGAs or risperidone should be switched to an SGA with less effect on prolactin.¹⁰¹

Hematologic System

Transient leukopenia can occur during initial treatment with antipsychotics; however, it typically does not progress to clinically significant parameters.¹⁰² If the WBC count is less than 3,000 mm³, or if the absolute neutrophil count (ANC) is less than 1,000 mm³, the antipsychotic should be discontinued, and the WBC monitored closely until it returns to normal. Agranulocytosis reportedly occurs in 0.01% of patients receiving FGAs, and more frequently with chlorpromazine and thioridazine. The onset is usually within the first 8 weeks of therapy. Agranulocytosis can initially manifest clinically as a local infection, with sore throat, leukoplakia, erythema, and ulcerations of the pharynx. These symptoms in any patient receiving antipsychotics should signal the immediate need for a WBC count. If either the WBC count or ANC falls below these parameters, the drug should be discontinued immediately and the patient monitored closely for the development of secondary infections. Isolated rare cases of thrombocytopenia and eosinophilia have been reported.

Agranulocytosis with clozapine significantly limits the clinical usefulness of this agent. Data on the incidence since the release of clozapine in February 1990 following stringent monitoring guidelines reveal that the 1-year treatment risk of developing agranulocytosis with clozapine is approximately 0.8%, and the 18-month risk is 0.91%.¹⁰³ Increasing age and female gender are associated with greater risk. Based on available data, the time period for greatest risk appears to be between months 1 and 6 of treatment, and weekly WBC monitoring for the first 6 months of therapy is mandated in the FDA-approved product labeling. After the first 6 months, the labeling allows the frequency of WBC monitoring to be decreased to every 2 weeks for months 7 through 12 after which it can be decreased to monthly if all WBCs are normal. If the total WBC count drops to less than 2,000 mm³, or the ANC is less than 1,000 mm³, clozapine should be discontinued and the patient monitored closely. Some clinicians have used the granulocyte colony-stimulating factor filgrastim with hopes of improving the outcome by hastening resolution or decreasing morbidity. In cases of mild to moderate neutropenia (granulocytes between 2,000 mm³ and 3,000 mm³, or ANC between 1,000 mm³ and 500 mm³), which occurs in up to 2% of patients, clozapine should be discontinued with daily monitoring of complete blood counts until values return to normal.

Dermatologic System

Allergic reactions are rare and usually occur within 8 weeks of initiating therapy, manifesting as maculopapular, erythematous, prur-

ritic rashes that are evident on the face, neck, trunk, or extremities. Drug discontinuation and topical steroids are recommended. Contact dermatitis, including the oral mucosa, can occur in patients or medical personnel. For patients, mixing the antipsychotic concentrate in a sufficient quantity of a nonacidic liquid and swallowing it quickly decreases problems in susceptible patients. Care should be taken in the handling and preparation of liquid FGAs.

Phenothiazine structures can absorb ultraviolet light and energy, resulting in the formation of free radicals, which can have damaging effects on the skin. Both SGAs and FGAs cause photosensitivity. Erythema and severe sunburns can occur. Exposure to sunlight should be limited, and patients should be educated about the use of a maximally blocking sunscreen, hats, protective clothing, and sunglasses.¹⁰⁴

Blue-gray or purplish skin coloration in areas exposed to sunlight occurs in patients receiving higher doses of low-potency phenothiazines during long-term administration, especially with chlorpromazine. It commonly occurs with concurrent corneal or lens pigmentation.

Miscellaneous Adverse Effects

A particularly curious and sometimes troubling side effect with clozapine is sialorrhea, which can occur in up to 54% of patients taking clozapine. The mechanism of clozapine-induced drooling is unclear, although α -adrenergic blockade and muscarinic₄ receptor agonist have been suggested as potential etiologies. α -Agonists such as clonidine and antimuscarinics such as benztropine have been suggested as potential treatments.¹⁰⁵

TOXICITY WITH OVERDOSE

Acute overdose with antipsychotics rarely results in serious symptomatology. Mild intoxication manifests as sedation, hypotension, and miosis, whereas with severe intoxication, agitation and delirium can typically progress to motor retardation, seizures, cardiac arrhythmias, respiratory arrest, and coma. Dystonias and pseudoparkinsonism symptoms also occur. Supportive measures, gastric lavage, and activated charcoal are recommended. Induction of emesis can be difficult because of effects on the chemoreceptor trigger zone, and dialysis is ineffective because of the degree of drug-protein binding. Phenytoin or sodium bicarbonate are useful in the treatment of quinidine-like cardiac conduction effects on the QRS or QTc. Physostigmine is not generally recommended to reverse anticholinergic toxicity because of deleterious effects on arrhythmias and seizure threshold.¹⁰⁶

USE IN PREGNANCY AND LACTATION

Minimal data exist regarding the effects of pregnancy on schizophrenia. However, the disorganized thought processes, impaired cognition, and negative symptoms can have a detrimental effect on the functioning and self-care of the mother, and therefore adversely affect the fetus.¹⁰⁷ Currently available data assessing the risk of teratogenesis with antipsychotic agents are insufficient. Epidemiologic studies show a slightly increased risk of birth defects with low-potency FGAs. Haloperidol is the best studied of all antipsychotics, and no relationship between its use and teratogenicity has been found. SGAs have been inadequately studied. However, concern has been expressed regarding the use of clozapine in pregnancy.¹⁰⁸ The weight gain associated with olanzapine and clozapine and potential risk of gestational diabetes should be considered in drug selection.

The risk of antipsychotic use must be weighed against the benefits of pharmacotherapy in pregnant women who may be experiencing disorganized thoughts, delusions about change in body image or pregnancy, or who are unable to provide adequate prenatal care.¹⁰⁷

Antipsychotics appear in breast milk with milk-to-plasma ratios of 0.5 to 1. However, 1 week after delivery, clozapine milk concentrations have been found to be as much as 279% of serum concentrations. Its use during breast-feeding is not recommended.¹⁰⁸ Overall,

little is known about breast-feeding and the potential effects of antipsychotics on the neonate. Although not contraindicated, the lowest dosage should be used in the mother, and the infant should be carefully monitored.

DRUG INTERACTIONS

Most drug interactions occur because of pharmacodynamic or pharmacokinetic interactions. Common examples of pharmacodynamic interactions resulting in enhanced effect include the excess sedation that can occur when antipsychotics are used concomitantly with other medications that have sedative side effects. Additive antimuscarinic effects of antipsychotics used with other medications with antimuscarinic effects can result in urinary retention, constipation, blurred vision, or other anticholinergic side effects.^{36,65} Both combined sedative and anticholinergic effects from multiple medications can result in impaired cognition, particularly in the elderly and other patients predisposed to such problems.⁶⁵ Patients can be more likely to experience symptomatic orthostatic hypotension when an antipsychotic is used with other medications that cause orthostasis. Although metoclopramide is prescribed for treating esophageal reflux, it is a DA antagonist, and patients are more likely to experience akathisia and other extrapyramidal side effects if it is used concomitantly with antipsychotics.⁶⁵ Although some SSRIs can interact with antipsychotics through enzyme inhibition, they can also interact through pharmacodynamic mechanisms. 5-HT₂ receptors are present on the presynaptic dopaminergic neuron, and their activation leads to decreased dopamine release from the presynaptic terminal. Increased availability of serotonin through SSRI effect can activate these receptors, decrease dopamine release, and add to the dopaminolytic effects of antipsychotic agents.⁶⁵ Thus in the absence of enzyme inhibition, SSRIs can still precipitate akathisia or extrapyramidal side effects when added to a patient stabilized on an antipsychotic medication. A potentially more dangerous interaction can occur when medications that slow myocardial conduction and thus prolong the QTc, are used in combination with antipsychotics that significantly prolong the QTc.^{65,109} Medications that prolong the QTc should also be monitored carefully in patients taking concomitant diuretics.⁶⁵ These effects can all increase the risk of clinically significant side effects.

Although atypical antipsychotics can be affected to varying degrees by enzyme inhibitors and inducers, none of the available atypical antipsychotics have been shown to significantly affect the pharmacokinetics of other medications. Table 70–6 lists the major pathways thought to be involved in the metabolism of SGAs. Risperidone is metabolized primarily by CYP2D6 to its active metabolite, 9-OH-risperidone (paliperidone), which is thought to have a similar pharmacodynamic profile.^{60,65} After single-dose administration, the mean bioavailability of quetiapine is 9% with significant interindividual variation.^{110, 111}

Based on current information, inhibitors of CYP1A2 have the greatest potential for causing interactions with clozapine and olanzapine.¹¹⁰ Examples include cimetidine, fluvoxamine, and fluoroquinolone antibiotics (e.g., ciprofloxacin) to varying degrees. To date, however, no serious inhibition interactions have been reported with olanzapine, which can be a result of olanzapine's wide therapeutic index. Carbamazepine has been reported to increase olanzapine elimination by as much as 50%.¹¹² Cigarette smoking is a potent inducer of CYP1A2, and one would expect lower mean olanzapine serum concentrations in smokers compared to nonsmokers.

Because of the risk of seizures with higher clozapine tissue concentrations, inhibition interactions with clozapine are potentially significant. In particular, fluvoxamine has been reported to increase clozapine serum concentrations by an average of two- to threefold and up to fivefold.^{110,112} Fluoxetine and erythromycin can increase clozapine serum concentrations in some patients but to a lesser degree.^{110,112} Mean clozapine serum concentrations are reported to be

32% lower in smokers compared with nonsmokers.¹¹² Carbamazepine can also induce clozapine metabolism and lead to lower serum concentrations.¹¹²

A study with the potent CYP3A4 inhibitor ketoconazole showed minimal effects on ziprasidone single-dose pharmacokinetics, with only a 33% mean increase in the ziprasidone area under the time-versus-concentration curve.⁶⁵ These results are consistent with data suggesting that aldehyde oxidase is the major metabolic pathway for ziprasidone, with only 30% to 35% being metabolized by CYP3A4.¹¹³

Modest elevations of aripiprazole serum concentration occur in the presence of ketoconazole or quinidine, which inhibit CYP2D6 and 3A4, respectively. Carbamazepine has been reported to decrease aripiprazole serum concentrations.^{33,110} Recently, an FDA-approved gene chip analysis became available for evaluating metabolism through several P450 enzymes. The clinical usefulness of this technology in routine psychiatric pharmacotherapy is as yet unclear. Table 70–9 summarizes potential antipsychotic drug interactions.

■ PHARMACOECONOMIC CONSIDERATIONS

It is estimated that approximately 80% of individuals suffering their first schizophrenic break will have recurrent episodes and significant lifetime psychosocial dysfunction. In 1994, the direct cost of treating schizophrenia in the United States was estimated to be \$45 billion.¹¹³ The public mental healthcare sector provides the majority of services for individuals with schizophrenia. Mental healthcare costs for schizophrenia represent disproportionate expenditures for crisis intervention and hospitalization as compared to comprehen-

sive outpatient services oriented toward maintaining remission and improving psychosocial functioning. The suboptimal or inadequate funding provided for efficient ambulatory mental health services further increases the demand for hospitalization, which diverts additional revenues that might be available for outpatient services. This has created a vicious revolving door cycle and is a major challenge facing public mental healthcare.

The advent of more expensive SGAs, accompanied by limited resources, has forced mental healthcare organizations to examine the outcomes and related economics of treating patients with the SGAs compared with the traditional, largely generic FGAs. Retrospective database studies have yielded conflicting results regarding the pharmacoeconomics of SGAs versus FGAs.¹¹⁴ In the prospective effectiveness study, CATIE, differences in mental health costs between SGAs and the FGA perphenazine were driven by the higher acquisition costs of the SGAs.¹¹⁵ Some studies have shown clozapine to result in lower overall mental healthcare costs, while others have shown no difference in costs compared to FGAs. Additionally, clozapine decreases suicidality more than comparator antipsychotics, and it is more effective in treatment-resistant schizophrenia.^{116,117}

Significant differences in acquisition costs among the SGAs have produced controversy regarding formulary decisions in organized healthcare settings.¹¹⁴ For example, although olanzapine has a higher acquisition cost, some studies have found no difference in total mental healthcare direct costs (i.e., medications plus services) when comparing olanzapine and risperidone.^{114,118} However, these findings are inconsistent, and the comparative pharmacoeconomics of SGAs remain controversial.^{114,115}

TABLE 70-9 Common Potential Drug Interactions with Antipsychotic Medications

Pharmacokinetic Drug Interactions with Antipsychotics		
Mechanism of Interaction	Interacting Drugs or Other Substances	Clinical Effect
Muscarinic receptor blockade	Anticholinergics Benztropine Diphenhydramine Trihexyphenidyl	↑ anticholinergic SE Blurred vision Constipation Impaired cognition Urinary retention
Additive or synergistic sedation	Sedatives Benzodiazepines Concomitant AP Diphenhydramine Melatonin and melatonin agonists Mirtazapine Trazodone TCAs Zaleplon Zolpidem Anticholinergics Benztropine Diphenhydramine Trihexyphenidyl Mirtazapine Metoclopramide	↑ sedation Lethargy Impaired cognition Impaired psychomotor activity ↑ risk of accidents
DA antagonist use for different indication		↑ EPS
Cardiovascular Interactions		
Additive effects on QTc	TCA Antidepressants Amitriptyline Clomipramine Imipramine	Antiarrhythmics Procainamide Quinidine
Electrolyte changes	Diuretics	↑ risk of ECG changes and dysrhythmias
Stimulation of presynaptic 5-HT receptors on DA neuron	SSRIs	↑ EPS
Sympatholytics: α blockade—↓ NE release	Clonidine Methyldopa Prazosin	↑ hypotension
↑ DA receptor binding	Antipsychotics	↑ SEs - particularly EPS

Perphenazine and Risperidone				
Note: Because risperidone's metabolite formed through CYP2D6 metabolism is active (paliperidone), the clinical significance of metabolic drug interactions with risperidone is undetermined.				
Inhibition of AP metabolis (CYP2D6)	Antidepressants	Miscellaneous		↑ AP effect
	Bupropion	Chlorpheniramine		↑ SE
	Duloxetine	Quinidine		
	Fluoxetine	Diphenhydramine		
	Paroxetine	Cimetidine		
Induction of AP metabolism		Haloperidol		
		Hydroxyzine		
		Quinidine		
	Dexamethasone			↓ AP effect
	Rifampin			
Ziprasidone				
The bioavailability of ziprasidone is increased twofold when it is taken with food. Consistent administration with food is recommended.				

AP, antipsychotic; DA, dopamine; EPS, extrapyramidal symptoms; 5-HT, serotonin; SE, side effect; SSRI, serotonin selective reuptake inhibitor; TCAs, tricyclic antidepressants. The assistance of Jessica Wu, PharmD in preparing this table is acknowledged.

EVALUATION OF THERAPEUTIC OUTCOMES

Assessment of response has traditionally been done subjectively or empirically (a relative sense of how the clinician feels the patient is doing). A formal mental status examination (MSE) is used to structure the patient interview and focus on items related to appearance, mood, sensorium, intellectual functioning, and thought processes. However, the MSE is not specific for the measurement of drug response. ¹⁰ Clinicians should be trained to use simple, standardized psychiatric rating scales to assist in objectively

rating patient drug responses.^{39,119} The Brief Psychiatric Rating Scale (BPRS) and the Positive and Negative Symptom Scale (PANSS) were developed for use in clinical trials as research tools to quantify symptoms and improvement seen with antipsychotic treatment.¹¹⁹ Objectively, the use of a numeric indicator (e.g., 20%, 30%, or 40% reduction in BPRS score) has been used to quantify overall symptom reduction and classify patients according to different degrees of response. However, these types of rating scales are too long and unwieldy to be routinely used within the time constraints of most clinical practices. Symptom scales used in clinical practice

TABLE 70-10 Brief Clinical Assessments for Monitoring Antipsychotic Response in Schizophrenia**4-Item Positive Symptom Rating Scale (PSRS)**

Use each item's anchor points to rate the patient.

1. Suspiciousness	NA ^a	1	2	3	4	5	6	7
2. Unusual thought content	NA	1	2	3	4	5	6	7
3. Hallucinations	NA	1	2	3	4	5	6	7
4. Conceptual disorganization	NA	1	2	3	4	5	6	7

Each item is scored from 1 (not present) to 7 (extremely severe)

SCORE: _____

Brief Negative Symptom Assessment (BNSA)

Use each item's anchor points to rate the patient.

1. Prolonged time to respond	1	2	3	4	5	6
2. Emotion: Unchanging facial expression, blank, expressionless face	1	2	3	4	5	6
3. Reduced social drive	1	2	3	4	5	6
4. Poor grooming and hygiene	1	2	3	4	5	6

Each item is scored from 1 (normal) to 6 (severe)

SCORE: _____

^aNA, not able to be assessed

To enhance consistency in ratings, the structured probes in the Administration Manual should be used each time the scales are used. The complete Administration Manual for the PSRS and the BNSA can be accessed from the appendices in the TIMA Procedure Manual: Schizophrenia Module at <http://www.mhmr.state.tx.us/centraloffice/medicaldirector/timasczman.pdf>.

This rating scale and the administration manual were created for the State of Texas, and they are in the public domain. They can be used with appropriate referencing and credit to the authors and the Texas Department of State Health Services.

Data from Miller et al.^{39,119}

must be sufficiently brief to be used during an ordinary clinic visit (e.g., 15 to 30 minutes) while measuring both positive and negative symptoms, and being sufficiently representative of overall symptomatology. The four-item Positive Symptom Rating Scale and the Brief Negative Symptom Assessment are brief scales that meet such criteria (Table 70-10).^{39,119} It is increasingly recognized that clinicians should be examining cognition as an outcome in treatment of schizophrenia. However, a brief cognition battery has recently been developed and validated, and it can be completed in 15 to 20 minutes.¹²⁰

Similarly, the pharmacotherapeutic plan should include specific monitoring parameters for potential side effects. The plan should include how the potential side effect will be evaluated, and the frequency of assessment (e.g., daily or weekly). Given the risk of weight gain, diabetes, and lipid abnormalities associated with many of the SGAs, a consensus task force led by the American Diabetes Association recommends the following baseline parameters before beginning antipsychotics: family history, weight, height, body mass index, waist circumference, blood pressure, fasting plasma glucose, and fasting lipid profile.⁷² They also recommend followup monitoring of these parameters after beginning or changing SGAs. Weight should be monitored monthly for the first 3 months, and quarterly thereafter. The other parameters should be assessed at the end of 3 months and then annually. If normal, serum lipids can be monitored less often. Self-assessments can be a useful adjunct in treating the patient. Although the patient with schizophrenia may not always be accurate in evaluating symptom severity, the use of patient self-assessments increases patient engagement in care, enhances therapeutic alliance, and gives the clinician an opportunity to identify misconceptions the patient can have regarding symptoms associated with the illness, medication side effects, and the like.^{46,119} Traditionally, clinicians have often accepted partial symptom response in schizophrenia as success, and have not been aggressive in attempting to achieve greater symptomatic remission. The advent of multiple different SGAs with varying, but overall favorable, side-effect profiles should encourage clinicians to be more assertive in attempting to achieve symptom remission. This is also consistent with an increasing focus on remission as a goal of treatment and evolving recovery movements with an increasing emphasis on consumerism in the care of the severely mentally ill.^{24,25}

CONCLUSIONS

Schizophrenia is a complex disease with multiple ramifications for patients and their families. Treatment issues remain clouded by the

fact that the etiology of the illness is unknown. It is clear, however, that no single treatment modality is adequate to properly manage a patient with schizophrenia. Antipsychotics are the bedrock of treatment. SGAs have substantially advanced the care of people with schizophrenia. However, notwithstanding such advances, the SGAs are not a panacea and have multiple adverse effects in addition to the limitations of their efficacy. However, when used within the context of multidisciplinary treatment, SGAs improve positive and negative symptoms and cognition so that patients can appropriately participate in psychosocial rehabilitation programs. Scientific advances continue to expand our understanding of CNS physiology and the abnormalities present in schizophrenia. Advances in our understanding of the pathophysiology of schizophrenia should, in turn, result in the development of treatments that are more specific and more effective. In practice, it is mandatory that clinicians appropriately use their expanding armamentarium. It is important that clinicians appreciate the pharmacodynamic basis for treatment interventions so that they can effectively design and implement rational pharmacotherapeutic regimens. Finally, it is critical that clinicians more objectively evaluate individual patient response to medication so that treatment can be optimized. With these strategies, the gap between practice and science can be narrowed and patients' lives benefited.

Depressive Disorders

CHRISTIAN J. TETER, JUDITH C. KANDO, BARBARA G. WELLS, AND PEGGY E. HAYES

KEY CONCEPTS

- 1 Extensive treatment guidelines are available to assist in the treatment of major depressive disorder, including medication management. Clinicians treating individuals with major depressive disorder should be familiar with these guidelines.
- 2 When evaluating a patient for the presence of depression, it is essential to rule out medical causes of depression and drug-induced depression.
- 3 The goal of pharmacologic treatment of depression is the resolution of current symptoms (i.e., remission) and the prevention of further episodes of depression (i.e., relapse or recurrence).
- 4 When counseling patients with depression who are receiving antidepressant medications, the patient should be informed that adverse effects might occur immediately, whereas resolution of symptoms can take 2 to 4 weeks or longer. Adherence to the treatment plan is essential to a successful outcome, and tools to help increase medication adherence should be discussed with each patient.
- 5 Antidepressants are generally considered equally efficacious for the treatment of major depressive disorder. Therefore, other factors, such as age, side effects, and past history of response, are used to guide clinicians in their selection of medication management.
- 6 When determining if a patient has been nonresponsive to a particular pharmacotherapeutic intervention, it must be determined whether the patient has received an adequate dose for an adequate duration and whether the patient has been medication adherent.
- 7 When evaluating response to an antidepressant, in addition to target signs and symptoms, the clinician must consider quality-of-life issues such as role, social functioning, and occupational function. In addition, the tolerability of the agent should be assessed because the occurrence of side effects can lead to medication nonadherence, especially given the chronicity of the disease and need for long-term medication management.

A diagnosis of major depressive disorder is given when an individual experiences one or more major depressive episodes without a

history of manic, mixed, or hypomanic episodes. A major depressive episode is defined by the criteria listed in the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR)*, published by the American Psychiatric Association.¹ Depression is associated with significant functional disability, morbidity, and mortality.

Newer generations of antidepressants have provided pharmacologic interventions that are effective and better tolerated than older agents such as the tricyclic antidepressants (TCAs) and the monoamine oxidase inhibitors (MAOIs). In addition, substantial efforts have been undertaken to improve the ability of clinicians to recognize and appropriately treat the signs and symptoms of depression. This chapter focuses exclusively on the diagnosis and treatment of major depressive disorder.

1 In the absence of well-accepted evidence-based medicine for the medication management of major depressive disorder, the reader is referred to the *Practice Guideline for the Treatment of Patients with Major Depressive Disorder, Second Edition*, which is available at www.psych.org. This extensive document is a practical guide to the management of depression based on the best available data as well as clinical consensus.²

EPIDEMIOLOGY

The true prevalence of depressive disorders in the United States is unknown. The National Comorbidity Survey Replication found that 16.2% of the population studied had a history of major depressive disorder in their lifetime, and more than 6.6% had an episode within the past 12 months.³ Women are at increased risk of depression from early adolescence until their mid-50s, with a lifetime rate that is 1.7 to 2.7 times greater than for men.⁴ Although depression can occur at any age, adults 18 to 29 years of age experience the highest rates of major depression during any given year.³ The estimated lifetime prevalence of major depression in individuals aged 65 to 80 years recently was reported to be 20.4% in women and 9.6% in men.⁵ Depressive disorders are common during adolescence, with comorbid substance abuse, suicide attempts, and deaths occurring frequently in these young patients.^{6,7} Depressive disorders and suicide tend to occur within families. For example, approximately 8% to 18% of patients with major depression have at least one first-degree relative (father, mother, brother, or sister) with a history of depression, compared with 5.6% of the first-degree relatives of those without depression.⁸ Furthermore, first-degree relatives of patients with depression are 1.5 to 3 times more likely to develop depression than normal controls.^{1,8,9} A recent meta-analysis found that the heritability of liability for major depression was 37%, whereas the remaining 63% of the variance in liability was caused by individual-specific environment.¹⁰ Therefore major depressive disorder is relatively common, occurs more frequently in women than men, and prevalence is influenced by both genetic and environmental factors.

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

ETIOLOGY

The etiology of depressive disorders is too complex to be totally explained by a single social, developmental, or biologic theory. Several factors appear to work together to cause or precipitate depressive disorders. The symptoms reported by patients with major depression consistently reflect changes in brain monoamine neurotransmitters, specifically norepinephrine (NE), serotonin (5-hydroxytryptamine [5-HT]), and dopamine (DA).^{11–13}

PATHOPHYSIOLOGY

BIOGENIC AMINE HYPOTHESIS

Several years before the introduction of antidepressants, the cause of depression was linked to decreased brain levels of the neurotransmitters NE, 5-HT, and DA, although the actual cause remains unknown. This biogenic amine hypothesis evolved as a result of several observations made in the early 1950s. It was noted that the antihypertensive drug reserpine depleted neuronal storage granules of NE, 5-HT, and DA and produced clinically significant depression in 15% or more of patients.¹⁴ Although the reuptake blockade of monoamines (e.g., NE and 5-HT) occurs immediately on administration of an antidepressant, the clinical antidepressant effects generally are not observed until after approximately 4 weeks of dosing.¹⁵ This delay can be the result of a cascade of events from receptor occupancy to gene transcription.¹⁶ This delay in onset of action has caused researchers to focus on the adaptive changes induced by antidepressants, as discussed below.¹²

THEORIES OF POSTSYNAPTIC CHANGES IN RECEPTOR SENSITIVITY

A more perplexing aspect of the observed effects of antidepressants is the discrepancy between monoamine reuptake blockade (immediate) and any measurable improvement in depressive symptoms (delayed therapeutic response).¹¹ Accordingly, theories that focus on adaptive (or chronic) changes in amine receptor systems compared with acute changes have emerged over the past decade.

In the mid-1970s it was recognized that chronic, but not acute, administration of antidepressants to animals caused desensitization of NE-stimulated cyclic adenosine monophosphate synthesis. In fact, for most antidepressants, downregulation of β -adrenergic receptors accompanies this desensitization.¹⁷ Studies of many antidepressants have demonstrated that either desensitization or downregulation of NE receptors corresponds to a clinically relevant time course for antidepressant effects.¹¹ Other studies have revealed desensitization of presynaptic 5-HT_{1A} autoreceptors following chronic administration of antidepressants.¹⁸ Thus a theory based on changes in receptor sensitivity provides a cogent explanation of the delayed onset of therapeutic response of antidepressant drugs.¹¹

DYSREGULATION HYPOTHESIS

The dysregulation hypothesis incorporates the diversity of antidepressant activity with the adaptive changes occurring in receptor sensitization over several weeks.¹⁹ In this theory, emphasis is placed on a failure of homeostatic regulation of neurotransmitter systems rather than on absolute increases or decreases in their activities. According to this hypothesis, effective antidepressant agents restore efficient regulation to the dysregulated neurotransmitter system.^{19,20}

5-HT/NE LINK HYPOTHESIS

It is apparent that no single neurotransmitter theory of depression is adequate. The 5-HT/NE link hypothesis maintains that both the serotonergic and noradrenergic systems are involved in an antidepressant response.¹⁷ This hypothesis is also consistent with the rationale of the postsynaptic alteration theory of depression, which emphasizes the importance of β -adrenergic receptor downregulation for achieving an antidepressant effect.¹⁷ Furthermore, both serotonergic and noradrenergic medications downregulate β -adrenergic receptors, and there is a link between 5-HT and NE.¹⁷ This implies that medications that are effective in the treatment of depression act at both of these neurotransmitter systems.

ROLE OF DA IN DEPRESSION

Traditional explanations of the biologic basis of depressive disorders have focused largely on NE and 5-HT; however, most of the evidence that coalesced into the biogenic amine hypothesis of depression does not clearly distinguish between NE and DA. There is an abundance of evidence suggesting that DA transmission is decreased in depression and that agents that increase dopaminergic transmission have been found to be effective antidepressants.²¹ Specifically, studies suggest that increased DA transmission in the mesolimbic pathway account for at least part of the mechanism of action of antidepressant medications.²¹ The mechanisms by which antidepressant drugs alter DA transmission remain unclear but can be mediated indirectly by primary actions at NE or 5-HT terminals. The complexity of the interaction between 5-HT, NE, and possibly DA is gaining greater appreciation, but a more in-depth understanding of the precise mechanism is needed.

BIOLOGIC MARKERS

Investigators continue to search for biologic or pharmacodynamic markers to assist in the diagnosis and treatment of depressed patients. Although no biologic marker has been discovered, several biologic abnormalities are present in many depressed patients. Approximately 45% to 60% of patients with major depression have a neuroendocrine abnormality, including hypersecretion of cortisol, lack of cortisol suppression after dexamethasone administration (i.e., a positive dexamethasone suppression test), or an abnormal or diminished thyroid-stimulating hormone response to the administration of thyrotropin-releasing hormone. The dexamethasone suppression test is the most specific measure of hypothalamic-pituitary-adrenal axis overactivity. Dexamethasone administration suppresses adrenal corticosteroid production in normal subjects for 24 hours. Failure of dexamethasone to suppress plasma cortisol concentrations indicates overactivity or dysregulation of the hypothalamic-pituitary-adrenal axis. Unfortunately, the high rate of false-positive and false-negative results limits the usefulness of testing for these markers, and has led to their relative lack of use in clinical practice.

Sleep studies conducted in a sleep laboratory in patients with major depression have identified several abnormalities that become more pronounced with advancing age. In depressed patients, the onset of rapid eye movement (REM) sleep occurs earlier during sleep (decreased REM latency), and there is a shift of REM sleep to the first half of the night. There also may be a decrease in the number of minutes spent in slow-wave sleep (stages 3 and 4), an increased number of awakenings during sleep, and early morning awakening.²² However, sleep abnormalities occur in other psychiatric disorders as well and are not diagnostic for major depression.

TABLE 71-1 Common Medical Conditions, Substance Use Disorders, and Medications Associated with Depressive Symptoms

General medical conditions	Metabolic disorders	Substance use disorders (including intoxication and withdrawal)
Endocrine diseases	Electrolyte imbalance	Alcoholism
Hypothyroidism	Hypokalemia	Marijuana abuse and dependence
Addison or Cushing disease	Hyponatremia	Nicotine dependence
Deficiency states	Hepatic encephalopathy	Opiate abuse and dependence (e.g., heroin)
Pernicious anemia	Cardiovascular disease	Psychostimulant abuse and dependence (e.g., cocaine)
Wernicke encephalopathy	Coronary artery disease	
Severe anemia	Congestive heart failure	
Infections	Myocardial infarction	
AIDS	Neurologic disorders	Drug therapy
Encephalitis	Alzheimer's disease	Antihypertensives
Human immunodeficiency virus	Epilepsy	Clonidine
Mononucleosis	Huntington's disease	Diuretics
Sexually transmitted diseases	Multiple sclerosis	Guanethidine sulfate
Tuberculosis	Pain	Hydralazine hydrochloride
Collagen disorder	Parkinson's disease	Methyldopa
Systemic lupus erythematosus	Poststroke	Propranolol
	Malignant disease	Reserpine
		Hormonal therapy
		Oral contraceptives
		Steroids/adrenocorticotrophic hormone
		Acne therapy
		Isotretinoin
		Other
		Interferon- β_{1a}

AIDS, acquired immune deficiency syndrome.

CLINICAL PRESENTATION

2 When a patient presents with depressive symptoms, it is necessary to investigate the possibility of a contributing medical or drug-induced etiology (Table 71-1). In fact, in the *DSM-IV-TR* there is a diagnostic category for both “Mood Disorder Due to a General Medical Condition” and “Substance-Induced Mood Disorder.”²¹ For example, up to 40% of patients with certain neurological disorders (e.g., stroke, Alzheimer's disease) develop depressive symptoms at some point during the course of their neurologic illness.¹ Furthermore, individuals experiencing withdrawal from substances of abuse (e.g., cocaine) can present with depressive symptoms.²³ All depressed patients should have a complete physical examination, mental status examination, and basic laboratory workup, including a complete blood count with differential, thyroid function tests, and electrolyte determinations to identify any potential medical problems. Lastly, a complete medication review should be performed because several medications can contribute to depressive symptoms (see Table 71-1).²⁴ Once a medical condition or concomitant medication has been ruled out as the cause of the depressive symptoms, the patient should be evaluated for a major depressive disorder.

According to the *DSM-IV-TR*, a single major depressive episode is characterized by five or more of the symptoms described in Table 71-2. At least one of the symptoms is depressed mood (often an irritable mood in children or adolescents) or loss of interest or pleasure in nearly all activities.¹ These symptoms must have been present nearly every day for at least 2 weeks and must represent a change from the patient's previous level of functioning. The clinician must consider presenting symptoms, their duration, and the patient's current level of social, occupational, or other important areas of functioning. Significant stressors or life events can trigger depression in some individuals but not others; and there can be an important precipitant at the beginning of the disorder.¹ A patient diagnosed with major depressive disorder may have one or more recurrent episodes of major depression during their lifetime.

EMOTIONAL SYMPTOMS

A major depressive episode is characterized by a persistent, diminished ability to experience pleasure. A loss of interest and pleasure

in usual activities, hobbies, or work is common. Patients appear sad or depressed, and they are often pessimistic and believe that nothing will help them feel better. The presence of feelings of worthlessness or inappropriate guilt can identify patients at risk for suicide.²⁵ Anxiety symptoms are present in almost 90% of depressed outpatients. Patients often have guilt feelings that are unrealistic, and these can reach delusional proportions. Patients can feel that they deserve punishment and can view their present illness as a punishment. A patient suffering from major depression with psychotic

TABLE 71-2 *DSM-IV-TR* Criteria for Major Depressive Episode

- Five (or more) of the following symptoms have been present during the same 2-week period and represent a change from previous functioning; at least one of the symptoms is either (1) depressed mood or (2) loss of interest or pleasure.

Note: Do not include symptoms that are clearly caused by a general medical condition or mood-incongruent delusions or hallucinations.

 - Depressed mood most of the day nearly every day
 - Markedly diminished interest or pleasure in all, or almost all, activities most of the day nearly every day
 - Significant weight loss when not dieting or weight gain (e.g., a change of more than 5% of body weight in a month), or decrease or increase in appetite nearly every day
 - Insomnia or hypersomnia nearly every day
 - Psychomotor agitation or retardation nearly every day (observable by others, not merely subjective feelings of restlessness or being slowed down)
 - Fatigue or loss of energy nearly every day
 - Feelings of worthlessness or excessive or inappropriate guilt nearly every day
 - Diminished ability to think or concentrate, or indecisiveness, nearly every day
 - Recurrent thoughts of death (not just fear of dying), recurrent suicidal ideation without a specific plan, or a suicide attempt or a specific plan for committing suicide
- The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- The symptoms are not due to the direct physiologic effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition (e.g., hypothyroidism).
- The symptoms are not better accounted for by bereavement (i.e., after the loss of a loved one), the symptoms persist for longer than 2 months or are characterized by marked functional impairment, morbid preoccupation with worthlessness, suicidal ideation, psychotic symptoms, or psychomotor retardation.

DSM-IV-TR, Diagnostic and Statistical Manual of Mental Disorders, 4th ed., text revision. Modified and reprinted with permission from American Psychiatric Association.¹

features can hear voices (auditory hallucinations) saying that he or she is a bad person and that he or she should commit suicide. Depression with psychotic features can require hospitalization, especially if the patient becomes a danger to self or others.

PHYSICAL SYMPTOMS

Physical symptoms often motivate patients, especially the elderly, to seek medical attention. Chronic fatigue is a common complaint, with a decreased ability to perform normal daily tasks. Fatigue often appears worse in the morning and does not improve with rest. Complaints of pain, especially headache, often accompany fatigue.

Sleep disturbances generally present as frequent early morning awakening with difficulty returning to sleep. This can coexist with difficulty falling asleep and frequent nighttime awakening. Less frequently, depressed patients complain of increased sleep (hypersomnia), although they experience daytime exhaustion or fatigue.

Appetite disturbances, including complaints of decreased appetite, often result in substantial weight loss, especially in the elderly.²⁶ Some patients lose 0.9 kg (2 lb) or more per week without dieting. Other patients, especially in the ambulatory setting, might overeat and gain weight, although they actually might not enjoy eating. They might crave specific foods. Some patients exhibit gastrointestinal complaints, others cardiovascular complaints, especially palpitations. Patients frequently present with a loss of sexual interest or libido.²⁷

INTELLECTUAL OR COGNITIVE SYMPTOMS

Intellectual or cognitive symptoms include a decreased ability to concentrate, slowed thinking, and a poor memory for recent events. Patients can appear confused and indecisive. Depression should be considered when cognitive symptoms are present in the elderly.²⁶

PSYCHOMOTOR DISTURBANCES

Patients can appear noticeably slowed or retarded in physical movements, thought processes, and speech (psychomotor retardation). Conversely, depression can be accompanied by psychomotor agitation, manifesting as purposeless, restless motion (e.g., pacing, wringing of hands, or outbursts of shouting).

SUICIDE RISK EVALUATION AND MANAGEMENT

The Center for Disease Control lists suicide as the third leading cause of death in those aged 15 to 24 years and the second leading cause of death in those aged 25 to 34 years.²⁸ All patients diagnosed with major depression should be assessed for suicidal thoughts. Widely held myths regarding suicide include the belief that people are more likely to commit suicide if they are asked about it, that people who attempt or talk about suicide are just looking for attention and are not serious, that suicidal people are crazy, and that most suicides are caused by a sudden traumatic event.

Factors that increase the risk for suicide include (in order of decreasing frequency), suicidal plans/attempts, being of male gender, being single or living alone, inpatient status, and having feelings of hopelessness.²⁹ Other identified risk factors include alcohol/substance abuse, having a general medical condition, more work hours missed in the past week, and relationship difficulties.³⁰ The presence of a very detailed plan with the intention and ability to carry it out indicates a high risk of suicide. Although women attempt suicide two to three times more often than men, men succeed about three times more frequently. Suicide is almost twice as common in the elderly as in the general population.³¹ This appears to be a result of more determina-

tion, carefully planned acts, and fewer warning signs.³¹ To assess the severity of suicidal thoughts, the clinician must be sensitive to hints of suicidal ideation, including a change in personality, a sudden decision to make a will or give away possessions, and any recent purchase of a gun or obtaining (or hoarding) a large supply of medications or other potentially toxic substances. It is important to remember that the risk of suicide in those recovering from major depression can increase as they develop the energy and capacity to act on a plan made earlier in a course of illness. It is not always possible to predict whether or when a depressed person will attempt suicide.

When suicidal intent is suspected, it is important to ask, "Are you thinking about harming or killing yourself?" If the risk is significant, the patient must be referred immediately to an appropriate health-care professional.

TREATMENT

Depressive Disorders

■ DESIRED OUTCOME

The goals of treatment are to reduce the symptoms of acute depression, facilitate the patient's return to a level of functioning before the onset of illness, and prevent further episodes of depression. Whether or not to hospitalize the patient is often the first decision that is made in consideration of the patient's risk of suicide, physical state of health, social support system, and presence of a psychotic and/or catatonic depression.

■ GENERAL APPROACH TO TREATMENT

③ There are three phases of treatment to consider when treating patients with major depressive disorder: (1) the *acute* phase lasting from 6 to 10 weeks in which the goal is remission (i.e., absence of symptoms); (2) the *continuation* phase lasting 4 to 9 months after remission is achieved, in which the goal is to eliminate residual symptoms or prevent relapse (i.e., return of symptoms within 6 months of remission); and (3) the *maintenance* phase lasting at least 12 to 36 months in which the goal is to prevent recurrence (i.e., a separate episode of depression).^{2,32} The risk of recurrence increases as the number of past episodes increase. The duration of antidepressant therapy depends on the risk of recurrence. Some investigators recommend lifelong maintenance therapy for persons at greatest risk for recurrence (persons younger than 40 years of age with two or more prior episodes and persons of any age with three or more prior episodes).²

④ Educating the patient and his or her support system (e.g., family and friends) regarding the delay in antidepressant effects and the importance of adherence should occur before and during the entire course of treatment. The treatment of major depressive disorder generally includes nonpharmacologic and pharmacologic strategies, which are discussed in further detail below.

■ NONPHARMACOLOGIC THERAPY

In addition to pharmacologic interventions, psychotherapy should be employed whenever the patient is able and willing to participate. Psychotherapy alone is not recommended for the acute treatment of patients with severe and/or psychotic major depressive disorder. However, if the depressive episode is mild to moderate in severity, psychotherapy can be the first-line therapy.³³ The effects of psychotherapy and antidepressant medications are considered to be additive. Combined treatment can be advantageous for patients with partial responses to either treatment alone and for those with a chronic course of illness. However, for uncomplicated, nonchronic major depressive disorder, combined treatment might provide no unique advantage.³³ Although not extensively evaluated, cognitive therapy, behavioral

therapy, and interpersonal psychotherapy appear equally effective.³³ Maintenance psychotherapy as the sole treatment to prevent recurrence generally is not recommended. Often, medication alone might prevent a depressive recurrence during the maintenance phase.³³

Electroconvulsive therapy (ECT) is a safe and effective treatment for certain severe mental illnesses, including major depressive disorder as well as other selected psychiatric illnesses. Patients with depression are candidates for ECT when a rapid response is needed, risks of other treatments outweigh potential benefits, there is a history of poor response to antidepressants and a history of good response to ECT, and the patient expresses a preference for ECT.³⁴ A course of ECT generally consists of either unilateral or bilateral ECT administered two to three times weekly for a total of 6 to 12 treatments. A rapid therapeutic response (10 to 14 days) has been reported. Although there are no absolute contraindications to the use of ECT, several conditions are associated with increased risk. These include increased intracranial pressure, cerebral lesions, recent myocardial infarction, recent intracerebral hemorrhage, bleeding, or otherwise unstable vascular condition. The use of an anesthetic as well as a nondepolarizing neuromuscular blocking agent decreases the morbidity associated with ECT.³⁴ Adverse effects of ECT include cognitive dysfunction, cardiovascular dysfunction, prolonged apnea, treatment-emergent mania, headache, nausea, and muscle aches. Cognitive changes associated with ECT include confusion immediately after the seizure and retrograde and anterograde memory disturbance. Most cognitive disturbances are transient, but some patients can report permanent loss of memory for events occurring over the months before, after, or during treatment.³⁴ Relapse rates during the year immediately following ECT are high unless

maintenance antidepressant medication is prescribed. Guidelines developed by the American Psychiatric Association include indications and contraindications for the appropriate use of ECT, procedures for obtaining informed consent, and issues in administering ECT.³⁴

Another nonpharmacologic treatment for depression is bright light therapy. Bright light therapy consists of the patient gazing into a 10,000-lux intensity light box, which is slanted downward toward the patient's face for approximately 30 minutes per day. It has shown effectiveness for treating both the winter "blues," also known as seasonal affective disorder (SAD), and for adjunctive use in major depressive disorder with seasonal exacerbations.² Light therapy is well tolerated, with minor visual complaints being the most frequently reported event.³⁵ Consequently, anyone undergoing light therapy should receive baseline and periodic eye examinations. The combination of bright light therapy and an antidepressant may provide additional benefit beyond either approach alone.²

■ PHARMACOLOGIC THERAPY

Antidepressants can be classified in several ways, including by chemical structure and the presumed mechanism of antidepressant activity. Although the link between the presumed mechanism of drug action and antidepressant response is tenuous, this classification has the advantage of being based on established pharmacology and clearly explains some of the common, but expected adverse effects. The knowledgeable clinician can use these facts to tailor treatment to individual patient needs and thereby optimize treatment outcome. Currently available antidepressants and initial dosages are shown in Table 71-3.

TABLE 71-3 Adult Dosages for Currently Available Antidepressant Medications^a

Generic Name	Trade Name	Suggested Therapeutic Plasma Concentration (ng/mL)	Initial Dose (mg/day)	Usual Dosage Range (mg/day)
Selective serotonin reuptake inhibitors				
Citalopram	Celexa		20	20–60
Escitalopram	Lexapro		10	10–20
Fluoxetine	Prozac		20	20–60
Fluvoxamine	Luvox		50	50–300
Paroxetine	Paxil		20	20–60
Sertraline	Zoloft		50	50–200
Serotonin/norepinephrine reuptake inhibitors				
Venlafaxine	Effexor		37.5–75	75–225
Duloxetine	Cymbalta		30	30–90
Aminoketone				
Bupropion	Wellbutrin		150	150–300
Triazolopyridines				
Nefazodone	Serzone		100	200–600
Trazodone	Desyrel		50	150–300
Tetracyclics				
Mirtazapine	Remeron		15	15–45
Tricyclics				
<i>Tertiary amines</i>				
Amitriptyline	Elavil	120–250 ^b	25	100–300
Clomipramine	Anafranil		25	100–250
Doxepin	Sinequan		25	100–300
Imipramine	Tofranil	200–350 ^c	25	100–300
<i>Secondary amines</i>				
Desipramine	Norpramin	100–300 ^c	25	100–300
Nortriptyline	Pamelor	50–150	25	50–200
Monoamine oxidase inhibitors				
Phenelzine	Nardil		15	30–90
Selegiline (transdermal)	Emsam		6 ^d	6–12 ^d
Tranylcypromine	Parnate		10	20–60

^aDoses listed are total daily doses; elderly patients are usually treated with approximately one-half of the dose listed.

^bParent drug plus metabolite.

^cIt has been suggested that combined imipramine + desipramine concentrations should fall between 150–240 ng/mL.

^dTransdermal delivery system designed to deliver stated dose continuously over a 24-hour period.

Data from American Psychiatric Association;² Baldessarini;¹⁵ Mann,³² Patkar et al.,⁴¹ and Watanabe and Winter.⁶⁶

5 Studies have found that antidepressants are of equivalent efficacy in groups of patients when administered in comparable doses. Because one cannot predict which antidepressant will be the most effective in an individual patient, the initial choice is made empirically. Factors that often influence the choice of an antidepressant include the patient's history of response, pharmacogenetics (history of familial antidepressant response), patient's concurrent medical history, presenting symptoms (e.g., fatigue as compared to psychomotor agitation), potential for drug-drug interactions, adverse events profile, patient preference, and drug cost.

Although the pathophysiology of major depression remains elusive, the clinician can now select from multiple approved drug therapies with different mechanisms of action.² Failure to respond to one antidepressant class or one antidepressant drug within a class does not predict a failed response to another drug class or another drug within the class. Approximately 65% to 70% of patients with varying types of depression improve with drug therapy, compared with 30% to 40% who are well-documented to improve with placebo.

■ MIXED SEROTONIN AND NOREPINEPHRINE REUPTAKE INHIBITORS

Although TCAs are effective in treating all depressive subtypes, their use has diminished greatly because of the availability of equally effective therapies that are much safer in overdose and better tolerated. All TCAs potentiate the activity of NE and 5-HT by blocking

their reuptake. However, the potency and selectivity of TCAs for the inhibition of reuptake of NE and 5-HT vary greatly among these agents (Table 71-4). Because TCAs affect other receptor systems including the cholinergic, neurologic, and cardiovascular systems, adverse events are reported frequently during TCA therapy.¹⁵

Venlafaxine inhibits 5-HT reuptake at low doses, with additional NE reuptake at higher doses; thus, it is referred to as a *serotonin-norepinephrine reuptake inhibitor* (SNRI). Duloxetine is also an SNRI with both 5-HT and NE reuptake inhibition across all doses. Some studies suggest that the SNRIs can be associated with higher rates of response and remission than other antidepressants; however, most of these studies involved venlafaxine and not all studies support this conclusion.³⁶

■ SELECTIVE SEROTONIN REUPTAKE INHIBITORS

The efficacy of selective serotonin reuptake inhibitors (SSRIs) is superior to placebo and comparable to other classes of antidepressants in treating patients with major depression.^{2,32} SSRIs are generally chosen as *first-line antidepressants* because of their safety in overdose and improved tolerability.

■ TRIAZOLOPYRIDINES

Trazodone and nefazodone have dual actions on serotonergic neurons, acting as both 5-HT₂ receptor antagonists and 5-HT reuptake

^bPrimarily serotonin (5-HT) at lower doses, norepinephrine (NE) at higher doses, and dopamine (DA) at very high doses.

^cBalanced 5-HT and NE reuptake inhibition.

^dAlso blocks dopamine reuptake.

Data from Baldessarini,¹⁵ Mann,³² Stahl et al.,³⁶ Horst and Preskorn,³⁸ and Patkar et al.⁴¹

inhibitors. They can also enhance 5-HT_{1A}-mediated neurotransmission.¹⁵ Trazodone blocks α_1 -adrenergic and histaminergic receptors leading to increased side effects (e.g., dizziness and sedation) that limit its use as an antidepressant. Nefazodone's use as an antidepressant has declined as well after reports of hepatic toxicity began to emerge. The FDA-approved nefazodone labeling includes a black box warning describing rare cases of liver failure.³⁷ The triazolopyridines are effective agents in treating major depression; however, they both carry risks that limit their usefulness as antidepressants.

■ AMINOKETONE

Bupropion has no appreciable effect on the reuptake of 5-HT, whereas having reuptake properties at both the NE and DA reuptake pumps.^{18,38} These pharmacologic properties make bupropion unique among all currently available antidepressants.

■ MIXED SEROTONIN-NOREPINEPHRINE EFFECTS

Mirtazapine enhances central noradrenergic and serotonergic activity through the antagonism of central presynaptic α_2 -adrenergic autoreceptors and heteroreceptors.³⁹ Furthermore, it antagonizes 5-HT₂ and 5-HT₃ receptors as well as histamine receptors. The antagonism of 5-HT₂ and 5-HT₃ receptors has been linked to lower anxiety and gastrointestinal side effects, respectively. Blockade of histamine receptors is associated with the sedative properties of mirtazapine.¹⁸

■ MONOAMINE OXIDASE INHIBITORS

MAOIs increase the concentrations of NE, 5-HT, and DA within the neuronal synapse through inhibition of the MAO enzyme. Studies have demonstrated that similarly to TCAs, chronic therapy causes changes in receptor sensitivity (i.e., downregulation of β -adrenergic, α -adrenergic, and serotonergic receptors).⁴⁰ The MAOIs phenelzine and tranylcypromine are nonselective inhibitors of MAO-A and MAO-B. Recently, a selegiline transdermal patch was approved by the FDA for treatment of major depressive disorder that allows inhibition of MAO-A and MAO-B in the brain, yet has reduced effects on MAO-A in the gut⁴¹ (see tyramine interactions with MAOIs below).

■ ST. JOHN'S WORT

Increasingly, consumers are choosing alternative forms of therapy, such as herbal medications including St. John's wort. Evaluations have found mixed results regarding the efficacy of the active ingredient in St. John's wort, hypericum, when compared with placebo and other antidepressants.⁴² St. John's wort is available as an over-the-counter medication. Although this can allow certain advantages such as reduced cost of therapy and self-treatment, it also has the potential to result in circumvention of the healthcare system. St. John's wort has been found to have significant drug interactions with commonly used medications.⁴² Perhaps most disconcerting is the fact that herbal medications are not regulated by the FDA, and manufacturers are not required to adhere to good manufacturing practices or provide proof of safety and/or efficacy. If St. John's wort is to be used, it should be administered under the guidance of a clinician trained in the treatment of depression, and a single-source product should be used continuously from a reputable and trusted manufacturer.

■ ADVERSE EFFECTS

TCAs

The adverse effects of antidepressant medications are summarized in Table 71-4. The TCAs affect several neurotransmitters and produce a wide range of pharmacologic actions, including several unwanted, but expected, adverse effects. The most commonly occurring side effects

are dose related and are associated with blockade of cholinergic receptors (anticholinergic effects) and include dry mouth, constipation, blurred vision, urinary retention, dizziness, tachycardia, memory impairment, and at higher doses, delirium.⁴⁰ Although some tolerance does develop to these adverse effects, they have the potential to impact patient adherence, particularly in the elderly and those receiving long-term maintenance therapy. Orthostatic hypotension is a common, dose-related, and potentially problematic adverse effect that has been attributed to the affinity of the TCAs for adrenergic receptors.⁴³ TCAs also cause cardiac conduction delays and can even induce heart block in patients with a preexisting conduction disorder. TCA overdose can produce severe arrhythmias.⁴³ Therefore, caution should be exercised when prescribing these agents, especially in higher doses, to patients with clinically significant cardiac disease. Other adverse effects that lead to patient nonadherence include weight gain and sexual dysfunction.⁴⁴ Abrupt withdrawal of TCAs is often associated with symptoms suggestive of cholinergic rebound (e.g., dizziness, nausea, diarrhea, insomnia, and restlessness), especially if the daily dose exceeds 300 mg.⁴⁵ Therefore, the dose should be tapered over several days.

Serotonin-Norepinephrine Reuptake Inhibitors

The most commonly reported adverse effects with venlafaxine are similar to those of the SSRIs and can be dose related; they include nausea, sexual dysfunction, and activation.² Venlafaxine can also cause a dose-related increase in diastolic blood pressure, and baseline blood pressure is not a useful predictor of the occurrence of this phenomenon. Blood pressure should be monitored regularly during venlafaxine therapy, and dosage reduction or discontinuation can be necessary if sustained hypertension occurs.⁴⁶ Duloxetine was relatively well tolerated in short-term clinical trials; however, experience with long-term studies and in a larger population of patients will more clearly define the risks and benefits of this newly approved antidepressant. The most commonly reported adverse events were nausea, dry mouth, constipation, decreased appetite, insomnia, and increased sweating.^{36,47}

Selective Serotonin Reuptake Inhibitors

The SSRIs include fluoxetine, citalopram, sertraline, paroxetine, escitalopram, and fluvoxamine. These drugs have a low affinity for histaminergic, α_1 -adrenergic, and muscarinic receptors, and therefore they produce fewer anticholinergic and cardiovascular adverse effects than the TCAs, and are not usually associated with significant weight gain.⁴⁸⁻⁵⁰ The most common adverse effects, which generally are mild and short lived, are gastrointestinal symptoms (i.e., nausea, vomiting, and diarrhea), sexual dysfunction in both males and females, headache, and insomnia.⁴⁹ A discontinuation or withdrawal syndrome can occur if the SSRIs are abruptly discontinued. The longer the half-life of the drug and its active metabolite, the less likely a withdrawal syndrome will occur.^{50,51} Although the SSRIs are known to improve the anxiety symptoms associated with depression, a few patients experience an increase in anxiety symptoms or agitation early in treatment.

Triazolopyridines

Trazodone and nefazodone have minimal anticholinergic effects and 5-HT agonist side effects, but they can cause orthostatic hypotension. Sedation, cognitive slowing, and dizziness are the most frequent dose-limiting side effects associated with trazodone.⁴⁰ Common adverse effects associated with nefazodone include light-headedness, dizziness, orthostatic hypotension, somnolence, dry mouth, nausea, and asthenia (weakness). Because of the potential for hepatic injury associated with nefazodone use (see black box warning above), treatment should not be initiated in individuals with active liver disease or with elevated baseline serum transaminases.³⁷ A rare but potentially serious adverse effect of trazodone is priapism, which is

reported to occur in approximately 1 in 6,000 male patients. Some cases have required surgical intervention (1 in 23,000), and permanent impotence can result.⁵² There have been no reports of priapism associated with nefazodone use in men, but there is a published case report of nefazodone-induced clitoral priapism.⁵³

Aminoketone

Adverse effects associated with bupropion include nausea, vomiting, tremor, insomnia, dry mouth, and skin reactions. The occurrence of seizures in patients taking bupropion appears to be strongly dose-related, and can be increased by predisposing factors such as history of head trauma and CNS tumor. Additionally, bupropion use is contraindicated in patients with eating disorders such as bulimia and anorexia, as these patients are prone to electrolyte abnormalities and are therefore at higher risk for seizure activity. At daily doses of 450 mg (the FDA-approved maximum dose) or less, the incidence of seizures is 0.4%.⁵⁴ Because of its pharmacologic profile (i.e., pro-adrenergic) bupropion can cause activation or agitation in some patients.¹⁸

Mixed Serotonin-Norepinephrine Effects

The most common adverse effects of mirtazapine are somnolence, weight gain, dry mouth, and constipation. Interestingly, side effects such as weight gain can be less with larger mirtazapine doses because of different mechanisms of action at different doses,⁵⁰ such as increased noradrenergic transmission as the dose is increased.

^aAccording to the FDA-approved prescribing information for the transdermal selegiline patch, patients receiving the 6 mg/24 h dose are not required to modify their diet. However, patients receiving the 9 or 12 mg/24 h are still required to follow the dietary restrictions similar to the other monoamine oxidase inhibitors (MAOIs).

^bClearly warrants absolute prohibition (e.g., English Stilton, blue, Camembert, cheddar).

^cUp to 56 g (2 oz) daily is acceptable.

^dAn 88 mL (3 oz) white wine or a single cocktail is acceptable.

^eUp to 56 g (2 oz) daily is acceptable: larger amounts of decaffeinated coffee are acceptable.

Recommended first-line drug and food interaction search engines: Lexi-Comp¹⁰¹ and Thomson Micromedex.¹⁰²

Monoamine Oxidase Inhibitors

The most common adverse effect of MAOIs is postural hypotension; this is more likely to occur with phenelzine than with tranylcypromine. Hypotensive reactions can be minimized through divided dosage scheduling. Other common adverse effects include weight gain and sexual side effects (e.g., decreased libido, anorgasmia).² Phenelzine, the most frequently prescribed MAOI, has mild to moderate sedating effects, whereas tranylcypromine can exert a stimulating effect, and therefore insomnia can occur. In addition, fever, myoclonic jerking, and brisk deep tendon reflexes can occur.⁵⁵

Hypertensive crisis, a potentially serious and life-threatening but rare adverse reaction, can occur when MAOIs are taken concurrently with certain foods, especially those high in tyramine (Table 71-5), or medications (Table 71-6). Ten milligrams of tyramine can cause a marked pressor effect, and 25 mg can result in serious hypertensive crisis.⁵⁶ These incidents can culminate in cerebrovascular accident and death. Symptoms of hypertensive crisis include occipital headache, stiff neck, nausea, vomiting, sweating, and sharply elevated blood pressure. Hypertensive crises can be treated with antihypertensive agents such as captopril.⁵⁷ Education of patients taking MAOIs regarding dietary and medication restrictions is extremely important. Printed and verbal patient instructions should be provided. It is important that patients be instructed to consult a healthcare professional before taking any over-the-counter medications, including non-FDA approved items sold as herbal/dietary supplements. Patients should be taught to recognize the symptoms of hypertensive crisis and to seek immediate treatment should those symptoms occur.

CLINICAL CONTROVERSY

In recent years, there have been numerous reports from the Food and Drug Administration warning healthcare providers of adverse effects associated with the use of the antidepressants in various populations. Many of these warnings have been accompanied by product labeling changes, including *black box warnings*. However, some of the warnings have not been unequivocally supported in the scientific literature. Therefore, the reader is encouraged to examine and understand these reports, and consider them within the context of the scientific literature.

PHARMACOKINETICS

The pharmacokinetics of the antidepressants are summarized in Table 71-7. Bioavailability is low (30% to 70% for most TCAs) as a

result of the first-pass hepatic effect, which shows great interindividual variation.⁵⁸ The TCAs have a large volume of distribution and concentrate in brain and cardiac tissue in laboratory animals. They are bound extensively and strongly to plasma albumin, erythrocytes, α_1 -acid glycoprotein, and lipoprotein.⁵⁸ The major metabolic pathways are demethylation, aromatic and aliphatic hydroxylation, and glucuronide conjugation. Enterohepatic cycling has been described.^{58,59} Metabolism of TCAs is linear within the usual dosage range. The elimination half-lives of the TCAs can vary greatly among individual patients.⁵⁸

Venlafaxine is metabolized to an active metabolite, O-desmethylvenlafaxine, which contributes to the overall pharmacologic effect.⁶⁰ Venlafaxine has the lowest plasma protein binding of any antidepressant (27%–30%), which reduces the likelihood of drug interactions via this mechanism. As might be expected, different formulations of venlafaxine with different pharmacokinetic profiles have led to different adverse-effect profiles. For example, venlafaxine extended-release, with its sustained plasma concentrations, has been associated with higher rates of sexual dysfunction among men (37%) as compared to the immediate release formulation (6%).⁶⁰

The diversity of the SSRIs is evident not only in their chemical structures but also in their pharmacokinetic profiles.^{61,62} These unique pharmacokinetic attributes of each SSRI can be used to guide treatment. For example, the long half-life of fluoxetine and its active metabolite norfluoxetine can be beneficial in instances of partial nonadherence (e.g., missed doses). Conversely, caution must be taken to monitor for drug-drug interactions prior to combining another medication with fluoxetine. The SSRIs are extensively distributed to the tissues, and all, with the possible exception of citalopram and sertraline, can have a nonlinear pattern of drug

accumulation with long-term administration.^{48,61} Therefore, the relationship between the dose and observed effect (e.g., side effect) can change over time for the nonlinear SSRIs, and this needs to be considered during treatment.

Bupropion is metabolized to multiple active metabolites (see Table 71–7). There are currently three formulations of bupropion (immediate release, sustained release, and extended release), which are considered bioequivalent.⁶³ The bupropion peak plasma concentrations are lower for the sustained-release formulation of bupropion, and it is believed this can contribute to a lower seizure risk with that formulation.⁶⁴

Mirtazapine undergoes extensive biotransformation to several metabolites⁶⁵ and is primarily eliminated in the urine (renal elimination). However, these metabolites are present at such low plasma concentrations as to minimally contribute to the overall pharmacologic profile of mirtazapine.

Altered Pharmacokinetics

Factors that influence TCA plasma concentrations include disease states, genetics, age, cigarette smoking, and concurrent drug administration. Hepatic disease can result in increased TCA plasma concentrations.⁶⁶ Renal failure does not alter nortriptyline metabolism, but the 10-hydroxy metabolite can accumulate, and protein binding can be diminished, with resulting enhanced sensitivity to the drug.⁵⁸ Clinicians should be alert to the possibility of higher-than-expected plasma concentrations of some TCAs in the elderly.

In cirrhotics, the half-lives of fluoxetine and norfluoxetine increased to 7.6 and 12 days, respectively.⁶¹ Patients with hepatic impairment had a twofold increase in plasma concentrations of

paroxetine.⁶⁷ Similarly, in patients with mild stable cirrhosis, the half-life of sertraline was 2.5 times greater than in patients without liver disease.⁶⁸ Patients with renal impairment had a two- to fourfold increase in paroxetine plasma concentrations compared with normal volunteers.⁶⁷ Plasma concentrations of SSRIs in the elderly are reported to be greater than in younger patients.⁶¹

The clearance of venlafaxine, mirtazapine, and their metabolites can be reduced among patients with hepatic or renal disease,⁶⁹ and doses should be adjusted accordingly. Elderly patients can require a dose reduction with mirtazapine.⁶⁹

Plasma Concentration and Clinical Response

Studies in acutely depressed patients have demonstrated a correlation between antidepressant effect and plasma concentrations for some TCAs. The patient's clinical response, not plasma concentration, dictates dosage adjustments. Some patients with plasma concentrations outside the suggested therapeutic plasma concentration range respond, whereas others are nonresponsive regardless of their plasma concentration. See Table 71–3 for a listing of suggested therapeutic plasma concentration ranges. There are four TCAs (nortriptyline, desipramine, imipramine, and amitriptyline) with evidence to support an association between plasma concentrations and clinical response. However, the best established therapeutic range is for nortriptyline (50–150 ng/mL),⁶⁶ which appears to demonstrate a curvilinear plasma concentration-response relationship.

For the newer antidepressants, a correlation has not been established between plasma concentration and clinical response or adverse effects.

Plasma Concentration Monitoring

Because of interindividual variations in plasma concentrations achieved by a given dose, interpretation of plasma concentrations can be very difficult for the TCAs.⁶⁶ Although plasma level monitoring is not performed routinely, some indications include inadequate response, relapse, serious or persistent adverse effects, use of higher-than-standard doses, suspected toxicity, elderly patients, pregnant patients, cardiac disease, suspected nonadherence, suspected pharmacokinetic drug interactions, and when the manufacturer of the product changes. If plasma concentration monitoring is used to detect nonadherence, a cutoff as low as 30 ng/mL for the TCAs has been suggested to avoid confusion with low bioavailability or unusually rapid metabolism. Plasma concentrations should be obtained at steady state, usually after a minimum of 1 week at constant dosage. Sampling should be performed during the drug elimination phase, usually in the morning, 12 hours after the last dose. Samples collected in this manner are comparable for patients on once-, twice-, or thrice-daily regimens.⁵⁸

■ DRUG INTERACTIONS

TCAs

Because the TCAs are metabolized in the liver through the cytochrome P450 system, they can interact with other drugs that modify hepatic enzyme activity or hepatic blood flow. TCAs are also extensively protein bound, which can cause drug interactions through displacement from protein-binding sites. Many commonly used medications can interact when given concurrently with TCAs. Pharmacokinetic and pharmacodynamic drug interactions involving TCAs are shown in Tables 71–8 and 71–9, respectively. Because of their frequent coadministration, a common drug interaction occurs between the TCAs and certain SSRIs, such as paroxetine and fluoxetine. These drugs are known to inhibit cytochrome P450 (e.g., CYP2D6) with the resultant increase in TCA plasma concentrations. Although MAOIs and TCAs can be coadministered safely in refractory patients with apparent

increased efficacy compared with monotherapy, severe reactions (e.g., hypertensive crisis) and fatalities have occurred.^{2,58} Therefore, this combination should be monitored extremely carefully.

SSRIs

Table 71–10 summarizes the drug interactions of newer-generation antidepressants. Drug-drug interactions can occur when an SSRI is

TABLE 71-9 Pharmacodynamic Drug Interactions Involving Tricyclic Antidepressants

Interacting Drug	Effect
Alcohol	Increased CNS depressant effects
Amphetamines	Increased effect of amphetamines
Androgens	Delusions, hostility
Anticholinergic agents	Excessive anticholinergic effects
Bepiridil	Increased antiarrhythmic effect
Clonidine	Decreased antihypertensive efficacy
Disulfiram	Acute organic brain syndrome
Estrogens	Increased or decreased antidepressant response; increased toxicity
Guanadrel	Decreased antihypertensive efficacy
Guanethidine	Decreased antihypertensive efficacy
Insulin	Increased hypoglycemic effects
Lithium	Possible additive lowering of seizure threshold
Methyldopa	Decreased antihypertensive efficacy; tachycardia; CNS stimulation
Monoamine oxidase inhibitors	Increased therapeutic and possibly toxic effects of both drugs; hypertensive crisis; delirium; seizures; hyperpyrexia; serotonin syndrome
Oral hypoglycemics	Increased hypoglycemic effects
Phenytoin	Possible lowering of seizure threshold and reduced antidepressant response
Sedatives	Increased CNS depressant effects
Sympathomimetics	Increased pharmacologic effects of direct-acting sympathomimetics; decreased effects of indirect-acting sympathomimetics
Thyroid hormones	Increased therapeutic and possibly toxic effects of both drugs; CNS stimulation; tachycardia

TABLE 71-10 Selected Drug Interactions of Newer-Generation Antidepressants

Antidepressant	Interacting Drug/Drug Class	Effect
Serotonin/norepinephrine reuptake inhibitors		
Venlafaxine	MAOIs	Potential for hypertensive crisis, serotonin syndrome, delirium
	Sibutramine	Serotonin syndrome
	Triptans	Serotonin syndrome
Duloxetine	MAOIs	Potential for hypertensive crisis, serotonin syndrome, delirium
	Sibutramine	Serotonin syndrome
	Thioridazine	Thioridazine C_{max} increased; prolonged QTc interval
	Triptans	Serotonin syndrome
Selective serotonin reuptake inhibitors		
Citalopram & escitalopram	MAOIs	Potential for hypertensive crisis, serotonin syndrome, delirium
	Linezolid (MAOI effects)	Serotonin syndrome
	Sibutramine	Serotonin syndrome
	Triptans	Serotonin syndrome
Fluoxetine	Alprazolam	Increased plasma concentrations and half-life of alprazolam; increased psychomotor impairment
	Antipsychotics (e.g., haloperidol and risperidone)	Increased antipsychotic concentrations; increased extrapyramidal side effects
	β -Adrenergic blockers	Increased metoprolol serum concentrations; increased bradycardia; possible heart block
	Carbamazepine	Increased plasma concentrations of carbamazepine; symptoms of carbamazepine toxicity
	Linezolid (MAOI effects)	Serotonin syndrome
	MAOIs	Potential for hypertensive crisis, serotonin syndrome, delirium
	Phenytoin	Increased plasma concentrations of phenytoin; symptoms of phenytoin toxicity
	TCA	Markedly increased TCA plasma concentrations; symptoms of TCA toxicity
	Sibutramine	Serotonin syndrome
	Triptans	Serotonin syndrome
Fluvoxamine	Thioridazine	Thioridazine C_{max} increased; prolonged QTc interval
	Alosetron	Increased alosetron AUC (sixfold) and half-life (threefold)
	Alprazolam	Increased AUC of alprazolam by 96%; increased alprazolam half-life by 71%; increased psychomotor impairment
	β -Adrenergic blockers	Fivefold increase in propranolol serum concentration; bradycardia and hypotension
	Carbamazepine	Increased plasma concentrations of carbamazepine; symptoms of carbamazepine toxicity
	Clozapine	Increased clozapine serum concentrations; increased risk for seizures and orthostatic hypotension
	Diltiazem	Bradycardia
	MAOIs	Potential for hypertensive crisis, serotonin syndrome, delirium
	Methadone	Increased methadone plasma concentrations; symptoms of methadone toxicity
	Ramelteon	Increased AUC (190-fold) and C_{max} (70-fold)
Paroxetine	Sibutramine	Serotonin syndrome
	TCA	Increased TCA plasma concentration; symptoms of TCA toxicity
	Theophylline & caffeine	Increased serum concentrations of theophylline or caffeine; symptoms of theophylline or caffeine toxicity
	Thioridazine	Thioridazine C_{max} increased; prolonged QTc interval
	Warfarin	Increased hypoprothrombinemic response to warfarin
	Antipsychotics (e.g., haloperidol, perphenazine and risperidone)	Increased antipsychotic concentrations; increased central nervous system and extrapyramidal side effects
	β -Adrenergic blockers	Increased metoprolol serum concentrations; increased bradycardia; possible heart block
	Linezolid (MAOI effects)	Serotonin syndrome
	MAOIs	Potential for hypertensive crisis, serotonin syndrome, delirium
	TCA	Markedly increased TCA plasma concentrations; symptoms of TCA toxicity
Sertraline	Sibutramine	Serotonin syndrome
	Triptans	Serotonin syndrome

coadministered with another drug metabolized through the cytochrome P450 system. Two of the isoenzymes of the cytochrome P450 system, CYP2D6 and CYP3A4, are responsible for the metabolism of over 80% of currently marketed drugs.⁷⁰ The ability of an SSRI, or any antidepressant, to inhibit or induce the activity of these

enzymes will be a significant contributory factor in determining its capability to cause a pharmacokinetic drug interaction when administered concomitantly. Table 71-11 shows the cytochrome P450 enzyme inhibitory potential of the second- and third-generation antidepressant agents. In patients receiving a stable dose of any

medication known to interact with the SSRIs, if an SSRI is to be initiated, the starting dose should be low and titrated carefully to evaluate the potential importance of the interaction.

Certain pharmacodynamic drug interactions that can occur with the SSRIs are concerning and require close monitoring. For example, the combination of an SSRI with another drug that augments serotonergic function (e.g., linezolid) can lead to the *serotonin syndrome*, which is characterized by symptoms such as clonus, hyperthermia, and mental status changes.⁷¹ Therefore, a washout period of 2 to 5 weeks (depending on the half-life of the SSRI) can be necessary before the initiation of another serotonergic medication.

Other Agents

In contrast to the SSRIs, which have potential for both pharmacokinetic and pharmacodynamic interactions, other newer-generation antidepressants such as venlafaxine, duloxetine, mirtazapine, and bupropion have drug interactions that are primarily pharmacodynamic. This can be partly explained by the relative lack of cytochrome P450 inhibition among these newer agents as compared to the SSRIs (see Table 71-11). As nefazodone use has been severely limited because of its potential to induce liver toxicity, and trazodone is primarily used as a non-FDA approved hypnotic at low doses, neither of these agents are likely to be involved in clinically significant drug interactions. However, it should be noted that nefazodone is a potent inhibitor of cytochrome P450 3A4.⁷⁰

SPECIAL POPULATIONS

Elderly Patients

Depression in the elderly is a major public health problem. Many elderly depressed patients are often inadequately treated, or depression is missed or mistaken for another disorder, such as dementia. In the elderly, depressed mood, the typical signature symptom of depression, can be less prominent than other depressive symptoms such as loss of appetite, cognitive impairment, sleeplessness, anergia, and loss of interest in and enjoyment of the normal pursuits of life.⁷² Older adults might not recognize common symptoms associated with depression such as anhedonia (inability to experience pleasure), fatigue, and concentration difficulties. In fact, somatic (physical) complaints are quite frequently the presenting symptoms in elderly depressed patients. Appropriate recognition and treatment of depression in the elderly is extremely important. In fact, individuals 65 years of age and older have the highest rates of suicide as compared to any other age group.⁷³ The increased suicidal attempts present in the depressed elderly can be because of access to firearms, diminished cognitive functions, sleep disruptions, poor social interactions, and inattention among primary caregivers.⁷³

Before initiating antidepressant treatment, a complete physical examination should be performed. In prescribing antidepressants, elderly patients can be either over- or undertreated. Overtreatment occurs when age-related pharmacokinetic and pharmacodynamic factors are overlooked. Undertreatment results from an overly conservative approach as a result of the patient's advanced age or concurrent medical problems. The SSRIs are usually selected as first-choice antidepressants in the elderly, and this can enable the clinician to avoid some of the problematic adverse effects commonly associated with the TCAs (e.g., sedative, anticholinergic, and cardiovascular-related side effects). Furthermore, there is evidence to suggest that the long-term use of antidepressants such as the SSRIs in the elderly, administered with either psychotherapy or clinical-management, can prevent a depressive relapse.⁷⁴ Bupropion and venlafaxine are often selected because of milder anticholinergic and less frequent cardiovascular side effects.⁷⁵

Pediatric Patients

Accumulating evidence indicates that childhood depression occurs quite commonly. Symptoms of depression in the young can vary from accepted diagnostic criteria and include several nonspecific symptoms such as boredom, anxiety, failing adjustment, and sleep disturbance.⁷⁶

Data collected under controlled conditions that support the efficacy of antidepressants in children and adolescents are sparse, and no antidepressant, except fluoxetine, is FDA-approved for the treatment of depression in patients younger than 18 years of age although other antidepressants (e.g., sertraline) have been studied in this population.⁷⁷

The use of antidepressants in children and adolescents was complicated when, in March 2004, the FDA issued a black box warning in the product labeling for antidepressant medications warning clinicians and patients of the increased risk of suicidal ideation and behavior when antidepressants are used in this population. However, several retrospective longitudinal reviews of the use of antidepressants in children found no significant increase in the risk of suicide attempts or deaths.^{78,79,80} Furthermore, adolescents suffering from depression who remain untreated may successfully commit suicide.^{81,82} Further study is needed to resolve this controversy.

Several cases of sudden death have been reported in children and adolescents taking antidepressants, such as desipramine. A baseline electrocardiogram (ECG) is recommended before initiating treatment with a TCA in children and adolescents, and many clinicians recommend an additional ECG when steady-state plasma concentrations are achieved.⁸³

The treatment of depression in children remains challenging, as depression can be difficult to diagnose and treat once identified. Antidepressants are used to treat depressed children and adolescents because no other definitive effective therapies are currently available. Also, demonstration of efficacy in this population, as well as in adults, is confounded by a high placebo response rate. However, the TCAs and several of the SSRIs remain viable treatment options when prescribed and monitored appropriately.

Pregnant and Lactating Patients

Approximately 14% of pregnant women develop a serious depression during pregnancy.⁸⁴ The data presented in several recent publications should be considered when making treatment decisions for pregnant women suffering from major depression.^{84,85,86} The first evaluation looked at the risk of discontinuing antidepressant therapy in pregnant women suffering from depression and found a significant risk of relapse. In this study, women who discontinued antidepressant therapy were five times more likely to have a relapse during their pregnancy than were women who continued treatment.⁸⁶ Another study used population health data to determine whether exposure to SSRIs and depression in pregnant women differs from exposure to

maternal depression alone. The authors found that prenatal exposure to SSRIs was associated with an increased risk of low birth weight and respiratory distress, and that this relationship remained after accounting for maternal illness severity.⁸⁴ A study by Chambers and colleagues reported a sixfold greater likelihood of the occurrence of persistent pulmonary hypertension of newborn infants exposed to an SSRI after the 20th week of gestation.⁸⁵ A recent editorial on the use of antidepressants in pregnancy lists four therapeutic principles to guide the clinician in treating women during pregnancy: (1) Pregnancy does not protect against the occurrence of depression, and the likelihood of relapse is very high in untreated women with recurrent illness; (2) Maternal depression adversely affects child development, and prenatal depression can adversely affect the offspring; (3) When attempting to balance benefit and risk, transient postnatal behavioral abnormalities in the offspring of treated mothers must not be assumed to portend long-term compromise; and (4) SSRIs, the most commonly used and best-tolerated treatment for depression, carry a small but significant risk for a serious medical consequence.⁸⁷

In summary, the risks and benefits of drug therapy during pregnancy must always be weighed, and concerns about the risks of untreated depression during pregnancy should be considered. These include the possibility of low birth weight secondary to poor maternal weight gain, suicidality, potential for hospitalization, potential for marital discord, inability to engage in appropriate obstetric care, and difficulty caring for other children.⁸⁸ Several different approaches exist for dealing with pregnancy and antidepressant use. First, discontinuation of an antidepressant before conception is an option for women who are stable and appear likely to remain well while not taking antidepressant medication. Secondly, continuation of the antidepressant until conception can be reasonable. For those who have a history of depressive relapse after medication discontinuation, the antidepressant should be continued throughout pregnancy. Further evaluations of the newer antidepressant agents are needed to fully understand the risks associated with their use at various stages of the gestational period. Again, the risks of not treating depression in a pregnant woman should not be underestimated or minimized.

Refractory Patients

The majority of “treatment-resistant” depressed patients are likely the result of inadequate therapy (relative resistance). In fact, the ongoing National Institutes of Health (NIH)-sponsored study, Sequenced Treatment Alternatives to Relieve Depression (STAR* D), has shown that one in three depressed patients who previously did not achieve remission using an antidepressant became symptom-free with the help of an additional medication (e.g., bupropion sustained release [SR]) and one in four achieved remission after switching to a different antidepressant (e.g., venlafaxine extended release [XR]).⁸⁹

⑥ Issues to be addressed in assessing the patient who has not responded to treatment include the following:

1. Is the diagnosis correct?
2. Does the patient have a psychotic depression?
3. Has the patient received an adequate dose and adequate duration of treatment?
4. Do adverse effects preclude adequate dosing?
5. Has the patient adhered to the prescribed regimen?
6. Was a stepwise approach to treatment used?
7. Was treatment outcome adequately measured?
8. Is there a coexisting or preexisting medical or psychiatric disorder?
9. Are there other factors that interfere with treatment?

When a patient fails to respond, nondrug modalities including environmental manipulation, family counseling, cognitive therapy, or interpersonal psychotherapy are often beneficial.²

More than 40% of patients with major depressive disorder do not achieve remission even after two optimal antidepressant trials.⁹⁰ Although several different definitions for treatment-resistant depression (TRD) have been proposed, the most widely accepted is patients who do not achieve remission even after two optimal antidepressant trials.⁹⁰ Three primary pharmacologic approaches are used when dealing with treatment nonresponse. The current antidepressant can be stopped, and a trial with an unrelated agent initiated. For example, the patient can be switched from a TCA to an SSRI. Second, the current antidepressant can be augmented (potentiated) by the addition of another agent, such as lithium. For example, the STAR* D trial recently evaluated the addition of lithium or T₃ to current antidepressant treatment.⁹⁰ These patients had failed to respond to or been unable to tolerate at least two previous antidepressant trials. After approximately 10 weeks of treatment, T₃ augmentation resulted in higher remission rates (24.7%) compared to lithium (15.9%). However, these results were modest and not statistically significant, and the use of lithium was associated with a greater incidence of adverse events.⁹⁰ A second evaluation in the STAR* D trial, compared switching to mirtazapine (up to 60 mg per day) versus nortriptyline (up to 200 mg per day) after two, consecutive failed medication treatments.⁹¹ This trial also found modest response rates that were not statistically significant. In the mirtazapine group, 12.3% of patients met the remission criteria of a score of seven or less on the Hamilton Depression (HAMD) scale, whereas 19.8% of nortriptyline patients met these criteria at the end of 14 weeks. There was no difference in tolerability between the two agents.

An additional strategy includes the use of atypical antipsychotic agents to augment the antidepressant response (antipsychotic medications are not FDA-approved for the treatment of depression). Risperidone has been shown to be effective in combination with fluvoxamine, paroxetine, or citalopram in TRD, with reported remission rates of 61% to 76%.^{92,93} The combination of olanzapine and fluoxetine has also been found to be safe and effective in TRD.⁹² Ziprasidone, aripiprazole, and quetiapine augmentation of SSRIs has been shown to be effective for TRD in open-label evaluations.⁹²

The American Psychiatric Association practice guideline for the treatment of patients with major depressive disorder offers guidance for managing patients who fail to respond. These guidelines advise that if patients fail to respond to medication after 6 to 8 weeks, a reappraisal of the treatment regimen should be considered.² Partial responders should consider changing the dose, augmenting the antidepressant, or adding psychotherapy or ECT. For those with no response, options include changing to a second antidepressant or the addition of psychotherapy or ECT. Comorbid medical or psychiatric conditions should be identified and treated because they can complicate treatment. Before changing a patient's treatment, the clinician is advised to evaluate the adequacy of the medication dosage and adherence with the prescribed regimen. A combination of two drugs should not be used when one drug will suffice.

CLINICAL CONTROVERSY

There are no universally agreed on algorithms or guidelines for individuals experiencing treatment-resistant depression. Approaches include discontinuing the current antidepressant and initiating treatment with a different agent (i.e., “switching”), augmenting the current treatment, or beginning a trial of combination antidepressant therapy (Fig. 71–1).

CLINICAL APPLICATION

A suggested algorithm for the management of depression is shown in Figure 71–1.

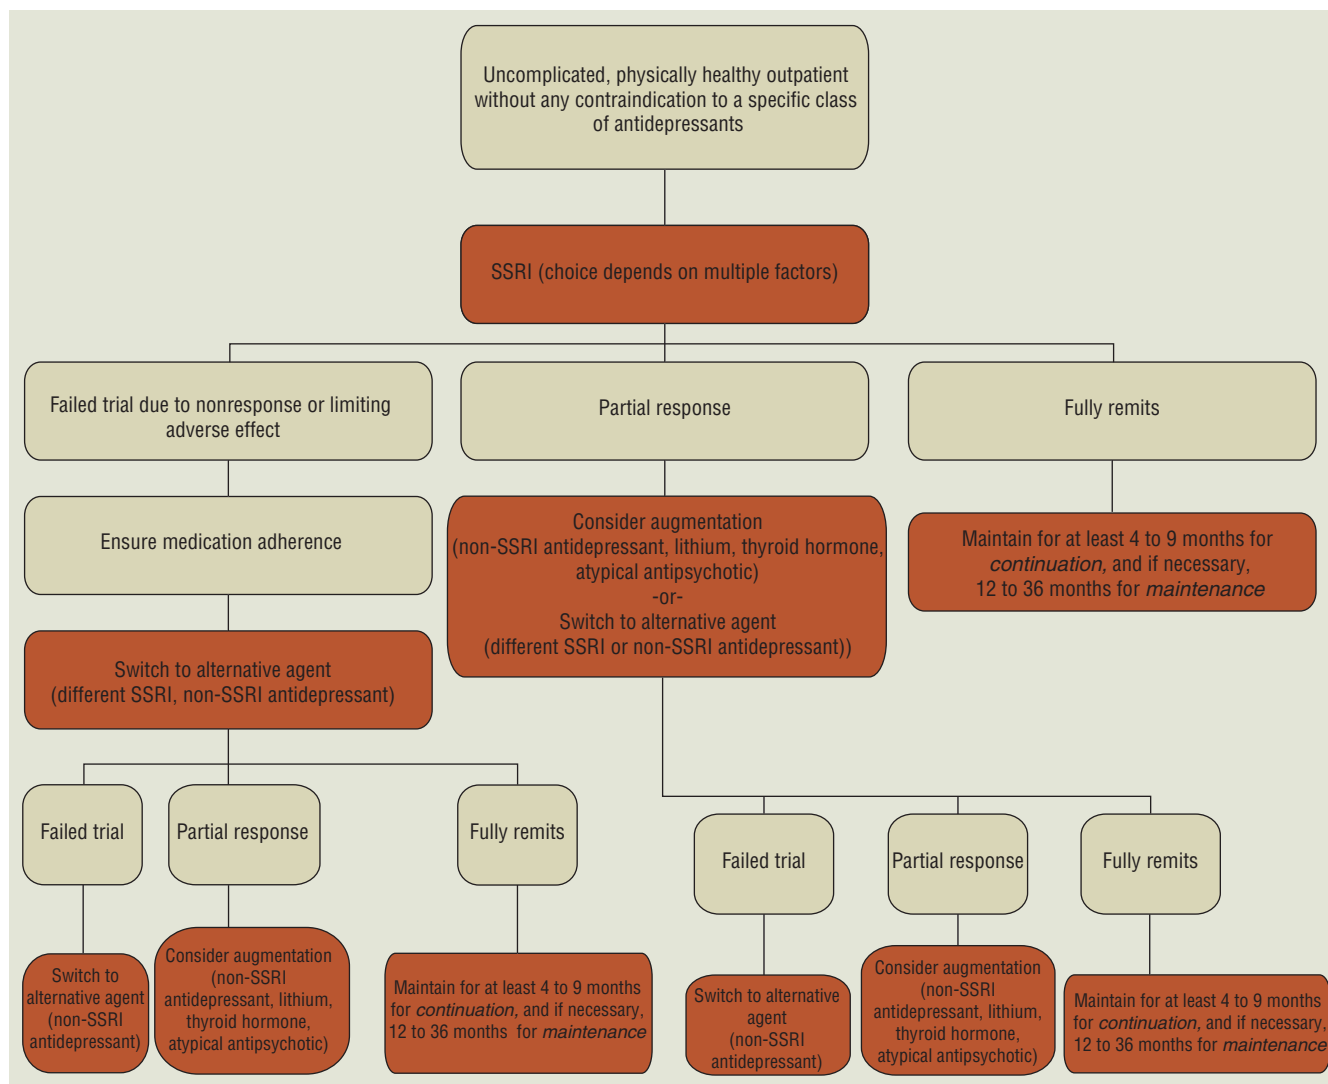

FIGURE 71-1. Algorithm for treatment of uncomplicated major depression. (SSRI, selective serotonin reuptake inhibitor.)

Dosing

Recommended initial doses and dosage ranges are shown in Table 71-3. In elderly patients, as a general rule, dosing is initiated at one-half the initial dose administered to younger adults, and the dose is increased at a slower rate.

The usual initial adult dose of most TCAs is 25 mg at bedtime, and the dose can be increased by 25 to 50 mg every third day. The recommended initial dose for the SSRIs, citalopram, fluoxetine, and paroxetine is 20 mg and 10 mg for escitalopram. The initial dose for fluvoxamine and sertraline is 50 mg/day. The doses are titrated upwards depending on symptom response and adverse effects.

The usual starting dose of venlafaxine is 75 mg/day and taken with food. Some patients can better tolerate a starting dose of 37.5 mg/day for a few days before beginning 75 mg/day. Depending on tolerability, the dose is then titrated to 150 mg/day. If needed, the dose can be further increased to 225 mg/day. Severely depressed patients can require doses as high as 375 mg/day. Both an immediate-release and extended release formulation of venlafaxine are now available. Duloxetine can be started at 30 mg and titrated upwards to 60 to 90 mg/day, given as a divided or single-daily dose. The recommended starting dose of mirtazapine is 15 mg/day administered in a single dose at bedtime, and the maximum recommended dose is 45 mg/day.

Bupropion is usually initiated at 75 mg twice daily, and this dose can be increased to 100 mg three times daily after a few days. Most

patients will respond at 300 mg/day; however, an increase to 450 mg/day, given as 150 mg three times daily, can be considered in patients with no clinical response after several weeks of treatment at 300 mg/day. Additionally, both a 12-hour and 24-hour sustained release formulation are available, allowing for less frequent dosing.

Caution is urged when switching from one antidepressant to another. It is important to remember that 3 to 4 weeks is usually required before a mood-elevating response is seen. A 6-week trial at a maximum dosage is considered an adequate trial.² It is crucial to counsel the patient about the expected lag time before the onset of clinical response. Patients uneducated in this regard often fail to comply with their prescribed regimens.

■ PHARMACOECONOMIC CONSIDERATIONS

Cost of illness studies attempt to provide an estimation of the amount spent on a particular disease and to identify different components of the cost.⁹⁴ Ideally, direct, indirect, and intangible costs would be included. Direct costs include medical and nonmedical costs such as outpatient costs, inpatient costs, medication costs, transportation costs, and social services costs. Indirect costs include loss of productivity or reduced productivity. Intangible costs result from a decreased quality of life for the depressed individual and their family. Intangible costs are often not considered in pharmacoeconomic models because an accurate quantification in monetary terms is difficult.⁹⁴ Most published studies do not include all of the

relevant aspects necessary for credible economic analyses.⁹⁵ In addition, there is wide variability among studies with regard to cost inclusion and evaluation of treatment withdrawals, relapses, toxicity, and adverse effects.⁹⁵

When SSRIs were introduced, many managed care organizations restricted these medications to those who had failed treatment with the TCAs or who had been unable to tolerate these agents, with the belief that the SSRIs represented a more expensive approach to the treatment of depression. One of the major claims for SSRIs is the greater tolerability and safety profile in overdose when compared to the TCAs.⁹⁶ Studies including the costs associated with hospitalization following TCA overdoses as opposed to SSRI overdoses indicate that overdoses with TCAs are significantly more expensive.⁹⁶ All of the randomized clinical trials evaluating total expenditure of SSRIs versus TCAs indicate a cost advantage associated with SSRIs. Recently, several of the SSRIs have lost patent exclusivity, and generic versions of these medications are available at substantially lower prices than the brand name version. Several older studies and a more recent evaluation conducted in the United Kingdom found lower costs associated with the use of the SNRI, venlafaxine, when compared to SSRIs and TCAs.^{97,98}

Additional longer-term studies in more diverse populations are necessary before judgments can be made regarding which of the newer antidepressant agents offers a cost advantage. It would be extremely useful if cost effective agents in various subpopulations and special populations (e.g., the elderly, those with comorbid substance abuse, those with comorbid anxiety disorders, and children) were identified. Also, the pharmacoeconomics of medication management of depressed patients in various healthcare environments such as public, private, psychiatry, or primary care, needs evaluation.

Pharmacoeconomic studies conducted to date are difficult to generalize, as there are no widely accepted uniform criteria and studies vary greatly in accounting for factors such as adherence, treatment withdrawals, relapses, toxicity, and adverse effects. There is also great variability in the type of costs included.⁹⁵

EVALUATION OF THERAPEUTIC OUTCOMES

7 Several monitoring parameters, in addition to plasma concentrations, are useful in managing patients. Patients must be monitored for adverse effects, such as sedation, anticholinergic effects, and sexual dysfunction, and for remission of previously documented target symptoms. The presence of side effects does not necessarily indicate adequate dosage. In addition, changes in social and occupational functioning should be assessed. Patients receiving venlafaxine should have their blood pressure monitored at regular intervals. Patients older than 40 years of age should receive a pretreatment ECG before starting TCA therapy, and followup ECGs should be performed periodically. Patients should be monitored for the emergence of suicidal ideation after initiation of any antidepressant. Weight gain and sexual dysfunction, common events associated with most antidepressants, are associated with nonadherence and should be monitored and discussed with the patient.

In addition to the clinical interview, psychometric rating instruments (e.g., patient-rated and clinician-rated scales) allow for rapid and reliable measurement of the nature and severity of depressive and associated symptoms (see Chap. 64). It is helpful to administer the rating scales prior to treatment, 6 to 8 weeks after initiation of therapy, and periodically thereafter. Interviewing a family member or friend (with the patient's permission) regarding symptoms and daily functioning also can assist in assessment of progress. Patients should be monitored at more frequent intervals early in treatment. Monitoring is then continued at regular intervals throughout the continuation and maintenance phases of treatment. Regular monitoring for reemergence of symptoms should be continued for several months after antidepressant therapy is discontinued.

Finally, one useful set of criteria that can be used with a variety of psychometric scales was suggested by Mann.³² Following these criteria, the following definitions are used: (1) *nonresponse* is less than 25% decrease in baseline symptoms, (2) *partial response* is a 26% to 49% decrease in baseline symptoms, and (3) *partial remission or response* is greater than a 50% decrease in baseline symptoms. Consistent with other recommendations, *remission* is a return to baseline functioning with no symptoms present.²

COLLABORATIVE PRACTICE

Significant evidence exists to show that depression is common, chronic, and causes significant morbidity and mortality.⁹⁹ Pharmacists, in conjunction with other healthcare providers can play a crucial role in the screening, recognition, and treatment of this disorder. In fact, the United States Preventive Services Task Force has recommended that clinicians “maintain an especially high index of suspicion for depressive symptoms in adolescents and young adults, persons with a family history or personal history of depression, those with chronic illnesses, those who perceive or have experienced a recent loss, and those with sleep disorders, chronic pain, or multiple unexplained somatic complaints.”¹⁰⁰ In addition, pharmacists and other healthcare clinicians play a crucial role in ensuring adherence to medication regimens through assessment of a patient's willingness and ability to take a medication, including an assessment of financial viability, and through patient education regarding dosing, side effects and drug interactions, and guidance regarding followup appointments with prescribing clinicians.¹⁰¹

CONCLUSIONS

Major depressive disorder remains one of the most commonly occurring mental illnesses in adults, and it is often undiagnosed and untreated. Pharmacologic intervention is the cornerstone of treatment for major depressive disorder. Antidepressant medications have a broad spectrum of neurochemical effects and influence a variety of receptors peripherally and centrally. Safe and effective use of antidepressants requires a thorough understanding of the pharmacology of these drugs and of the principles of monitoring efficacy and adverse effects. It also requires that the patient adhere to the prescribed antidepressant regimen. Clinicians must have a thorough understanding of antidepressant drug interactions and factors that can influence the pharmacokinetics of antidepressant drugs. Pharmacists are in an ideal position to accomplish these treatment goals. The search for more effective antidepressants with more favorable adverse-effect profiles must continue.

SHANNON J. DRAYTON AND BENJAMIN WEINSTEIN

KEY CONCEPTS

- 1 Bipolar disorder is a cyclic mental illness with recurrent mood episodes that occur over a person's lifetime. The symptoms, course, severity, and response to treatment differ among individuals.
- 2 Bipolar disorder is likely caused by genetic factors, environmental triggers, and the dysregulation of neurotransmitters, neurohormones, and second messenger systems in the brain.
- 3 The goal of therapy for bipolar disorder should be to improve functioning of the patient by reducing mood episodes. This is accomplished by maximizing adherence to therapy and limiting adverse effects.
- 4 Patients and family members should be educated about bipolar disorder and treatments. Long-term monitoring and adherence to treatment are major factors in obtaining stabilization of the disorder.
- 5 Lithium and valproate are the mainstays of treatment for both acute mania and prophylaxis for recurrent manic and depressive episodes. Anticonvulsants, such as lamotrigine, carbamazepine, and oxcarbazepine, and atypical antipsychotics, such as aripiprazole, olanzapine, risperidone, quetiapine, and ziprasidone are alternative or adjunctive treatments for bipolar disorder. Anticonvulsants can be more effective than lithium in several mood subtypes (e.g., mixed states and rapid cycling). Lamotrigine and lithium can be more effective for recurrent bipolar depression.
- 6 Some patients can be stabilized on one mood stabilizer, but others may require combination therapies or adjunctive agents during an acute mood episode. If possible, adjunctive agents should be tapered and discontinued when the acute mood episode remits and the patient is stabilized. Adjunctive agents can include antidepressants, additional mood stabilizers, antipsychotics, and benzodiazepines.
- 7 Baseline and followup laboratory tests are required for some medications to monitor for adverse effects.

- 1 Bipolar disorder (manic-depressive illness) is one of the most common of the severe chronic psychiatric disorders. The cyclic

mood disorder is characterized by recurrent fluctuations in mood, energy, and behavior encompassing the extremes of human experiences.¹⁻⁴ Bipolar disorder differs from recurrent major depression (or unipolar depression) in that a manic, hypomanic, or mixed episode occurs during the course of the illness.² Bipolar disorder is a lifelong illness with a variable course and requires both nonpharmacologic and pharmacologic treatments for mood stabilization.^{2,3}

EPIDEMIOLOGY

The lifetime prevalence of bipolar I disorder (one or more manic or mixed episodes) is 0.4% to 1.6%; that for bipolar II disorder (recurrent major depressive episodes with hypomanic episodes) is approximately 0.5%.^{2,3} A national comorbidity survey reported that the lifetime prevalence rate of a manic episode is 1.6% \pm 0.3% for men and 1.7% \pm 0.3% for women in the United States (approximately 4 million people).⁵ Bipolar I disorder occurs equally in men and women, whereas bipolar II disorder is more common in women.^{2,3} Of the 1.9 million Americans who have either bipolar I or II disorder, it is estimated that only 50% of these individuals are receiving any type of treatment for their illness.¹

ETIOLOGY

- 2 The exact etiology of bipolar disorder is unknown. Bipolar disorder is thought to be a complex genetic disease that is environmentally influenced and caused by a wide range of neurobiologic abnormalities. Stressful life events, alcohol or substance use, and changes in the sleep-wake cycle can elicit the expression of genetic or biologic vulnerabilities that cause dysregulation of neurotransmitters, neuroendocrine pathways, and second messenger systems.⁴ Table 72-1 summarizes the etiologic theories of bipolar disorder.

PATHOPHYSIOLOGY

- 2 Many theories have been proposed regarding the pathophysiology of mood disorders.⁴ Family, twin, and adoption studies report an increased lifetime prevalence risk of having mood disorders among first-degree relatives of patients with bipolar disorder.^{3,11} Genetic linkage studies suggest multiple gene loci can be involved in the heredity of mood disorders.^{6-9,12} Neuroimaging studies have found neurochemical, anatomic, and functional abnormalities in bipolar patients.^{12,13} Environmental or psychosocial stressors, nutritional deficiencies, infections, immunologic reactions, sleep deprivation, and disruption of circadian rhythms can cause dysregulation in neurotransmitters, hormones, endocrine function, neuropeptides, cations, intracellular second messengers, and signal transduction pathways.^{3,4,7,12-18}

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

TABLE 72-1 Etiologic Theories of Bipolar Disorder**Genetic factors**

80–90% of patients with bipolar disorder have a biologic relative with a mood disorder (e.g., bipolar disorder, major depression, cyclothymia, or dysthymia).

First-degree relatives of bipolar patients have a 15–35% lifetime risk of developing any mood disorder and a 5–10% lifetime risk for developing bipolar disorder.

The concordance rate of mood disorders is 60–80% for monozygotic twins and 14–20% for dizygotic twins.

Linkage studies suggest that certain loci on genes and the X chromosome may contribute to genetic susceptibility of bipolar disorder.

Nongenetic factors*Perinatal insult**Head trauma**Environmental factors*

Desynchronization of circadian or seasonal rhythms cause diurnal variations in mood and sleep patterns and can result in seasonal recurrences of mood episodes.

Changes in the sleep-wake cycle or light-dark cycle can precipitate episodes of mania or depression.

Bright light therapy can be used for the treatment of winter depression and can precipitate hypomania, mania, or mixed episodes.

Psychosocial or physical stressors

Stressful life events often precede mood episodes and can increase recurrence rates and prolong time to recovery from mood episodes.

Nutritional factors

Deficiency of essential amino acid precursors in the diet can cause a dysregulation of neurotransmitter activity (e.g., L-tryptophan deficiency causes a decrease in 5-HT and melatonin synthesis and activity).

Deficiency in essential fatty acids (e.g., omega-3 fatty acids) can cause a dysregulation of neurotransmitter activity.

Neurotransmitter/neuroendocrine/hormonal theories

Dysregulation between excitatory and inhibitory neurotransmitter systems; excitatory: NE, DA, glutamate, and aspartate; inhibitory: 5-HT and GABA.

Monoamine hypothesis

An excess of catecholamines (primarily NE and DA) cause mania.

Agents that decrease catecholamines are used for the treatment of mania (e.g., DA antagonists and α_2 -adrenergic agonists).

Deficit of neurotransmitters (primarily NE, DA, and/or 5-HT) cause depression.

Agents that increase neurotransmitter activity are used for the treatment of depression (e.g., 5-HT and NE/DA reuptake inhibitors and MAOIs).

Dysregulation of amino acid neurotransmitters

Deficiency of GABA or excessive glutamate activity causes dysregulation of neurotransmitters (e.g., increased DA and NE activity).

Agents that increase GABA activity or decrease glutamate activity are used for the treatment of mania and for mood stabilization (e.g., benzodiazepines, lamotrigine, lithium, or valproic acid).

Cholinergic hypothesis

Deficiency of acetylcholine causes an imbalance in cholinergic-adrenergic activity and can increase the risk of manic episodes.

Agents that increase acetylcholine activity can decrease manic symptoms (e.g., use of cholinesterase inhibitors or augmentation of muscarinic cholinergic activity).

Increased central acetylcholine levels can increase the risk of depressive episodes.

Agents that decrease acetylcholine activity can alleviate depressive symptoms (i.e., anticholinergic agents).

Secondary messenger system dysregulation

Abnormal G protein functioning dysregulates adenylate cyclase activity, phosphoinositide responses, sodium/potassium/calcium channel exchange, and activity of phospholipases. Abnormal cyclic adenosine monophosphate and phosphoinositide secondary messenger system activity.

Abnormal protein kinase C activity and signaling pathways.

Hypothalamic-pituitary-thyroid axis dysregulation

Hyperthyroidism can precipitate manic-like symptoms.

Hypothyroidism can precipitate a depression and be a risk factor for rapid cycling; thyroid supplementation can be used for refractory rapid cycling and augmentation of antidepressants in unipolar depression.

Positive antithyroid antibody titers reported in patients with bipolar disorder.

Hormonal changes during the female life cycle can cause dysregulation of neurotransmitters (e.g., premenstrual, postpartum, and perimenopause).

Membrane and cation theories

Abnormal neuronal calcium and sodium activity and homeostasis cause neurotransmitter dysregulation.

Hypocalcemia has been associated with causing anxiety, mood irritability, mania, psychosis, and delirium.

Hypercalcemia has been associated with causing depression, stupor, and coma.

Extracellular and intracellular calcium concentrations may affect the synthesis and release of NE, DA, and 5-HT, as well as the excitability of neuronal firing.

Sensitization and kindling theories

Recurrences of mood episodes causes behavioral sensitivity and electrophysiologic kindling (similar to the amygdala-kindling models for seizures in animals) and can result in rapid or continuous mood cycling.

DA, dopamine; GABA, γ -aminobutyric acid; 5-HT, serotonin; MAOI, monoamine oxidase inhibitor; NE, norepinephrine.

Data from Torrey and Knable,¹ Goldberg and Harrow,⁴ Kelso,⁶ Manji et al.,⁷ Lenox et al.,⁸ Baron,⁹ Bezchlibnyk and Young,¹⁰ Goodnick,¹² Soares,¹³ Manji et al.,¹⁴ Gould and Manji,¹⁵ Sobczak et al.,¹⁶ Freeman et al.,¹⁷ Ketter and Wang,¹⁸ White,¹⁹ Rasgon et al.,²⁰ and Mahmood and Silverstone.²¹

NEUROCHEMICAL THEORIES

The kindling and behavioral sensitization model postulates that psychosocial stressors can result in manic or depressive episodes because various brain networks are sensitized for exaggerated and spontaneous reactions secondary to neurotransmitter imbalances or dysregulation and voltage-gated ion channel abnormalities.^{4,19} Dysregulation between neurotransmitters, neuropeptides, hormones, and secondary messenger systems can produce a cyclic rhythm disturbance in the central nervous system.^{1,4,7,12,19} Abnormal calcium, potassium, and sodium homeostasis can alter neurotransmitter release and the secondary messenger system.^{7,19} Hormonal changes during the menstrual cycle, postpartum period, and perimenopausal phase can contribute to mood dysregulation.^{17,20}

The “permissive serotonin hypothesis” proposes that serotonin (5-hydroxytryptamine or 5-HT) plays a critical role in modulating brain activity (e.g., stabilization of the catecholamine system and inhibition of dopamine [DA] release), and is low in both mania and depression.^{12,21} The type of affective state that is expressed with the permissive hypothesis is determined secondarily by the level of norepinephrine (NE) (e.g., increased amounts of NE lead to mania, decreased amounts lead to depression). L-tryptophan or 5-HT deficiency and changes in the light–dark cycle may result in reduced melatonin secretion from the pineal gland that disrupts the sleep–wake cycle, alters circadian rhythms, and causes seasonal affective changes.^{1,12,21}

The catecholamine hypothesis of mood disorders suggests that increased DA and norepinephrine activity contribute to hyperactivity and psychosis associated with the severe stages of mania, and reduced activity causes depression.^{4,12} A γ -aminobutyric acid (GABA) deficiency theory has been proposed for mania as it inhibits NE and DA activity.^{4,7,12} Glutamate and aspartate, excitatory amino acid neurotransmitters, may be overactive and involved in causing manic episodes.⁷ Cholinergic underactivity has been proposed to cause mania and overactivity of acetylcholine to cause depression.^{7,12} Acetylcholine is an antagonist of the catecholamine system and contributes to the interaction between phosphatidylinositol and phosphatidylcholine secondary messenger systems.⁷

DIAGNOSTIC DIFFICULTY

Several medical, medication-induced, or substance-related causes of mania and depression have been identified (see Table 72–2 for causes of mania and Table 71–1 in Chap. 71 for causes of depression).^{1–3} A complete medical, psychiatric, and medication history; physical examination; and laboratory testing are necessary to rule out any organic causes of mania or depression.³ An accurate diagnosis is important because some psychiatric and neurologic disorders present with manic-like or depressive-like symptoms.^{3,4} For example, attention-deficit/hyperactivity disorder and a manic episode have similar characteristics; thus individuals with bipolar disorder can be misdiagnosed and prescribed central nervous system stimulants.^{11,22} Use of any substance that affects the central nervous system (e.g., alcohol, antidepressants, caffeine, central nervous system stimulants, hallucinogens, or marijuana) can worsen symptoms of mania or depression and decrease response to treatment.^{3,12,23–25}

Another disease state that has a similar presentation to bipolar disorder is schizoaffective disorder. This disease is a mix between schizophrenia and bipolar disorder. Patients with schizoaffective disorder have mood episodes, but the distinguishing factor from bipolar disorder is that these patients experience psychosis even between mood episodes during periods of euthymia. Clinicians must rely on family members or others that know the patient to determine if the patient is psychotic between mood episodes. It can

TABLE 72-2 Secondary Causes of Mania

Medical conditions that induce mania

- CNS disorders (brain tumor, strokes, head injuries, subdural hematoma, multiple sclerosis, systemic lupus erythematosus, temporal lobe seizures, Huntington's disease)
- Infections (encephalitis, neurosyphilis, sepsis, human immunodeficiency virus)
- Electrolyte or metabolic abnormalities (calcium or sodium fluctuations, hyper- or hypoglycemia)
- Endocrine or hormonal dysregulation (Addison's disease, Cushing's disease, hyper- or hypothyroidism, menstrual-related or pregnancy-related or perimenopausal mood disorders)

Medications or drugs that induce mania

- Alcohol intoxication
- Drug withdrawal states (alcohol, α_2 -adrenergic agonists, antidepressants, barbiturates, benzodiazepines, opiates)
- Antidepressants (MAOIs, TCAs, 5-HT and/or NE and/or DA reuptake inhibitors, 5-HT antagonists)
- DA-augmenting agents (CNS stimulants: amphetamines, cocaine, sympathomimetics; DA agonists, releasers, and reuptake inhibitors)
- Hallucinogens (LSD, PCP)
- Marijuana intoxication precipitates psychosis, paranoid thoughts, anxiety, and restlessness
- NE-augmenting agents (α_2 -adrenergic antagonists, β -agonists, NE reuptake inhibitors)
- Steroids (anabolic, adrenocorticotrophic hormone, corticosteroids)
- Thyroid preparations
- Xanthines (caffeine, theophylline)
- Over-the-counter weight loss agents and decongestants (ephedra, pseudoephedrine)
- Herbal products (St. John's wort)

Somatic therapies that induce mania

- Bright light therapy
- Sleep deprivation

CNS, central nervous system; DA, dopamine; 5-HT, serotonin; LSD, lysergic acid diethylamide; MAOI, monoamine oxidase inhibitor; NE, norepinephrine; PCP, phencyclidine; TCA, tricyclic antidepressant. Data from Torrey and Knable,¹ American Psychiatric Association,² American Psychiatric Association,³ and Goodnick.¹²

be difficult for clinicians to obtain a full psychiatric history on patients, thus making schizoaffective disorder widely diagnosed. Schizoaffective disorder is treated with mood stabilizers and antipsychotics as maintenance therapy.

CLINICAL PRESENTATION

1 The essential feature of bipolar spectrum disorders are a history of mania or hypomania that is not caused by any other medical condition, substance, or psychiatric disorder (see Table 72–2 for secondary causes of mania).^{2,3} The *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR)* of the American Psychiatric Association (APA) details the present understanding of mood disorders.² Bipolar disorder is divided into four subtypes based on the identification of specific mood episodes: bipolar I, bipolar II, cyclothymic disorder, and bipolar disorder not otherwise specified. See Table 72–3 for a definition of mood disorders by type of episode. The mood states are further separated into four subcategories to differentiate the current or most recent mood episode: major depressive, manic, hypomanic, or mixed. See Table 72–4 for the evaluation and diagnostic criteria of mood episodes. A new concept of “bipolar spectrum disorder” has been suggested that broadens the diagnosis to include dysthymia, cyclothymia, drug-induced hypomania, and recurrent unipolar depression.^{4,26} Bipolar disorder is a cyclic mood disorder in which patients can move from one episode to another with or without a period of normal mood (euthymia) between. Persons with bipolar disorder can have mood fluctuations that continue for months, or after one episode they can sometimes go

TABLE 72-3 Mood Disorders Defined by Episodes

Disorder Subtype	Episode(s) ^a
Major depressive disorder, single episode	Major depressive episode
Major depressive disorder, recurrent	Two or more major depressive episodes
Bipolar disorder, type I ^b	Manic episode ± major depressive or mixed episode
Bipolar disorder, type II ^c	Major depressive episode + hypomanic episode
Dysthymic disorder	Chronic subsyndromal depressive episodes
Cyclothymic disorder ^d	Chronic fluctuations between subsyndromal depressive and hypomanic episodes (2 years for adults and 1 year for children and adolescents)
Bipolar disorder not otherwise specified	Mood states do not meet criteria for any specific bipolar disorder

^aThe length and severity of a mood episode and the interval between episodes varies from patient to patient. Manic episodes are usually briefer and end more abruptly than major depressive episodes. The average length of untreated manic episodes ranges from 4 to 13 months. Episodes can occur regularly (at the same time or season of the year) and often cluster at 12-month intervals. Women have more depressive episodes than manic episodes, whereas men have a more even distribution of episodes.

^bFor bipolar I disorder, 90% of individuals who experience a manic episode later have multiple recurrent major depressive, manic, hypomanic, or mixed episodes alternating with a normal mood state.

^cApproximately 5–15% of patients with bipolar II disorder will develop a manic episode over a 5-year period. If a manic or mixed episode develops in a patient with bipolar II disorder, the diagnosis is changed to bipolar I disorder.

^dPatients with cyclothymic disorder have a 15–50% risk of later developing a bipolar I or II disorder. Data from American Psychiatric Association,² Goldberg and Harrow,⁴ and Goodnick.¹²

years without recurrence of any type of mood episode. Comorbid psychiatric disorders associated with bipolar disorder include but are not limited to the following: alcohol and substance abuse, personality disorders, and anxiety disorders such as panic disorder, social anxiety disorder, and obsessive-compulsive disorder.^{2–4,12,23,25, 27,28}

MAJOR DEPRESSIVE EPISODE

Bipolar depression is often underdiagnosed and is frequently misdiagnosed as major depressive disorder.^{3,29} Approximately 95% of patients with bipolar disorder experience episodes of depression during their lifetime.^{2,4} Compared to manic episodes, depressive episodes are more frequent, longer lasting, and occur more often in bipolar II than in bipolar I disorder.^{4,30} Over a person's lifetime, depressive episodes can account for up to 80% of all mood episodes. Recurrent depressive episodes are more common in women compared to men.⁴ In bipolar depression, patients have an increased suicide risk and often have mood lability, hypersomnia, low energy, psychomotor retardation, cognitive impairment, anhedonia, decreased sexual activity, slowed speech, carbohydrate craving, and weight gain (also called atypical depressive features).^{4,30,31} Delusions, hallucinations, and suicide attempts are more common in bipolar depression than in unipolar depression.⁴

MANIC EPISODE

For a diagnosis of mania, the symptoms must last at least 1 week, the mood must be elevated (expansive or irritable), and there must be an impairment in functioning.² Acute mania usually begins abruptly, and symptoms escalate over several days. Common symptoms of mania include grandiosity, decreased need for sleep or food, pressured speech, flight of ideas (racing thoughts), distractibility, increased activity, poor judgment, and involvement in pleasurable activities with potentially negative consequences.² Patients with acute mania often have psychotic symptoms, thus some patients are incorrectly diagnosed as having schizophrenia.¹² Mania symptoms that can resemble paranoid schizophrenia are bizarre behavior, hallucinations, and paranoid or grandiose delusions. Seasonal changes, stressors,

sleep deprivation, antidepressants, central nervous system stimulants, or bright light can precipitate a manic episode.

HYPOMANIC EPISODE

Hypomania is a less severe form of mania, and by definition does not cause a marked impairment in social or occupational functioning, and no delusions or hallucinations are present.^{2,4} Patients with hypomania often do not seek treatment until they have a depressive episode, thus hypomania may not be recognized or reported.³ Symptoms found in hypomanic episodes are similar to those of cocaine- or antidepressant-induced mood disorders; thus the differential diagnosis should rule out any substance-induced or medical conditions that present with elevated mood.²⁵ Hypomanic states should be closely monitored, because 5% to 15% of patients can rapidly switch to a manic episode.⁴

MIXED EPISODE

Bipolar “mixed episode” (previously known as mixed state, dysphoric mania, or depressive mania) is defined as the simultaneous occurrence of manic and depressive symptoms.^{2,4} Mixed mood states occur in up to 40% of all episodes and are more common in younger and older patients and in females.⁴ Mixed episodes are often difficult to diagnose and treat because of the fluctuating clinical presentation. Patients with mixed states often have comorbid alcohol and substance abuse, severe anxiety symptoms, a higher suicide rate, and a poorer prognosis.^{4,25}

COURSE OF ILLNESS

1 Bipolar disorder is frequently not recognized and treated for many years because of its fluctuating course and episodic mood states.^{3,4,12} The onset of bipolar disorder is rare before puberty, but its incidence increases during late adolescence and into early adulthood (usually between the ages of 15 and 30 years).² The average age of onset of a first manic episode is 21 years for both men and women.³ The first episode in females is more likely to be a major depressive episode, whereas males are more likely to first experience a manic episode.^{2,3} Women are more likely to have mixed states, depressive episodes, and rapid cycling compared to men.^{2,3} Onset of manic episodes after the age of 60 years is rare and is likely caused by a medical or neurologic condition (e.g., stroke, tumor, or dementia), medications, or substance use.³

More than 80% of patients have more than 4 mood episodes during their lifetime; untreated patients can have 10 or more episodes during their lifetime.³ Episodes can become longer in duration and more frequent with aging.³ The kindling theory is used to explain why bipolar disorder progresses over one's life and why preventative treatment is imperative. Usually there is a period of normal functioning between episodes, but approximately 20% to 30% of patients with bipolar I disorder and 15% with bipolar II disorder have no period of euthymia because of mood lability, residual mood symptoms, or a direct switch to the opposite polarity.²

Rapid cycling (more than four mood episodes per year) is more common in females and occurs in approximately 10% to 20% of bipolar I and II disorder patients.^{1–4,17,24} Frequent and severe episodes of depression appear to be the most common hallmark of rapid cycling. Use of alcohol, stimulants, antidepressants, sleep deprivation, hypothyroidism, and seasonal changes can play a role in rapid cycling.^{4,24,32} Seasonal patterns of mania in the summer and depression during the winter have been observed.¹ Rapid-cycling patients have a poorer long-term prognosis and often require combination therapies.⁴

Bipolar disorder affects an estimated 1% of children and adolescents and is often harder to recognize, diagnose, and treat than in a

TABLE 72-4 Evaluation and Diagnostic Criteria of Mood Episodes

Diagnostic workup depends on clinical presentation and findings		<ul style="list-style-type: none"> • Mental status examination • Psychiatric, medical, and medication history • Physical and neurologic examination • Basic laboratory tests: complete blood count, blood chemistry screen, thyroid function, urinalysis, urine drug screen • Psychological testing • Brain imaging: magnetic resonance imaging and functional scan; alternative: computed tomography scan, positron emission tomography scan • Lumbar puncture • Electroencephalogram
Diagnosis Episode	Impairment of Functioning or Need for Hospitalization ^a	DSM-IV-TR Criteria ^b
Major depressive	Yes	<p>>2-Week period of either depressed mood or loss of interest or pleasure in normal activities, associated with at least five of the following symptoms:</p> <ul style="list-style-type: none"> • Depressed, sad mood (adults); can be irritable mood in children • Decreased interest and pleasure in normal activities • Decreased appetite, weight loss • Insomnia or hypersomnia • Psychomotor retardation or agitation • Decreased energy or fatigue • Feelings of guilt or worthlessness • Impaired concentration and decision making • Suicidal thoughts or attempts
Manic	Yes	<p>>1-Week period of abnormal and persistent elevated mood (expansive or irritable), associated with at least three of the following symptoms (four if the mood is only irritable):</p> <ul style="list-style-type: none"> • Inflated self-esteem (grandiosity) • Decreased need for sleep • Increased talking (pressure of speech) • Racing thoughts (flight of ideas) • Distractible (poor attention) • Increased activity (either socially, at work, or sexually) or increased motor activity or agitation • Excessive involvement in activities that are pleasurable but have a high risk for serious consequences (buying sprees, sexual indiscretions, poor judgment in business ventures)
Hypomanic	No	<p>At least 4 days of abnormal and persistent elevated mood (expansive or irritable); associated with at least three of the following symptoms (four if the mood is only irritable):</p> <ul style="list-style-type: none"> • Inflated self-esteem (grandiosity) • Decreased need for sleep • Increased talking (pressure of speech) • Racing thoughts (flight of ideas) • Increased activity (either socially, at work, or sexually) or increased motor activity or agitation • Excessive involvement in activities that are pleasurable but have a high risk for serious consequences (buying sprees, sexual indiscretions, poor judgment in business ventures)
Mixed	Yes	Criteria for both a major depressive episode and manic episode (except for duration) occur nearly every day for at least a 1-week period
Rapid cycling	Yes	>4 Major depressive or manic episodes (manic, mixed, or hypomanic) in 12 months

^aImpairment in social or occupational functioning; need for hospitalization because of potential self-harm, harm to others, or psychotic symptoms.

^bThe disorder is not caused by a medical condition (e.g., hypothyroidism) or substance-induced disorder (e.g., antidepressant treatment, medications, electroconvulsive therapy).

Data from Torrey and Knable,¹ American Psychiatric Association,² American Psychiatric Association.³

typical adult patient.^{2,3,24,33} Late adolescence (ages 15 to 19 years) is a period with increased vulnerability for the onset of bipolar disorder.¹² Approximately 10% to 15% of adolescents with recurrent major depressive episodes have a subsequent episode of mania or hypomania.² Early stressful experiences in childhood (e.g., physical or sexual abuse) can precipitate an earlier onset and result in faster cycling, increased suicide risk, and alcohol or substance abuse.^{4,12} Before the onset of mania, adolescents can exhibit irritability, hyperactivity, impulsivity, emotional lability, poor judgment, marked anxiety, insomnia, depression, and psychosis.^{2,12,22} Early-onset bipolar disorder (before age 7 years) often presents similarly to attention-deficit/hyperactivity disorder with extreme irritability or rages. A delay in diagnosing bipolar disorder can be a factor in causing treatment-refractory mixed states or rapid cycling.

Fluctuations in hormones and neurotransmitters during the luteal phase of the menstrual cycle, postpartum period, and during perimenopause (starting approximately 10 years before menopause) can precipitate mood changes and increase cycling.^{2,17,20}

Women with bipolar I disorder are at greater risk for relapse into mania or depression during the postpartum period.³ If a severe mood episode occurs postpartum, there is an increased risk for recurrences during subsequent postpartum periods.³

Alcohol and substance abuse is common among patients with bipolar disorder and can have a significant impact on the age of onset, course of the illness, and response to treatment.^{4,12,23,28} Alcohol and drug abuse or dependence has been reported in 46% and 41% of bipolar patients, respectively.^{3,12} Patients with substance use disorders are more likely to have an earlier onset of their illness, mixed states, higher rates of relapse, a poorer response to treatment, comorbid personality disorders, increased suicide risk, and more psychiatric hospitalizations.⁴ Bipolar patients can self-medicate with substances such as alcohol or cocaine during episodes, resulting in further impairment of judgment, poor impulse control, treatment nonadherence, and a worsening of the clinical course.^{3,4,25}

More than one-half (55% to 65%) of bipolar I patients have some degree of functional disability after the onset of their illness, and

approximately 10% to 20% of bipolar patients have severe impairment in their psychosocial and occupational functioning.^{1-4,34} In a 1-year longitudinal study in 258 bipolar patients, two-thirds had four or more mood episodes a year despite comprehensive pharmacologic treatment, and approximately 33.2% of the year was spent being depressed compared to 10.8% of the time in a manic phase.³⁴

Compared with the general population, individuals with bipolar disorder have a 2.3-times higher mortality rate.¹ Suicide attempts occur in up to 50% of patients with bipolar disorder, and approximately 10% to 19% of individuals with bipolar I disorder commit suicide.^{2-4,35} Recent studies suggest patients with bipolar II disorder have more suicide attempts than bipolar I patients.³¹ Suicidal ideation and attempts are most likely to occur in a depressive or mixed state and in patients with personality disorders, psychotic features, and/or a comorbid alcohol- and substance-use disorder.^{3,4,36} Acutely manic or depressed patients can need hospitalization because they are suicidal, have violent or aggressive behavior, or lack appropriate judgment and insight.³ Accidental deaths are more frequent during manic episodes when the person has grandiosity, hallucinations, or delusions that result in risk-taking behaviors.^{1,3} In addition, bipolar patients have a higher mortality from endocrine, respiratory, and cardiovascular disease that can be related to higher rates of obesity, smoking, alcohol and substance abuse, infections, and lack of medical care.^{1,3}

The best predictor for level of functioning during a person's lifetime is adherence with medication treatment. Medication discontinuation occurs in up to 50% of patients secondary to intolerance of drug-induced side effects.³⁷ Failure to recognize the disorder, reluctance to acknowledge it, or poor adherence with treatment are reasons an estimated two-thirds of patients with bipolar disorder do not receive appropriate treatment.¹ Nonadherence with pharmacologic treatment and substance abuse are major factors in relapse and hospitalizations.^{3,4}

TREATMENT

Bipolar Disorder

■ DESIRED OUTCOME

3 The desired outcome for bipolar disorder is to prevent acute manic, hypomanic, or depressive episode, to maintain good functioning, and to prevent further episodes of mania or depression.^{1,3,4} The general principles and goals for the management of bipolar disorder are found in Table 72-5.

■ GENERAL APPROACH TO TREATMENT

4 Treatment of bipolar disorder must be individualized because the clinical presentation, severity, and frequency of episodes vary widely among patients. Treatment approaches should include both nonpharmacologic and pharmacologic strategies.⁴ Patients and family members should be educated about bipolar disorder (e.g., symptoms, causes, and course) and treatment options. Long-term adherence to treatment is the most important factor in achieving stabilization of the disorder.

5 The treatment of bipolar disorder can vary depending on what type of episode a patient is experiencing. Once diagnosed with bipolar disorder patients should remain on a mood stabilizer (e.g. lithium, valproate) for life. During acute episodes medications can be added and then tapered once a patient is stabilized and euthymic. For example, when treating a patient for mania with psychotic features, the patient should be on a mood stabilizer and antipsychotic. If the antipsychotic is the patient's maintenance therapy, the dose should be increased or perhaps changed altogether. If treating

TABLE 72-5 General Principles for the Management of Bipolar Disorder

Goals of treatment

- Eliminate mood episode with complete remission of symptoms (i.e., acute treatment)
- Prevent recurrences or relapses of mood episodes (i.e., continuation phase treatment)
- Return to complete psychosocial functioning
- Maximize adherence with therapy
- Minimize adverse effects
- Use medications with the best tolerability and fewest drug interactions
- Treat comorbid substance use and abuse
- Eliminate alcohol, marijuana, cocaine, amphetamines, and hallucinogens
- Minimize nicotine use and stop caffeine intake at least 8 hours prior to bedtime
- Avoidance of stressors or substances that precipitate an acute episode

Monitor for

- Mood episodes: document symptoms on a daily mood chart (document life stressors, type of episode, length of episode, and treatment outcome); monthly and yearly life charts are valuable for documenting patterns of mood cycles
- Medication adherence (missing doses of medications is a primary reason for nonresponse and recurrence of episodes)
- Adverse effects, especially sedation and weight gain (manage rapidly and vigorously to avoid noncompliance)
- Suicidal ideation or attempts (suicide completion rates with bipolar I disorder are 10–15%; suicide attempts are primarily associated with depressive episodes, mixed episodes with severe depression or presence of psychosis)

Frequency of visits

- Severely ill patients should be seen more often (i.e., weekly) compared with less ill patients who are symptomatic (i.e., every 2 weeks)
- When starting new medications or switching therapies, frequent monitoring is recommended (e.g., every 2 weeks) to assess adherence, efficacy, dosing, and adverse effects
- When a patient is stabilized on medication, less frequent monitoring is possible during the continuation phase (e.g., every month for the first 3 months, then every 2–3 months)
- Patients should be encouraged to call their clinician if any problems or adverse events occur or if mood episodes occur between scheduled appointments; rapidly identifying and correcting potential problems or making dosage adjustments is essential in achieving mood stabilization

Data from Torrey and Knable,¹ American Psychiatric Association,³ Goodnick,¹² and Suppes et al.⁴²

a patient for a severe depressive episode, add an antidepressant to the mood stabilizer and an antipsychotic if psychosis is also present.

Nonpharmacologic Therapy

4 The basics of nonpharmacologic approaches should address issues of adequate nutrition, sleep, exercise, and stress reduction.^{1,4} Sleep deprivation, high stress, and deficiencies in dietary essential amino acids, fatty acids, vitamins, and minerals can exacerbate mood episodes and result in poorer outcomes.⁴ Mood charting is an effective strategy in detecting early signs and symptoms of mania and depression. Another effective treatment is to combine medications with adjunctive psychoeducational programs, supportive counseling, insight-oriented psychotherapy (individual or group), couples or family therapy, cognitive behavioral therapy, and communication enhancement training.^{1,3,4,12,38}

Most communities have self-help, support groups, and mental health organizations that provide information, educational materials, and support. For public information, individuals can contact the Depression and Bipolar Support Alliance at 800-826-3632 and www.dbsalliance.org; the National Alliance on Mental Illness (NAMI) at 800-950-6264 (help line) and www.nami.org; Mental Health America (National Mental Health Association) 800-969-6642 (resource center) and www.nmha.org; and National Institute of Mental Health at 866-615-6464 or www.nimh.nih.gov.^{1,3}

TABLE 72-6 Efficacy Ratings of Pharmacological Treatments Used in Bipolar I Disorder

Drug	Acute Mania or Mixed States	Acute Bipolar Depression	Continuation or Maintenance Therapy
Lithium			
Lithium carbonate	A+: monotherapy	A	A+
Anticonvulsants			
Carbamazepine	A: monotherapy	B	B
Divalproex	A+: monotherapy	C	A
Gabapentin	X: monotherapy and adjunctive	D	D
Lamotrigine	C: monotherapy B: rapid cycling	A	A+
Levetiracetam	D	D	D
Oxcarbazepine	B: monotherapy	D	B
Tiagabine	X: monotherapy D: adjunctive	D	D
Topiramate	C: monotherapy or adjunctive	C: adjunctive	C: adjunctive
Zonisamide	C: monotherapy	D	D
Antipsychotics			
Aripiprazole	A+: monotherapy	D	D
Clozapine	A: monotherapy for treatment-resistant patients	D	D
Haloperidol	A: monotherapy or adjunctive	D	D
Olanzapine	A+: monotherapy or adjunctive	B: adjunctive with fluoxetine	A+
Risperidone	A+: monotherapy or adjunctive	B: adjunctive	D
Quetiapine	A+: monotherapy or adjunctive	A+	D
Ziprasidone	A+: monotherapy	D	D

Definition of Ratings:

A = Efficacy established by two or more randomized, double-blind, placebo-controlled or comparator trials and/or recommended as a first-line agent by APA Practice Guidelines for the Treatment of Patients with Bipolar Disorder (Revision) or Texas Consensus Panel on Medication Treatment of Bipolar Disorder; + = approved by the FDA.

B = Efficacy suggested by one randomized, double-blind, placebo-controlled or comparator trial; recommended as a second-line (alternative) agent by APA Practice Guidelines for the Treatment of Patients with Bipolar Disorder (Revision) or Texas Consensus Panel on Medication Treatment of Bipolar Disorder; not approved by the FDA.

C = Efficacy suggested by two or more open-label and/or non-placebo-controlled trials; not approved by the FDA.

D = No controlled clinical trials and/or efficacy not established for monotherapy in bipolar disorder.

X = Not recommended due to negative results or no significant difference from placebo on a randomized, placebo-controlled or comparator trial.

APA, American Psychiatric Association, FDA, Food and Drug Administration.

Data from American Psychiatric Association,³ Suppes et al.,⁴² Sachs,⁴⁴ Keck and McElroy,⁴⁷ and Kuskamkar.⁴⁸

Several nonpharmacologic treatment strategies (e.g., electroconvulsive therapy [ECT], high-intensity bright light therapy, phase-advanced sleep schedule, and partial or complete sleep deprivation) have been used in the treatment of bipolar disorder.^{1,3,4} The use of ECT for severe episodes of mania, depression, psychotic features (e.g., hallucinations or delusions), mixed episodes, or rapid cycling is still considered the best acute treatment approach for those patients who do not respond to first-line mood stabilizers such as lithium and valproate.^{3,4} Repetitive transcranial magnetic stimulation has been reported to be effective in unipolar depression, but effectiveness in bipolar disorder is unknown.^{3,4,39}

Pharmacologic Therapy

5 Pharmacotherapy is crucial for the acute and maintenance treatment of bipolar disorder and includes lithium, valproate, carbamazepine, lamotrigine, atypical antipsychotics, and adjunctive agents such as antidepressants and benzodiazepines.

Medication Treatment of Choice

Published Guidelines and Treatment Protocols. Currently there are no published evidence-based studies that compare different agents and combination therapies for the treatment of acute mania, mixed states, and depression, and for the maintenance phase.^{3,40–45} An example of efficacy ratings for various medications used in bipolar I disorder is found in Table 72–6.^{3,42,44,47,48}

5 The term *mood stabilizer* is often used to describe the class of medications used in the treatment of bipolar disorder, but this may not be accurate as some medications are more effective for acute mania, some for the depressive episode, and others for the maintenance phase.^{3,47,49} Lithium, valproate (or divalproex sodium), aripiprazole, olanzapine, quetiapine, risperidone, and ziprasidone are currently approved by the Food and Drug Administration (FDA)

for the treatment of acute mania in bipolar disorder; only lithium, olanzapine, and lamotrigine are approved for the maintenance treatment of bipolar disorder. Quetiapine is the only antipsychotic that is FDA approved for bipolar depression. Lithium is the drug of choice for bipolar disorder with euphoric mania, whereas valproate has better efficacy for mixed states, irritable/dysphoric mania, and rapid cycling compared to lithium.³

Combination therapies (e.g., lithium plus valproate or carbamazepine; lithium or valproate plus an atypical antipsychotic) can provide better acute response and long-term prevention of relapse and recurrence than monotherapy in some bipolar patients particularly those with mixed states or rapid cycling.^{3,4,50} Controlled efficacy and safety studies addressing the combination of specific antidepressants with mood-stabilizing agents for acute versus long-term therapy are lacking.^{3,4,46}

6 Several guidelines and algorithms have been published regarding the treatment of bipolar disorder, and these are generally based on the best available data and the clinical consensus of experts. One excellent reference is the *Practice Guideline for the Treatment of Patients with Bipolar Disorder (Revision)* that was published in 2002 and revised in 2006 by the APA.³ The APA guidelines address the diagnosis, clinical course, epidemiology, and treatment strategies for adults but are not intended to be used as a standard of psychiatric care. The Texas Department of Mental Health and Mental Retardation has developed and implemented algorithms in the public mental health system to improve treatment outcomes with bipolar I disorder.^{42,51} Several other states have also adopted and implemented programs similar to the Texas algorithm project. In addition, an international task force of the World Federation of Societies of Biological Psychiatry has published guidelines for the treatment of bipolar depression and mania.^{43,52}

Based on the APA guidelines,³ the Texas algorithms for bipolar disorder,⁴² available research, and current marketing of medications,

TABLE 72-7 Algorithm and Guidelines for the Acute Treatment of Mood Episodes in Patients with Bipolar I Disorder

Acute Manic or Mixed Episode		Acute Depressive Episode	
General guidelines Assess for secondary causes of mania or mixed states (e.g., alcohol or drug use) Taper off antidepressants, stimulants, and caffeine if possible Treat substance abuse Encourage good nutrition (with regular protein and essential fatty acid intake), exercise, adequate sleep, stress reduction, and psychosocial therapy Optimize the dose of mood stabilizing medication(s) before adding on benzodiazepines; if psychotic features are present, add on antipsychotic; ECT used for severe or treatment-resistant manic/mixed episodes or psychotic features		General guidelines Assess for secondary causes of depression (e.g., alcohol or drug use) Taper off antipsychotics, benzodiazepines or sedative-hypnotic agents if possible Treat substance abuse Encourage good nutrition (with regular protein and essential fatty acid intake), exercise, adequate sleep, stress reduction, and psychosocial therapy Optimize the dose of mood stabilizing medication(s) before adding on lithium, lamotrigine, or antidepressant (e.g., bupropion or an SSRI); if psychotic features are present, add on an antipsychotic; ECT used for severe or treatment-resistant depressive episodes or for psychosis or catatonia	
Hypomania First, optimize current mood stabilizer or initiate mood-stabilizing medication: lithium, ^a valproate, ^a or carbamazepine. ^a Consider adding a benzodiazepine (lorazepam or clonazepam) for short-term adjunctive treatment of agitation or insomnia if needed Alternative medication treatment options: carbamazepine ^a ; If patient does not respond or tolerate, consider atypical antipsychotic (e.g., olanzapine, quetiapine, risperidone) or oxcarbazepine. Second, if response is inadequate, consider a two-drug combination: <ul style="list-style-type: none"> Lithium^a plus an anticonvulsant or an atypical antipsychotic Anticonvulsant plus an anticonvulsant or atypical antipsychotic 	Mania First, two or three drug combinations: lithium ^a or valproate ^a plus a benzodiazepine (lorazepam or clonazepam) for short-term adjunctive treatment of agitation or insomnia; lorazepam is recommended for catatonia. If psychosis is present, initiate atypical antipsychotic in combination with above. Alternative medication treatment options: carbamazepine ^a ; If patient does not respond or tolerate, consider oxcarbazepine. Second, if response is inadequate, consider a three-drug combination: <ul style="list-style-type: none"> Lithium^a plus an anticonvulsant plus an atypical antipsychotic Anticonvulsant plus an anticonvulsant plus an atypical antipsychotic Third, if response is inadequate, consider ECT for mania with psychosis or catatonia ^d ; or add clozapine for treatment-refractory illness	Mild to Moderate Depressive Episode First, initiate and/or optimize mood-stabilizing medication: lithium ^a or lamotrigine ^b Alternative anticonvulsants: valproate, ^a carbamazepine, ^a or oxcarbazepine.	Severe Depressive Episode First, two or three drug combinations: lithium ^a or lamotrigine ^b plus an antidepressant ^c ; lithium plus lamotrigine. If psychosis is present, initiate atypical antipsychotic in combination with above. Alternative anticonvulsants: valproate, ^a carbamazepine, ^a or oxcarbazepine. Second, if response is inadequate, consider adding an atypical antipsychotic (quetiapine). Third, if response is inadequate, consider a three drug combination: <ul style="list-style-type: none"> Lamotrigine^b plus an anticonvulsant plus an antidepressant Lamotrigine^b plus lithium^a plus an antidepressant Fourth, if response is inadequate, consider ECT for treatment-refractory illness and depression with psychosis or catatonia ^d

ECT, electroconvulsive therapy; MAOI, monoamine oxidase inhibitor; SNRI, serotonin-norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant.

^aUse standard therapeutic serum concentration ranges if clinically indicated; if partial response or breakthrough episode, adjust dose to achieve higher serum concentrations without causing intolerable adverse effects; valproate is preferred over lithium for mixed episodes and rapid cycling; lithium and/or lamotrigine is preferred over valproate for bipolar depression.

^bLamotrigine is not approved for the acute treatment of depression, and the dose must be started low and slowly titrated up to decrease adverse effects if used for maintenance therapy of bipolar I disorder. A drug interaction and a severe dermatologic rash can occur when lamotrigine is combined with valproate (i.e., lamotrigine doses must be halved from standard dosing titration).

^cAntidepressant monotherapy is not recommended for bipolar depression. Bupropion, SSRIs, (e.g., citalopram, escitalopram, or sertraline), and SNRIs (e.g., venlafaxine) have shown good efficacy and fewer adverse effects in the treatment of unipolar depression; MAOIs and TCAs have more adverse effects (e.g., weight gain) and can have a higher risk of causing antidepressant-induced mania; fluoxetine, fluvoxamine, nefazodone, and paroxetine inhibit liver metabolism and should be used with caution in patients on concomitant medications that require cytochrome P450 clearance; paroxetine and venlafaxine have a higher risk for causing a discontinuation syndrome.

^dECT is used for severe mania or depression during pregnancy and for mixed episodes; prior to treatment, anticonvulsants, lithium, and benzodiazepines should be tapered off to maximize therapy and minimize adverse effects.

Data from American Psychiatric Association,³ Suppes et al.,⁴² Sachs,⁴⁴ Keck and McElroy,⁴⁷ and Kuskmar.⁴⁸

an example treatment algorithm and guidelines for acute mood episodes in adult patients with bipolar I disorder are listed in Table 72-7.^{42,44,47,48} Because newer anticonvulsants, atypical antipsychotics, and combination therapies are under investigation for bipolar disorder, published guidelines, algorithms, and decision trees can be out of date as new scientific knowledge evolves. Selection of treatments for acute mood episodes (e.g., manic or mixed, depressive, or rapid cycling) and for maintenance strategies to prevent relapses of mood episodes should be individualized. Treatment plans should be based on patient-specific characteristics, comorbid psychiatric and medical conditions, and avoidance of drug interactions and adverse effects.³

There are few controlled studies in children and adolescents with bipolar disorder, thus little is known about the long-term efficacy and safety of specific agents or for combination therapies in this population.^{3,4,11,33,53} Published guidelines for treatment of bipolar disorder in children and adolescents include *Treatment Guidelines for Children and Adolescents with Bipolar Disorder: Child Psychiatric Workgroup on Bipolar Disorder*⁵⁴ and the *Practice Parameters for the Assessment and*

Treatment of Children and Adolescents with Bipolar Disorder by the American Academy of Child and Adolescent Psychiatry.¹¹

General Information Regarding Efficacy and Safety. Lithium was first used in 1949 as a treatment for mania and was approved in 1972 in the United States for the treatment of acute mania and for maintenance therapy. Lithium was the first established mood stabilizer, and is still considered a first-line agent for acute mania and continuation treatment of bipolar I and II disorder.^{47,55,56} Lithium is the only bipolar medication approved for children and adults aged 12 years and older. Long-term lithium treatment has been shown to reduce suicide risk in several studies.^{3,57} Patients with rapid cycling or mixed states may not respond as well to lithium monotherapy compared to some anticonvulsants.^{32,54} Lithium requires regular assessment of renal and thyroid functioning and lithium blood level monitoring to minimize adverse effects.³

In the 1980s, anticonvulsants were investigated for manic-depressive illness as the disorder had similar characteristics to episodic neurologic disorders such as epilepsy and migraines. Divalproex

sodium (known as sodium valproate) was marketed in 1995 for the acute treatment of mania in adults and is now the most prescribed mood stabilizer in the United States. Divalproex sodium is FDA approved only for the treatment of acute manic or mixed episodes; however it is commonly used in clinical practice as maintenance monotherapy for bipolar disorder. Although carbamazepine is commonly used for both acute and maintenance therapy, it is not approved in the United States for bipolar disorder. There are some data to support the use of oxcarbazepine, a 10-keto analogue of carbamazepine, in the treatment of bipolar disorder, however it is not approved for the treatment of bipolar disorder in the United States. Valproate, carbamazepine, and oxcarbazepine each have a wide range of neurologic, gastrointestinal, electrolyte, and hematologic adverse effects that requires regular assessment and routine blood work.

Lamotrigine, a newer anticonvulsant, was approved in 2003 in the United States for the maintenance treatment of bipolar I disorder.^{58,59} Lamotrigine add-on or monotherapy has been used for treatment-refractory bipolar depression.^{3,58} Lamotrigine is associated with causing hypersensitivity reactions and rare life-threatening skin rashes and requires slow dosage titration.³

Atypical antipsychotics such as aripiprazole, olanzapine, quetiapine, risperidone, and ziprasidone are effective as monotherapy or adjunctive therapy with lithium and valproate in the treatment of acute mania.⁶⁰ Some antipsychotics have the potential to cause adverse effects such as extrapyramidal reactions, sedation, emotional blunting, sexual dysfunction, metabolic syndrome, and orthostatic hypotension.^{12,61} Prophylactic use of antipsychotics can be needed for some patients with recurrent mania or mixed states, but the risks versus benefits must be weighed because of long-term adverse effects (e.g., obesity, type 2 diabetes, hyperlipidemia, hyperprolactinemia, cardiac disease, and tardive dyskinesia).^{48,62}

Alternative Drug Treatments **6** Although monotherapy with an established mood stabilizer is preferred for long-term maintenance, combinations of different types of medications can be necessary for patients during an acute episode of depression, mania, or mixed episodes who have partial or nonresponse to monotherapy, and for those who experience rapid cycling.^{3,48,63}

Benzodiazepines. High potency benzodiazepines such as clonazepam and lorazepam are commonly used as an alternative to or in combination with antipsychotics when patients are experiencing acute mania, agitation, anxiety, panic, and insomnia, or cannot take mood stabilizers (e.g., during the first trimester of pregnancy).^{3,4,27,64,65} Lorazepam is available for intramuscular injection and is useful in the acute management of agitation. Benzodiazepines cause minimal adverse effects compared to antipsychotics, and at higher doses, rapidly sedate agitated patients.⁴ Benzodiazepines can cause central nervous system depression, sedation, cognitive and motor impairment, dependence, and withdrawal reactions. Relative contraindications for long-term therapy with benzodiazepines are drug or alcohol abuse or dependency. When no longer required, benzodiazepines should be gradually tapered and discontinued to avoid withdrawal symptoms.

Antidepressants. Antidepressants are routinely added for the treatment of acute depression, but some studies have reported that specific classes such as the tricyclic antidepressants can carry an increased risk of inducing mania in bipolar I disorder and possibly cause rapid cycling.^{3,4} Some guidelines recommend avoiding antidepressants in the treatment of bipolar depression or limiting their use to brief intervals, but recent evidence suggests that the coadministration of mood stabilizers can reduce the risk of antidepressant-induced switching.⁴⁹ It is very important that before initiating therapy with an antidepressant, the patient should be on a therapeutic dosage or blood level of a primary mood stabilizer.³ Patients who have a history of mania after a depressive episode or who have

frequent cycling should be treated cautiously with antidepressants.^{3,4} In general, the antidepressant should be gradually withdrawn 2 to 6 months after remission, and the patient maintained on a mood-stabilizing agent.^{30,41} For patients with recurrent depressive episodes, long-term adjunctive treatment with antidepressants can be required to avoid relapses, particularly in bipolar II disorder.^{3,48,66} Treatment-resistant depression is often associated with using inadequate dosages and duration of treatment for mood-stabilizing agents and antidepressants, alcohol and substance abuse, poor compliance, and rapid cycling. For more information, see Chap. 71 for comparisons between antidepressants.

Calcium Channel Antagonists. Calcium channel antagonists inactivate voltage-sensitive calcium channels, thus inhibiting neurotransmitter synthesis and release and neuronal signal transmission.^{7,12} Verapamil, a nondihydropyridine, has demonstrated mood stabilizing properties in some studies but negative results were found in other trials.^{3,4,12,67} Nimodipine, a dihydropyridine, can be more effective than verapamil for rapid-cycling bipolar disorder because of its anticonvulsant properties, high lipid solubility, and good penetration into the brain.^{3,4,7,12,32,67} Calcium channel blockers are generally well tolerated, and the most common adverse effects are bradycardia and hypotension. The low teratogenic effects of these agents can make them a preferable choice over lithium or anticonvulsants during pregnancy and breastfeeding.¹² These are seldom used in everyday clinical practice.

Newer Anticonvulsants. Third-generation anticonvulsants have been investigated for treating bipolar disorder with the hope that a different mechanism of action would be beneficial for mood stabilization.^{1,68,69} Despite early reports of efficacy based on open-label trials, agents such as gabapentin and topiramate were not effective for acute mania in double-blind comparator trials.^{70–72} There is negative data for topiramate monotherapy in the treatment of acute mania from two placebo-controlled trials and two placebo-controlled trials with active comparator (lithium).⁷³ Topiramate has been used as an add-on weight-reduction medication, but there are no randomized controlled trials supporting its use in bipolar disorder.^{62,74} The effectiveness of gabapentin and topiramate as adjunctive agents for bipolar depression or for the maintenance phase still needs to be evaluated in controlled studies.^{4,69–71}

Newer anticonvulsants such as levetiracetam and zonisamide have several published case reports or open trials showing efficacy in mania and treatment-refractory rapid cycling, but it is too early to predict whether they have a place in either acute or maintenance therapy.^{46,69,71} Tiagabine has caused seizures in patients with bipolar disorder and has two negative open-label trials, thus there is little support for its safety and efficacy as a mood stabilizer.⁶⁹

CLINICAL CONTROVERSY

The place in therapy of the newer anticonvulsants, such as gabapentin, levetiracetam, tiagabine, topiramate, and zonisamide, is controversial. Many clinicians consider these agents to be less effective than established mood stabilizers based on initial studies and avoid them for monotherapy in bipolar disorder.

No published algorithms and guidelines have addressed the long-term use of combination therapies; thus the concurrent use of psychotropic agents from different classes remains controversial. At present the best approach is to maximize the dose and/or blood levels of the established mood stabilizer, and if possible, to taper off any adjunctive agent once the mood episode has resolved.

Novel Agents and Dietary Intake. Disturbances in 5-HT neurotransmission secondary to inadequate dietary L-tryptophan or

abnormalities in tryptophan hydroxylase, 5-HT transporters, and 5-HT receptors was implicated in the pathophysiology of manic-depressive illness as early as 1958.¹² Low 5-HT activity can be a trait marker for bipolar disorder.²¹ If available 5-HT is low, the synthesis and secretion of melatonin can be disrupted, thus causing circadian rhythm changes.¹² Acute tryptophan depletion has been shown to reverse the antidepressant effects of 5-HT reuptake inhibitors in depressed patients in remission, but may not negatively affect mood in lithium-stabilized bipolar patients.⁷⁵ Randomized controlled studies of L-tryptophan or 5-hydroxytryptophan have shown positive results in the acute treatment and prophylaxis of bipolar disorder.¹² Because 5-HT synthesis in the brain is dependent on dietary L-tryptophan intake, the importance of adequate and regular ingestion of animal-derived protein should be discussed with patients.¹²

A dietary deficiency in essential fatty acids (found in certain fish oils and flaxseed oil that contains α -linolenic acid) has been proposed as a potential cause of mood disorders.^{76,77} Omega-3 fatty acids have been shown to suppress neuronal pathways and inhibit kindling processes by several mechanisms (e.g., inhibition of phosphatidylinositol and G-protein secondary messengers and blocking L-type calcium channels). Seafood and fish are rich dietary sources of omega-3 essential fatty acids, specifically docosahexaenoic acid and eicosapentaenoic acid.⁷⁷ It seems that omega-3 fatty acids may have more antidepressant effects than antimanic.⁷⁷ Data reported by Keck and colleagues for bipolar depression and rapid cycling did not support the use of eicosapentaenoic acid.⁷⁸ The data supporting the use of omega-3 fatty acids is controversial and needs to be evaluated further.

Special Populations

The approach for treating bipolar disorder in special populations (e.g., comorbid medical or psychiatric disorders, pregnancy, or breast-feeding) can vary among clinicians. Patients with comorbid medical conditions or concomitant substance abuse, those older than 65 years of age, and pregnant patients can require different treatment approaches. Approximately 20% to 50% of women with bipolar disorder relapse postpartum; therefore prophylaxis with mood stabilizers is recommended immediately postpartum to decrease the risk of relapse.⁷⁹

Prophylactic medications such as lithium or valproate can prevent postpartum episodes in women with bipolar disorder.³ Pharmacotherapy during pregnancy is complicated, and the risk-to-benefit ratio must be weighed. Infants whose mothers took lithium during the first trimester of pregnancy may have a lower incidence of cardiovascular defects (particularly Epstein's anomaly) than was previously thought.^{3,12} Initial estimates of Epstein's anomaly in infants exposed to lithium during the first trimester was 400 times higher than in the general population rate of approximately 1:20,000 live births.⁸⁰ Current estimates of this malformation during the first trimester are estimated between 1:1,000 and 1:2,000.⁸⁰ Lithium freely crosses the placenta and is found in equal concentrations in maternal and fetal blood.⁸¹ When lithium is used during pregnancy, it should be tapered down to the lowest effective dose necessary to decrease the risk of relapse. Lithium can cause a "floppy" infant syndrome (e.g., low Apgar scores, lethargy, hypotonia, bradycardia, cyanosis, shallow respiration, and poor sucking), hypothyroidism, and nontoxic goiters. Milk concentrations of lithium range from 30% to 50% of the mother's serum concentration, and serum concentrations in the nursing infant are 10% to 50% of the mother's; thus breast-feeding is usually discouraged.^{3,12,82}

The use of anticonvulsants also pose a teratogenic risk when used during pregnancy. Neural tube defects cause the most concern for clinicians treating pregnant patients during their first trimester of pregnancy. Carbamazepine's risk of neural tube defects is estimated

to be 0.5% to 1% and valproate's risk is higher at 5% to 9%.⁸⁰ Carbamazepine is excreted in breast milk (the milk-to-maternal plasma ratio of carbamazepine is approximately 0.4).⁴ Craniofacial, developmental delays, microcephaly, and other abnormalities are also of concern when using anticonvulsants. Lamotrigine's registry of 1,081 cases as of September 2003 shows 9 major defects in women treated with monotherapy.⁸⁰ Data thus far on lamotrigine shows major malformation rates similar to the general population, but data for lamotrigine is much more limited than for some older anticonvulsants.⁸⁰ Valproate is usually not recommended during the first trimester of pregnancy because of a 1% to 5% risk of neural tube birth defects, primarily spina bifida.^{81,83} Administration of folate can reduce the risk of neural tube defects; therefore the risks versus benefits of using valproate during pregnancy must be discussed with the patient.¹² Valproic acid is excreted into human breast milk in low concentrations (less than 1% to 10% of the mother's serum level), so is considered to be compatible with breast-feeding.⁴ One case report of thrombocytopenia and anemia from valproate exposure has been reported in a nursing infant. If the mother receives valproate during breast-feeding, mother and infant should have identical laboratory monitoring. Caution should be used when prescribing antipsychotics during pregnancy. There are far more data on the use of typical than atypical antipsychotics during pregnancy. The most data are available for chlorpromazine, and these data show no elevated rate of physical malformations during first trimester exposure.

Treatment of catatonia also varies from standard treatment in that mood stabilizers and antipsychotics have minimal effect. Catatonic features such as mutism, motor excitement, stereotypic movements, waxy flexibility, negativism, echopraxia, and echolalia are best treated with benzodiazepines, specifically lorazepam. The use of antipsychotics in catatonia should be minimized because of an increased risk of neuroleptic malignant syndrome. ECT is usually a treatment of choice in this patient population.

DRUG CLASS INFORMATION

Product information, dosing and administration, clinical use, and proposed mechanism of action for agents used in the treatment of bipolar disorder are found in Table 72–8.

7 Recommendations for baseline and routine laboratory testing for patients receiving carbamazepine, lamotrigine, lithium, atypical antipsychotics, oxcarbazepine, and valproate are found in Table 72–9.

Antipsychotics

Pharmacology and Mechanism of Action Typical (conventional) antipsychotic agents that block DA₂ receptors and newer atypical antipsychotics that block both DA₂ and 5-HT_{2A} receptors are used to decrease DA activity in the treatment of mania and mixed states.

Pharmacokinetics A summary of the absorption, distribution, metabolism, and elimination data on antipsychotics can be found in Chap. 70.

Efficacy Typical antipsychotic agents (e.g., chlorpromazine and haloperidol) are effective in up to 70% of patients with acute mania, particularly those with psychosis and psychomotor agitation. Atypical antipsychotics have demonstrated similar efficacy and fewer side effects than typical antipsychotics for the treatment of acute mania associated with agitation, aggression, and psychosis.^{3,60,61,84,85} Currently aripiprazole, olanzapine, quetiapine, risperidone, and ziprasidone are FDA approved for the treatment of acute manic episodes in bipolar I disorder. Depot antipsychotics (e.g., haloperidol decanoate, fluphenazine decanoate, and risperidone long-acting injection) can have a place in maintenance treatment of bipolar disorder patients with noncompliance or treatment-resistance.³ Controlled studies in

TABLE 72-8 Product Formulations, Dosage and Administration, Clinical Use, and Proposed Mechanism of Action of Agents Used in the Treatment of Bipolar Disorder

Generic Name	Trade Name	Formulations	Dosage and Administration	Clinical Use	Proposed Mechanism of Action
<i>Lithium salts: FDA-approved for bipolar disorder</i>					
Lithium carbonate	Eskalith	Capsule: 300 mg	900–2,400 mg/day in 2–4 divided doses, preferably with meals. There is wide variation in the dosage needed to achieve therapeutic response and trough serum lithium concentration (i.e., 0.6–1.2 mEq/L for maintenance therapy and 1.0–1.2 mEq/L for acute mood episodes taken 8–12 hours after the last dose).	Use alone or in combination with other drugs (e.g., valproate, carbamazepine, antipsychotics) for the acute treatment of mania and for maintenance treatment.	Normalizes or inhibits secondary messenger systems (e.g., inhibits phosphoinositide and adenylate cyclase signaling; normalizes guanine nucleotide-binding protein [G protein] signal transduction system); Decreases 5-HT reuptake and increases postsynaptic 5-HT receptor sensitivity; Inhibits the synthesis of DA, decreases the number of β -adrenergic receptors and inhibits DA2 and β -adrenergic receptor supersensitivity; Enhances GABAergic activity and normalizes GABA levels; Reduces glutamatergic activity (e.g., increases glutamate uptake) with chronic therapy. Decreases Ca ⁺ transport into cells, interferes with Ca ⁺ -Na ⁺ active transport system, increases renal tubular reabsorption of Ca ⁺ and increases serum Ca ⁺ and parathyroid concentrations; Increases choline in red blood cells and potentiates the cholinergic secondary messenger system.
	Eskalith CR	Extended-release tablet: 450 mg			
	Lithobid	Extended-release tablet: 300 mg			
Lithium citrate	Generic	Tablet: 300 mg (scored)			
		Capsule: 150, 300, 600 mg			
	Cibalith-S	8 mEq/5 mL			
<i>Anticonvulsants: FDA-approved for bipolar disorder</i>					
Divalproex sodium	Depakote	Enteric-coated, delayed-release tablet: 125, 250, 500 mg	750–3,000 mg/day (20–60 mg/kg per day) given once daily or in divided doses for delayed-release divalproex or valproic acid.	Use alone or in combination with other drugs (e.g., lithium, carbamazepine, antipsychotics) for the acute treatment of mania and for maintenance treatment. Use caution when combining with lamotrigine because of potential drug interaction.	Increases GABA levels in plasma and CNS; inhibits GABA catabolism, increases synthesis, and release; can prevent GABA reuptake; enhances the action of GABA at the GABA _A receptor; Normalizes Na ⁺ and Ca ⁺ channels; Reduces intracellular inositol and protein kinase C isozymes; Can modulate gene expression. Antikindling properties can decrease rapid cycling and mixed states.
		Sprinkle capsule: 125 mg	Extended-release divalproex can be given once daily at bedtime after stabilization.		
	Depakote ER	Enteric-coated extended release tablet: 250, 500 mg	A loading dose of divalproex (20–30 mg/kg per day) can be given, then 20 mg/kg per day and titrated to a serum concentration of 50–125 mcg/mL or clinical response.		
Valproic acid	Depakene	Capsule: 250 mg	50–400 mg/day in divided doses.	Use alone or in combination with other drugs (e.g., lithium, carbamazepine) for long-term maintenance treatment for bipolar I disorder. Lamotrigine can have efficacy for prevention of bipolar depression	Blocks voltage-sensitive Na ⁺ and Ca ⁺ channels; Modulates or decreases presynaptic aspartate and glutamate release; Antikindling properties may decrease rapid cycling and mixed states.
Valproate sodium	Depakene	Syrup: 250 mg/5 mL	Dosage should be slowly increased (e.g., 25 mg/day for 2 weeks, then 50 mg/day for weeks 3 and 4, then 50-mg/day increments at weekly intervals up to 200 mg/day).		
Lamotrigine	Lamictal	Tablet: 25, 100, 150, 200 mg Chewable tablet: 2, 5, 25 mg	When combined with valproate, initial and titration dosing should be decreased by 50% to minimize the risk of a serious rash.		
<i>Anticonvulsants: Not FDA-approved for bipolar disorder</i>					
Carbamazepine	Tegretol, Epitol	Tablet: 200 mg	200–1,800 mg/day in 2–4 divided doses.	Use alone or in combination with other medications (e.g., lithium, valproate, antipsychotics) for the acute and long-term maintenance treatment of mania or mixed episodes for bipolar I disorder. APA guidelines recommend reserving it for patients unable to tolerate or who have inadequate response to lithium or valproate.	Blocks voltage-sensitive Na ⁺ channels; Stimulates the release of antidiuretic hormone and decreases Na ⁺ serum concentrations; Blocks Ca ⁺ influx through the NMDA glutamate receptor and decreases Ca ⁺ serum concentrations; Modulates presynaptic aspartate and glutamate release; Antikindling properties may decrease rapid cycling and mixed states.
		Chewable tablet: 100 mg	Dosage should be slowly increased according to response and adverse effects (e.g., 100–200 mg twice daily and increase by 200 mg/day at weekly intervals). Dose can be increased rapidly for inpatients.		
	Suspension: 100 mg/5 mL				
	Tegretol-XR	Extended-release tablet: 100, 200, 400 mg	Administer conventional tablets and suspension with meals. Extended-release tablets should be swallowed whole and not be broken or chewed.		
	Carbatrol	Extended-release capsule: 200, 300 mg	Carbatrol capsules can be opened and contents sprinkled over food.		
Equetro	Extended-release capsule: 100, 200, 300 mg				

(continued)

(continued)

TABLE 72-8 Product Formulations, Dosage and Administration, Clinical Use, and Proposed Mechanism of Action of Agents Used in the Treatment of Bipolar Disorder (continued)

Generic Name	Trade Name	Formulations	Dosage and Administration	Clinical Use	Proposed Mechanism of Action
Oxcarbazepine	Trileptal	Tablet: 150, 300, 600 mg Suspension: 300 mg/5 mL	300–1,200 mg/day in two divided doses. Dosage should be slowly adjusted up and down according to response and adverse effects (e.g., 150–300 mg twice daily and increase by 300–600 mg/day at weekly intervals). Dose can be increased rapidly for inpatients.	Can have fewer adverse effects and be better tolerated than carbamazepine	Oxcarbazepine and its monohydroxy metabolite increase K ⁺ conductance; modulates the activity of high-voltage activated Ca ⁺ channels; and blocks Na ⁺ channels.
Clonazepam	Klonopin	Tablet: 0.5, 1, 2 mg	0.5–20 mg/day in divided doses or one dose at bedtime. Dosage should be slowly adjusted up and down according to response and adverse effects.	Use in combination with other drugs (e.g., antipsychotics, lithium, valproate) for the acute treatment of mania or mixed episodes. Use as a short-term adjunctive sedative-hypnotic agent.	Binds to the benzodiazepine site and augments the action of GABA _A by increasing the frequency of Cl ⁻ channel opening, which causes hyperpolarization (a less excitable state) and inhibits neuronal firing.
Lorazepam	Ativan	Tablet: 0.5, 1, 2 mg Oral solution: 2 mg/mL Injection: 2, 4 mg/mL	2–40 mg/day in divided doses or one dose at bedtime. Dosage should be slowly adjusted up and down according to response and adverse effects.		
<i>Atypical antipsychotics: FDA-approved for bipolar disorder</i>					
Aripiprazole	Abilify	Tablet: 5, 10, 15, 20, 30 mg	10–30 mg/day once daily	Use in combination with lithium or valproate for the acute treatment of mania or mixed states (primarily with psychotic features) for bipolar I disorder. Only olanzapine is FDA-approved at this time for maintenance treatment and only quetiapine for bipolar depression.	Antagonist of postsynaptic DA ₂ receptors; atypical agents also block 5-HT _{2A} receptors that increase the presynaptic release of DA, thus lowering the risk of extrapyramidal symptoms and prolactin release
Olanzapine	Zyprexa	Tablet: 2.5, 5, 7.5, 10, 15, 20 mg	5–20 mg/day once daily or in divided doses		Receptor blockade varies by agent: DA ₄ , 5-HT _{2A-2C} , α_{1-2} -adrenergic, muscarinic, and histamine ₁ .
	Zyprexa Zydis	Tablet, orally disintegrating: 5, 10, 15, 20 mg			
Quetiapine	Seroquel	Tablet: 25, 50, 100, 200, 300, 400 mg	50–800 mg/day in divided doses or once daily when stabilized		
Risperidone	Risperdal	Tablet: 0.25, 0.5, 1, 2, 3, 4 mg Oral solution: 1 mg/mL	0.5–6 mg/day once daily or in divided doses		
	Risperdal M-Tab	0.5, 1, 2, 3, 4 mg			
Ziprasidone	Geodon	Capsule: 20, 40, 60, 80 mg	40–160 mg/day in divided doses		
<i>Calcium channel blockers: Not FDA-approved for bipolar disorder</i>					
Nimodipine	Nimotop	Capsule: 30 mg	30–120 mg/day	Use as third-line agent for combination with other drugs (e.g., carbamazepine, valproate, antipsychotics).	Blocks Ca ⁺ influx through L-type Ca ⁺ channels
Verapamil	Verelan	Capsule: 120, 180, 240, 360 mg	80–480 mg/day		Alters Ca ⁺ -Na ⁺ exchange Decreases 5-HT, DA, and endorphin activity
	Calan, Isoptin	Film-coated tablet: 40, 80, 120 mg Extended-release tablet: 120, 180, 240 mg			

APA, American Psychiatric Association; Ca⁺, calcium; Cl⁻, chloride; DA, dopamine; FDA, Food and Drug Administration; GABA, γ -aminobutyric acid; 5-HT, serotonin; K⁺, potassium; Na⁺, sodium; NMDA, N-methyl-D-aspartate; NE, norepinephrine.

Compiled data from Torrey and Knable,¹ American Psychiatric Association,³ Goldberg and Harrow,⁴ Manji et al.,^{7,9} Goodnick,^{12,17} and White.^{19,24}

acute mania with lithium or valproate plus an antipsychotic suggest greater efficacy with combination therapies compared with any of these agents alone.^{3,60} Adjunctive atypical antipsychotics can be beneficial in the treatment of breakthrough manic episodes or if there is incomplete response to monotherapy with lithium or valproate.

Olanzapine has shown efficacy in the treatment of acute manic, mixed, and depressive phases with or without psychotic features in double-blind trials (compared with placebo, lithium, valproate, and haloperidol).^{60,84} Olanzapine is also efficacious for maintenance therapy in bipolar disorder. When compared to placebo, olanzapine increases time to symptomatic relapse of any mood episode (22 days, 174 days, respectively).⁸⁶ Olanzapine is the only antipsychotic that has FDA approval for bipolar maintenance therapy.

Risperidone, in combination with other mood-stabilizing agents (lithium or valproate), and as monotherapy (versus haloperidol, lithium, and placebo) has demonstrated efficacy in several double-blind acute mania trials.^{3,12,60,87} Quetiapine at higher doses (e.g., 400 to 800 mg/day) has been reported to be effective for monotherapy and as an adjunctive agent with standard mood stabilizers in acute mania in double-blind, placebo-controlled trials.^{88,89} Ziprasidone was more effective than placebo in a double-blind, placebo-controlled study for acute mania but has also been associated with inducing mania or hypomania.⁹⁰ Aripiprazole, has been evaluated in three randomized, placebo-controlled studies in bipolar I disorder patients with an acute manic or mixed episode.⁹¹ Aripiprazole was statistically significantly better than placebo in one 3-week study at

TABLE 72-9 Guidelines for Baseline and Routine Laboratory Tests and Monitoring for Agents Used in the Treatment of Bipolar Disorder

	Baseline: Physical Examination & General Chemistry ^a	Hematologic Tests ^b		Metabolic Tests ^c		Liver Function Tests ^d		Renal Function Tests ^e		Thyroid Function Tests ^f		Serum Electrolytes ^g		Dermatologic ^h

Oxcarbazepine ^m	X											X	X		
Valproate ⁿ	X	X	X	X	X	X	X							X	X

^aScreen for drug abuse and serum pregnancy.^bComplete blood cell count (CBC) with differential and platelets.^cFasting glucose, serum lipids, weight.^dLactate dehydrogenase, aspartate aminotransferase, alanine aminotransferase, total bilirubin, alkaline phosphatase.^eSerum creatinine, blood urea nitrogen, urinalysis, urine osmolality, specific gravity.^fTriiodothyronine, total thyroxine, thyroxine uptake, and thyroid-stimulating hormone.^gSerum sodium.^hRashes, hair thinning, alopecia.ⁱAtypical antipsychotics: Monitor for increased appetite with weight gain (primarily in patients with initial low or normal body mass index); monitor closely if rapid or significant weight gain occurs during early therapy; cases of hyperlipidemia and diabetes reported.^jCarbamazepine: Manufacturer recommends CBC and platelets (and possibly reticulocyte counts and serum iron) at baseline, and that subsequent monitoring be individualized by the clinician (e.g., CBC, platelet counts, and liver function tests every 2 weeks during the first 2 months of treatment, then every 3 months if normal). Monitor more closely if patient exhibits hematologic or hepatic abnormalities or if the patient is receiving a myelotoxic drug; discontinue if platelets are $<100,000/\text{mm}^3$, if white blood cell (WBC) count is $<3,000/\text{mm}^3$ or if there is evidence of bone marrow suppression or liver dysfunction. Serum electrolyte levels should be monitored in the elderly or those at risk for hyponatremia. Carbamazepine interferes with some pregnancy tests.^kLamotrigine: If renal or hepatic impairment, monitor closely and adjust dosage according to manufacturer's guidelines. Serious dermatologic reactions have occurred within 2–8 weeks of initiating treatment and are more likely to occur in patients receiving concomitant valproate, with rapid dosage escalation, or using doses exceeding the recommended titration schedule.^lLithium: Obtain baseline electrocardiogram for patients older than 40 years or if preexisting cardiac disease (benign, reversible T-wave depression can occur). Renal function tests should be obtained every 2–3 months during the first 6 months, then every 6–12 months; if impaired renal function, monitor 24-hour urine volume and creatinine every 3 months; if urine volume $>3 \text{ L/day}$, monitor urinalysis, osmolality, and specific gravity every 3 months. Thyroid function tests should be obtained once or twice during the first 6 months, then every 6–12 months; monitor for signs and symptoms of hypothyroidism; if supplemental thyroid therapy is required, monitor thyroid function tests and adjust thyroid dose every 1–2 months until thyroid function indices are within normal range, then monitor every 3–6 months.^mOxcarbazepine: Hyponatremia (serum sodium concentrations $<125 \text{ mEq/L}$) has been reported and occurs more frequently during the first 3 months of therapy; serum sodium concentrations should be monitored in patients receiving drugs that lower serum sodium concentrations (e.g., diuretics or drugs that cause inappropriate antidiuretic hormone secretion) or in patients with symptoms of hyponatremia (e.g., confusion, headache, lethargy, and malaise). Hypersensitivity reactions have occurred in approximately 25–30% of patients with a history of carbamazepine hypersensitivity and requires immediate discontinuation.ⁿValproate: Weight gain reported in patients with low or normal body mass index. Monitor platelets and liver function during first 3–6 months if evidence of increased bruising or bleeding. Monitor closely if patients exhibit hematologic or hepatic abnormalities or in patients receiving drugs that affect coagulation, such as aspirin or warfarin; discontinue if platelets are $<100,000/\text{mm}^3/\text{L}$ or if prolonged bleeding time. Pancreatitis, hyperammonemic encephalopathy, polycystic ovary syndrome, increased testosterone, and menstrual irregularities have been reported; not recommended during first trimester of pregnancy due to risk of neural tube defects.Data from American Psychiatric Association,³ Goodnick,¹² McEvoy et al.,⁹⁵ McEvoy et al.,⁹⁶ McEvoy et al.,⁸¹ McEvoy et al.,⁸³ and McEvoy et al.¹⁰³

doses of 30 mg/day, however clinical significance is low because there was only a five point difference between aripiprazole and placebo in rating scale scores.⁹² Clozapine monotherapy has acute and long-term mood-stabilizing effects in refractory bipolar disorder, including conditions with mixed mania and rapid cycling, but requires regular white blood cell monitoring for agranulocytosis.^{3,12,79} The long-term safety and efficacy of antipsychotics for monotherapy or as an adjunctive treatment for bipolar depression and as a prophylactic agent in bipolar disorder still needs to be evaluated.^{3,49,84,85}

Adverse Effects A summary of adverse effects for antipsychotics can be found in Chap. 70.

Drug-Drug Interactions A summary of drug interactions with antipsychotics can be found in Chap. 70.

Dosing and Administration For acute mania, higher initial doses of antipsychotics can be required (e.g., olanzapine 20 mg/day in hospitalized patients). Once acute mania is controlled (usually within 7 to 28 days), the antipsychotic can be gradually tapered and discontinued, and the patient maintained on the mood stabilizer alone.

Carbamazepine

Pharmacology and Mechanism of Action Carbamazepine, a dibenzazepine derivative, is structurally related to the tricyclic antidepressants.^{12,92} The precise mechanism of action of carbamazepine in affective disorders remains to be elucidated.⁹ Proposed mechanisms of action for carbamazepine are listed in Table 72–8.

Pharmacokinetics A summary of the absorption, distribution, metabolism, and elimination data for carbamazepine can be found in Chap. 58.

Efficacy Carbamazepine is not a first-line agent for bipolar disorder, and is generally reserved for lithium-refractory patients, rapid cyclers, or for mixed states.^{1,3,12} Carbamazepine has acute antimanic effects comparable to lithium and chlorpromazine, but its long-term effectiveness is unclear.^{3,12} One comparison trial in hospitalized manic patients indicated that carbamazepine was less effective and needed more rescue adjunctive medications than valproate.³ Other comparison studies with lithium have reported carbamazepine to be less effective than lithium for maintenance therapy.³ In a double-blind, placebo-controlled crossover study and in an open study, carbamazepine showed efficacy in the treatment of bipolar depression.^{3,12} Studies with treatment-refractory patients have reported that carbamazepine has both acute and long-term prophylactic effects.^{4,12} A gradual loss of efficacy over time (similar to lithium and valproate) has been reported in some patients.^{4,12}

The combination of carbamazepine with lithium, valproate, and antipsychotics is often used for treatment-resistant patients experiencing a manic episode.¹² Carbamazepine increases the hepatic metabolism of antidepressants, anticonvulsants, and antipsychotics; thus dosage increases can be necessary (see drug-drug interactions).

tions).^{12,93} Calcium channel blockers (i.e., verapamil and diltiazem) increase carbamazepine blood levels; thus combination therapy should be closely monitored.⁹³ The combination of carbamazepine with nimodipine for treatment-refractory bipolar illness can have potential benefit.⁹⁴

Adverse Effects A summary of adverse effects for carbamazepine can be found in Chap. 58. Acute overdoses of carbamazepine are potentially lethal, and serum levels above 15 mcg/mL are associated with ataxia, choreiform movements, diplopia, nystagmus, cardiac conduction changes, seizures, and coma.³ Gastric lavage, hemoperfusion, and symptomatic treatment are recommended for the management of carbamazepine toxicity.

Drug-Drug Interactions Carbamazepine significantly induces the hepatic cytochrome P450 isoenzyme 3A4 and to a lesser degree 1A2, 2C9/10, and 2D6, which increases the metabolism of many medications.^{3,4,93} Women who receive carbamazepine require higher dosages of oral contraceptives or alternative contraceptive methods.⁴

Carbamazepine is metabolized to an active 10,11-epoxide metabolite, thus medications that inhibit 3A4 isoenzymes can result in carbamazepine toxicity (e.g., cimetidine, diltiazem, erythromycin, fluoxetine, fluvoxamine, isoniazid, itraconazole, ketoconazole, nefazodone, propoxyphene, and verapamil).^{3,4,12,93} When carbamazepine is combined with valproate, the carbamazepine dose should be reduced because valproate displaces carbamazepine from protein binding sites, thus increasing free levels.^{4,12} Combining clozapine and carbamazepine is not recommended because of the possibility of bone marrow suppression with both agents.¹²

Dosing and Administration During an acute manic episode in most hospitalized patients, carbamazepine can be started at 400 to 600 mg/day in divided doses with meals and increased by 200 mg/day every 2 to 4 days up to 10 to 15 mg/kg per day. In outpatients the initial dose of carbamazepine should be lower and titrated gradually in order to avoid adverse effects. In clinical practice many patients are able to tolerate once daily dosing of carbamazepine once their mood episode has stabilized. The dose of carbamazepine should be gradually increased until response is achieved or there is evidence of toxicity. During the first month of therapy, serum concentrations of carbamazepine can decrease because of its autoinduction of cytochrome P450 3A4 enzymes, and the dose can need to be increased to maintain serum concentrations.⁹³

Carbamazepine serum levels are usually obtained every 1 to 2 weeks during the first 2 months, and then every 3 to 6 months during maintenance therapy. Serum levels should be drawn 10 to 12 hours after the dose (trough levels) and at least 4 to 7 days after a dosage change. Although there is no correlation between carbamazepine serum concentration and degree of antimanic or antidepressant response, most clinicians attempt to maintain levels between 6 and 10 mcg/mL (although some treatment-resistant patients can require serum concentrations of 12 to 14 mcg/mL).¹ Recommended baseline and routine laboratory tests for carbamazepine are listed in Table 72–9.

Lamotrigine

Pharmacology and Mechanism of Action Lamotrigine blocks voltage-sensitive sodium channels, modulates or decreases glutamate and aspartate release, and has antikindling properties (see Table 72–8).^{4,7,59,95,96}

Pharmacokinetics A summary of the absorption, distribution, metabolism, and elimination data for lamotrigine can be found in Chap. 58.

Efficacy The effectiveness of lamotrigine for the maintenance treatment of bipolar I disorder in adult patients was established in two

multicenter double-blind, placebo-controlled studies.³ Doses of 200 mg/day were more effective than lower doses, and there were no advantages to using 400 mg/day. Lamotrigine has both antidepressant and mood-stabilizing effects, it may have augmenting properties when combined with lithium or valproate, and has low rates of switching patients to mania.^{95,97} Although lamotrigine is less effective for acute mania compared to standard mood stabilizers, it may be beneficial in the maintenance therapy of treatment-resistant bipolar I and II disorders, in rapid-cycling dysphoric mania, and in mixed states.^{3,4,72,95} Lamotrigine seems to be most effective for the prevention of bipolar depression, therefore clinically it is often used in the treatment of patients with bipolar II. In a small 1-year outcome study of lamotrigine plus lithium, the combination did not show long-term prophylactic response.⁹⁸ There are case reports of possible lamotrigine induced mania when added to lithium, carbamazepine, and valproic acid.⁹⁹ In each of the cases reported the patients had depressive mood symptoms or rapid mood changes requiring additional therapy.⁹⁹

Adverse Effects Common adverse effects include headache, nausea, dizziness, ataxia, diplopia, drowsiness, tremor, rash, and pruritus.^{95,96} Approximately 10% of patients in premarketing clinical trials developed a maculopapular rash and required discontinuation of therapy.^{95,96} Although most rashes are self-limiting and resolve with continued treatment, some cases progressed to life-threatening conditions such as Stevens-Johnson's syndrome. The incidence of rash appears to be greatest with coadministration of valproate, with higher than recommended initial doses, and with rapid dose escalation.⁹⁶ Patients should be warned about the rash, and the need for discontinuing lamotrigine if the rash is diffuse, involves mucosal membranes, and is accompanied by a fever or sore throat. For an in-depth discussion of the adverse effects of lamotrigine, see Chap. 58.

Drug-Drug Interactions Valproate decreases the clearance of lamotrigine (i.e., more than doubles the half-life), and lamotrigine must be administered at a reduced dosage (approximately half the standard dose).⁹⁶ For an in-depth discussion of drug-drug interactions with lamotrigine see Chap. 58.

Dosing and Administration For the maintenance treatment of bipolar disorder, the usual dosage range of lamotrigine is 50 to 300 mg/day. The target dose is generally 200 mg/day (100 mg/day in combination with valproate and 400 mg/day in combination with carbamazepine).^{95,96} For patients not taking medications that affect lamotrigine's clearance, the dose is 25 mg/day for the first 2 weeks of therapy, 50 mg/day for weeks 3 and 4, 100 mg/day for week 5, and 200 mg/day for week 6 and beyond.^{3,95,96} Patients who stop lamotrigine therapy for more than a few days should be restarted on the recommended dosage escalation titration schedule.

Lithium

Pharmacology and Mechanism of Action Despite numerous investigations into the biologic and clinical properties of lithium, there is no unified theory for its mechanism of action (see Table 72–8).^{7,12,14,100} Chronic lithium administration may modulate gene expression and have neuroprotective effects.

Pharmacokinetics Lithium has unique pharmacokinetics because it is a monovalent cation. Lithium is rapidly absorbed, is widely distributed with no protein binding, is not metabolized, and is excreted unchanged in the urine and in other body fluids.⁸¹

Efficacy Early placebo-controlled studies with lithium reported up to a 78% response rate in aborting an acute manic or hypomanic episode, but more recent studies suggest a slower onset of action and a more moderate effectiveness when compared to other agents.^{3,4,56} Lithium has displayed efficacy in acute mania trials

similar to that of valproate, carbamazepine, risperidone, olanzapine, chlorpromazine, and other typical antipsychotics.³ In placebo-controlled studies in bipolar depression, lithium has been found to have efficacy, but there can be a 6- to 8-week delay for its antidepressant effects.³ Lithium is more effective for pure or elated (classic) mania, and can be less effective for mania with psychotic features, mixed episodes, rapid or continuous cycling, alcohol and drug abuse, and in organic-induced mood states.^{3,4,55}

Long-term lithium therapy is more effective in patients with fewer prior episodes, with a history of euthymia or good functioning between episodes, and with a family history of bipolar illness with a positive response to lithium.^{4,12} Lithium produces a prophylactic response in up to two-thirds of patients and reduces suicide risk by 8- to 10-fold.^{3,55-57}

Patients maintained on standard serum concentrations of lithium (between 0.8 and 1 mEq/L) may have fewer relapses than patients maintained on lower serum concentrations (0.4 to 0.6 mEq/L).^{3,4} Abrupt discontinuation or noncompliance with lithium therapy can increase the risk of relapse.^{3,4} Discontinuation-induced refractoriness has been reported in approximately one-fifth of patients who previously were stabilized on lithium.^{3,4}

Lithium augmentation of antidepressants, carbamazepine, lamotrigine, and valproate can improve treatment response in bipolar I disorder.^{3,101} Concomitant use of lithium with valproate or carbamazepine appears to be well tolerated but can increase the risk of sedation, weight gain, gastrointestinal complaints, and tremor.

Lithium is frequently combined with both typical and atypical antipsychotics in euphoric acute mania with psychotic features. Case reports of neurotoxicity (e.g., delirium, cerebellar dysfunction, extrapyramidal symptoms, and severe tremors) have been reported in elderly patients receiving lithium and traditional antipsychotics.⁸¹ Combining lithium with calcium channel blockers is not recommended because of reports of neurotoxicity and severe bradycardia with verapamil and diltiazem.⁸¹ Acute neurotoxicity and delirium have been reported in patients receiving ECT with lithium (even at reduced dosages); therefore lithium should be withdrawn and discontinued at least 2 days before ECT and should not be resumed until 2 to 3 days after the last treatment.

Adverse Effects Approximately 35% to 93% of patients treated with lithium will experience adverse effects. These are divided into those that occur early in therapy but are generally innocuous and transient, those that occur with long-term therapy and are usually not dose-related, and toxic effects that occur with high serum concentrations.^{1,3,81}

Initial side effects are often dose-related and are worse at peak serum concentrations (1 to 2 hours postdose).³ Standard approaches for minimizing adverse effects include lowering the dose, taking smaller doses with food, using extended-release products, and trying once-daily dosing at bedtime.³ Gastrointestinal distress (e.g., nausea, vomiting, dyspepsia, and diarrhea) can be minimized by the standard approaches or by adding antacids or antidiarrheal agents.³ Diarrhea can sometimes be managed by switching from the tablet or capsule formulation to the liquid formulation. Diarrhea produced by lithium is commonly an osmotic diarrhea, and therefore switching to a formulation that clears the gut quickly can ameliorate symptoms. Muscle weakness and lethargy develop in about 30% of patients, but these symptoms are usually transient. Polydipsia with polyuria and nocturia occurs in up to 70% of patients and can be managed by changing to once-daily bedtime dosing.

As many as 40% of patients complain of headache, memory impairment, confusion, poor concentration, and impaired motor performance.¹² A fine hand tremor can be evident in up to 50% of patients. Stress, concomitant use of antidepressants or antipsychotics, caffeine, sympathomimetics, and impending toxicity can exacer-

bate the tremor. Strategies to reduce the tremor include standard approaches (e.g., switch to long acting preparation, lower dose if possible) or adding a β -adrenergic antagonist (e.g., propranolol 20 to 120 mg/day).

Lithium reduces the kidney's ability to concentrate urine and can cause a nephrogenic diabetes insipidus characterized by low urine specific gravity and a low osmolality polyuria (urine volumes greater than 3 L/day).^{3,81} Lithium-induced nephrogenic diabetes insipidus is treated with loop diuretics, thiazide diuretics, or triamterene. If a thiazide diuretic is used (e.g., hydrochlorothiazide 50 mg/day), lithium doses should be decreased by 50%, and potassium levels need to be monitored.³ Amiloride, a potassium-sparing diuretic, has weaker natriuretic effects than thiazides and appears to be relatively safe with minimal effect on lithium clearance. Potassium supplements have been suggested as another treatment for lithium-induced polyuria.¹² Fluid restriction is not recommended because dehydration increases the risk of lithium toxicity. If edema occurs, treatment approaches include lowering sodium intake or using a diuretic (e.g., spironolactone); close monitoring for lithium toxicity is necessary because these treatments often increase lithium concentrations.

Patients on long-term lithium therapy have a 10% to 20% risk of developing morphologic renal changes (e.g., glomerular sclerosis, tubular atrophy, and interstitial nephritis) that is associated with impairment of water resorption and increased serum creatinine concentrations.³ Lithium rarely causes nephrotoxicity if patients are maintained on the lowest effective dose, if once-daily dosing is used, if adequate hydration is maintained, and if toxicity is avoided.¹² Lithium should be avoided in patients with preexisting renal disease unless there is frequent monitoring.

Lithium is concentrated in the thyroid gland, interferes with thyroid hormone synthesis and can induce the formation of thyroid antibodies.⁸¹ Up to 30% of patients on maintenance lithium therapy develop transiently elevated thyroid-stimulating hormone concentrations, and 5% to 35% of patients develop a goiter and/or hypothyroidism.³ Lithium-induced hypothyroidism is not dose-related, is observed 10 times more frequently in women (particularly in those with rapid cycling), and usually occurs after 6 to 18 months of therapy.³ Hypothyroidism does not require discontinuation of lithium, because exogenous thyroid hormone (i.e., levothyroxine) can be added to the regimen. When lithium is discontinued, the need for exogenous thyroid hormone should be reassessed, because hypothyroidism can be reversible.

Lithium can cause a variety of benign and reversible cardiac effects, particularly T-wave flattening or inversion (in up to 30% of patients), atrioventricular block, and bradycardia.^{3,12,81} Lithium rarely causes myocarditis, sinus node dysfunction, or sinoatrial block but can aggravate ventricular arrhythmias and atrial premature contractions. If a patient has significant preexisting cardiac disease, consultation with a cardiologist and an electrocardiogram is recommended at baseline and during lithium therapy.

Other late-appearing lithium side effects include benign reversible leukocytosis and a variety of dermatologic effects (e.g., acne and acneiform eruptions, alopecia, exacerbation of psoriasis, pruritic dermatitis, maculopapular rashes, and folliculitis).^{3,12} Weight gain is common (approximately 20% of patients gain more than 10 kg) and can be related to fluid retention, the consumption of high-calorie beverages as a result of polydipsia, or to a decreased metabolic rate because of hypothyroidism.^{12,74,102} Decreased libido, sexual dysfunction, dry mouth, alterations in taste, changes in glucose tolerance, hypercalcemia, and hyperparathyroidism have been reported.^{3,12,81} Severe neurologic disturbances such as coarse hand tremors, ataxia, slurred speech, myasthenia gravis, extrapyramidal syndrome, pseudotumor cerebri, and papilledema are occasionally observed.

CLINICAL CONTROVERSY

The issue of medication-induced weight gain in psychiatric patients has received considerable attention in the literature because of the medical complications of obesity. The optimal management of weight gain and its consequences on physical and mental health remains controversial. Clinicians must strive to reduce weight gain because it decreases adherence to treatment and results in increased morbidity and mortality.

Lithium is an extremely toxic drug if accidentally or intentionally taken in overdose. Lithium toxicity can occur with blood levels greater than 1.5 mEq/L, but elderly patients can have symptoms at therapeutic levels.³ Severe lithium intoxication occurs when concentrations are higher than 2 mEq/L, and there is a worsening in several key symptoms: *gastrointestinal* (e.g., vomiting, diarrhea, or incontinence); *coordination* (e.g., severe fine to coarse hand tremor, unstable gait, slurred speech, and muscle twitching); and *cognition* (e.g., poor concentration, drowsiness, disorientation, apathy, and coma).³ Several reports of seizures, cardiac dysrhythmia, permanent neurologic impairments with ataxia and deficits in memory, and kidney damage with reduced glomerular filtration rate have been reported after lithium intoxication.³

Situations that predispose patients to lithium toxicity include: sodium restriction, dehydration, vomiting, diarrhea, and drug interactions that decrease lithium clearance. Heavy exercise, sauna baths, hot weather, and fever can promote sodium loss. Patients should be cautioned to maintain adequate sodium and fluid intake (2.5 to 3 quarts per day of fluids) and to avoid the excessive use of coffee, tea, cola, and other caffeine-containing beverages and alcohol.

If lithium toxicity is suspected, the person should go to an emergency room to be monitored, and lithium should be discontinued.³ Gastric lavage and intravenous fluids can be needed, and the patient should be monitored for fluid balance, renal and electrolyte status, and neurologic changes. In cases of overdose with sustained-release lithium products, the development and duration of toxicity can be prolonged.³ When lithium concentrations are above 3.5 to 4 mEq/L, intermittent hemodialysis (12 hours on and 12 hours off) can be started and continued until the lithium concentration is below 1 mEq/L when taken 12 hours after the last dialysis. Hemodialysis is generally required when serum lithium levels are above 4 mEq/L for patients on long-term treatment, and greater than 6 to 8 mEq/L after acute poisoning.³ Rebound increases in serum lithium concentrations can occur 5 to 8 hours after dialysis, thus repeat dialysis can be needed.³

Drug-Drug Interactions Thiazide diuretics, nonsteroidal antiinflammatory drugs, cyclooxygenase-2 inhibitors, angiotensin-converting enzyme inhibitors, and salt-restricted diets can elevate lithium levels.^{1,3} Neurotoxicity can occur when lithium is combined with carbamazepine, diltiazem, losartan, methyl dopa, metronidazole, phenytoin, and verapamil.^{3,81} Analgesics such as acetaminophen or aspirin and loop diuretics are less likely to interfere with lithium clearance. Caffeine and theophylline can enhance the renal elimination of lithium. Because lithium has no effect on hepatic metabolizing enzymes, it has fewer drug-drug interactions compared with carbamazepine, oxcarbazepine, and valproate.

Dosing and Administration Lithium dosing depends on the patient's age and weight, tolerance to adverse effects, and the acuity of the illness. Dosing is generally titrated up to achieve steady-state serum lithium concentrations of 0.6 to 1.2 mEq/L.³ Lithium therapy is usually initiated with low to moderate doses (600 mg/day) for prophylaxis and higher doses (900 to 1,200 mg/day) for acute mania, using a two- to three-times daily dosing regimen.^{3,81} Immediate-release lithium preparations should be given in two or three divided daily doses,

whereas extended-release products can be given once or twice daily. In clinical practice many clinicians dose the immediate-release and extended-release preparations once daily. It can be best to initially begin a patient on divided dosing, but once stabilized many patients are able to switch to once daily dosing without decompensating.

Lithium levels are considered to be at steady state at approximately day 5, and serum samples should be drawn 12 hours postdose. Once a desired serum concentration has been achieved, levels should be drawn in 2 weeks and then if stable every 3 to 6 months or as clinically indicated. Maintenance lithium serum concentrations are usually measured every 3 months, but can be adjusted to every 6 months for stabilized patients, and every 1 to 2 months for patients with frequent mood episodes.³ Lithium clearance rates increase by 50% to 100% during pregnancy and return to normal postpartum; thus lithium levels should be determined monthly during pregnancy and weekly the month before delivery. At delivery, rapid fluid changes can significantly increase lithium levels, thus a reduction to prepregnancy lithium doses and adequate hydration are recommended.³

The recommended guidelines for baseline and routine laboratory testing for lithium are listed in Table 72–9. The 12-hour postdose lithium serum concentration can be 12% to 33% higher with extended-release preparations and lower with regular-release tablets with divided dosage schedules. The dose should be adjusted based on the steady-state serum concentration drawn 12 hours (± 30 minutes) after the last dose.⁸¹ A therapeutic trial for outpatients should last a minimum of 4 to 6 weeks with lithium serum concentrations of 0.6 to 1.2 mEq/L. Acutely manic patients can require serum concentrations of 1 to 1.2 mEq/L, and some need up to 1.5 mEq/L to achieve a therapeutic response. Although serum concentrations less than 0.6 mEq/L are associated with higher rates of relapse, some patients can do well at 0.4 to 0.7 mEq/L.³ For bipolar prophylaxis in elderly patients, serum concentrations of 0.4 to 0.6 mEq/L are recommended because of increased sensitivity to adverse effects.³

Oxcarbazepine

Pharmacology and Mechanism of Action Oxcarbazepine, a 10-keto analog of carbamazepine, blocks voltage-sensitive sodium channels, modulates voltage-activated calcium currents, and increases potassium conductance.¹⁰³

Pharmacokinetics A summary of the absorption, distribution, metabolism, and elimination data for oxcarbazepine can be found in Chap. 58.¹⁰³

Efficacy Initial trials suggested oxcarbazepine has mood-stabilizing effects similar to those of carbamazepine, with the advantages of milder adverse effects, no autoinduction of liver enzymes, and potentially fewer drug interactions.³ There are currently less data supporting the use of oxcarbazepine than carbamazepine in the treatment of bipolar disorder. The APA treatment guidelines recommend the use of oxcarbazepine in any situation where one would use carbamazepine. However, many clinicians prefer to use oxcarbazepine only after a patient has failed treatment with carbamazepine because of an adverse reaction or side effects.³ Genuine debate exists regarding drug interactions, side effects, and rates of hyponatremia with oxcarbazepine.

Adverse Effects Oxcarbazepine has dose-related adverse effects of dizziness, sedation, headache, ataxia, fatigue, vertigo, abnormal vision, diplopia, nausea, vomiting, and abdominal pain.¹⁰³ In one study hyponatremia was reported to occur in patients taking oxcarbazepine and carbamazepine at rates of 29.9% and 13.5% respectively.¹⁰⁴ Severe hyponatremia (sodium less than or equal to 128 mEq/L) was reported by Dong and coworkers as 12.4% and 2.8% of patients for oxcarbazepine and carbamazepine, respectively.¹⁰⁴ An in-depth discussion of adverse effects can be found in Chap. 58.

Drug-Drug Interactions Oxcarbazepine, a cytochrome P450 2C19 enzyme inhibitor and a 3A3/4 enzyme inducer, has the potential for causing drug interactions.¹⁰³ Oxcarbazepine induces the metabolism of oral contraceptives, thus alternative contraceptive measures are required.^{3,105}

Dosing and Administration Initial dosing is usually 150 to 300 mg twice daily, and daily doses can be increased by 300 to 600 mg every 3 to 6 days up to 1,200 mg/day in divided doses (with or without food).¹⁰³

Valproate Sodium and Valproic Acid

Pharmacology and Mechanism of Action The exact mechanism of action of valproic acid is not known (see Table 72–8).^{7,12,14,83}

Pharmacokinetics A summary of the absorption, distribution, metabolism, and elimination data for valproate can be found in Chap. 58.

Efficacy Valproic acid is a branched chain fatty acid and was originally used as an organic solvent before it was discovered in the 1960s to have anticonvulsant properties. Valproate has antimigraine, mood-stabilizing, and antiaggressive effects.⁸³ In 1995 the enteric-coated formulation divalproex sodium (valproate) was approved for the acute treatment of mania. Several controlled studies have shown valproate to be as effective as lithium and olanzapine in patients with pure mania, and it can be more effective than lithium in certain subtypes of bipolar disorder (e.g., rapid cycling, mixed states, bipolar disorder, and comorbid substance abuse).^{3,4,24,12,106} Placebo- and lithium-controlled and open studies report that valproate reduces or prevents recurrent manic, depressive, and mixed episodes.^{3,4,12} Although valproate is not approved for bipolar disorder in children and adolescents, studies suggest that it is effective and well tolerated.^{12,33}

Giving lithium, carbamazepine, antipsychotics, or benzodiazepines with valproate can augment its antimanic effects. The addition of valproate to lithium can have synergistic effects in treatment-refractory rapid cycling and mixed states, and the combination has demonstrated efficacy in maintenance therapy for bipolar I disorder.²⁴ Combinations of valproate and carbamazepine can have synergistic effects, but the potential drug interactions make blood level monitoring of both agents essential.¹² Adding adjunctive atypical antipsychotics to valproate can be effective for breakthrough mania or if there is incomplete or partial response to monotherapy. Clozapine, olanzapine, and quetiapine can increase the risk of sedation and weight gain when combined with valproate. The combination of valproate and lamotrigine can be effective, but there is an increased risk of rashes, ataxia, tremor, sedation, and fatigue.^{83,95}

Adverse Effects The most frequent dose-related adverse effects with valproate are gastrointestinal complaints (anorexia, nausea, indigestion, vomiting, mild diarrhea, and flatulence), fine hand tremors, and sedation.^{3,12,83} The gastrointestinal complaints are usually transient, but giving the drug with food, using lower initial doses with gradual increases in doses, switching to divalproex sodium extended-release tablets, or adding a histamine₂ antagonist such as famotidine or ranitidine can minimize them.^{3,12} Reduction of the dose or the addition of a β -blocker can alleviate tremors, and giving the total daily dose at bedtime can minimize daytime sedation.^{3,12}

Other adverse effects of valproate include ataxia, lethargy, alopecia, changes in the texture or color of hair, pruritus, prolonged bleeding because of inhibition of platelet aggregation, transient increases in liver enzymes, and hyperammonemia.^{12,83} Increased appetite and weight gain occurs in approximately 50% of patients on long-term valproate therapy. Thrombocytopenia can occur at higher doses, and patients should be monitored for bleeding and bruising. Lowering the valproate dose can restore platelet counts to normal levels.³ Fatal necrotizing hepatitis is a rare idiosyncratic, non-dose-related adverse

effect that has occurred in children with epilepsy receiving multiple anticonvulsants.^{12,83} A life-threatening hemorrhagic pancreatitis has been reported in both children and adults.^{3,12,83} An in-depth discussion of adverse effects can be found in Chap. 58.

Drug-Drug Interactions A summary of drug-drug interactions for valproate can be found in Chap. 58.

Dosing and Administration For healthy inpatient adults with acute mania, the initial starting dosage of valproate is typically 20 mg/kg per day in divided doses over 12 hours. The daily dose is adjusted by 250 to 500 mg every 1 to 3 days based on clinical response and tolerability. Maximum recommended dosing is 60 mg/kg per day (see Table 72–8).^{3,12,83} For outpatients who are hypomanic, euthymic, or for elderly patients, the initial starting dose is generally lower (5–10 mg/kg per day in divided doses) and gradually titrated to avoid adverse effects. Once an optimal dose has been achieved, the total daily dose can be given twice daily or at bedtime if tolerated.^{3,12,83} Extended-release divalproex can be administered once daily, but bioavailability can be 15% lower than immediate-release products, thus requiring slightly higher doses.³ In clinical practice patients with bipolar disorder who are stable can be switched between formulations without having to change the dose. This is not the case for patients with seizure disorder.

Recommended baseline and routine laboratory tests for valproate are listed in Table 72–9. Data from clinical trials in acutely manic patients indicated that there was an earlier response when trough serum levels were greater than 45 mcg/mL during the first week of treatment.⁴ Although therapeutic serum concentrations of valproic acid have not been established in bipolar disorder, most clinicians use the anticonvulsant therapeutic serum range of 50 to 125 mcg/mL taken 12 hours after the last dose.^{3,12} In one study patients with valproate levels greater than 94.1 mcg/mL had greater efficacy for bipolar mania.¹⁰⁷ Patients with cyclothymia or mild bipolar II disorder can have a therapeutic response to lower doses and blood levels, whereas some patients with a more severe form of bipolar disorder can require up to 150 mcg/mL. Serum valproic acid levels are most useful when assessing for compliance and toxicity.

CLINICAL CONTROVERSY¹⁰⁸

In the treatment of seizure disorders monitoring serum concentrations are controversial for valproate, and the same is true in bipolar disorder. Some clinicians feel that therapeutic blood level monitoring is essential for the appropriate treatment of bipolar disorder, whereas others feel that blood level monitoring is overused and, in many cases, unwarranted. Antiepileptic blood level monitoring should be viewed as a tool to be used as part of overall treatment optimization. Achievement of a specific “therapeutic” level should not be an absolute goal in and of itself.

PHARMACOECONOMIC CONSIDERATIONS

Bipolar disorder is one of the leading causes of chronic disability worldwide and shares characteristics of both major depressive disorder and schizophrenia.^{4,108} Bipolar disorder is primarily treated in the public mental health sector, and a majority of patients receive lifelong disability coverage because of compromised functioning.⁴ The total cost to society for bipolar disorder is enormous and is exceeded only by the costs for treating individuals with schizophrenia.¹² It is estimated that the total annual economic impact of bipolar disorder in the United States is approximately \$45 billion.¹

Despite the prevalence, morbidity, mortality, and costs associated with the illness, there are few pharmacoeconomic or evidence-based outcome studies.^{4,109,110} To address some of these issues, the Stanley

Foundation Bipolar Network was created to obtain longitudinal data (among five core sites and a number of affiliated sites) from double-blind, randomized controlled trials using consistent methodology and reliable and validated instruments.¹¹¹ A Systematic Treatment Enhancement Program for Bipolar Disorder (STEP-BD) is a 5-year outpatient study funded by the National Institute of Mental Health (www.stepbd.org) to determine which treatments or combination of treatments are most effective for bipolar disorder. The results from these controlled studies will help to provide the data for evidence-based outcomes and pharmacoeconomic considerations.

EVALUATION OF THERAPEUTIC OUTCOMES

4 The establishment and maintenance of a therapeutic alliance with a clinician is essential in monitoring a patient's psychiatric status and safety; enhancing treatment adherence; promoting good nutrition, sleep, and exercise; identifying stressors; recognizing new mood episodes; and minimizing adverse reactions and drug interactions.^{1,3} Patients who have a partial response or nonresponse to established bipolar therapies should be reassessed for an accurate diagnosis, concomitant medical or psychiatric conditions, and medications or substances that exacerbate mood symptoms. Nonadherence to medication treatment, delusional symptoms, alcohol or substance abuse, rapid cycling, or mixed states are often associated with poorer treatment outcomes.

The evaluation of therapeutic outcomes for bipolar disorder requires regular monitoring by a clinician. More frequent office visits, telephone calls, and intensive outpatient programs are first-line strategies to prevent hospitalization during the acute treatment phase of a manic or depressive episode.³ Patients (and family members if needed) should be actively involved with their treatment and help to monitor target symptoms, efficacy of treatment, and adverse effects.^{1,3}

Standardized rating scales for mania and depression are used to measure severity and changes in symptoms in clinical trials (e.g., Young Mania Rating Scale, brief bipolar disorder symptoms scale, Hamilton Rating Scale for Depression, and Montgomery-Asberg Depression Rating Scale). Patient-rated life mood charts, a timeline of stressful life events, and a graphic display of sleep patterns are helpful in recognizing early symptoms of mood episodes and in documenting patterns and lengths of episodes.³ A mood disorder questionnaire, a 13-item self-reported screening tool, was developed to differentiate bipolar disorder from other mood disorders (www.dbsalliance.org/questionnaire/screening_intro.asp).^{3,26} Health-related quality of life scales such as the Short Form (SF)-36 and the Psychological General Well Being Scale have been recommended to assess the quality of life in individuals with bipolar disorder.¹¹²

Anxiety Disorders I: Generalized Anxiety, Panic, and Social Anxiety Disorders

CYNTHIA K. KIRKWOOD AND SARAH T. MELTON

KEY CONCEPTS

- 1 The long-term goal in generalized anxiety disorder is remission with minimal or no anxiety symptoms and no functional impairment.
- 2 Antidepressants are the agents of choice for the management of generalized anxiety disorder.
- 3 Antidepressants have a lag time of 2 to 4 weeks or longer before antianxiety effects occur in generalized anxiety disorder.
- 4 When monitoring the effectiveness of antidepressants in panic disorder, it is important to allow an adequate amount of time (8 to 12 weeks) to achieve full therapeutic response.
- 5 Clonazepam and alprazolam extended-release are alternatives to alprazolam immediate-release for patients with panic disorder having breakthrough panic symptoms at the end of a dosing interval.
- 6 The optimal duration of panic therapy is unknown; 12 to 24 months of pharmacotherapy is recommended before gradual drug discontinuation over 4 to 6 months is attempted.
- 7 Social anxiety disorder is a chronic long-term illness requiring extended therapy. After improvement, at least a 1-year medication maintenance period is recommended to maintain response and decrease the rate of relapse.
- 8 The selective serotonin reuptake inhibitors or venlafaxine are considered first-line pharmacotherapy for social anxiety disorder, especially in patients with comorbid depression, other anxiety disorders, or substance abuse.
- 9 An adequate trial of antidepressants in generalized social anxiety disorder lasts at least 8 weeks, and maximal benefit may not be seen until 12 weeks.
- 10 The three principal domains in which improvement should be observed in generalized social anxiety disorder are symptoms, functionality, and well being.

Anxiety is an emotional state commonly caused by the perception of real or perceived danger that threatens the security of an individual. It allows a person to prepare for or react to environmental changes. Everyone experiences a certain amount of nervousness and apprehension when faced with a stressful situation. This is an adaptive response and is transient in nature.

Learning objectives, review questions,
and other resources can be found at
www.pharmacotherapyonline.com.

Anxiety can produce uncomfortable and potentially debilitating psychologic (e.g., worry or feeling of threat) and physiologic arousal (e.g., tachycardia or shortness of breath) if it becomes excessive. Some individuals experience persistent, severe anxiety symptoms and possess irrational fears that significantly impair normal daily functioning. These persons often suffer from an anxiety disorder.¹

Anxiety disorders are among the most frequent mental disorders encountered in clinical practice. Healthcare professionals often mistake anxiety disorders for physical illnesses, and only 23% of patients receive appropriate treatment.² Failure to diagnose and manage anxiety disorders results in negative outcomes including overuse of healthcare resources, increased morbidity, and mortality.³ Individuals with anxiety disorders develop cardiovascular, cerebrovascular, gastrointestinal, and respiratory disorders at a significantly higher rate than the general population.⁴

To treat anxiety appropriately, the clinician must make a reliable diagnosis. It is essential that the distinction between short-term symptoms of anxiety and anxiety disorders be understood. Common or situational anxiety is a normal response to a stressful circumstance. Although symptoms can be severe, they are temporary and usually last no more than 2 or 3 weeks. Although short-term, “as needed” treatment with an anxiolytic agent such as a benzodiazepine is common and can provide some symptomatic relief, prolonged drug therapy is unnecessary.⁵

EPIDEMIOLOGY

Anxiety disorders, as a group, are the most commonly occurring psychiatric disorders. According to the National Comorbidity Survey Replication of the prevalence, severity, and comorbidity estimates of mental disorders in the United States, the 1-year prevalence rate for anxiety disorders was 18.1% in persons aged 18 years and older. Specific phobias were the most common anxiety disorder, with a 12-month prevalence of 8.7%. The 1-year prevalence of generalized anxiety disorder (GAD) was 3.1%, that of panic disorder was 2.7%, and that of social anxiety disorder (SAD) was 6.8%.⁶

In general, anxiety disorders are a group of heterogeneous illnesses that develop before age 30 years and are more common in women, individuals with social issues, and those with a family history of anxiety and depression. Patients often develop another anxiety disorder, major depression, or substance abuse.¹⁻³ The clinical picture of mixed anxiety and depression is much more common than an isolated anxiety disorder.²

ETIOLOGY

The differential diagnosis of anxiety disorders includes medical and psychiatric illnesses and certain drugs.² Family studies show that SAD can be inherited. The frequency of generalized SAD is mark-

TABLE 73-1 Common Medical Illnesses Associated with Anxiety Symptoms

Cardiovascular
Angina, arrhythmias, congestive heart failure, ischemic heart disease, myocardial infarction
Endocrine and metabolic
Cushing's disease, hyperparathyroidism, hyperthyroidism, hypothyroidism, hypoglycemia, hyponatremia, hyperkalemia, pheochromocytoma, vitamin B ₁₂ or folate deficiencies
Neurologic
Dementia, migraine, Parkinson's disease, seizures, stroke, neoplasms, poor pain control
Respiratory system
Asthma, chronic obstructive pulmonary disease, pulmonary embolism, pneumonia
Others
Anemias, systemic lupus erythematosus, vestibular dysfunction

Data from Roy-Byrne² and Chen et al.¹⁰

edly increased (approximately 10 times greater) among first-degree relatives of patients.⁷ Behavioral inhibition (i.e., wariness, decreased social interaction, and withdrawal) is a genetic trait that can contribute to SAD.^{7,8} Patients with SAD commonly report having overprotective parents. Parental dysfunction and abuse are potential risk factors for developing SAD.^{8,9}

MEDICAL DISEASES ASSOCIATED WITH ANXIETY

Anxiety symptoms are an inherent part of the initial clinical presentation of several diseases, thus complicating the distinction between anxiety disorders and medical disorders.² If the anxiety symptoms are secondary to a medical illness, they usually will subside as the medical situation stabilizes. However, the knowledge that one has a physical illness (e.g., cancer or diabetes) can trigger anxious feelings and further complicate therapy. Persistent anxiety subsequent to a physical illness requires further assessment for an anxiety disorder. Symptoms of anxiety frequently present in medical disorders include palpitations, tachycardia, chest pain or tightness, shortness of breath, and hyperventilation. Medical disorders most closely associated with anxiety are listed in Table 73–1.^{2,10} Approximately 50% of patients with GAD have irritable bowel syndrome.²

PSYCHIATRIC DISEASES ASSOCIATED WITH ANXIETY

Anxiety can be a presenting feature of several major psychiatric illnesses. Anxiety symptoms are extremely common in patients with mood disorders, schizophrenia, delirium, dementia, and substance-use disorders. Most psychiatric patients will have two or more concurrent psychiatric disorders (comorbidity) within their lifetime.⁶ It is important to diagnose and treat all comorbid psychiatric conditions in patients with anxiety disorders.

DRUG-INDUCED ANXIETY

Drugs are a common cause of anxiety symptoms (Table 73–2). Anxiety occurs during the use of central nervous system (CNS) stimulating drugs in a dose-dependent manner, but ingestion of minimal amounts can result in marked anxiety, including panic attacks, in some individuals. The onset of drug-induced anxiety is usually rapid after the initiation of therapy; look for a recent drug or dosage change to rule out drug etiologies for anxiety.

Anxiety occurs occasionally during the use of CNS depressants, especially in children and the elderly; however, anxiety complaints are more common as complications of drug withdrawal after the abrupt discontinuation of these agents.^{10,11}

TABLE 73-2 Drugs Associated with Anxiety Symptoms

Anticonvulsants: carbamazepine
Antidepressants: selective serotonin reuptake inhibitors, tricyclic antidepressants
Antihypertensives: felodipine
Antibiotics: quinolones, isoniazid
Bronchodilators: albuterol, theophylline
Corticosteroids: prednisone
Dopa agonists: levodopa
Herbals: ma huang, ginseng, ephedra
Nonsteroidal anti-inflammatory drugs: ibuprofen
Stimulants: amphetamines, methylphenidate, caffeine, cocaine
Sympathomimetics: pseudoephedrine
Thyroid hormones: levothyroxine
Toxicity: anticholinergics, antihistamines, digoxin
Withdrawal: alcohol, sedatives

Data from American Psychiatric Association¹ and Chen et al.¹⁰

PATHOPHYSIOLOGY

Data from biochemical and neuroimaging studies indicate that the modulation of normal and pathologic anxiety states is associated with multiple regions of the brain and abnormal function in several neurotransmitter systems, including norepinephrine (NE), γ -aminobutyric acid (GABA), serotonin (5-HT), corticotrophin-releasing factor (CRF), and cholestykinin.¹² Current neuroanatomic models of fear (i.e., the response to danger) and anxiety (i.e., the feeling of fear that is disproportionate to the actual threat) include some key brain areas. The amygdala, a temporal lobe structure, plays a critical role in the assessment of fear stimuli and learned response to fear.¹² The locus ceruleus (LC), located in the brain stem, is the primary NE-containing site, with widespread projections to areas responsible for implementing fear responses (e.g., vagus, lateral and paraventricular hypothalamus). The hippocampus is integral in the consolidation of traumatic memory and contextual fear conditioning. The hypothalamus is the principal area for integrating neuroendocrine and autonomic responses to a threat.¹²

NEUROCHEMICAL THEORIES

Noradrenergic Model

The basic premise of the noradrenergic theory is that the autonomic nervous system of anxious patients is hypersensitive and overreacts to various stimuli. Many anxious patients clearly display symptoms of peripheral autonomic hyperactivity. In response to threat or fearful situations, the LC serves as an alarm center, activating NE release and stimulating the sympathetic and parasympathetic nervous systems. Chronic central noradrenergic overactivity downregulates α_2 -adrenoceptors in patients with GAD. This receptor is hypersensitive in some patients with panic disorder.¹² Patients with SAD appear to have a hyperresponsive adrenocortical response to psychologic stress.¹³

By administering drugs that have a relatively specific effect on the LC, researchers have further explored the NE theory of anxiety and panic disorder. Drugs with anxiogenic effects (e.g., yohimbine [an α_2 -adrenergic receptor antagonist]) stimulate LC firing and increase noradrenergic activity. NE in turn increases glutamate release (an excitatory neurotransmitter).¹² This produces subjective feelings of anxiety and can precipitate a panic attack in those with panic disorder, but not in normal volunteers or those with other psychiatric illnesses.¹⁴ Drugs with anxiolytic or antipanic effects (e.g., benzodiazepines, antidepressants, and clonidine) inhibit LC firing, decrease noradrenergic activity, and block the effects of anxiogenic drugs.¹²

GABA Receptor Model

There are two superfamilies of GABA protein receptors: GABA_A and GABA_B. Drugs to reduce anxiety and produce sedation target the

GABA_A receptor. The GABA_B receptor is a G-protein coupled receptor postulated to be involved in the presynaptic inhibition of GABA release.¹² GABA_A receptors are ligand-gated ion channels composed of five protein subunits. Several classes of subunits (i.e., α_{1-6} , β_{1-3} , γ_{1-3} , δ , ϵ , θ , ρ_{1-3}) surround a central pore and the receptor is connected to the cytoskeleton.¹⁵ Benzodiazepine ligands enhance the inhibitory effects of GABA.¹² GABA, the major inhibitory neurotransmitter in the CNS, has a strong regulatory or inhibitory effect on the 5-HT, NE, and dopamine (DA) systems. When GABA binds to the GABA_A receptor, neuronal excitability is reduced.

The specific role of the GABA receptors in anxiety disorders has not been established. The number of GABA_A receptors can change with alterations in the environment (e.g., chronic stress), and the subunit expression can be altered by hormonal changes.¹⁶ In patients with GAD, benzodiazepine binding in the left temporal lobe is reduced.¹⁶ Abnormal sensitivity to antagonism of the benzodiazepine binding site and decreased binding was demonstrated in panic disorder.^{12,16} This is consistent with the suggestion that panic disorder is secondary to a lack of central inhibition that results in uncontrolled elevations in anxiety during panic attacks.¹⁶ Growth hormone response to baclofen in patients with generalized SAD suggests an abnormality of central GABA_B receptor function.¹⁷

Serotonin Model

Although there are data suggesting that the 5-HT system is dysregulated in patients with anxiety disorders, definitive evidence that shows a clear abnormality in 5-HT function is lacking. 5-HT is primarily an inhibitory neurotransmitter that is used by neurons originating in the raphe nuclei of the brain stem and projecting diffusely throughout the brain (e.g., cortex, amygdala, hippocampus, and limbic system). The diverse actions of 5-HT are regulated by at least 14 different postsynaptic receptor subtypes.¹² Abnormalities in serotonergic functioning through release and uptake at the presynaptic autoreceptors (5-HT_{1A/1D}), the serotonin reuptake transporter (SERT) site, or effect of 5-HT at the postsynaptic receptors (e.g., 5-HT_{1A}, 5-HT_{2A}, and 5-HT_{2C}) may play a role in anxiety disorders.¹² Preclinical models suggest that greater 5-HT function facilitates avoidance behavior; however, primate studies show that reducing 5-HT increases aggression.¹² It is postulated that greater 5-HT activity reduces NE activity in the LC, inhibits defense/escape response via the periaqueductal gray region, and reduces hypothalamic release of CRF. The selective serotonin reuptake inhibitors (SSRIs) acutely increase 5-HT levels by blocking the SERT to increase the amount of 5-HT available postsynaptically, and are efficacious in blocking the manifestations of panic and anxiety.¹² The precise role of 5-HT in panic disorder is unclear; however, 5-HT might play a role in anticipatory anxiety development.¹⁴

Low 5-HT activity may lead to a dysregulation of other neurotransmitters. NE and 5-HT systems are closely linked, and interactions between the two are reciprocal and vary. NE may act at presynaptic 5-HT terminals to decrease 5-HT release, and its activity at postsynaptic receptors can cause increased 5-HT release. Stimulation of the postsynaptic 5-HT_{2A} receptors in the limbic system results in anxiety and avoidance behavior.

Bupirone is a selective 5-HT_{1A} partial agonist that is effective for GAD but not for panic disorder. Because the selective 5-HT_{1A} partial agonists reduce serotonergic activity, GAD symptoms may reflect excessive 5-HT transmission or overactivity of the stimulatory 5-HT pathways. Patients with SAD have greater prolactin response to bupirone challenge compared with healthy controls, indicating an enhancement of central serotonergic response.¹⁸ The comparable efficacy of the serotonin-norepinephrine reuptake inhibitor (SNRI), venlafaxine extended-release, at high and low dosages suggests that 5-HT (rather than NE) reuptake blockade contributes to the therapeutic effect in SAD.¹⁹

NEUROIMAGING STUDIES

Functional neuroimaging studies suggest that frontal and occipital brain areas are integral to the anxiety response. In GAD there is an abnormal increase in cortical activity and a decrease in basal ganglia activity. After benzodiazepine treatment, basal ganglia activity increases, and cortical activity is reduced.¹⁴ Patients with panic disorder have abnormal activation of the parahippocampal region and prefrontal cortex at rest, and reduced GABA concentrations in the occipital region.¹⁴ Panic anxiety is associated with activation of brain stem and basal ganglia areas.¹⁴ Both pharmacotherapy and psychotherapy decreased cerebral blood flow in the amygdala, hippocampus, and surrounding cortical areas in patients with SAD.^{7,19}

CLINICAL PRESENTATION

The *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision* classifies anxiety disorders into several categories: GAD, panic disorder (with or without agoraphobia), agoraphobia, SAD, specific phobia, obsessive-compulsive disorder, posttraumatic stress disorder, and acute stress disorder.¹ The characteristic features of these illnesses are anxiety and avoidance behavior. Anxiety symptoms must cause significant distress, and impairment in social, occupational, or other areas of functioning and should not be secondary to a drug or illicit substance or a general medical disorder, or occur solely as part of another psychiatric disorder.¹ Obsessive-compulsive disorder and posttraumatic stress disorder are discussed in Chap. 74.

GENERALIZED ANXIETY DISORDER

The diagnostic criteria for GAD require persistent symptoms for most days for at least 6 months.¹ The essential feature of GAD is unrealistic or excessive anxiety and worry about a number of events or activities.¹ The clinical presentation of GAD appears in Table 73-3. The anxiety or apprehensive expectation is accompanied by at least three psychologic or physiologic symptoms. Anxiety and worry are not confined to features of another psychiatric illness (e.g., having a panic attack, being embarrassed in public).¹

The onset, course of illness, and comorbid conditions of GAD are important considerations. GAD has a gradual onset with an average age of 21 years; however, there is a bimodal distribution. If GAD is the primary disorder, the patient can present in their teens. GAD can be exacerbated or precipitated in later life by severe psychologic stressors. Most patients present between the ages of 35 and 45 years. GAD is the most common anxiety disorder in patients older than 55 years of age.¹¹ Tense life events also can play a role in the persistence of symptoms. The course of the illness is chronic (i.e., episodes can last

TABLE 73-3 Presentation of Generalized Anxiety Disorder

Psychologic and cognitive symptoms

- Excessive anxiety
- Worries that are difficult to control
- Feeling keyed up or on edge
- Poor concentration or mind going blank

Physical symptoms

- Restlessness

for a decade or longer); there is a high percentage of relapse and low rates of recovery. The likelihood of remission at 2 years is 25%.¹ Patients report substantial interference with their lives and have a high probability of seeking treatment.³ The majority of patients with GAD eventually will develop another mental disorder. GAD is usually the primary disorder in patients with comorbid anxious depression.

PANIC DISORDER

Panic disorder begins as a series of unexpected (spontaneous) panic attacks involving an intense, terrifying fear similar to that caused by life-threatening danger. The unexpected panic attacks are followed by at least 1 month of persistent concern about having another panic attack, worry about the possible consequences of the panic attack, or a significant behavioral change related to the attacks.¹ During an attack, patients describe at least four physiologic and physical symptoms (Table 73-4).¹ Panic attacks usually last no more than 20 to 30 minutes, with the peak intensity of symptoms within the first 10 minutes. Often patients seek help at a physician's office or emergency department, only to have their symptoms resolve before or on arrival. Because panic symptoms mimic those present in several medical conditions, patients often are misdiagnosed, and multiple referrals are common.¹

Secondary to the panic attacks, many patients develop agoraphobia. Agoraphobia is anxiety about being in places or situations in which escape might be difficult or where help might not be available in the event of a panic attack.¹ As a result, patients often avoid specific situations (e.g., being in a crowd or flying) in which they fear a panic attack might occur.¹

Panic disorder has an adverse impact on the patient's quality of life (QOL), including a significant degree of social and work impairment. Complications include depression (10% to 65% have major depressive disorder), alcohol abuse, and high use of health services and emergency rooms.¹ Patients with panic disorder have a high lifetime risk for suicide attempts compared with the general population.²¹ The usual course is chronic but waxing and waning.

SOCIAL ANXIETY DISORDER

SAD is characterized by an intense, irrational, and persistent fear of being negatively evaluated or scrutinized in at least one social or performance situation. Exposure to the feared circumstance usually

TABLE 73-5 Presentation of Social Anxiety Disorder

Fears

- Being scrutinized by others
- Being embarrassed
- Being humiliated

Some feared situations

- Addressing a group of people
- Eating or writing in front of others
- Interacting with authority figures
- Speaking in public
- Talking with strangers
- Use of public toilets

Physical symptoms

- Blushing
- "Butterflies in the stomach"
- Diarrhea
- Sweating
- Tachycardia
- Trembling

Types

- Generalized type: fear and avoidance extend to a wide range of social situations
- Nongeneralized type: fear is limited to one or two situations

Data from American Psychiatric Association,¹ Schneier,⁹ and Ballenger.²²

provokes an immediate situation-related panic attack. Symptoms of SAD are found in Table 73-5. Blushing is the principal physical indicator and distinguishes SAD from other anxiety disorders. Adults with SAD usually recognize their fear is excessive and unreasonable; however, they are unable to overcome it without treatment. If necessary, the feared situation is avoided or endured with significant distress.¹ In individuals younger than 18 years of age, the duration of symptoms must be at least 6 months to meet the diagnostic criteria.¹

The mean age of onset of SAD is during the mid-teens. Rates of SAD are slightly higher among women than men and more frequent in younger cohorts. It is a chronic disorder with a mean duration of 20 years.¹ People with social anxiety can be reluctant to seek professional help despite the existence of beneficial treatments because consultation with a clinician is perceived as a feared social interaction.^{9,19}

Differentiating SAD from other anxiety disorders can be difficult. Panic attacks occur in both SAD and panic disorder, but the distinction between the two is the rationale behind fear; fear of anxiety symptoms is characteristic of panic disorder, whereas fear of embarrassment from social interaction typifies SAD.¹ GAD is likely the diagnosis if anxiety regarding social situations are part of a pattern of multiple worries. A majority of SAD patients eventually develop a concurrent mood, anxiety, or substance abuse disorder.^{9,22}

SPECIFIC PHOBIA

Specific phobia is marked and persistent fear of a circumscribed object or situation (e.g., insects, heights, or injections). Apart from contact with the feared object or situation, the patient is usually free of symptoms. Most persons simply avoid the feared object and adjust to certain restrictions on their activities.¹

TREATMENT

Generalized Anxiety Disorder

■ DESIRED OUTCOME

The goals of therapy in the acute management of GAD are to reduce the severity and duration of the anxiety symptoms and to improve overall functioning. ① The long-term goal in GAD is remission with minimal or no anxiety symptoms, no functional impairment,

and increased QOL.²³ Patients with comorbid depression should have minimal depressive symptoms.

■ GENERAL APPROACH TO TREATMENT

Once GAD is diagnosed, a patient-oriented treatment plan, which usually consists of both psychotherapy and drug therapy, is developed. The plan depends on the severity and chronicity of symptoms, age, drug history, and comorbid medical and psychiatric conditions.²⁰ Psychotherapy is the least invasive and safest treatment modality. Antianxiety medication is indicated for patients experiencing anxiety symptoms severe enough to produce functional disability. Table 73–6 lists drug choices for GAD, panic disorder, and SAD. Many questions remain unanswered regarding how to manage treatment-resistant GAD.

■ NONPHARMACOLOGIC THERAPY

Nonpharmacologic treatment modalities in GAD include psychoeducation, short-term counseling, stress management, psychotherapy, meditation, or exercise. Psychoeducation includes information on the etiology and management of GAD. Anxious patients should be instructed to avoid caffeine, nonprescription stimulants, diet pills, and excessive use of alcohol. Most patients with GAD require psychologic therapy, alone or in combination with antianxiety drugs, to overcome fears and to learn to manage their anxiety and worry.⁵ Cognitive behavioral therapy (CBT) is the most effective psychologic therapy in GAD patients. Psychotherapy or medication alone have comparable efficacy in acute treatment.²⁰ The relapse rate with CBT is less than that of other types of psychologic modalities.²⁰ Controlled trials comparing the efficacy of combining drug and psychotherapy over long-term treatment are lacking.²⁰ The current literature is not clear regarding when to use CBT.

■ PHARMACOLOGIC THERAPY

The benzodiazepines are the most effective, safe, and commonly prescribed drugs for the rapid relief of acute anxiety symptoms (Table 73–7). All benzodiazepines are equally effective anxiolytics, and consideration of pharmacokinetic properties and the patient's clinical situation will assist in the selection of the most appropriate agent. Pharmacokinetic properties vary, and the clinician must monitor response to the initial treatment regimen after 2 to 4 weeks.⁵

Because of the lack of dependency and tolerable adverse effect profile, antidepressants have emerged as the treatment of choice for the management of chronic anxiety, especially in the presence of comorbid depressive symptoms. Buspirone is an additional anxiolytic

TABLE 73-7 Benzodiazepine Antianxiety Agents

Generic Name	Brand Name	Approved Dosage Range (mg/day) ^a	Approximate Equivalent Dose (mg)
Alprazolam ^b	Niravam, ^c Xanax, Xanax XR	0.75–4 1–10 ^d	0.5

option (Table 73–8) in patients without comorbid depression or other anxiety disorders (e.g., panic disorder and SAD). Because of the high risk of adverse effects and toxicity, barbiturates, antipsychotics, antipsychotic-antidepressant combinations, and antihistamines generally are not indicated in the treatment of GAD.²⁴ The benzodiazepines are more effective in treating the somatic and autonomic symptoms of GAD as opposed to the psychic symptoms (e.g., apprehension and worry), which are reduced by antidepressants.⁵

The most recent treatment guidelines from the British Society for Psychopharmacology and National Institute for Clinical Excellence are evidence-based.^{20,33} An algorithm for the pharmacologic management of GAD is shown in Fig. 73–1, but the current literature is not conclusive on the optimal sequence of pharmacologic therapies.²⁰

Alternative Drug Treatments

Hydroxyzine, kava kava, and pregabalin are alternatives. Patients with GAD demonstrated continued efficacy for 3 months with hydroxyzine or bromazepam (not marketed in the United States), but not with placebo.³⁴ Efficacy was maintained in 86% of the hydroxyzine group and 88% of the bromazepam group.³⁴ Analysis of data from a

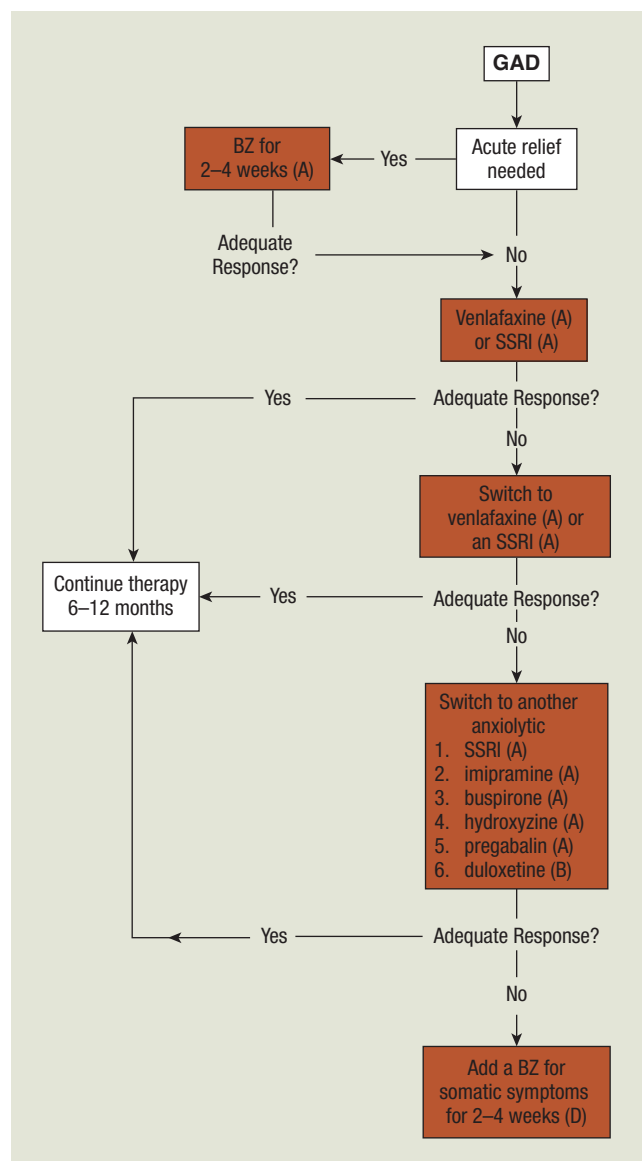

FIGURE 73-1. Algorithm for the pharmacotherapy of GAD. Strength of recommendations: A = directly based on category I evidence (i.e., meta-analysis of randomized clinical trials [RCT] or at least one RCT); B = directly based on category II evidence (i.e., at least one controlled study without randomization or one other type of quasi-experimental study); D = directly based on category IV evidence (i.e., expert committee reports or opinions and/or clinical experience of respected authorities). (BZ, benzodiazepine; SSRI, selective serotonin reuptake inhibitor.) (Data from Baldwin et al.,²⁰ and NICE.³³)

pooled sample of three placebo-controlled trials found kava kava to be no more effective than placebo.³⁴ Because of reports of hepatotoxicity, kava kava is not recommended as an anxiolytic.³⁵ Pregabalin, which binds to the $\alpha_2\delta$ subunit of voltage-gated calcium channels to reduce nerve terminal calcium influx, acts on “hyper-excited” neurons. Pregabalin produced anxiolytic effects similar to lorazepam, alprazolam, and venlafaxine in acute efficacy trials.³² Sedation and dizziness were the most common adverse effects, and the dose should be tapered over a week on discontinuation.

Special Populations

The management of anxiety in pregnancy, children, elderly patients, and those with hepatic impairment requires special consideration in the choice of anxiolytic. The literature is unclear if the potential risks of anxiolytic therapy outweigh the benefits of treating anxiety

during pregnancy. Clinical practice guidelines for anxiety disorders indicate that the use of SSRIs or tricyclic antidepressants (TCAs) in pregnancy does not pose increased teratogenic risk; however, perinatal syndromes (e.g., jitteriness, myoclonus, irritability) in the neonate and premature delivery were reported.^{20,36}

Cleft lip, cleft palate, and other teratogenic effects are associated with benzodiazepine use, but a causal relationship is inconclusive. Clinicians should avoid benzodiazepine use during the first trimester, use the lowest dosage for the shortest period of time, divide the total daily dosage into two or three doses to prevent high peak plasma levels, and use the agent as monotherapy.³⁷ Benzodiazepine risks during the third trimester include sedation, withdrawal symptoms, and “floppy baby syndrome” (e.g., hypotonia, low Apgar scores, hypothermia). Alprazolam and lorazepam should be avoided during pregnancy because of neonatal withdrawal.³⁷ Diazepam is the benzodiazepine with the longest safety record. If drug therapy is required during pregnancy, the antidepressants are favored based on safety considerations.³⁶ Diazepam and clonazepam should not be used if the mother is nursing because infants can experience sedation, lethargy, and weight loss.³⁷

In the elderly, secondary to a decreased capacity for oxidation and alterations in the volume of distribution, drug accumulation can result. Patients with hepatic disease also are at risk for drug accumulation and subsequent complications. Duloxetine use should be avoided in patients with hepatic insufficiency.²⁷ Therefore, intermediate- or short-acting benzodiazepines without active metabolites are preferred for chronic use. Elderly patients are also sensitive to the CNS adverse effects of benzodiazepines (regardless of half-life), and their use is associated with a high frequency of falls and hip fractures.³⁸ Venlafaxine and citalopram showed efficacy in elderly patients with GAD.^{20,39}

There are few controlled clinical trials of drugs in children and adolescents with GAD. CBT alone or in conjunction with antidepressants can have long-term benefits.⁴⁰ Randomized controlled trials of sertraline and fluvoxamine, and open trials of alprazolam, clonazepam, and fluoxetine indicate short-term efficacy;⁴¹ however, behavioral activation was reported with clonazepam.^{40,41} To date, fluoxetine is FDA-indicated for treatment of both depression and obsessive-compulsive disorder (OCD), and fluvoxamine and sertraline are FDA-indicated for OCD in children and adolescents. Other SSRIs and SNRIs have not been proved safe and effective in children and adolescents. There are reports of hostility, suicidal ideation, and self-harm with paroxetine in children with major depression, young adults with psychiatric disorders, and venlafaxine in children with major depression or GAD.^{29,30} Increased monitoring for behavioral activation with benzodiazepines and suicide-related adverse effects with antidepressants is necessary if these agents are prescribed for anxiety in children and adolescents. The FDA placed a black box warning on the use of all antidepressants in children and adolescents, and specific monitoring parameters were defined. The reader is referred to the official approved labeling for each antidepressant and to the FDA for additional information.

Antidepressant Therapy

2 Antidepressants are considered first-line agents in the management of GAD. Venlafaxine extended-release, duloxetine, paroxetine, and escitalopram are FDA-approved antidepressants for GAD. Imipramine is considered when patients fail to respond to SSRIs or venlafaxine (see Table 73-8). 3 The antianxiety response of antidepressants is delayed by 2 to 4 weeks or longer.²³ The pharmacokinetics and drug interactions of the antidepressants are reviewed in the chapter on depressive disorders (Chap. 71).

Efficacy Antidepressants are efficacious in the acute and long-term management of GAD. Data support the use of the SSRIs, escitalo-

pram, paroxetine, sertraline, and the SNRIs, venlafaxine extended-release and duloxetine, for acute therapy (8–12 week trials). The acute response and remission rates were approximately 60% to 68% and 30%, respectively.^{20,42} Preliminary data suggests that duloxetine 60 mg and 120 mg daily produces similar remission rates as other antidepressants.⁴³ In a comparative trial, there was no difference in efficacy between paroxetine and sertraline.⁴⁴ Escitalopram 10 mg was superior to paroxetine 20 mg in a fixed-dose study.⁴⁵

Studies with continued treatment after acute response to SSRIs showed further improvement with escitalopram or paroxetine over 6 months (escitalopram group had fewer withdrawals).⁴⁶ Continued venlafaxine therapy was associated with a 61% rate of remission.⁴⁷ Relapse-prevention studies found that patients continued on paroxetine or escitalopram achieved remission rates of 73% and 65%, respectively.^{47,48} In a four parallel-group comparison, diazepam and trazodone were found to be equivalent in anxiolytic activity (remission rates of 66% and 69%, respectively) compared with placebo (47% remission rate), but imipramine's rate of remission (73%) exceeded that of the other three treatments.⁴¹

Mechanism of Action The mechanism of action of antidepressants in anxiety disorders is not fully understood. Research indicates that antidepressants modulate receptor activation of neuronal signal transduction pathways connected to the neurotransmitters 5-HT, DA, and NE. As a result these cascades modify the expression of certain genes and the proteins that are produced (e.g., increase messenger RNA [mRNA] for glucocorticoid receptors and brain-derived neurotrophic factor for tyrosine kinase type B [trkB] receptors, and reduce mRNA expression for corticotropin-releasing hormone).⁴⁹ It is theorized that by activating stress-adapting pathways, SSRIs and SNRIs reduce the somatic anxiety symptoms and the general distress experienced by patients.⁴⁹

Adverse Effects Paroxetine was associated with a high rate of somnolence, nausea, abnormal ejaculation, dry mouth, decreased libido, and asthenia compared with placebo.^{11,30} Escitalopram caused nausea, insomnia, fatigue, decreased libido, ejaculation disorders, and decreased libido at a higher rate than placebo in patients with GAD.²⁸ The most common adverse events of venlafaxine in patients with GAD were nausea, somnolence, and dry mouth.³⁰ The package insert warns of toxicity in venlafaxine overdose.³⁰ The use of TCAs can be limited by troublesome adverse events (e.g., sedation, orthostatic hypotension, anticholinergic effects, and weight gain) in some patients and the risk of toxicity in overdose.⁵ However, in a meta-analysis of antidepressant trials there was no difference in dropout rates between antidepressants (e.g., paroxetine, venlafaxine, and imipramine) compared with placebo, suggesting equivalent tolerability between antidepressants.⁴¹

Dosing and Administration The antidepressants can be dosed once a day (see Table 73–8). Some patients require small initial daily doses for the first week of therapy. Paroxetine doses greater than 20 mg/day have not been found to be more effective, but it can be increased by 10 mg/day every week.²⁹

Benzodiazepine Therapy

The benzodiazepines are the most frequently prescribed drugs for the acute treatment of anxiety. Although all benzodiazepines possess anxiolytic properties, only 7 of the 13 currently marketed agents have FDA approval for the treatment of GAD (see Table 73–7). Estazolam, flurazepam, temazepam, quazepam, and triazolam are marketed as sedative-hypnotic agents. Clonazepam is marketed as an antipanic agent and anticonvulsant,⁵⁰ and midazolam is labeled for preoperative sedation. Alprazolam is indicated for the treatment of panic disorder with or without agoraphobia, as well as GAD, and is also available in once-daily extended-release tablets.⁵¹

Pharmacology and Mechanism of Action The GABA receptor model of anxiety (described in the Pathophysiology section) theorizes that benzodiazepines ameliorate anxiety through potentiation of the inhibitory activity of GABA.¹² The GABA receptor is composed of protein subunits arranged in a pentamer with an ion channel in the center. Benzodiazepines bind on the GABA_A receptor at the α_1 , α_2 , α_3 , and α_5 subunits in combination with a β subunit and the γ_2 subunit.¹⁵ The anxiolytic effects of benzodiazepines are mediated at the α_2 site while sedative effects result from binding at the α_1 subunit. The binding sites of benzodiazepines and GABA are at the receptor interfaces of α/β and α/γ_2 , respectively. The GABA receptor controls tonic inhibition to reduce neuronal excitability.¹⁵ Other neurotransmitters (e.g., 5-HT, NE, and DA) can be involved in benzodiazepine activity.

Pharmacokinetics A wide difference in milligram potency exists between the benzodiazepine compounds; however, when dosage adjustments are made, all agents share similar anxiolytic and sedative-hypnotic activity. The variations in lipid solubility between compounds influence the pharmacokinetic properties of benzodiazepines. Different pharmacokinetic and pharmacodynamic properties can assist the clinician in choosing an appropriate anxiolytic (Table 73–9). After a single dose, the onset, intensity, and duration of pharmacologic effects are important factors to consider when using benzodiazepines for the short-term, intermittent, or as-needed treatment of anxiety.

The primary determinant of a drug's onset of effect after a single oral dose is the rate of drug absorption. Because of high lipophilicity, diazepam and clorazepate are absorbed rapidly and distributed quickly into the CNS. Therefore the onset of anxiolytic effect occurs within 30 to 60 minutes, which results in a rapid and intense relief

TABLE 73-9 Pharmacokinetics of Benzodiazepine Antianxiety Agents

Generic Name	Time to Peak Plasma Level (h)	Elimination Half-Life, Parent (h)	Metabolic Pathway	Clinically Significant Metabolites	Protein Binding (%)

^aDesmethyldiazepam (DMDZ) half-life 50–100 h.

Data from Bailey et al.⁵² and Facts and Comparisons.⁵³

of anxiety. High lipophilicity also increases the extent of drug redistribution into the periphery, particularly adipose tissue, resulting in a shorter duration of effect after a single dose than indicated by single-dose elimination half-life studies.⁵² Clinically, patients perceive a rapid onset of action, but some experience an unpleasant feeling of drowsiness or loss of control. This “rush” can be euphoric and contribute to abuse. Chlordiazepoxide’s onset of action is much slower because of decreased lipophilicity, slower absorption, and delayed passage into the CNS.

Compared with diazepam, lorazepam, and oxazepam are relatively less lipophilic and have a slower onset of effect. These benzodiazepines have smaller volumes of distribution and a resulting longer duration of action.⁵² Oxazepam absorption is slow, and peak levels are not obtained until 2 to 4 hours after a single dose; however, like lorazepam, oxazepam’s anxiolytic effects are long lasting because extensive distribution does not occur.

Parenteral administration via the intramuscular route should be avoided with diazepam and chlordiazepoxide secondary to variability in the rate and extent of drug absorption. Intramuscular lorazepam provides rapid, reliable, and complete absorption.

After multiple dosing, the rate and extent of drug accumulation are functions of the drug’s elimination half-life in relation to dosing intervals, clearance, and formation of active metabolites. Differences in clinical effects that occur during and after repeated dosages with the benzodiazepines are related in part to variability in metabolism and metabolite accumulation.⁵²

The benzodiazepines undergo two primary metabolic processes, hepatic oxidation (catalyzed by cytochrome P450 3A4) and glucuronide conjugation. With the exception of lorazepam and oxazepam (which are conjugated only) and clonazepam (which undergoes nitroreduction), all benzodiazepines are oxidized first and then conjugated and excreted renally.⁵² Diazepam’s metabolism is also catalyzed by cytochrome P450 2C19. Oxidation can be impaired in patients with liver disease, in the elderly, and in those who simultaneously use drugs that inhibit oxidation resulting in higher levels of the parent drug and/or an active metabolite.

Many benzodiazepines are converted to desmethyldiazepam (DMDZ), an active metabolite with a long elimination half-life⁵² (see Table 73–9). DMDZ is further oxidized to oxazepam and then conjugated and excreted. After multiple dosing, accumulation of DMDZ is slow and extensive, providing a long-lasting antianxiety effect. If oxidation of DMDZ is impaired, the half-life is prolonged, and drug accumulation can result with repeated dosing.

Clorazepate is a prodrug and possesses no anxiolytic effects until metabolized to DMDZ. Before absorption, clorazepate is metabolized rapidly in the stomach through a pH-dependent process under acidic conditions.

Benzodiazepines with shorter half-lives (e.g., alprazolam, lorazepam, and oxazepam) reach steady-state plasma concentrations rapidly, and drug accumulation after repeated dosing is minimal. Oxazepam and lorazepam are not converted into active metabolites.

Benzodiazepine protein binding is extensive, especially for the drugs with a long elimination half-life. After a single dose of a benzodiazepine with a long elimination half-life, the expected duration of clinical activity may not parallel the drug’s pharmacokinetic half-life because of drug redistribution.⁵² After multiple dosing, drugs with long elimination half-lives and active metabolites require 1 to 2 weeks to reach steady state.

Efficacy Clinical trials of benzodiazepines show that 65% to 75% of patients with GAD have a marked to moderate response, with most of the improvement occurring in the first 2 weeks of therapy. Benzodiazepines are more effective on the somatic symptoms of anxiety and fail to obviate the cognitive or psychic symptoms (e.g., worry).^{11,23} Up to 50% of patients fail to reach remission with benzodiazepine therapy, and rates of relapse exceed that of the antidepressants.²³

Adverse Effects The most common adverse events associated with benzodiazepine therapy involve CNS depression. This is manifested clinically as drowsiness, sedation, psychomotor impairment, and ataxia.²³ A transient mild drowsiness is experienced commonly by patients during the first few days of treatment; however, tolerance often develops. Disorientation, depression, confusion, irritability, aggression, and excitement are reported.²³

Impairment of memory and recall also can occur during benzodiazepine treatment. The memory loss induced by the benzodiazepines typically is limited to events occurring after drug ingestion (anterograde amnesia).²³ Anterograde amnesia is secondary to disordered consolidation processes that store information and is not impairment in the perception or retrieval of information.² Benzodiazepines with high affinity for binding to the benzodiazepine receptor (e.g., lorazepam) appear to possess a higher potential for amnesia.²⁶

Abuse, Dependence, Withdrawal, and Tolerance Two serious complications of benzodiazepine therapy are the potential for abuse and development of physical dependence. Benzodiazepine abuse is rare in the general population of users; however, individuals with a history of multiple drug abuse (e.g., alcohol or sedatives) are at the greatest risk for becoming benzodiazepine abusers.⁵

Because of the chronicity of illness, persons with GAD and panic disorder are at high risk of developing benzodiazepine dependence. Benzodiazepine dependence is a physiologic phenomenon demonstrated by the appearance of a predictable abstinence syndrome (withdrawal symptoms) on abrupt discontinuation of therapy.²⁶ Withdrawal symptoms can result because of the sudden dissociation of a benzodiazepine from its receptor site. After abrupt discontinuation, an acute decrease in GABA neurotransmission results, producing a less inhibited CNS.

Benzodiazepine Discontinuation After benzodiazepine therapy is discontinued suddenly, several events can occur. Rebound anxiety represents an immediate but transient return of original symptoms having an increased intensity compared with baseline. Recurrence or relapse is the return of original symptoms with similar intensity as before treatment.

Withdrawal symptoms are the emergence of new symptoms and a worsening of preexisting symptoms after benzodiazepine discontinuation. Symptoms can persist for days to weeks and resolve gradually over months.

Common symptoms of benzodiazepine withdrawal include anxiety, insomnia, restlessness, muscle tension, and irritability. Less frequently occurring symptoms are nausea, malaise, coryza, blurred vision, diaphoresis, nightmares, depression, hyperreflexia, and ataxia. Tinnitus, confusion, paranoid delusions, hallucinations, seizures, and psychosis occur rarely. Seizures can occur with both therapeutic and high doses of benzodiazepines with a short elimination half-life, usually within 3 days of drug discontinuation. They can occur approximately 1 week after discontinuation of agents with a long elimination half-life. High benzodiazepine doses, a long duration of therapy, and concurrent ingestion of drugs that lower the seizure threshold are risk factors for withdrawal seizures.

The onset of withdrawal symptoms in patients ingesting benzodiazepines with short elimination half-lives occurs much earlier (within 24 to 48 hours) than in those taking benzodiazepines with long elimination half-lives (within 3 to 8 days). Other factors associated with an increased incidence and severity of benzodiazepine withdrawal include high doses and long-term benzodiazepine therapy.

Several strategies to minimize the severity of benzodiazepine withdrawal include a 25% per week reduction in dosage until 50% of the dose is reached, and then dosage reduction by one-eighth every 4 to 7 days.²⁶ If therapy exceeds 8 weeks, a slow dosage taper over 2 to 3 weeks is recommended; however, if the duration of treatment is 6 months, a taper over 4 to 8 weeks should ensue.⁵ Long-term use of

benzodiazepines (i.e., 1 year or longer) requires a 2- to 4-month slow taper.⁵ Tapering will not eliminate the emergence of withdrawal symptoms entirely but will prevent severe withdrawal. Slow drug taper is extremely important for the drugs with a short elimination half-life, because some individuals have greater difficulty with discontinuation. Adjunctive use of certain drugs (e.g., imipramine, valproic acid, or buspirone) or CBT can help to reduce withdrawal symptoms during the benzodiazepine taper.⁵ If patients experience difficulties, especially with the agents with a short elimination half-life, then substitution of an agent with a long elimination half-life should be considered. Although tolerance develops to the sedative, muscle relaxant, and anticonvulsant activities, the benzodiazepines do not appear to lose anxiolytic or antipanic efficacy. The anxiolytic efficacy of benzodiazepines in long-term clinical trials (greater than 6 to 8 months of chronic use) has not been reported.⁵

Drug Interactions Drug interactions with the benzodiazepines generally fall into two categories: pharmacodynamic and pharmacokinetic (Table 73–10). Simultaneous use of alcohol and a benzodiazepine results in additive CNS depressant effects. In addition, concurrent use of a benzodiazepine and other drugs with CNS depressant properties (e.g., narcotic agonists, antipsychotics, and antihistamines) can potentiate the adverse sedative effects. When ingested alone in an overdose attempt, benzodiazepines are rarely life-threatening; however, the combination of benzodiazepines with alcohol or other CNS depressant agents is potentially fatal.

Dosing and Administration Benzodiazepine dosage requirements vary widely among patients and must be individualized. Therapy should be initiated using low doses (e.g., alprazolam 0.25 mg three times a day or equivalent doses of other benzodiazepines) and titrated upward to relieve anxiety symptoms and avoid adverse events. After an initial treatment response is achieved, agents with long elimination half-lives can be dosed at bedtime. Dosage adjustments should be made weekly. Three to four weeks of a daily dose at the maximum dose constitutes an adequate clinical trial (see Table 73–7).⁵

The duration of benzodiazepine therapy for the acute management of anxiety generally should not exceed 2 to 4 weeks. Benzodiazepines can be prescribed on an as-needed basis, and if several acute courses

are necessary a benzodiazepine-free period of 2 to 4 weeks should be implemented between courses.⁵ Individuals with persistent symptoms should be managed with antidepressants because of the risk of dependence with continued benzodiazepine therapy.²³

Patient education should include the anticipated length of drug therapy, potential side effects, and consequences of the ingestion of alcohol and other CNS depressants. Patients should understand that benzodiazepines provide symptomatic relief but do not solve underlying psychologic problems. Patients should be instructed not to decrease or discontinue benzodiazepine usage without contacting their prescriber.

Buspirone Therapy

Buspirone is a nonbenzodiazepine anxiolytic that lacks anticonvulsant, muscle relaxant, hypnotic, motor impairment, and dependence properties. It is considered to be a second-line agent for GAD because of inconsistent reports of efficacy (particularly long term), delayed onset of effect (i.e., 2 weeks or longer), and lack of efficacy for other potential concurrent depressive and anxiety disorders.^{20,23} Unlike benzodiazepines, buspirone is effective for the psychic symptoms of anxiety.²³

Pharmacology and Mechanism of Action Buspirone's anxiolytic mechanism of action is unknown. It is thought to exert its anxiolytic effect through 5-HT_{1A} partial agonist activity at the presynaptic 5-HT receptors by reducing the firing of 5-HT neurons.¹²

Pharmacokinetics After an oral dose, buspirone is absorbed rapidly and completely and undergoes extensive first-pass metabolism. The mean elimination half-life is 2.5 hours, and it must be dosed two to three times daily, which adversely affects adherence to the drug regimen.²³

Adverse Effects Adverse events include dizziness, nausea, and headaches.²³

Drug Interactions Drugs that inhibit cytochrome P450 3A4 (e.g., verapamil, itraconazole, fluvoxamine) can increase buspirone levels. Rifampin caused a 10-fold reduction in buspirone levels. Buspirone reportedly increases haloperidol levels and elevates blood pressure in patients taking a monoamine oxidase inhibitor (MAOI).

Dosing and Administration The dose of buspirone can be titrated in increments of 5 mg/day every 2 to 3 days as needed.²³ The onset of improvement in psychic symptoms precedes the relief of somatic symptoms; maximum therapeutic benefit might not be evident for 4 to 6 weeks.

Buspirone is an agent of choice in the management of uncomplicated GAD, in patients who fail other anxiolytic therapies, or in patients with a history of substance abuse. It is not useful in clinical situations requiring immediate anxiolysis or for situations requiring as-needed anxiolytic therapy. The use of benzodiazepines within the month previous to initiation of buspirone therapy was associated with reduced efficacy of buspirone because of its delayed onset in the reduction of somatic symptoms.²³

■ PHARMACOECONOMIC CONSIDERATIONS

The annual economic burden of anxiety disorders in the United States was estimated to be \$42.3 billion in 1990 (\$63.1 billion in 1998 dollars).³ Nonpsychiatric medical treatment costs represented more than half of this figure, with expenses of \$13.3 billion for psychiatric treatment, \$4.1 billion for indirect workplace costs, and \$1.2 billion in mortality costs.

GAD is associated with high rates of healthcare use and disability. The number of days missed from work increases when GAD is concurrent with one or more other psychiatric disorders. Patients with GAD tend to use family practitioners and gastroenterologists

TABLE 73-10 Pharmacokinetic Drug Interactions with the Benzodiazepines

Drug	Effect
Carbamazepine	Decreased Cl of alprazolam
Ciprofloxacin	Decreased Cl of diazepam and increased $t_{1/2}$
Erythromycin	Decreased Cl of alprazolam
Fluoxetine	Decreased Cl of diazepam
Fluvoxamine	Decreased Cl of alprazolam and diazepam and prolonged $t_{1/2}$
Isoniazid	Decreased Cl of diazepam and increased $t_{1/2}$
Ketoconazole	Decreased Cl and Vd of chlordiazepoxide; increased AUC of alprazolam
Nefazodone	Decreased Cl of alprazolam, AUC doubled, and $t_{1/2}$ prolonged
Omeprazole	Decreased Cl of diazepam and prolonged $t_{1/2}$
Oral contraceptives	Decreased Cl and increased $t_{1/2}$ of diazepam and chlordiazepoxide; decreased $t_{1/2}$ of lorazepam and oxazepam
Paroxetine	Decreased Cl of alprazolam
Phenytoin	Increased Cl of diazepam and reduced $t_{1/2}$
Propoxyphene	Decreased Cl of alprazolam and prolonged $t_{1/2}$
Propranolol	Decreased Cl of diazepam and prolonged $t_{1/2}$
Rifampin	Increased metabolism of diazepam
St. John's wort	Decreased AUC of alprazolam
Valproate	Decreased Cl of lorazepam

AUC, area under the plasma concentration curve; BZ, benzodiazepine; Cl, clearance; $t_{1/2}$, elimination half-life; Vd, volume of distribution.

Data from Drug Facts and Comparisons⁵³ and Madabushi.⁵⁴

more frequently than healthy controls.² GAD ranks third among anxiety disorders in the rate of use of primary care physician time, and it is the leading cause of disability in the workplace in the United States.² Two decision analyses for GAD were published by researchers in the United Kingdom: venlafaxine was more cost-effective than diazepam,⁵⁵ and escitalopram was associated with higher treatment success, and lower discontinuation rates and costs than paroxetine.⁵⁶

CLINICAL CONTROVERSIES

It is unclear if combining pharmacotherapy with CBT confers greater overall efficacy than treatment with either approach alone. CBT is an option if patients fail treatment with consecutive trials of antidepressants. Clinicians should be aware that many patients lack access to CBT and should take this into consideration during treatment planning.

EVALUATION OF THERAPEUTIC OUTCOMES

Initially, anxious patients should be monitored once every 2 weeks³³ for a reduction in the frequency, duration, and severity of anxiety symptoms and improvement in functioning. The clinician should assess the patient for response to treatment by asking about specific target symptoms of anxiety and emergence of adverse events. Ideally, the patient should have no or minimal anxiety or depressive symptoms and no functional impairment. Use of an objective measurement of remission of GAD (e.g., Hamilton Rating Scale for Anxiety score less than 7 to 10 and a Sheehan Disability Scale score less than or equal to 1 on each item) can assist in the evaluation of drug response.²³ If a patient has only a partial response, the dose should be increased after 4 to 6 weeks of antidepressant therapy (or 2 weeks of acute therapy with benzodiazepines). The length of therapy should be individualized, with some patients requiring up to 1 year of antidepressant therapy.^{5,20,33}

TREATMENT

Panic Disorder

DESIRED OUTCOME

The goal of therapy in panic disorder is remission. Patients should be free of panic attacks, have no or minimal anticipatory anxiety and agoraphobic avoidance, and no functional impairment.⁵⁷ Naturalistic studies indicate that after pharmacotherapy, over 50% of patients have occasional panic attacks, 40% experience agoraphobic avoidance, and most continue to take medications.⁵⁸

GENERAL APPROACH TO TREATMENT

Therapeutic options include single or combined pharmacologic agents, concurrent psychotherapy, or psychotherapy followed by pharmacotherapy. Most patients without agoraphobic avoidance will improve with pharmacotherapy alone; however, if avoidance is present, CBT typically is initiated concurrently. With all effective drug therapies, resolution of agoraphobic avoidance tends to occur slowly. A meta-analysis of 11 randomized clinical trials comparing the use of SSRIs, TCAs, and CBT showed the effect on global anxiety and response to be similar among all treatments.⁵⁹

In the most comprehensive study to date, efficacy of imipramine alone and CBT alone were equivalent in acute therapy for 3 months and during 6 months of maintenance therapy. Combined imipramine and CBT therapy was not significantly better than CBT or imipramine alone for acute therapy but was significantly better

during maintenance. At 6 months after discontinuation, only patients previously treated with CBT maintained improvement (4% relapse) compared with a 25% relapse rate in patients previously treated with imipramine.⁶⁰ Patients who failed to respond to CBT and had paroxetine added to therapy had a significant improvement in agoraphobic behavior and anxiety symptoms.⁶¹

NONPHARMACOLOGIC THERAPY

Patients should be educated to avoid substances that can precipitate panic attacks, including caffeine, drugs of abuse, and nonprescription stimulants.¹ CBT is associated with short-term improvement in 80% to 90% of patients and 6-month improvement in 75% of patients. A course of CBT for panic disorder is 16 to 20 hours in length conducted over a period of 4 months.³³ Bibliotherapy (the use of self-help books), exercise, and Internet-based CBT are other options.^{20,33}

PHARMACOLOGIC THERAPY

Panic disorder is treated effectively with several drugs including the SSRIs, the TCA imipramine, and the benzodiazepines alprazolam and clonazepam^{21,24,57} (Table 73-11). Alprazolam, clonazepam, sertraline, paroxetine, and venlafaxine are approved for this indication. SSRIs are the first-line agents because of their tolerability and efficacy in acute and long-term studies;^{24,25,58} however, the benzodiazepines are the most commonly used drug for panic disorder.⁵⁷ In a meta-analysis of the pharmacotherapy of panic disorder, the effect size of SSRIs and TCAs did not differ; however, the number of dropouts in the TCA group (31%) was significantly higher than in the SSRI group (18%).⁶² A second meta-analysis comparing efficacy of benzodiazepines, TCAs,

TABLE 73-11 Drugs Used in the Treatment of Panic Disorder

Class/Generic Name	Brand Name	Starting Dose	Antipanic Dosage ^a Range (mg)
Selective serotonin reuptake inhibitors			
Citalopram ^b	Celexa	10 mg per day	20–60
Escitalopram	Lexapro	5 mg per day	10–20
Fluoxetine ^b	Prozac	5 mg per day	10–30
Fluvoxamine ^b	Luvox	25 mg per day	100–300
Paroxetine ^b	Paxil	10 mg per day	20–60 ^c
	Paxil CR	12.5 mg per day	25–75 ^c
Sertraline ^b	Zoloft	25 mg per day	50–200 ^c
Serotonin norepinephrine reuptake inhibitors			
Venlafaxine XR	Effexor XR	37.5 mg per day	75–225 ^c
Benzodiazepines			
Alprazolam ^b	Xanax	0.25 mg three times a day	4–10 ^c
	Xanax XR	0.5–1 mg per day	1–10 ^c
Clonazepam ^b	Klonopin	0.25 mg once or twice per day	1–4 ^c
Diazepam ^b	Valium	2–5 mg three times a day	5–20
Lorazepam ^b	Ativan	0.5–1 mg three times a day	2–8
Tricyclic antidepressant

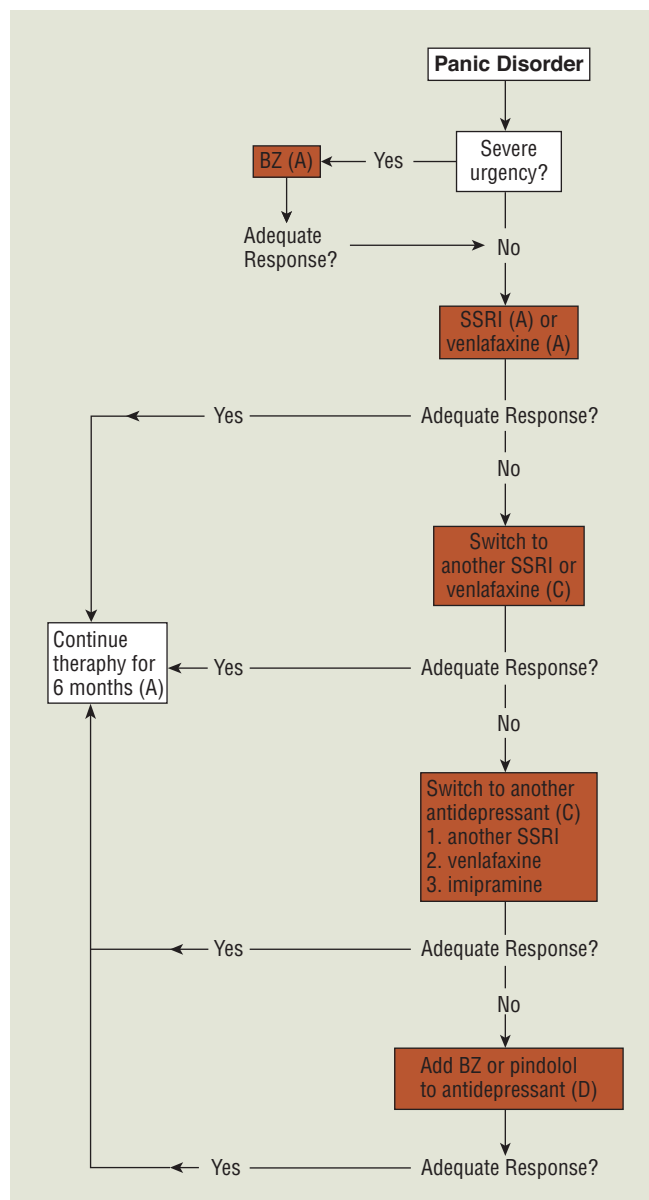

FIGURE 73-2. Algorithm for the pharmacotherapy of panic disorder. Strength of recommendations: A = directly based on category I evidence (i.e., meta-analysis of randomized clinical trials [RCT] or at least one RCT); B = directly based on category II evidence (i.e., at least one controlled study without randomization or one other type of quasi-experimental study); C = directly based on category III evidence (i.e., nonexperimental descriptive studies); D = directly based on category IV evidence (i.e., expert committee reports or opinions and/or clinical experience of respected authorities). (BZ, benzodiazepine; SSRI, selective serotonin reuptake inhibitor.) (Data from Baldwin et al.²⁰ and NICE.³³)

and SSRIs in panic disorder concluded that all treatments were equally efficacious with 50% to 80% of patients responding to treatment; however benzodiazepines were less effective for depression.⁵⁹ Four practice guidelines^{24,25,33,58} are published. An algorithm for the pharmacologic therapy of panic disorder appears in Fig. 73–2.

The efficacy of antidepressants was demonstrated in acute and long-term trials. Three 12-week, acute trials compared antidepressants. Escitalopram, but not citalopram, reduced the frequency of panic attacks although both improved QOL and reduced disease severity.⁶³ There was no difference in outcomes between paroxetine 40 to 60 mg and sertraline 50 to 150 mg daily.⁶⁴ Venlafaxine extended-release (75 mg or 150 mg) and paroxetine 40 mg achieved a 44% remission rate compared with that of placebo (24%).⁶⁵

Double-blind trials indicated that continuing sertraline, citalopram, or imipramine from 3 months to 1 year improved response rates.²⁰ Relapse prevention trials with fluoxetine, imipramine, paroxetine, sertraline, and venlafaxine extended-release resulted in reduced relapse rates compared with placebo.^{20,66}

Benzodiazepines are considered second-line agents. Because of the risk of dependency, benzodiazepines should be used only after several trials of antidepressants have failed.^{24,25} Because of potential emergence of depressive symptoms during treatment, benzodiazepines should not be used as monotherapy in a patient who is clinically depressed or has a history of depression. In patients whose illness is complicated by a history of alcohol or drug abuse, benzodiazepine use should be avoided.²⁵ Limited data support the combined use of SSRIs and benzodiazepines in the first weeks of treatment to offset the delay in the SSRI effect.²⁰

Alternative Drug Treatments

Buspirone, trazodone, bupropion, antipsychotics, antihistamines, and β -blockers are ineffective in panic disorder.^{20,24,58} The majority of studies assessing the efficacy of MAOIs in treating panic disorder were open-labeled. These trials lacked sufficient dosage and duration of treatment, adequate sample size, and valid ratings of panic attacks. No maintenance trials of MAOIs are published. MAOIs are reserved for the most refractory or difficult patients.²⁴

Special Populations

Elderly patients with panic disorder have fewer, less intense symptoms and avoidant behavior than younger patients.⁶⁷ Youth often present with fear that they are dying or being smothered, and agoraphobia can be manifested as a fear of leaving home.⁶⁸ Antidepressants, especially the SSRIs, are preferred for management of panic disorder,^{67,68} and benzodiazepines are second-line agents because of potential problems with disinhibition in these two populations.

Antidepressant Therapy

Tricyclic Antidepressants

Efficacy. Imipramine is the most studied TCA, alleviating panic attacks in 75% of patients with panic disorder. Imipramine effectively blocks panic attacks within at least 4 weeks; however, maximal improvement (including antiphobic response) does not occur until 8 to 12 weeks.²⁵

Adverse Effects. Up to 40% of patients experience stimulant-like side effects, including anxiety, insomnia, and jitteriness.²⁵ These side effects often affect patient compliance, prevent medication dosage increases, and interfere with the overall treatment outcome.

Problems with TCA use in panic disorder are well documented and include stimulatory side effects, anticholinergic effects, orthostatic hypotension, delayed onset of antipanic effects, and toxicity in overdose.²⁵ Approximately 25% of patients reportedly discontinue treatment because of side effects. Weight gain is problematic with long-term therapy.²⁵

Dosing and Administration. When using imipramine, treatment should be slowly increased by 10 mg every 2 to 4 days as tolerated.

Selective Serotonin Reuptake Inhibitors

Efficacy. Clinical studies indicate that all SSRIs are effective in panic disorder.^{20,21,58} The percentage of patients who become panic-free ranges between 60% and 80%.²⁵ 4 The antipanic effect of SSRIs is delayed for at least 4 weeks, and some patients do not respond for 8 to 12 weeks.^{25,33}

Adverse Effects. Typical antidepressant doses of SSRIs can cause side effects of insomnia, jitteriness, restlessness, and agitation, and

lead to drug discontinuation in patients with panic disorder. Transient gastrointestinal disturbances occur more frequently with SSRIs than with TCAs. Thus low initial SSRI doses should be prescribed.^{21,24,57} Sleep disturbances, headaches, and sexual dysfunction often are problematic.^{24,57}

Dosing and Administration. Low initial doses of SSRIs are recommended (see Table 73–11) to avoid stimulatory side effects (e.g., insomnia or nervousness), and should be maintained for the first week of therapy. Doses at the upper end of the dosing range can be necessary to achieve response.³³

Serotonin Norepinephrine Reuptake Inhibitors

Efficacy. Approximately 54% to 60% of patients were panic-free on venlafaxine-extended release 75 mg or 150 mg daily. The remission rates were 44% for both dosages in acute efficacy studies.⁶⁵

Adverse Effects. The most common adverse effects of venlafaxine extended-release in panic trials were nausea, somnolence, tremors, sweating, and abnormal sexual functioning (ejaculation difficulties and anorgasmia).³⁰

Dosing and Administration. The dosage of venlafaxine can be increased at weekly intervals. A dose-response relationship was not evident in clinical trials.³⁰

Benzodiazepines

Efficacy. The high-potency benzodiazepines clonazepam and alprazolam are the preferred agents.^{5,21} Diazepam and lorazepam are possibly effective in treating panic disorder when taken in sufficiently high doses.²⁵ Alprazolam is an ideal agent for patients who need rapid relief. Therapeutic response to benzodiazepines occurs in 1 to 2 weeks. Relapse rates of 50% or higher are common despite slow drug tapering.²⁵

Adverse Effects. Patient acceptance of benzodiazepines usually is not a problem, and except for sedation, side effects are reported rarely.

Dosing and Administration. Doses of clonazepam can be increased by 0.25 or 0.5 mg every 3 days to 4 mg/day if needed.⁵⁰ Alprazolam can be slowly increased over several weeks to reach an ideal dose. **6** The duration of action of immediate-release alprazolam can be as little as 4 to 6 hours with resulting breakthrough symptoms; use of the extended-release alprazolam or clonazepam will avoid this problem. Most patients require 3 to 6 mg/day of alprazolam, and some need higher doses to obtain a full therapeutic (antipanic and antiphobic) response.

Treatment Resistance. Common reasons for treatment failures are comorbid psychiatric disorders, rapid dosage increases with resulting intolerable side effects, and underdosage.²⁵ All standard treatments should be tried before using augmentation strategies. The most common strategy used in patients with a partial response to one agent is to augment it with low doses of another antipanic agent (e.g., a TCA, benzodiazepine, or an SSRI).²⁵

Phases of Therapy

Acute Phase. The main goal of therapy in the acute phase is reduction of symptoms (e.g., resolution of panic attacks, reduction in anxiety and phobic fears, resumption of the patient's usual activities).²⁵ The duration of this phase is generally 1 to 3 months depending on the choice of drug. The duration of the acute phase with antidepressants is about 12 weeks.²⁵ Therapy should be altered if there is no response after 6 to 8 weeks of an adequate dose. The duration of the acute phase with benzodiazepines is approximately 1 month because response is rapid.

The guiding principle for using drugs in panic disorder is to start low, use an adequate dose, and treat for an appropriate period of time. Side effects with the antidepressants, often from too high an

initial dose, can prevent achievement of an optimal dosage, compromise treatment response, and contribute to patient noncompliance.

Maintenance Phase and Discontinuation. **6** The optimal length of therapy is unknown; however, the total duration of therapy appears to be 12 to 24 months before drug discontinuation over 4 to 6 months is attempted.^{24,25} The dose used in the acute phase is continued into the maintenance phase.²⁴ Citalopram, clomipramine, fluoxetine, sertraline, and imipramine have been shown to maintain clinical effects for up to 1 year of treatment.^{20,24} When drugs are discontinued too early, a high rate of relapse occurs; thus longer periods of treatment are associated with more sustained response. Reinstitution of drug usually results in renewed clinical response.²⁵ Patients successfully treated with imipramine for 6 months had the same rate of relapse after discontinuation as those treated for 12 to 30 months.⁶⁹ Pharmacotherapy, even at long duration, might not prevent relapse, and many patients require long-term therapy.

The most important determinant of compliance with maintenance therapy is the tolerability of adverse events.²⁵ Some adverse events which are experienced short term become unbearable during long-term management (e.g., sexual dysfunction and weight gain). The primary risk of long-term benzodiazepine use is the development of dependency and withdrawal reactions on discontinuation. Abuse of benzodiazepines usually is confined to patients with a personal or family history of substance or alcohol use.⁵ TCAs, SSRIs (except fluoxetine), and venlafaxine can be associated with discontinuation symptoms.

Patient education is essential. Patients should be informed regarding the lag time before a therapeutic response will occur and any problematic side effects. Many patients are reluctant to take drugs for fear that their illness will worsen or that they will become addicted. Adverse events are often perceived as a worsening of the illness and can contribute to nonadherence or prevent necessary dosage increases. Patients receiving benzodiazepines and antidepressants should be told not to decrease or discontinue therapy unless authorized by their clinician.³³

■ PHARMACOECONOMIC CONSIDERATIONS

Patients with panic disorder have high rates of unemployment and receive welfare, disability benefits, and healthcare services.³ They also have impaired emotional and physical health status and experience poor marital and social functioning.^{20,21} Measures of QOL improved with imipramine, clonazepam, sertraline, and venlafaxine. Treatment with clomipramine, paroxetine, or fluoxetine improved work, social, and family responsibilities. Improvements in anxiety and phobic avoidance were significantly associated with QOL improvements.^{20,21} In a cost comparison, group CBT was more cost-beneficial than pharmacotherapy for the initial 4 months of therapy.⁷⁰

CLINICAL CONTROVERSY

The optimal sequence of treatments for panic disorder is not well defined by the current literature. When initial SSRI therapy fails, there is no clear evidence on which alternative therapeutic treatment modality to initiate. Most clinicians will prescribe a second SSRI.

■ EVALUATION OF THERAPEUTIC OUTCOMES

During the first few weeks of the acute phase of therapy, patients with panic disorder should be seen every 2 weeks to adjust drug dosages based on improvement in panic symptoms and to monitor for adverse events.³³ Subsequently, visits every 2 months should

suffice.³³ The patient should be counseled to maintain a diary to record the date, time, frequency, and duration of panic episodes and the severity of symptoms. Treatment outcomes can be assessed objectively by use of the Hamilton Rating Scale for Anxiety (with a desired score of less than or equal to 7 to 10).⁷¹ At scheduled visits, the clinician can inquire about the level of disability experienced by the patient and have the patient complete the Sheehan Disability Scale (with a goal of less than or equal to 1 point on each item).⁷¹ During drug discontinuation, the frequency of appointments should be increased to evaluate for emergence of withdrawal symptoms and monitor for relapse.

TREATMENT

Social Anxiety Disorder

■ DESIRED OUTCOME

The goals of therapy in the acute phase of treatment are to reduce physiologic symptoms of anxiety (e.g., tachycardia, flushing, and sweating), social anxiety, and phobic avoidance. The duration of this phase is 4 to 12 weeks, depending on the drug therapy.

The goals of therapy in the continuation phase (3 to 6 months) are to extend the therapeutic benefits, especially the patient's ability to participate in social activities, and improve QOL. Although the primary goal of treatment is to reduce anxiety symptoms to manageable levels, even modest reductions in avoidance and discomfort can be highly valued by patients.⁹

7 SAD is a chronic, long-term illness. At least a 1-year maintenance period is recommended to maintain improvement and decrease the rate of relapse.^{19,22} Situations suggesting a possible need for long-term treatment include the presence of unresolved symptoms or comorbidity, an early onset of disease, and a prior history of relapse.^{19,22} The long-term goal in the treatment of SAD is remission with the disappearance of the core symptoms of social anxiety, little or no anxiety, and no functional impairment or concurrent depressive symptoms.⁷¹

■ GENERAL APPROACH TO TREATMENT

Generalized SAD is associated with significant morbidity, and patients should be treated aggressively. Obstacles to effective treatment include patient avoidance of therapy secondary to fear and shame, treatment directed toward somatic symptoms or concurrent conditions, and financial barriers.⁷² Patients with SAD often respond to treatment more slowly and less completely than patients with other anxiety disorders. Therefore it is important to set reasonable expectations for response to therapy. The patient's symptoms, prior treatments, concurrent conditions, and history of substance abuse direct treatment selections.

CBT and pharmacotherapy are effective in the treatment of SAD.^{9,19,73} Pharmacotherapy is often the most practical choice because CBT might not be available outside of large urban areas secondary to the lack of trained therapists and high treatment costs. Studies suggest the acute treatment outcomes for CBT and pharmacotherapy are equal.^{9,19} Drug therapy tends to be superior in reducing subjective general anxiety in acute treatment, although CBT can lead to a greater likelihood of maintaining response after treatment termination.^{9,19,74}

There are no data to predict which patients will respond best to pharmacotherapy, CBT, or a combination,⁹ or maintain gains after discontinuing pharmacotherapy. The only significant predictor of treatment response in pharmacotherapy is duration of treatment.⁷⁵ Some patients elect lifelong therapy, and many are reluctant to attempt drug discontinuation because of fear of relapse. Discontinuation of drug therapy after only 2 to 3 months resulted in higher

rates of relapse than when therapy was continued for 5 to 12 months.⁹ Data show that relapse rates after discontinuation of CBT are significantly less than those after discontinuation of effective pharmacotherapy.^{9,19,74} Sertraline is the only medication approved for the long-term treatment of SAD, although paroxetine, escitalopram, and venlafaxine prevented relapse.^{76–78}

■ NONPHARMACOLOGIC THERAPY

Patients should be educated about SAD and effective therapeutic options. Support groups are helpful for some patients. Self-help group programs that focus on effective communication can benefit people with public-speaking phobia.

CBT for SAD consists of exposure therapy, cognitive restructuring, relaxation training techniques, and social skills training.⁹ Through CBT, patients learn to overcome anxiety in social situations and change the beliefs and responses that maintain this behavior. Therapy usually lasts several months and often is conducted in a group setting. In clinical trials, one-half to two-thirds of patients responded at 12 weeks.⁹

■ PHARMACOLOGIC THERAPY

Special Populations

SAD can present in children of preschool to elementary school age. If the disorder is not treated, it can persist into adulthood and increase the risk of depression and substance abuse. CBT and social skills training are effective nonpharmacologic therapies in children.^{8,9} Placebo-controlled and open-label trials have provided evidence of efficacy of pharmacotherapy with an SSRI or SNRI in children 6 to 17 years of age.^{9,19} Children and adolescents prescribed an SSRI or SNRI for social anxiety (or for other purposes) should be closely monitored for increased risk of suicidal ideation. Headache, nausea, drowsiness, insomnia, jitteriness, and stomach aches were reported in children receiving antidepressants.⁸

Benzodiazepines should be reserved as the last-line agents in children with SAD.⁸ If prescribed, they should be used for the shortest time period possible. The adverse effects of benzodiazepines in children include drowsiness, oppositional behavior, disinhibition, fatigue, and nausea.

Approximately one-fifth of patients with SAD also suffer from an alcohol use disorder. Many people with SAD report that they use alcohol to cope with their anxiety. Most clinical trials evaluating pharmacotherapy for SAD excluded patients with alcohol use disorder. Paroxetine significantly reduced social anxiety and decreased the frequency and severity of alcohol use in patients with SAD and an alcohol use disorder.⁷⁹ MAOIs and benzodiazepines are not appropriate therapy for patients with SAD and alcohol use disorder. The tyramine present in many alcoholic beverages can precipitate a hypertensive crisis in patients on an MAOI. People who abuse alcohol are at risk for abusing or becoming dependent on benzodiazepines. SSRI therapy is the treatment of choice in this patient population.

Antidepressant Therapy

8 The SSRIs and venlafaxine have the benefits of antidepressant activity for concurrent depression and safety when used in patients with substance abuse. Paroxetine, sertraline, and venlafaxine extended-release are approved for the treatment of generalized SAD and are considered first-line agents because of their efficacy and tolerability (Table 73–12). Escitalopram has also been found to be effective in the treatment of generalized social anxiety.^{20,80,81} Controlled trials comparing different SSRIs, or SSRIs and an SNRI, demonstrated equivalent efficacy between agents.⁹ TCAs are not effective in SAD.⁹ The International Consensus Group on Depression and Anxiety published a consensus statement on SAD,²² and

TABLE 73-12 Drugs Used in the Treatment of Generalized Social Anxiety Disorder

Class/Generic Name	Brand Name	Starting Dose	Dosage Range ^a (mg/day)

^aDosage used in clinical trials but not FDA approved.^bAvailable generically.^cDosage is FDA approved.^dUsed as augmenting agent.Data from Schneier,⁹ Ballenger et al,²² Paxil package insert,²⁷ Effexor XR package insert,²⁸ and Blanco et al.⁷³

evidence-based guidelines for the treatment of SAD were published by the British Association for Psychopharmacology.²⁰ An algorithm for the pharmacotherapy of generalized SAD appears in Fig. 73–3.

Selective Serotonin Reuptake Inhibitors

Efficacy. The efficacy and safety of SSRIs in the treatment of SAD were established in large placebo-controlled trials.⁸⁰ Response rates to SSRIs ranged from 50% to 80% after 8 to 12 weeks of treatment.^{80,81}

Patients treated with paroxetine, sertraline, escitalopram, and fluvoxamine showed improvement in anxiety and avoidance symptoms and a decrease in disability.⁸⁰ Daily doses up to 60 mg of paroxetine, 200 mg of sertraline, 20 mg of escitalopram, and 300 mg of fluvoxamine were well tolerated, and emergent adverse effects were similar to those of depression trials (e.g., nausea, sexual dysfunction, sweating, and somnolence). The onset of effect was delayed 4 to 8 weeks, and maximum benefit was often not observed until 12 weeks or longer. Sertraline was effective in disabled patients suffering from the marked to severe form of generalized SAD.⁸² Limited data suggest that citalopram is also effective in treating SAD.⁸³ Fluoxetine was not effective in SAD.⁸⁴

Dosing and Administration. SSRIs should be initiated at doses similar to those used for the treatment of depression and administered as a single daily dose (see Table 73–12). If the patient suffers from comorbid panic disorder, the SSRI dose should be started at one-fourth or one-half of the dose. Safety for paroxetine in SAD was demonstrated in doses up to 60 mg/day, but additional therapeutic benefits above 20 mg/day were not shown.⁸⁵

The dose response curve for SSRIs tends to be relatively flat, but individual patients can require higher doses.^{9,19} When discontinuing an SSRI, the dosage should be tapered monthly (i.e., decreasing sertraline by 50 mg or paroxetine by 10 mg) to reduce the risk of relapse and discontinuation symptoms. Escitalopram produced significantly fewer discontinuation symptoms compared with paroxetine in patients with SAD.²⁰

Venlafaxine

Efficacy. Venlafaxine extended-release was significantly better than placebo in improving social interaction, performance, avoidance factors, and some fear factors (e.g., public speaking).⁸⁶ Beneficial effects were seen by week 3. Venlafaxine was effective in patients who failed to respond to therapy with SSRIs.¹⁹

Adverse Effects. Adverse effects included anorexia, dry mouth, nausea, insomnia, and sexual dysfunction.

Dosing and Administration. Additional therapeutic benefits of venlafaxine above 75 mg/day were not shown.⁸⁶ Venlafaxine should be tapered slowly (i.e., decreasing by 37.5 mg/mo) to decrease the risk of relapse during discontinuation.

Mirtazapine Mirtazapine reduced social anxiety and improved QOL in women with SAD over 10 weeks. The dose was 30 mg/day, and mirtazapine was well tolerated.⁸⁷

Alternate Agents

Benzodiazepines Benzodiazepines are commonly used in the treatment of patients who cannot tolerate or fail to respond to antidepressants.⁹ Benzodiazepines are not considered first-line therapy for SAD because of concerns over the adverse effects, potential for dependence, the possibility of rebound anxiety, and ineffectiveness in the treatment of depression.^{19,20} Clonazepam is the most extensively studied benzodiazepine for the treatment of generalized SAD.⁸⁸ Clonazepam improved fear and phobic avoidance, interpersonal sensitivity, fears of negative evaluation, and disability measures.⁸⁸ Adverse effects included sexual dysfunction, unsteadiness, dizziness, and poor concentration.⁸⁸

If clonazepam is prescribed, the acute phase of therapy is about 1 month. The initial dose of 0.25 mg/day can then be increased as tolerated over several weeks up to 3 mg/day. The average daily dose in clinical trials was 2.4 mg.^{69,73} Patients should be instructed not to decrease or discontinue clonazepam without consulting their clinician because of the risks of rebound anxiety and withdrawal symptoms.

Benzodiazepines must be slowly tapered on discontinuation. Patients on clonazepam for 6 months who were slowly tapered over 5 months maintained their treatment response.⁸⁸ Clonazepam should be gradually tapered at a rate not to exceed 0.25 mg every 2 weeks.⁹

Anticonvulsants Anticonvulsants are another therapeutic option in SAD. Gabapentin, a nonbenzodiazepine GABA analog, was effective for SAD in a 14-week placebo-controlled trial.^{9,19} The onset of effect occurred within 2 to 4 weeks. Patients reported dizziness and dry mouth. Pregabalin was superior to placebo in an 11-week, placebo-controlled trial. The effective dose was 600 mg/day and adverse effects included dizziness and somnolence.⁸⁹

β-Blockers β-Blockers decrease the perception of anxiety by blunting the peripheral autonomic symptoms of arousal (e.g., rapid heart rate, sweating, blushing, and tremor), and they are often used to decrease anxiety in performance-related situations. For patients with specific SAD, 10 to 80 mg of propranolol or 25 to 100 mg of atenolol can be taken one hour before a performance as needed.^{9,19} A test dose should be taken at home before the presentation to assure that β-blockade is sufficient and there are no adverse events. The effect of a single dose can last up to several hours. Controlled trials with β-blockers do not support daily use in generalized SAD.¹⁹

FIGURE 73-3. Algorithm for the pharmacotherapy of generalized social anxiety disorder. Strength of recommendations: A = directly based on category I evidence (i.e., meta-analysis of randomized clinical trials [RCT] or at least one RCT); B = directly based on category II evidence (i.e., at least one controlled study without randomization or one other type of quasi-experimental study); C = directly based on category III evidence (i.e., nonexperimental descriptive studies); D = directly based on category IV evidence (i.e., expert committee reports or opinions and/or clinical experience of respected authorities). (SSRI, selective serotonin reuptake inhibitor.) (Data from reference Baldwin *et al.*²⁰)

Treatment Resistance There are no data to guide clinicians in the choice of treatments if there is a lack of response to antidepressants. Patients who have an incomplete response to a first-line agent can benefit from augmentation with buspirone.^{9,73} Clonazepam can be used as an augmenting agent in patients without a history of substance abuse.²⁰ When clonazepam was combined with paroxetine over 10 weeks in a placebo-controlled trial, clonazepam did not lead to more rapid resolution of SAD symptoms.⁹⁰ However, the group that received the combination therapy had a higher response rate.

9 An adequate trial usually consists of 8 to 12 weeks (at maximum dosages) to determine if a drug will be effective. Subsequent options include a trial of a second SSRI or venlafaxine extended-release. Some patients experience clinical benefit during the first 4 weeks of therapy.^{9,19} If nonresponsiveness continues, a trial of an alternative agent is warranted.

The MAOIs are reserved for treatment-resistant patients. Although phenelzine is effective in 77% of patients with SAD,^{22,73} dietary restrictions, potential drug interactions and adverse effects (e.g., weight gain and hypertensive crisis) have limited its use. If a patient is switched from another antidepressant to phenelzine, an appropriate washout period should be followed.

■ PHARMACOECONOMIC CONSIDERATIONS

Generalized SAD is associated with lower health-related QOL, a higher rate of lifetime suicide attempts, diminished educational and occupational attainment, and increased use of healthcare resources.²² Patients with SAD have a low employment status.

Early intervention is important in the treatment of SAD. Pharmacotherapy can dramatically improve QOL. Patients treated with fluvoxamine, sertraline, paroxetine, or escitalopram showed a significantly greater improvement in functioning, disability, and QOL compared with placebo-treated patients.^{78,82,91,92} In a relapse pre-

vention study, patients treated with escitalopram experienced a better health-related QOL and more cost-effective therapy than placebo.⁹² The acquisition cost of escitalopram was more than offset by a decrease in total costs of care.⁹² Healthcare professionals can assist patients who qualify for pharmaceutical manufacturer patient access-to-care programs to ease the burden of drug costs.

CLINICAL CONTROVERSY

The role of benzodiazepines in the treatment of SAD is controversial. Some clinicians prescribe benzodiazepines in combination with an antidepressant in the initial acute management of SAD, then taper the benzodiazepine after 3 to 4 weeks. Recent data indicate that the addition of a benzodiazepine to an SSRI during the acute treatment of SAD does not provide more rapid response, although these patients tended to have better outcomes at the end of the trial.

■ EVALUATION OF THERAPEUTIC OUTCOMES

10 The pharmacotherapy of SAD can be monitored in three principal domains: SAD symptoms (e.g., fears and physical symptoms), functionality, and well-being or overall improvement.²² Response to pharmacotherapy in SAD is defined as a stable, clinically meaningful improvement; patients no longer have the full range of symptoms but typically continue to experience more than minimal symptoms.²²

During the acute phase of treatment, patients should be seen weekly while the drug dosage is titrated. Once the patient responds and the dosage is stabilized, the patient can be seen monthly. At each visit, the patient should be asked about adverse effects and improvement in symptoms. The patient should be instructed to

keep a diary to record fear levels, physical symptoms, cognitions, and anxious behaviors in actual exposures to social situations. The Liebowitz Social Anxiety Scale is a clinician-rated scale of clinical severity and change in SAD that can be used to monitor response.^{9,22} Patients can use the Social Phobia Inventory for self-assessment of SAD symptoms.²² Full remission is a complete resolution of symptoms across the three SAD domains that is maintained for 3 months²² or a Liebowitz Social Anxiety Scale score of less than or equal to 30 points.⁷¹

Patient counseling is important. The patient should be instructed about the gradual onset of effect and that the full therapeutic effect might not be achieved for up to 12 weeks. Patients should be told that long-term therapy is required. When drug therapy is discontinued, the dosage will need to be gradually decreased over several months, and the patient should be seen more frequently to monitor for signs and symptoms of relapse or withdrawal.

It is important to remember that although pharmacotherapy usually leads to improvement in social and occupational functioning, most patients do not achieve a full remission. Many patients require additional treatment, often in the form of CBT.

TREATMENT

Specific Phobia

Specific phobia is considered unresponsive to drug therapy, although highly responsive to CBT. The use of benzodiazepines or paroxetine in patients who failed CBT is supported by limited data. Benzodiazepines can be detrimental in patients with specific phobias treated with CBT.²⁰

CONCLUSIONS

Anxiety disorders are common in the population and occur concurrently with other psychiatric disorders. The proper management of anxiety disorders begins with the correct diagnosis; not all patients should receive antianxiety agents. Nonpharmacologic interventions often are effective alone or when combined with drug therapy.

There are several subtypes of anxiety disorders, and the diagnosis determines the type of drug and nonpharmacologic intervention selected. Although benzodiazepines remain the drugs of choice for situational anxiety, antidepressants have emerged as first-line therapy for GAD, panic disorder, and SAD. Benzodiazepines are reserved for use in situations requiring immediate anxiety relief or for use on an as-needed basis. Antidepressants, including the SSRIs and SNRIs, and the benzodiazepines clonazepam and alprazolam, are used extensively in patients with GAD, panic disorder, and SAD.

The long-term goal of therapy for GAD, panic disorder, and SAD is remission of core anxiety symptoms with no impairment in functionality, minimal anxiety, and no depressive symptoms. Clinicians can use the pharmacologic armamentarium effectively to achieve this goal for patients.

ABBREVIATIONS

CBT: cognitive behavioral therapy
 CNS: central nervous system
 CRF: corticotrophic releasing factor
 DA: dopamine
 DMDZ: desmethyldiazepam
 GABA: γ -aminobutyric acid
 GAD: generalized anxiety disorder

FDA: Food and Drug Administration

5-HT: serotonin

LC: locus ceruleus

MAOI: monoamine oxidase inhibitor

NE: norepinephrine

QOL: quality of life

SAD: social anxiety disorder

SERT: serotonin reuptake transporter site

SNRI: serotonin-norepinephrine reuptake inhibitor

SSRI: selective serotonin reuptake inhibitor

TCA: tricyclic antidepressant

Anxiety Disorders II: Posttraumatic Stress Disorder and Obsessive-Compulsive Disorder

CYNTHIA K. KIRKWOOD, EUGENE H. MAKELA, AND BARBARA G. WELLS

KEY CONCEPTS

- 1 The short-term goal in posttraumatic stress disorder is reduction in core symptoms, whereas the long-term goal is remission.
- 2 Cognitive behavioral therapy and eye movement desensitization and reprocessing are the most effective nonpharmacologic methods to reduce symptoms of posttraumatic stress disorder.
- 3 The selective serotonin reuptake inhibitors are considered first-line treatment for posttraumatic stress disorder.
- 4 An adequate trial of selective serotonin reuptake inhibitors in posttraumatic stress disorder requires appropriate dosing, titration, and duration of treatment.
- 5 Posttraumatic stress disorder compares with depression in the level of disability it imposes on patients.
- 6 The selective serotonin reuptake inhibitors are the drugs of choice for the treatment of obsessive-compulsive disorder.
- 7 Clomipramine should be considered after two or three failed selective serotonin reuptake inhibitor trials for obsessive-compulsive disorder.
- 8 Typically, a taper of antidepressants and discontinuation can be considered after 1 to 2 years of treatment for obsessive-compulsive disorder.
- 9 Long-term or lifetime prophylactic maintenance medication is recommended for obsessive-compulsive disorder after two to four severe relapses or three to four mild to moderate relapses.

Recent world events (e.g., wars, terrorist attacks, hurricanes, and tsunamis) have placed a renewed focus on posttraumatic stress disorder (PTSD). Initially diagnosed in veterans of war, PTSD is now acknowledged as a significant psychiatric illness in the civilian population.¹ PTSD continues to be poorly recognized and diagnosed in clinical practice.² Because of its co-occurrence with other anxiety disorders, depression, and substance abuse, the overlapping symptoms can lead to diagnostic uncertainty. Advances in the science and treatment of PTSD can assist clinicians in all fields of healthcare to screen patients for a history of trauma and effectively manage PTSD if it is present.

Patients with obsessive-compulsive disorder (OCD) experience significant impairment in their quality of life (QOL) with reduc-

tions in social, family, and occupational functioning.^{3,4} OCD affects far more individuals than was thought in the past. Because of the nature and potential severity of signs and symptoms and the resultant negative effects on QOL, OCD is considered a major medical condition. Clinicians should be able to identify OCD and understand the current treatment options.

EPIDEMIOLOGY

The prevalence data on anxiety disorders were recently revised to encompass clinically significant cases in the community.⁵ According to the modified prevalence estimates of mental disorders in the United States, the prevalence of PTSD is 3.6%.⁵ The prevalence of OCD is 2.4% in persons aged 18 to 54 years and 1.5% in those older than age 55 years.⁵

The epidemiology of PTSD is associated with the incidence of trauma. It is estimated that approximately 50% of men and 60% of women are exposed to a life-threatening traumatic event. Of these individuals 8.2% of men and 20% of women will develop PTSD.⁶ Previous exposure to a trauma and the intensity of response to the event increase the risk of PTSD.⁶ Individuals with a history of childhood sexual abuse are at higher risk of developing PTSD as adults.⁷ Men tend to be assaulted more frequently, but women have a higher rate of PTSD after assault. The incidence of PTSD is equal between men and women after rape (i.e., 50%) and natural disasters (i.e., less than 5%).⁶ Genetic factors can increase vulnerability to PTSD if an individual is exposed to a traumatic event. Offspring of Holocaust survivors had a higher lifetime prevalence rate of PTSD compared with a control group.⁶

OCD usually begins early in life, with 20% of cases occurring in childhood, 29% in adolescence, and 49% of cases occurring by age 20. The onset of illness is earlier in men than women.¹ The average patient first reports minor symptoms at age 12 years, meets diagnostic criteria at age 18 years, and receives initial treatment at 29 years of age. Individuals with early-onset OCD report more first-degree relatives with a probable diagnosis of OCD and higher rates of panic disorder, eating disorders, and obsessive-compulsive personality disorder.⁸ Twin studies revealed significantly higher concordance rates in monozygotic versus dizygotic twins, but there is probably nongenetic as well as genetic influences over expression of OCD, because the concordance rate for monozygotic twins is less than 100%. Individuals have an 11% to 12% risk of developing the illness if a first-degree relative has OCD; however, this familial relationship may be age-sensitive. In one epidemiologic study, no cases of OCD were found in relatives of patients developing the illness after 18 years of age.⁹

Irritable bowel syndrome is more common in individuals with anxiety and depressive disorders. Approximately 35% of patients with OCD meet criteria for irritable bowel syndrome compared with 2.5% of a control group.¹⁰

and other resources can be found at
www.pharmacotherapyonline.com.

ETIOLOGY

The exact etiologies of PTSD and OCD are not known. It is likely that abnormalities in several areas of brain functioning interact to cause these chronic anxiety disorders. Genetics may play a role in expression of PTSD and OCD, but environmental factors likely are also involved.

OCD has been characterized as a pediatric autoimmune neuropsychiatric disorder associated with streptococcal infections. In response to streptococcal infection, antibodies are produced in some individuals that temporally precipitate sudden onset or exacerbation of symptoms of OCD. Neuroimaging studies suggest that in these patients the antibodies produce inflammation of the basal ganglia. This leads to increased volumes of the caudate, putamen, and the globus pallidus, and subsequently to smaller caudate volumes potentially reflective of scarring or atrophy related to streptococcal infection.¹¹ Although most patients with OCD do not have a streptococcal etiology, an accurate medical history regarding onset of illness is imperative because specific treatment strategies are indicated.

PATHOPHYSIOLOGY

Research findings in the areas of neuroendocrinology, neurobiology, and neuroimaging have advanced a number of theories on the pathophysiology of anxiety disorders. Neuroendocrine changes in the hypothalamic-pituitary-adrenal (HPA) axis are implicated in the pathophysiology of PTSD.⁶ As reviewed in the previous chapter (Chap. 73), data from neurochemical and neuroimaging studies indicate that the modulation of normal and pathologic anxiety states is associated with multiple regions of the brain (e.g., amygdala, hippocampus, thalamus, and prefrontal cortex). Abnormal function in several neurotransmitter systems, including norepinephrine (NE), γ -aminobutyric acid (GABA), glutamate, dopamine (DA), and serotonin (5-HT) may affect the manifestations of anxiety disorders.^{6,13}

NEUROENDOCRINE THEORIES

Neuroendocrine studies provide data that abnormalities occurring pretrauma, during trauma, and posttrauma contribute to PTSD.⁶ Normally the immediate reaction to stress occurs as an automatic response from the amygdala to the sympathetic and parasympathetic systems and the HPA axis. The release of corticotropin-releasing factor stimulates cortisol secretion from the adrenal gland. Both catecholamines and cortisol levels rise in tandem. Cortisol reduces the stress response by tempering the sympathetic reaction through negative feedback on the pituitary and hypothalamus.⁶ These systems return to normal after a few hours.

Patients with PTSD have a hypersecretion of corticotropin-releasing factor but demonstrate subnormal levels of cortisol at the time of trauma and chronically.⁶ Dysregulation of the HPA axis is postulated to be a risk factor for eventual development of PTSD.⁶

NEUROCHEMICAL THEORIES

Several neurotransmitters may be involved in the pathophysiology of PTSD. 5-HT and NE are associated with the processing of emotional and somatic contents of memories in the amygdala. The cortex and hippocampus are involved in storing the facts and related cues of memory.¹⁴ The noradrenergic theory posits that the autonomic nervous system of anxious patients is hypersensitive and overreacts to stimuli. The alarm center, the locus ceruleus, releases NE to stimulate the sympathetic and parasympathetic nervous systems. Patients with PTSD tend to experience sustained elevated heart rates during trauma and enhanced startle effects starting a month after trauma exposure. Patients with chronic central noradrenergic over-

activity have downregulated α_2 -adrenoreceptors.¹⁵ Dysregulation of the processing of sensory input and memories may contribute to the dissociative and hypervigilant symptoms in PTSD. Preliminary data indicate that the 5-HT and 5-HT₂ antagonist *meta*-chlorophenylpiperazine (*m*-CPP) causes increased anxiety symptoms in patients with PTSD.¹⁴ Abnormalities of GABA inhibition may lead to increased awareness or response to stress, as seen in PTSD.¹⁴

Both 5-HT and DA are implicated in the pathogenesis of OCD. Selective and potent serotonergic reuptake inhibitors have consistently been shown to be effective for symptoms of the illness. Results of challenge studies using 5-HT agonists support a role for this neurotransmitter as well. However, to date there is no specific identified abnormality in the 5-HT system with OCD.¹³ DA dysregulation may contribute to some forms of OCD. Neurologic symptoms (e.g., tics) are part of the clinical presentation in some patients with OCD. Tourette's disorder, a disorder of DA dysfunction, is often a concurrent disease.¹ Patients with OCD and tics benefit from the addition of an antipsychotic drug to their treatment regimen.¹³

NEUROIMAGING STUDIES

Neuroimaging studies suggest that certain areas of the brain are altered by psychological trauma. In PTSD most functional neuroimaging studies have involved amygdala, ventromedial prefrontal cortex (vmPFC), and the hippocampus. Findings of increased activation of the amygdala after symptom provocation (e.g., via personal trauma script, visual imagery, or audio tape of combat sounds) indicate that this structure plays a role in the formation of emotional memory.¹⁶ Hypofunctioning of the vmPFC is theorized to prevent extinction in patients with PTSD.^{16,17} The most consistent findings are decreased hippocampal volumes and *N*-acetylaspartate levels in patients with PTSD.¹⁷ In twin studies, the unaffected twin of patients with PTSD also demonstrated smaller hippocampi compared with twins without PTSD.¹⁷ These findings suggest that lower hippocampal volumes in patients with PTSD are likely a precursor associated with vulnerability for subsequent development of PTSD.¹²

Recent neuroimaging studies support the roles of 5-HT and DA in the pathophysiologic expression of OCD.¹⁸ The reader is referred to Friedlander and Desrocher for a review of neuroimaging abnormalities in patients with OCD.¹⁹

CLINICAL PRESENTATION

The *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision* classifies anxiety disorders into several categories: generalized anxiety disorder, panic disorder (with or without agoraphobia), social anxiety disorder, specific phobia, OCD, PTSD, and acute stress disorder (ASD).¹ The characteristic features of these illnesses are anxiety and avoidance behavior. Generalized anxiety disorder, panic disorder, and social anxiety disorder are discussed in Chap. 73.

POSTTRAUMATIC STRESS DISORDER

Exposure to a traumatic event is required for a diagnosis of PTSD.¹ The person must have witnessed, experienced, or have been confronted with a situation that involved definite or threatened death or serious injury, or possible harm to themselves or others. The patient's response to the trauma must include intense fear, helplessness, or horror.¹ Some examples of traumatic events include physical attacks by an intimate partner, motor vehicle accidents, natural disasters, rape, being held hostage, child sexual abuse, and witnessing a murder or injury of another.

The resulting PTSD symptoms include persistent reexperiencing of the traumatic event, avoidance of stimuli associated with the

TABLE 74-1 Presentation of Posttraumatic Stress Disorder

Reexperiencing symptoms
<ul style="list-style-type: none"> • Recurrent, intrusive distressing memories of the trauma • Recurrent, disturbing dreams of the event • Feeling that the traumatic event is recurring (e.g., dissociative flashbacks) • Physiologic reaction to reminders of the trauma
Avoidance symptoms
<ul style="list-style-type: none"> • Avoidance of conversations about the trauma • Avoidance of thoughts or feelings about the trauma • Avoidance of activities that are reminders of the event • Avoidance of people or places that arouse recollections of the trauma • Inability to recall an important aspect of the trauma • Anhedonia • Estrangement from others • Restricted affect • Sense of a foreshortened future (e.g., does not expect to have a career, marriage)
Hyperarousal symptoms
<ul style="list-style-type: none"> • Decreased concentration • Easily startled • Hypervigilance • Insomnia • Irritability or angry outbursts
Subtypes
<ul style="list-style-type: none"> • Acute: duration of symptoms is less than 3 months • Chronic: symptoms last for longer than 3 months • With delayed onset: onset of symptoms is at least 6 months posttrauma
Screening questions
<ul style="list-style-type: none"> • Have you ever experienced a significant trauma in your life? • Did this experience have a lasting negative impact or change your life?

Data from American Psychiatric Association¹ and Ballenger et al.¹²

trauma, numbing of general responsiveness, and persistent symptoms of hyperarousal (Table 74-1). Patients must have at least one reexperiencing symptom, at least three signs or symptoms of persistent avoidance of stimuli associated with the trauma, and at least two symptoms of increased arousal.¹ Symptoms from each category need to be present for longer than 1 month and cause significant distress or impairment in functioning. Most persons diagnosed with PTSD also meet criteria for another mental disorder.¹

Anxiety and dissociative symptoms (e.g., sense of numbing or absence of emotional responsiveness, derealization, depersonalization, inability to recall important features of the event) emerging within 1 month after exposure to a traumatic stressor are classified as ASD. Symptoms of ASD are experienced during or immediately after the trauma, last for at least 2 days and resolve within 4 weeks.¹

The age of onset and course of PTSD are variable. PTSD can occur at any age. The presentation is not predictable because symptoms are related to the duration and intensity of the trauma, the presence of other psychiatric disorders, and how the patient deals with the trauma. The average duration of symptoms in patients in treatment is approximately 36 months. In those not receiving treatment, symptoms can last for a mean of 5 years. Approximately one-third of patients with PTSD have a poor prognosis for recovery.⁷ Approximately 80% of patients with PTSD have a concurrent depression or anxiety disorder.⁷ More than one-half of men with PTSD suffer from comorbid alcohol abuse or dependence.⁷ Approximately 20% of patients with PTSD attempt suicide.⁷

OBSESSIVE-COMPULSIVE DISORDER

Patients with OCD exhibit a great variety of symptoms on presentation to clinicians (Table 74-2). The diversity and oddity of symptoms that manifest can obscure accurate diagnosis and delay appropriate treatment of the disorder. Patients can be secretive about symptoms and purposefully refuse to report or deny symptoms.²⁰ Patients can present in a seemingly incongruous manner to nonpsychiatrists for other complaints—dermatologists for eczema

TABLE 74-2 Presentation of Obsessive-Compulsive Disorder

Obsessions
<ul style="list-style-type: none"> • Repetitive thoughts (e.g., feeling contaminated after touching an object, doubting whether the stove was turned off) • Repetitive images (e.g., recurrent sexually explicit pictures) • Repetitive impulses (e.g., need for symmetry or putting things in specific order, impulse to shout out obscenities in a church)
Compulsions
<ul style="list-style-type: none"> • Repetitive activities (e.g., hand washing, checking, ordering, need to ask, need to confess) • Repetitive mental acts (e.g., counting, repeating words silently, praying)
Screening questions
<ul style="list-style-type: none"> • Do you have repetitive thoughts that make you anxious and that you cannot get rid of? • Do you check things excessively? • Do you feel the need to wash your hands frequently? • Do you keep things exceptionally clean?

Data from American Psychiatric Association¹ and Jenike.²⁰

or chapped skin, pediatricians for parental concerns over a child's compulsive hand washing, neurologists for tics, or dentists for gum lesions from compulsive teeth brushing.

The diagnostic criteria for OCD requires the presence of either obsessions and/or compulsions (although most patients have both) that are severe enough to cause marked distress, to be time-consuming (occupy more than 1 hour per day), or to cause significant impairment in social or occupational functioning.¹ An obsession is a recurrent, persistent idea, thought, impulse, or image that is experienced as intrusive and inappropriate and produces marked anxiety. Common obsessions involve thoughts about contamination (e.g., concern with germs or dirt), repeated doubts, and needing to have things in a particular order.¹

Individuals must recognize that their obsessions or compulsions are excessive or unreasonable. Obsessions must be acknowledged as products of the individual's own mind and attempts must be made to ignore or suppress them. The obsessions produce marked feelings of anxiety and are not simply excessive worry about a real life situation.¹

A compulsion is defined as a repetitive behavior or mental act generally performed in response to an obsession. The most common compulsions involve washing and cleaning, counting, checking, and requesting or demanding assurances. Diagnostically, compulsive behavior is not pleasurable and is designed to prevent discomfort or the occurrence of a dreaded event that is often unknown. For example, many patients are obsessed with feelings of doubt (e.g., whether a door was left unlocked), causing them marked distress, and leading to repetitive checking (or compulsive behaviors). These behaviors are usually performed according to certain rules or in a stereotyped fashion. Because patients recognize their compulsive behavior as silly or senseless, they become extremely adept at denying symptoms, disguising their rituals, and concealing their illness from friends and family.¹

Patients with OCD often have concurrent depression, anxiety disorders, and alcohol abuse or dependence.²⁰ It is a chronic illness in most patients, with severity of symptoms varying in intensity over time. Many patients with OCD have significantly impaired QOL and ability to function.²⁰

TREATMENT

Posttraumatic Stress Disorder

■ DESIRED OUTCOME

1 The short-term goal of therapy in the management of PTSD is reduction in core symptoms (i.e., intrusive reexperiencing, avoid-

ance, and hyperarousal). Patients should also have improvements in disability, concurrent psychiatric conditions, and QOL. The long-term goal in PTSD is remission.²¹

■ GENERAL APPROACH TO TREATMENT

In general, patients who seek treatment acutely after a trauma and are in intense distress should receive therapy based on their presenting symptoms (e.g., a nonbenzodiazepine hypnotic for difficulty sleeping). Short courses of trauma-focused cognitive behavioral therapy (TFCBT) can be helpful to prevent chronic PTSD in patients who present during the first 3 months of the event.²² If symptoms (e.g., hyperarousal, avoidance, dissociation, sleep difficulties, or depressed mood) persist for 3 to 4 weeks and the patient experiences marked social, occupational, and/or interpersonal impairment, they can be treated with pharmacotherapy, psychotherapy, or both. Many patients with PTSD will improve substantially with pharmacotherapy but retain some symptoms. Treatment regimens usually combine psychoeducation, psychosocial support and/or treatment, and pharmacotherapy.¹²

■ NONPHARMACOLOGIC THERAPY

Psychotherapy can be used when a patient suffers from mild symptoms, in patients who prefer not to use medications, or in conjunction with drugs in patients with severe symptoms to improve response.¹² Patients who have experienced trauma should be educated that they can experience anxiety, depression, nightmares, and even flashbacks as a normal reaction to the event.¹² Brief courses of cognitive behavioral therapy (CBT) in close proximity to the traumatic event resulted in lower rates of PTSD 3 and 6 months later.¹² Single-session critical incident stress debriefing was not shown to be effective in preventing development of PTSD and actually can cause harm.^{12,22}

② Psychotherapies for treating PTSD include stress management, TFCBT and eye movement desensitization and reprocessing (EMDR), and psychoeducation.^{22,23} Short-term reductions in symptoms can be achieved with stress management, group therapy, hypnosis, or psychodynamic therapy.²³ Cognitive and behavioral approaches are more effective than stress management or group therapy to reduce symptoms of PTSD.²⁴ Either TFCBT or EMDR can be used if symptoms are evident for longer than 3 months postevent.²² Followup studies after a 3-month course of CBT demonstrated continued benefit for 3 to 12 months.²⁴ An 8-week comparison found EMDR more successful in maintaining improvements in PTSD scores than fluoxetine or placebo.²⁵ Psychoeducation includes information about the disease state, treatment options, and avoidance of excessive use of alcohol, nicotine, and other substances of abuse.

■ PHARMACOLOGIC THERAPY

③ Antidepressants are the major pharmacotherapeutic treatment for PTSD. In addition to their efficacy in PTSD, these agents are also effective for concurrent depression and anxiety disorders. The selective serotonin reuptake inhibitors (SSRIs) are the first-line pharmacotherapy of PTSD.²⁶ Other antidepressants (e.g., venlafaxine, tricyclic antidepressants [TCAs] and monoamine oxidase inhibitors [MAOIs]) can also be effective, but they have less favorable side-effect profiles (Table 74-3). Sertraline and paroxetine are both approved for the acute treatment of PTSD,^{29,30} and sertraline is approved for the long-term (i.e., 52 weeks) management of PTSD.³⁰ A number of drugs can be used as augmentation agents (e.g., antiadrenergic drugs and atypical antipsychotics).²⁷ Benzodiazepines are not effective for PTSD.^{12,28} Four practice guidelines^{22,23,27,28} and one consensus statement for the treatment of PTSD are published.¹² An algorithm for the treatment of PTSD appears in Fig. 74-1.

TABLE 74-3 Antidepressants Used in the Treatment of Posttraumatic Stress Disorder

Class/Generic Name	Starting Dose	Dosage Range ^a (mg/day)
Selective serotonin reuptake inhibitors		
Citalopram ^c	20 mg per day	20–60
Escitalopram	10 mg per day	10–20
Fluoxetine ^c	10–20 mg per day	10–80
Fluvoxamine ^c	50 mg per day	100–250
Paroxetine ^c	10–20 mg per day	20–50 ^b
Sertraline ^c	25–50 mg per day	50–200 ^b
Other agents		
Amitriptyline ^c	25–50 mg per day	50–300
Imipramine ^c	25–50 mg per day	50–300
Mirtazapine ^c	15 mg at bedtime	15–45
Phenelzine	15 mg every night	15–90
Venlafaxine extended-release	37.5 mg per day	37.5–225

^aDosage used in clinical trials but not FDA approved.

^bDosage is FDA approved.

^cAvailable generically.

Data from Ballenger et al.,¹² Baldwin et al.,²⁷ Bandelow et al.,²⁸ Paxil package insert,²⁹ Zoloft package insert,³⁰ and Schoenfeld et al.³¹

Special Populations

Children who experience stress and trauma (e.g., sexual or physical abuse or loss of a parent) are predisposed to develop mood and anxiety disorders. The SSRIs are the initial pharmacologic agents of choice in this patient population. Psychotherapy is also a treatment option (e.g., play therapy).³²

Antidepressant Therapy

Selective Serotonin Reuptake Inhibitors The SSRIs act pharmacologically to enhance serotonergic functioning. Large prospective studies documented the efficacy of sertraline and paroxetine in the acute management of PTSD. In a 12-week trial sertraline (mean dose 146 mg/day) was effective across the spectrum of PTSD-specific, global, and functional outcome measures. Approximately 60% of the patients improved on symptom clusters of arousal and avoidance/numbing but not on reexperiencing.³³ Sixty percent of patients with PTSD receiving a paroxetine dose of 20 mg/day and 54% of patients receiving 40 mg/day responded; response was not related to dose.³⁴ In a flexible-dose trial, paroxetine significantly improved all three PTSD symptom clusters and disability compared with placebo at 12 weeks.³⁵ Fluoxetine showed efficacy in a placebo-controlled trial,³⁶ and fluvoxamine was efficacious in an open trial in acute PTSD.³⁷ In a comparison between sertraline and citalopram, PTSD symptoms improved significantly in both groups, but sertraline was significantly better in reducing avoidance/numbing than citalopram.³⁸ In general, the SSRIs reduced the numbing symptoms of PTSD, whereas other drugs have not. Adverse reactions reported in patients with PTSD treated with SSRIs include gastrointestinal symptoms, sexual dysfunction, insomnia, and agitation. The results of two long-term trials indicate that sertraline (12 months) and fluoxetine (9 months) were effective in preventing relapse.^{36,39}

Other Antidepressants Other antidepressants have been studied in controlled trials. Mirtazapine was effective on global ratings of symptoms in 64% of patients with PTSD in doses up to 45 mg/day.⁴⁰ In a 12-week, placebo-controlled trial comparing venlafaxine extended-release and sertraline, venlafaxine was effective in reducing the avoidance/numbing and hyperarousal clusters of PTSD, whereas sertraline improved all PTSD symptom clusters.⁴¹ The remission rates for venlafaxine extended release were 30.2% after 12

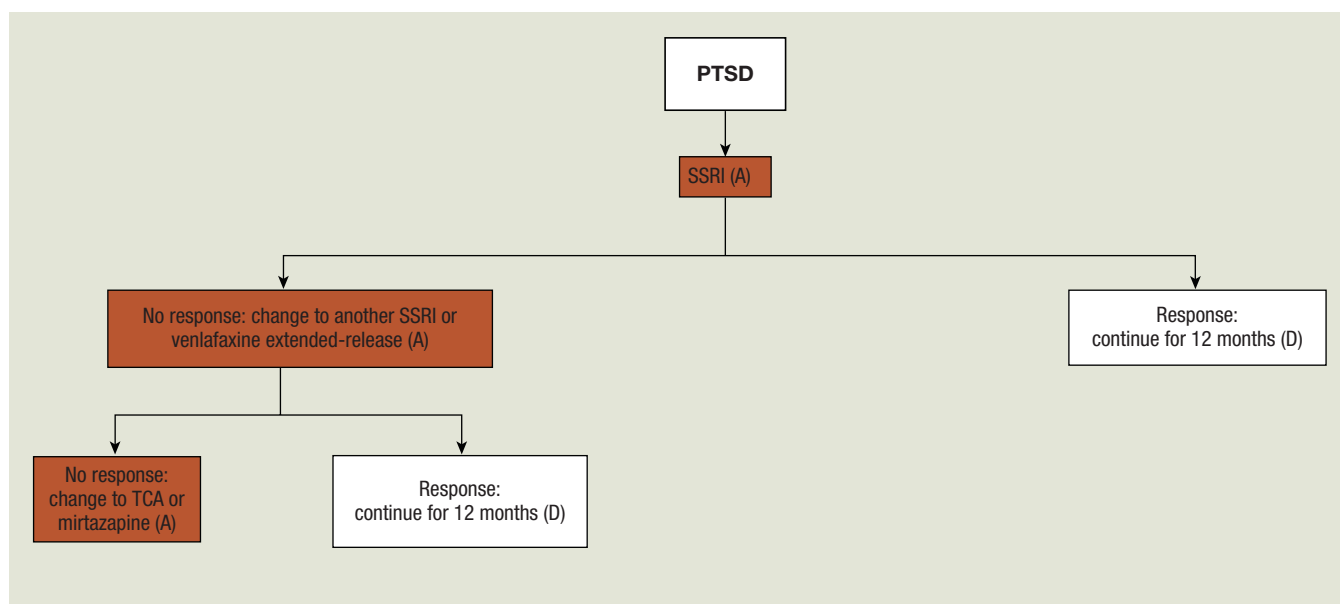

FIGURE 74-1. Algorithm for the pharmacotherapy of posttraumatic stress disorder. Strength of recommendations: A = directly based on category I evidence (i.e., meta-analysis of randomized clinical trials [RCT] or at least one RCT); D = directly based on category IV evidence (i.e., expert committee reports or opinions and/or clinical experience of respect authorities). (PTSD, posttraumatic stress disorder; SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant.) (Data from Ballenger et al.,¹² Baldwin et al.,²⁷ and Bandelow et al.²⁸)

weeks⁴¹ and 50.1% after 6 months.⁴² Bupropion sustained release was not effective in patients with chronic PTSD.⁴³

The TCAs amitriptyline and imipramine and the MAOI phenelzine can be considered second- or third-line antidepressants if therapeutic trials of SSRIs have failed. Phenelzine decreased insomnia, nightmares, and flashbacks. TCAs are associated with a higher burden of adverse effects compared with SSRIs (e.g., daytime drowsiness, toxicity in overdose, and poor compliance).^{28,31}

Alternative Drug Treatments

Atypical antipsychotics can be used as augmentation therapy in cases of partial response to SSRI therapy.²⁷ Risperidone reduced PTSD symptoms in combat veterans on antidepressants with and without psychosis.^{44,45} Quetiapine (mean dose 216 mg/day) reduced core PTSD symptoms over a 8-week period when added to concurrent therapy.⁴⁶ Olanzapine (mean dose 15 mg/day) added adjunctively to SSRIs decreased PTSD symptoms and significantly improved sleep compared with placebo. Patients gained an average of 13.2 pounds (6 kg) over the course of the 8-week trial.⁴⁷

Prazosin, an α_1 -adrenergic antagonist, can be useful in some patients with PTSD. Prazosin decreased nightmares and sleep disturbances, and improved the core PTSD symptoms in daily doses of 1 to 4 mg. Its presumed mechanism of action is reduction of noradrenergic transmission.⁴⁸

Dosage and Administration

Acute Phase PTSD symptoms respond slowly to pharmacotherapy, and some patients might never experience full resolution. SSRIs should be started 3 to 4 weeks after exposure to a trauma in patients with no improvement in their acute stress response.¹² The initiation of an SSRI should be at a low dose with gradual titration upward toward antidepressant doses. **4** Eight to twelve weeks is an appropriate duration of antidepressant therapy to determine response.⁴⁹

The dose of sertraline can be increased in weekly intervals by 50 mg/day up to a maximum dosage of 200 mg/day. Paroxetine can be increased by 10 mg/day in weekly intervals to a target dose of 40 mg/day. The dosing of other antidepressants is shown in Table 74-3.

Continuation Phase Many patients are undergoing psychotherapy during the continuation phase of therapy, and dosages can vary as patients deal with past traumatic experiences. During this phase symptoms continue to improve, and the maximal drug benefit (i.e., improvement of disability) accrues.⁴⁹ Six-month relapse prevention trials in patients responsive to fluoxetine or sertraline indicate low rates of relapse with SSRI therapy compared with placebo.^{27,49}

Maintenance and Discontinuation Patients with PTSD who respond to pharmacotherapy should continue treatment for at least 12 months.^{28,49} If residual symptoms persist, drug therapy should be continued. The decision about when to discontinue therapy is based on response to therapy, presence of ongoing stresses, and adverse effects. The patient must be confident in the discontinuation plan and can require extra support throughout the process. Drug therapy should be withdrawn and tapered slowly over a period of at least 1 month to reduce the potential for relapse.

CLINICAL CONTROVERSY

The use of propranolol immediately after a traumatic event is postulated to prevent PTSD symptoms (e.g., hyperarousal secondary to traumatic memories).^{27,49} Study results are conflicting as to whether propranolol actually prevents the emergence of PTSD symptoms.

■ PHARMACOECONOMIC CONSIDERATIONS

5 PTSD compares with depression in the level of disability it imposes on patients with the disorder.⁵⁰ Individuals fail to realize their potentials for career development, marriage, and education. Decreased productivity leads to a financial loss of more than \$3 billion per year, and this figure does not include economic loss associated with the failure of PTSD patients to achieve their educational or career goals.⁵⁰ Women in a healthcare maintenance organization with high scores on the Posttraumatic Stress Disorder Checklist had more than twice the adjusted total annual median cost (\$1,283) of care (i.e., outpatient, specialty care, primary care,

pharmacy and mental healthcare costs) than those with a low score (\$609).⁵¹ Treatment with effective pharmacotherapy can improve the QOL and functioning of these patients.⁵²

Evaluation of Therapeutic Outcomes

During the acute phase of therapy, patients should be seen weekly for a month and then every other week. During months 3 to 6 of therapy, the patient can be seen monthly, and in months 6 to 12, visits can be extended to every 1 to 2 months. After a year of pharmacotherapy patients can be seen every 3 months. On each visit the patient should be asked about previously identified target symptoms of PTSD as well as other symptoms including sleep, anger outbursts, irritability, and disability. The patient should maintain a diary to record the date and presence of symptoms of reexperiencing, avoidance behavior, and hyperarousal, as well as concurrent conditions (e.g., panic attacks, obsessions and compulsions, or suicidal ideation). A remission or good response in patients with PTSD is defined as a greater than 75% reduction in symptoms and response maintained for at least 3 months. Patients who have a 25% to 75% reduction in symptoms are considered partial responders. Before deciding that a patient is not responsive to pharmacotherapy, the clinician should ensure that the medication trial has been adequate in both dose and duration. Use of an objective measurement of remission of PTSD (e.g., a Treatment Outcome PTSD Scale [TOPS-8] score less than or equal to 5 points and a Sheehan Disability Scale less than or equal to 1 point on each item) can assist in the evaluation of drug response.²¹

Many patients with PTSD are sensitive to the adverse effects of drugs. They should be monitored carefully for adverse reactions that can delay the escalation of drug dosages or cause the patient distress. When pharmacotherapy is discontinued, patients should be seen more frequently and monitored carefully for signs of relapse or withdrawal.

TREATMENT

Obsessive-Compulsive Disorder

■ DESIRED OUTCOMES

Goals of therapy for OCD include reduction in the frequency of obsessive thoughts and in the time spent performing compulsive acts and reduction in the degree of anxiety. Treatment for OCD might not completely eliminate obsessions or compulsions, but patients can feel remarkably improved with partial resolution of their symptoms. Treatment should provide the patient with an optimal level of psychosocial and occupational functioning and an overall improved QOL. Efforts should be made to minimize adverse drug events and prevent drug interactions.

■ GENERAL APPROACH TO TREATMENT

It is important at the outset of therapy to identify and document the specific target symptoms for pharmacotherapy. Rating scales can be used to measure symptom severity at baseline and during treatment to ascertain the degree of improvement. The Yale-Brown Obsessive-Compulsive Scale (YBOCS) is the most widely used clinician-administered scale. The Padua Inventory is a useful self-report questionnaire.⁵³ A QOL scale can assist the clinician in identifying other areas to target for treatment (e.g., depression and reduced physical well-being).⁵⁴

The Food and Drug Administration (FDA) has approved five antidepressants for the management of OCD: clomipramine, fluoxetine, fluvoxamine, paroxetine, and sertraline. In adolescents with OCD, CBT is generally selected first for mild OCD, but CBT plus an SSRI (e.g., fluoxetine, fluvoxamine, sertraline, or paroxetine) are

used for more severe OCD. In adults, CBT is the initial choice for mild OCD, and CBT plus an SSRI or an SSRI alone is selected for more severe OCD. Figure 74–2 is an algorithm for the treatment of OCD. Although some OCD symptoms can improve over the first few weeks of therapy, an adequate trial of any medication is considered to be 8 to 12 weeks at maximum tolerated dosage.

■ NONPHARMACOLOGIC TREATMENTS

CBT is the treatment of choice for mild OCD in both adolescents and adults. In the management of OCD, CBT involves exposure plus response prevention combined with cognitive therapy. When available, CBT should be offered to every OCD patient.⁵⁵ Exposure involves having the patient perform actions that were formerly avoided. For instance, if a patient avoided touching the flush handle on a bathroom toilet, exposure would involve holding onto the handle. Response prevention involves having the patient resist the compulsive rituals that are performed. The ritualistic washing behavior often associated with a contamination obsession might be the focus, and the patient would be asked to delay the washing behavior as long as possible. At the beginning of CBT treatment patients are often unable to perform these activities, and imaginal exposure is used as the first step in the treatment process. Over time in a gradual manner the patient is exposed to feared objects/activities and is trained to resist rituals for longer periods of time.

Most patients who continue in CBT therapy generally respond. CBT should be added to the regimen when a patient is a nonresponder or a partial responder to SSRI or clomipramine monotherapy. CBT should be used alone if the patient is intolerant to adverse drug effects, is pregnant, or has a medical condition that contraindicates medication.⁵⁵ Behavioral therapy appears to have stronger effects on compulsive rituals than for the associated obsessions.

Exposure and response prevention therapies, applied individually or in groups, have longer-lasting effects after discontinuation, and produce greater improvement compared with drug therapy.^{57–59} Techniques such as teaching patients to prevent relapse through self-exposure and self-imposed ritual prevention are suggested to foster optimal nonpharmacologic therapy.⁵⁷ Exposure with response prevention is particularly helpful for contamination or other fears, symmetry rituals, counting/repeating, hoarding, and aggressive urges. Cognitive therapy is beneficial for scrupulosity, moral guilt, and pathologic doubt. Thirteen to twenty sessions are typically required to treat uncomplicated OCD.⁵⁵

A major barrier to the application of nonpharmacologic therapy is availability and cost of treatment. CBT requires specific training. Many psychiatrists are not adequately trained and/or do not have the time or desire necessary to apply this therapy. Some psychologists and social workers are skilled in this discipline; however, availability can be restricted in some areas.

■ PHARMACOLOGIC THERAPY

6 The Expert Consensus Panel report reflects comprehensive opinions of a large number of leading authorities in the field of OCD treatment.⁵⁵ New consensus guidelines from the American Psychiatric Association are expected in late 2007. The SSRIs are considered to be the drugs of choice in the treatment of OCD. Drug therapy is reserved for patients with moderate to severe symptoms. Antidepressants can be combined with CBT or used alone in adults with moderate to severe symptoms. An SSRI should be added when there has been no response or partial response to CBT alone. Generally, an SSRI is selected before clomipramine, and whenever anticholinergic, cardiovascular, sexual, sedative, or weight-gain adverse effects are a major concern. If one SSRI is ineffective, then another SSRI should be tried. Treatment resistance can be defined as failure to achieve at least a 25% reduction in baseline scores on

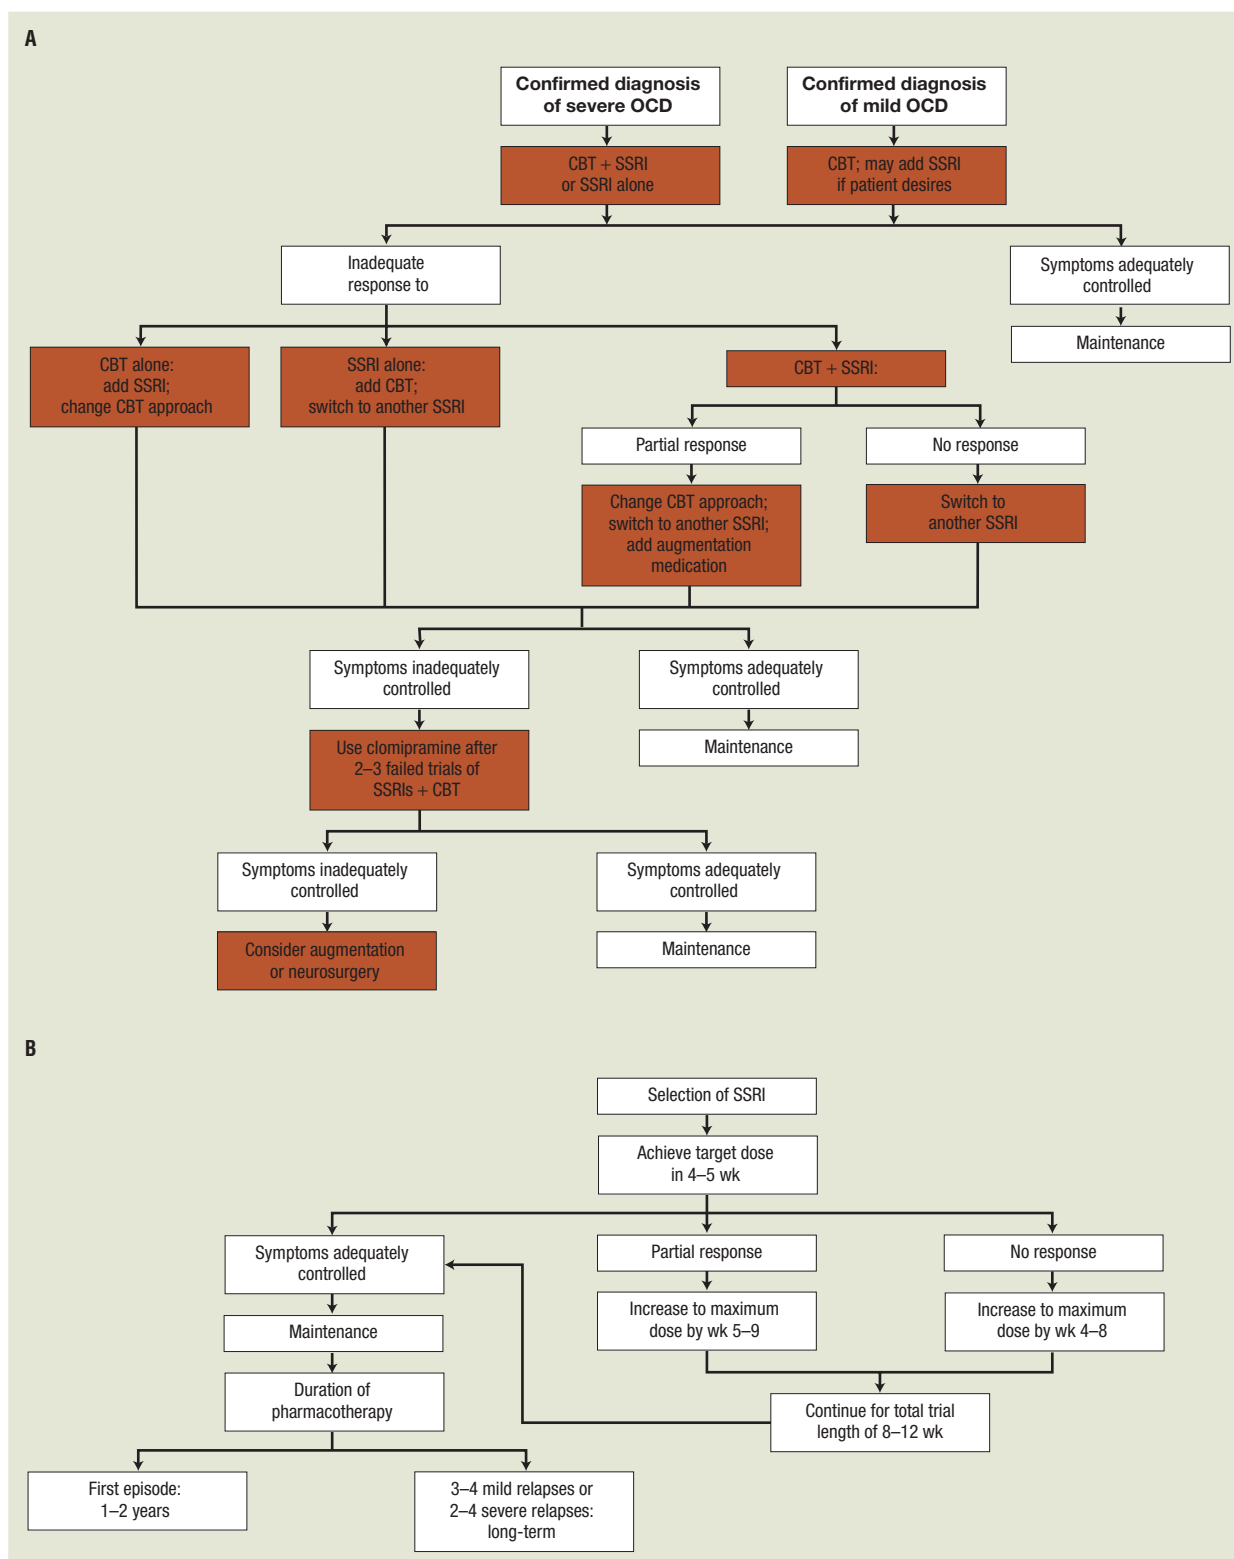

FIGURE 74-2. Algorithm for management of obsessive-compulsive disorder in adults. **A.** Overall approach to treatment. **B.** Pharmacotherapeutic approach to treatment. (CBT, cognitive behavioral therapy; OCD, obsessive-compulsive disorder; SSRI, selective serotonin reuptake inhibitor. (Derived from Expert Consensus Panel for Obsessive-Compulsive Disorder⁵⁵ and American Pharmaceutical Association.⁵⁶)

the YBOCS.^{20,55} 7 Clomipramine can be selected after two to three failed SSRI trials. Clomipramine can be used to augment an SSRI in partially responsive or nonresponsive patients.⁵⁵

Special Populations

Children and Adolescents OCD affecting children and adolescents is prevalent. There are symptom and treatment similarities

and differences between OCD developing earlier in life and that which develops later. Younger patients exhibit poorer insight regarding obsessions, have more obsessions involving fear of harm and separation, and possess more rituals involving family members.⁶⁰ CBT provided in the group setting has been shown to be effective and is an alternative to individual CBT or medication treatment.⁶¹ Clomipramine, fluvoxamine, sertraline, and fluoxetine are approved by the FDA for treatment of OCD in children and

adolescents.⁶² Childhood and adult OCD appear to respond similarly to drug therapy. The SSRIs appear to be effective and well tolerated in treatment of OCD in children and are generally considered first-line agents.⁶³ Treatment with an SSRI produces a favorable response in 75% of children and adolescents with OCD. A combination of SSRI and CBT is preferred in most cases.⁶⁴ In children, the most commonly described side effects of SSRI therapy include nausea, headache, tremor, gastrointestinal complaints, drowsiness, akathisia, insomnia, disinhibition, and agitation.⁶⁴

Hepatic and Renal Disease Clomipramine, fluoxetine, sertraline, paroxetine, fluvoxamine, and citalopram are extensively metabolized in the liver, and patients with significant liver disease should be prescribed these drugs cautiously and in lower doses than those used in healthy subjects. The pharmacokinetics of fluoxetine and fluvoxamine were similar in patients with renal failure and in healthy subjects; however, the manufacturer recommends starting with a lower dose in patients with renal impairment. The pharmacokinetics of sertraline are not altered in patients with significant renal dysfunction, and dosage adjustment is not necessary in these patients.³⁰ Increased plasma concentrations of paroxetine occur in subjects with renal impairment.²⁹ The initial dose of paroxetine should be reduced in patients with severe renal impairment, and upward titration should occur more slowly.²⁹ No dosage adjustment is necessary for patients with mild to moderate renal impairment receiving citalopram.

Elderly Little information is available on treating OCD in the elderly. Case reports and anecdotal information suggest that the anti-obsessional drugs are likely to be equally effective in the elderly and in younger adults.⁶⁵ Selection of medication for an elderly person with OCD, however, should be based on history of response and adverse side-effect profile. Treatment should be initiated with low doses in elderly patients, and doses should be increased slowly, with vigilance for emergence of side effects. Some elderly patients can ultimately require doses similar to those used in younger adults, but doses must be individualized according to response and tolerance of side effects.

In elderly patients refractory to SSRIs, an augmentation strategy with minimal risk is to add buspirone to SSRI therapy. The use of clonazepam should be avoided because of the potential for excess sedation, particularly in frail elderly patients and those with gait disturbances.⁶⁶ Because of clomipramine's sedative and anticholinergic side effects, it is not usually chosen as first-line therapy for elderly OCD patients.⁶⁶ The safety of fluvoxamine has not been adequately studied in the elderly and patients with cardiovascular disease. Dosage should be reduced and titrated slowly during initiation of fluvoxamine therapy in elderly patients.

Sertraline plasma clearance in elderly patients was approximately 40% lower than in a group of younger individuals. Clearance of desmethylsertraline was also decreased in elderly men but not in elderly women.³⁰ In a multiple-dose study in the elderly, the minimal concentrations of paroxetine were 70% to 80% greater than in nonelderly subjects. The manufacturer recommends that the initial dose be reduced in the elderly (10 mg/day), and total daily doses should not exceed 40 mg.²⁹

Pregnancy In general, CBT alone should be used for pregnant patients except in cases in which the risks of untreated OCD outweigh the risks of drug use (e.g., a pregnant woman who will not eat because of contamination fears).⁵⁵ Women with a history of OCD should be informed that OCD can worsen during pregnancy and during the postpartum period. OCD symptoms can exacerbate during the first trimester, especially if pharmacotherapy is discontinued just before conception or early in pregnancy. Symptoms often improve during the second trimester and worsen during the third trimester. The use of SSRIs in pregnancy and lactation is discussed in the chapter on depression (Chap. 71).

If drug therapy during pregnancy is required, fluoxetine appears to be the safest choice. However, the neurobehavioral effects of prenatal exposure on the neonate and the child have not been fully elucidated. Clomipramine should be avoided during pregnancy.⁶⁷ Clonazepam can be considered for OCD symptoms in pregnant women with disabling anxiety, but with higher doses (2 to 5 mg/day), hypotonia, apnea, and failure to feed have been observed in newborns.⁶⁷

Antidepressant Therapy

Serotonergic Antidepressants The only medications consistently demonstrating efficacy in controlled trials are the TCA clomipramine and the SSRIs fluoxetine, fluvoxamine, paroxetine, and sertraline. Sixty-five to seventy percent of patients with OCD respond to their first SSRI treatment, and up to 90% ultimately respond with additional drug trials. Improvement in symptoms is incomplete, and ranges from 25% to 60%. Most patients continue to have symptoms that limit their functioning.⁶² Obsessive-compulsive symptoms improve over a 4- to 10-week treatment period.⁶⁸

Current evidence indicates that 5-HT is important for the anti-obsessional effects of medication. The SSRIs and clomipramine inhibit 5-HT reuptake into the presynaptic neuron. Inhibiting reuptake of 5-HT makes more 5-HT available to postsynaptic receptors and reduces formation of the 5-HT metabolite 5-hydroxyindoleacetic acid. Although other antidepressants, such as imipramine and amitriptyline, inhibit 5-HT reuptake, they are less potent and selective than the SSRIs. Prolonged exposure to increased amounts of 5-HT after chronic antidepressant treatment (2 to 3 weeks) leads to altered responsiveness of postsynaptic 5-HT receptors or presynaptic autoregulatory receptors that govern 5-HT release in specific brain regions.⁶⁸

The most impressive and consistent evidence supporting a role for 5-HT in treating OCD is that only potent 5-HT reuptake inhibitors appear to be effective. Furthermore, an improvement in obsessional symptoms may correlate with plasma concentrations of clomipramine but not desmethylclomipramine, the metabolite of clomipramine with less selectivity for 5-HT reuptake inhibition. With clomipramine treatment, the decrease in obsessional symptoms correlates with a decrease in the concentration of 5-hydroxyindoleacetic acid in cerebrospinal fluid, and a decrease in platelet 5-HT content. The effectiveness of serotonergic agents in treating OCD lends support to the role of 5-HT in the etiology of OCD. Because many patients fail to respond to these agents, the role of other neurotransmitter systems in the pathophysiology of OCD must continue to be explored.

Pharmacokinetics. Clomipramine is rapidly absorbed following oral administration. Maximum plasma concentrations occur within 3 to 8 hours. It is highly protein-bound (greater than 90%) in the blood and has a half-life of 15 hours.⁶⁹ The drug is metabolized to desmethylclomipramine, which is pharmacologically active. The pharmacokinetics of the SSRIs are discussed in Chap. 71.

Efficacy. The SSRIs are effective in the treatment of OCD. Well-conducted trials comparing these medications with placebo, head-to-head comparative trials, and meta-analyses have established that fluoxetine, fluvoxamine, paroxetine, sertraline, and citalopram are equally effective and that clomipramine may be somewhat more effective.⁷⁰

Most experts agree that the SSRIs are better tolerated than clomipramine. The SSRIs are less likely to cause cardiovascular, sedative, anticholinergic, and weight-gain side effects. Clomipramine is less likely than the SSRIs to cause insomnia, akathisia, nausea, and diarrhea. Side effects can be more severe when larger doses are used and with faster dose escalation. Tolerance to adverse effects often develops over 6 to 8 weeks of treatment, and tolerance is more likely to develop to nausea, diarrhea, sedation, diminished

libido and/or orgasm, anxiety, restlessness, insomnia, and anticholinergic side effects than to akathisia.^{55,70}

Other Antidepressants Venlafaxine, which acts as a serotonin and norepinephrine reuptake inhibitor, can be effective for OCD.⁷⁰

Alternative Drug Treatments

If there is no response or partial response to combined CBT and three adequate antidepressant trials (one of which is clomipramine), augmentation with another drug and more intensive CBT can be tried. Augmentation of SSRI treatment with low doses of risperidone, quetiapine, and olanzapine may be helpful, but more research is needed. Typical antipsychotics are generally not recommended because of an increased likelihood of extrapyramidal symptoms.^{70,71} It is suggested that attempts at augmentation be conducted with the use of rating scales or careful symptom severity assessment so that the benefit of the added drug therapy is clearly assessed and documented.

Dosage and Administration

Table 74-4 summarizes dosing guidelines for the SSRIs and clomipramine. If there is inadequate response to an average dose, then it should be incrementally increased to the maximum dose within 4 to 9 weeks from the start of treatment. If there is an inadequate response after 4 to 6 weeks at the maximum dose, then another SSRI should be tried. Eight to thirteen weeks is considered an adequate trial before changing to another drug or augmenting with another agent.

After patients have responded to the acute phase of treatment, treatment gains are maintained with maintenance-phase strategies. **8** Monthly followup visits are recommended for at least 3 to 6 months, and a medication taper can be considered after 1 to 2 years of treatment. Medication should not be rapidly discontinued, and booster CBT sessions can reduce the risk of relapse when medication is withdrawn. The drug dosage can be decreased by 25%, and then 2 months should lapse before again decreasing the dose, depending on response.

9 Long-term or lifelong prophylaxis with pharmacotherapy is recommended after two to four severe relapses or three to four mild relapses.⁵⁵ Although the appropriate maintenance dose of antidepressants is unknown, it is notable that one investigator was successful in reducing the dose of clomipramine from a mean of 270 mg/day to 165 mg/day in the maintenance phase. Mundo and colleagues studied patients successfully treated with clomipramine or fluvoxamine and reduced their doses by 33% to 66% for maintenance therapy, with clear advantages for tolerability and compliance. However, the study duration was only 102 days.⁷²

CLINICAL CONTROVERSY

The use of atypical antipsychotics for patients having both schizophrenia and OCD can be problematic. Some studies have shown that atypical antipsychotics worsen symptoms of OCD in this patient population, but other studies report benefits from atypical antipsychotic use. Patients with schizophrenia have a higher incidence of OCD than patients without schizophrenia. Therefore, OCD symptoms should be monitored closely when changing antipsychotic medication or adjusting the dosage.

Pharmacoeconomic Considerations

The annual outpatient direct costs for patients seeking treatment for OCD in the United States in 1995 were \$5.1 billion. In 1990, the total cost to the economy was \$8 billion, which includes expenditures for direct (\$2.1 billion) and indirect costs. Direct costs include costs of hospitalization, outpatient professional services, and drugs. Indirect costs include costs associated with lost productivity, work

TABLE 74-4 Dosing of Serotonin Reuptake Inhibitors in Treatment of OCD

Generic Name	Usual Initial Daily Dose (mg)	Daily Dosage Range (mg)	Usual Target Daily Dose (mg)
Citalopram ^a	20	20–60	40
Clomipramine	10	100–250	150–200
Fluoxetine	20	20–80	40–60
Fluvoxamine	50	100–300	200
Paroxetine	20	20–60	40
Sertraline	50	75–200	150

OCD, obsessive-compulsive disorder.

Data from Expert Consensus Panel for Obsessive-Compulsive Disorder⁵⁵ and Ellingrod.⁶⁸

loss, early retirement, and absenteeism. As OCD frequently has its onset in childhood or adolescence, loss of income over a lifetime is substantial.⁷³

Another pharmacoeconomic consideration that impacts the provision of optimal treatment for patients with OCD relates to inability to pay for nonpharmacologic therapy. Although CBT has been shown to be a very effective modality, very often the patient cannot afford this therapy or does not have medical insurance that helps pay the associated costs.

Evaluation of Therapeutic Outcomes

Target symptoms of OCD should be monitored closely. The degree of response can indicate a need to modify dosage, change drug, or augment therapy. Rating scales can be used to monitor symptom response to therapy for OCD and changes in QOL. The clinician should inquire about and address problematic adverse effects (including the emergence of suicidal ideation) reported by the patient. Drug interactions should be monitored. Changes in social and occupational functioning should be assessed.

Patients older than 40 years of age should receive a pretreatment electrocardiogram before starting clomipramine. In patients with liver disease, baseline and periodic liver function tests are recommended when clomipramine is used. If clomipramine is given concurrently with sympatholytic antihypertensive agents, blood pressure should be regularly monitored. Patients receiving clomipramine who develop fever and sore throat should have leukocyte and differential white blood cell counts assessed to evaluate for agranulocytosis.

CONCLUSIONS

The past decade has brought a renewed interest in the recognition and management of PTSD. Healthcare workers are sensitized to the devastating effects that PTSD can have on patient functioning, QOL, and use of healthcare resources. Adequately detecting and appropriately managing PTSD is important to improving the lives of patients who suffer from this illness. Data on the efficacy of the SSRIs supports their use for both acute and long-term management of the symptoms of PTSD. The SSRIs are the first-line pharmacotherapy of PTSD and OCD. Research in OCD has resulted in new pharmacologic treatment strategies, especially with augmentation therapies.

ABBREVIATIONS

ASD: acute stress disorder

CBT: cognitive behavioral therapy

DA: dopamine

EMDR: eye movement desensitization and reprocessing

FDA: Food and Drug Administration

5-HT: serotonin

GABA: γ -aminobutyric acid

HPA: hypothalamic-pituitary-adrenal axis

MAOI: monoamine oxidase inhibitor

m-CPP: *meta*-chlorophenylpiperazine

NE: norepinephrine

OCD: obsessive-compulsive disorder

PTSD: posttraumatic stress disorder

QOL: quality of life

SSRI: selective serotonin reuptake inhibitor

TCA: tricyclic antidepressant

TFCBT: trauma-focused cognitive behavioral therapy

TOPS-8: Treatment Outcome PTSD Scale (8 items)

vmPFC: ventromedial prefrontal cortex

YBOCS: Yale-Brown Obsessive Compulsive Scale

JOHN M. DOPP AND BRADLEY G. PHILLIPS

KEY CONCEPTS

- 1 Common causes of insomnia include concomitant psychiatric disorders, significant psychosocial stressors, excessive alcohol use, caffeine intake, and nicotine use.
- 2 Good sleep hygiene, including relaxing before bedtime, exercising regularly, establishing a regular bedtime and wake-up time, and discontinuing alcohol, caffeine, and nicotine, alone and in combination with drug therapy should be part of patient education and treatments for insomnia.
- 3 Long-acting benzodiazepines should be avoided in the elderly.
- 4 Benzodiazepine tolerance and dependence are avoided by using low-dose therapy for the shortest possible duration.
- 5 Obstructive sleep apnea can be an independent risk factor for the development of hypertension. When hypertension is present, it is often refractory to drug therapy until sleep disordered breathing is alleviated.
- 6 Nasal continuous positive airway pressure is the first-line therapy for obstructive sleep apnea, and weight loss should be encouraged in all obese patients.
- 7 Pharmacologic management of narcolepsy is focused on two primary areas: treatment of excessive daytime sleepiness and cataplexy.
- 8 Short-acting benzodiazepine receptor agonists or melatonin taken at appropriate target bedtimes for east or west travel reduce jet lag and shorten sleep latency.
- 9 Dopamine agonists are effective for restless legs syndrome and have replaced levodopa as first-line therapy.

Approximately 70 million Americans suffer with a sleep-related problem, and as many as 60% of those experience a chronic disorder.¹ In a study by the National Institute of Aging, of 9,000 patients age 65 years and older, more than 80% report a sleep-related disturbance.¹

INTRODUCTION TO SLEEP

SLEEP CYCLES

Sleep is divided into two phases: nonrapid eye movement (NREM) sleep and rapid eye movement (REM) sleep. Humans typically

experience four to six cycles of NREM and REM sleep, with each cycle lasting between 70 and 120 minutes.²

There are four stages of NREM sleep. Healthy sleep will typically progress through the four stages of NREM sleep prior to the first REM period. From wakefulness, sleep typically progresses quickly through stages 1 and 2. Stage 1 of NREM sleep is the stage between wakefulness and sleep, and individuals describe this experience as being awake, being drowsy, or as being asleep. During stages 3 and 4 NREM, both metabolic activity and brain waves slow. This slow-wave sleep occurs most frequently early in the sleep period. Stage 3 and stage 4 sleep is called *delta sleep* as the sleep is characterized by high-amplitude slow activity known as delta waves (0.5 to 3 Hz). In this stage eye movements are absent and muscle tone is atonic.³

REM sleep involves a dramatic physiologic change from NREM sleep, to a state in which the brain becomes electrically and metabolically activated.² REM occurs in bursts, and is accompanied by a 62% to 173% increase in cerebral blood flow, generalized muscle atonia, bursts of bilateral rapid eye movements, poikilothermia, dreaming, and fluctuations in respiratory and cardiac rate.² REM cycles tend to lengthen in the later stages of the sleep cycle.²

CIRCADIAN RHYTHM

At birth human infants spend up to 20 hours a day sleeping. At 3 to 6 months of age there is a differentiation between REM and NREM sleep: By age 3 the ultradian sleep-wake rhythm changes to a circadian pattern. The suprachiasmatic nucleus of the brain serves as the biologic clock and paces the circadian rhythm. Although the length of a day is 24 hours, in environments devoid of light cues, the sleep-wake cycle lasts 24.2 hours.³ In midlife, there is a gradual decline in sleep efficiency and sleep time.² The elderly have lighter and more fragmented sleep, with intermittent arousals, shifts in the sleep stages, and a gradual reduction of slow wave sleep.

NEUROCHEMISTRY

The neurochemistry of sleep is complex as sleep cannot be localized to either a specific area of the brain or neurotransmitter. NREM sleep appears to be controlled by the basal forebrain, the area surrounding the solitary tract in the medulla and the dorsal raphe nucleus, which is primarily serotonergic.³ Sleep is reduced when there are decreases in serotonin or destruction of the dorsal raphe nucleus in the brainstem, which contains most of the brain's serotonergic bodies. REM sleep appears to be turned on by cholinergic cells in the mesencephalic, medullary, and pontine gigantocellular regions. REM sleep appears to be turned off by the dorsal raphe nucleus, the locus coeruleus, and the nucleus parabrachialis lateris, the latter two of which are primarily noradrenergic. The ascending reticular activating system and the posterior hypothalamus facilitate arousal and wakefulness.⁴ Dopamine has an alerting effect: Decreases in dopamine promote sleepiness.⁵ Neurochemicals

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

involved in wakefulness include norepinephrine and acetylcholine in the cortex and histamine and neuropeptides such as substance P and corticotropin-releasing factor in the hypothalamus.^{5,6}

POLYSOMNOGRAPHY

Sleep is typically measured and observed in sleep laboratories using an electroencephalogram (EEG), electro-oculograms of each eye, electrocardiogram, electromyogram, air thermistors, abdominal and thoracic strain belts, and oxygen saturation monitor. This study is named polysomnography (PSG) and is used to assess and record variables that characterize sleep and aid in diagnosis of sleep disorders. Variables obtained during PSG include sleep onset, arousals, sleep stages, eye movements, leg and jaw movements, arrhythmias, airflow during sleep, respiratory effort, and oxygen desaturations.

CLASSIFICATION OF SLEEP DISORDERS

The *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR)* classifies sleep disorders into four categories based on etiology (Table 75-1) and requires a minimum of 1 month before a sleep disorder can be diagnosed.^{7,8} Primary sleep disorders are those disorders in which there is no other etiology (mental disorder, substance-related disorder, or medical condition) responsible for the disorder. Primary sleep disorders appear to be based on an endogenous abnormality of the sleep-wake cycle, or circadian rhythm, and they are divided into dyssomnias or parasomnias.

INSOMNIA

Insomnia is the most common complaint in general medical practice.⁹ It causes distress, frequently because of a fear or a feeling of not being able to fall asleep at bedtime and can impair work-related productivity because of daytime fatigue or drowsiness. Insomnia is subjectively characterized as a complaint of difficulty falling asleep, difficulty maintaining sleep, or experiencing nonrestorative sleep.⁸ Insomnia lasting two or three nights because of jet lag, for example, is considered to be transient insomnia, whereas short-term insomnia usually resolves in less than 3 weeks. Insomnia, according to the *DSM-IV-TR*, is considered to be chronic when it lasts longer than 1 month.⁸

Epidemiology

Primary insomnia usually begins in early or middle adulthood and is rare in childhood or adolescence. More than 50% of the population complains of insomnia in their lifetime.¹ A 1-year prevalence study of insomnia in the United States reports that one-third of the individuals surveyed complained of insomnia, and 17% reported that the symptoms were serious.¹ Conservative estimates of chronic insomnia range from 9% to 12% in adulthood and up to 20% in the elderly.^{1,10} Although young adults are more likely to complain that they have difficulty falling asleep, middle-aged and elderly adults are more likely to complain that they have middle-of-the-night awakening or early morning awakening. Women complain of insomnia twice as frequently as men. Individuals who are elderly, unemployed, separated or widowed, and those with a lower socioeconomic status reported a significantly higher incidence of insomnia than the general population. Forty percent of individuals with insomnia also had a concurrent psychiatric disorder (anxiety, depression, or substance abuse).⁹

Despite the prevalence of insomnia, only 5% of individuals seek medical attention for management of their insomnia. Approximately 10% to 20% use nonprescription drugs or alcohol to self-treat. Of the 3% of the population who are prescribed sedative-hypnotics for insomnia, 11% report use exceeding 1 year.¹¹

Differential Diagnosis

Primary insomnia is considered to be an endogenous disorder caused by either a neurochemical or structural disorder affecting the sleep-wake cycle. Individuals with primary insomnia can be light sleepers who are easily aroused by noise, temperature, or anxiety. Some studies suggest that primary insomnia is a “hyperarousal state,” in that insomnia patients have increased metabolic rates compared with controls, and thus, take longer to fall asleep.² Evaluation of patients with a complaint of transient or short-term insomnia should focus on recent stressors, such as a separation, a death in the family, a job change, or college exams.

① Chronic insomnia is frequently associated with psychiatric or medical conditions. A complete diagnostic examination should be completed in these individuals and include routine laboratory tests, physical and mental status examinations, as well as ruling out any medication- or substance-related causes.¹² Special consideration should also be given to other sleep disorders that can have a similar presentation, including restless legs syndrome, periodic limb movements of sleep, and sleep apnea. Common causes of insomnia are listed in Table 75-2.

Selective serotonin reuptake inhibitors

Steroids

Stimulants

TREATMENT

Insomnia

Therapeutic management of insomnia is initially based on whether the individual has experienced a transient, short-term, or chronic sleep disturbance. Clinical history should assess the onset, duration, and frequency of the symptoms, effect on daytime functioning, sleep hygiene habits, and history of previous symptoms or treatment.¹³ Management of all patients with insomnia should include identifying the cause of the insomnia, patient education on sleep hygiene, and stress management. Any unnecessary pharmacotherapy should be eliminated.¹⁰ Transient insomnia, which occurs as a result of an acute stressor, is expected to resolve quickly, and should be treated with good sleep hygiene and careful use of sedative-hypnotics.¹⁴ Short-term insomnia, lasting up to 3 weeks, associated with situational, personal, or medical stress can be treated similarly.¹³ Chronic insomnia requires careful assessment for possible underlying medical causes, nonpharmacologic techniques, and careful use of sedative-hypnotics.¹²

■ NONPHARMACOLOGIC THERAPY

2 In many cases insomnia can be treated without sedative-hypnotics. Education about normal sleep and habits for good sleep hygiene are often sufficient interventions.² Nonpharmacologic interventions for insomnia frequently consist of short-term cognitive behavioral therapies, most commonly stimulus control therapy, sleep restriction, relaxation therapy, cognitive therapy, paradoxical intention, and education on good sleep hygiene (Table 75–3).^{10,15,16} In patients age 55 and older, a recent study indicates that cognitive behavioral therapy may be more effective than pharmacologic therapy at improving certain measures of insomnia.¹⁷

CLINICAL CONTROVERSY

Pharmacologic treatment is indicated for transient and short-term insomnia. Historically, the use of sedative hypnotic agents for greater than 1 month was frowned on and discouraged in fear of the patient developing drug dependence. Experts now agree that clinicians should encourage hypnotic therapy using the lowest effective dose for short-term periods whenever possible. However, long-term use of hypnotics is not contraindicated unless the patient has another contraindication (e.g., history of substance abuse, pregnancy, etc.).

TABLE 75-3 Nonpharmacologic Recommendations for Insomnia

Stimulus control procedures

1. Establish regular times to wake up and to go to sleep (including weekends).
2. Sleep only as much as necessary to feel rested.
3. Go to bed only when sleepy. Avoid long periods of wakefulness in bed. Use the bed only for sleep or intimacy; do not read or watch television in bed.
4. Avoid trying to force sleep; if you do not fall asleep within 20–30 minutes, leave the bed and perform a relaxing activity (e.g., read, listen to music, or watch television) until drowsy. Repeat this as often as necessary.
5. Avoid daytime naps.
6. Schedule worry time during the day. Do not take your troubles to bed.

Sleep hygiene recommendations

1. Exercise routinely (three to four times weekly) but not close to bedtime because this can increase wakefulness.
2. Create a comfortable sleep environment by avoiding temperature extremes, loud noises, and illuminated clocks in the bedroom.
3. Discontinue or reduce the use of alcohol, caffeine, and nicotine.
4. Avoid drinking large quantities of liquids in the evening to prevent nighttime trips to the restroom.
5. Do something relaxing and enjoyable before bedtime.

■ PHARMACOLOGIC THERAPY

Miscellaneous Agents

Antihistamines exhibit sedating properties and are included in many over-the-counter sleep agents. They are effective in the treatment of mild insomnia and are generally safe.¹³ Diphenhydramine and doxylamine are more sedating than pyrilamine. Increasing the dose of antihistamines will not produce a linear increase in response. The safety and efficacy of antihistamines over placebo have been documented in several studies. Antihistamines are considered to be less effective than benzodiazepines, and have the disadvantages of anticholinergic side effects, which are especially troublesome in the elderly.^{13,18}

Antidepressants are alternatives for patients with nonrestorative sleep who should not receive benzodiazepines, especially those who have depression, pain, or a risk of substance abuse. Using antidepressants for insomnia without depression is common but not well studied.¹⁸ Sedating antidepressants such as amitriptyline, doxepin, and nortriptyline are effective for inducing sleep continuity, although daytime sedation and side effects can be significant.¹⁸ Anticholinergic activity, adrenergic blockage, and cardiac conduction prolongation can be problematic, especially in the elderly and in overdose situations.¹⁸ Some of the new generation of antidepressants such as mirtazapine and nefazodone are also sedating. Mirtazapine can cause daytime sedation and weight gain.

Trazodone in doses of 25 to 100 mg at bedtime is sedating and can improve sleep continuity.¹¹ Trazodone is popular for the treatment of insomnia in patients prone to substance abuse, as dependence is not a problem. Trazodone is frequently used in patients with selective serotonin reuptake inhibitor (SSRI) and bupropion-induced insomnia.¹¹ Caution should be used to avoid serotonin syndrome when used in these combinations. Other side effects include carryover sedation and α -adrenergic blockade. Orthostasis can occur at any age, but it is more dangerous in the elderly. Priapism is a rare but serious side effect.¹⁹

Ramelteon is a melatonin receptor agonist that has recently been approved for the treatment of sleep onset insomnia. Ramelteon is selective for the MT1 and MT2 melatonin receptors that are thought to regulate the circadian rhythm and sleep onset. The recommended dose is 8 mg taken at bedtime to induce sleep and although generally well-tolerated, the most common adverse events reported are headache, dizziness, and somnolence. Ramelteon is not a controlled substance and can be a viable option for patients with a history of substance abuse.

Valerian is an herbal sleep remedy that has been studied for its sedative-hypnotic properties in patients with insomnia. The mechanism of action is not fully understood but may involve increasing concentrations of γ -aminobutyric acid (GABA). The recommended dose for insomnia ranges from 300 to 600 mg. An equivalent dose of dried herbal valerian root is 2 to 3 g soaked in 1 cup of hot water for 20 to 25 minutes.²⁰

CLINICAL CONTROVERSY

The over-the-counter supplement melatonin is a popular treatment for insomnia. Although melatonin has demonstrated efficacy for inducing sleep, its use for the treatment of insomnia is not well-supported by clinical studies. Further research is needed before melatonin can be recommended for the treatment of insomnia.

Benzodiazepine Receptor Agonists

The most commonly used treatments for insomnia have been the benzodiazepine receptor agonists. All benzodiazepine receptor agonists are effective as sedative-hypnotics, and are Food and Drug

TABLE 75-4 Pharmacokinetics of Benzodiazepine Receptor Agonists

Generic Name (Brand Name)	t_{max} (hours) ^a	Half-Life ^b (hours)	Daily Dose Range (mg)	Metabolic Pathway	Clinically Significant Metabolites

Administration (FDA) labeled for the treatment of insomnia (Table 75–4). The benzodiazepine receptor agonists consist of the newer nonbenzodiazepine GABA_A agonists and the traditional benzodiazepines. All benzodiazepine receptor agonists bind to GABA_A receptors in the brain resulting in stimulatory effects on GABAergic transmission and hyperpolarization of neuronal membranes. Traditional benzodiazepines have sedative, anxiolytic, muscle relaxant, and anticonvulsant properties; newer nonbenzodiazepine GABA agonists possess only sedative properties.

Benzodiazepine Hypnotics

Benzodiazepines relieve insomnia by reducing sleep latency and increasing total sleep time. Benzodiazepines increase stage 2 sleep while decreasing REM, stage 3, and stage 4 sleep.¹¹ Benzodiazepines are very safe, and fatal overdoses are rare unless they are taken in combination with central nervous system (CNS) depressants or alcohol.¹¹ Benzodiazepine hypnotics should not be prescribed for individuals with sleep apnea, a history of substance abuse, or during pregnancy. Patients should be instructed to avoid alcohol and other CNS depressants.

Pharmacokinetics The choice of a particular benzodiazepine can be based on its pharmacokinetic profile. When used as a single dose, the extent of distribution and elimination half-life is important in predicting the duration of action. However, after multiple doses, the elimination half-life and formation of active metabolites determine the extent of drug accumulation and resultant clinical effects.¹¹ Elderly patients, liver dysfunction, and drug interactions can prolong drug effects. The pharmacokinetic profiles of benzodiazepine receptor agonists are summarized in Table 75–4.

Adverse Effects Side effects are dose dependent and vary according to the pharmacokinetics of the individual benzodiazepine. High doses with long or intermediate elimination half-lives have a greater potential for producing daytime sedation and performance impairment. These effects include excessive drowsiness, psychomotor incoordination, decreased concentration, and cognitive deficits. Tolerance to benzodiazepine hypnotic effects develops sooner with triazolam (after 2 weeks of continuous use) than with other benzodiazepine hypnotics.¹¹ Most traditional benzodiazepines maintain hypnotic efficacy for 1 month. However, tolerance can develop with time. Rapidly eliminated benzodiazepines have less potential for daytime sedation.¹¹

Anterograde amnesia, an impairment of memory and recall of events occurring after the dose is taken, has been reported with most benzodiazepine receptor agonists.¹¹ Rebound insomnia is characterized by increased wakefulness beyond baseline amounts that last for one to two nights after abrupt discontinuation of benzodiazepine receptor agonists. Rebound insomnia occurs more frequently after

high doses of triazolam, even when ingested intermittently.¹¹ The lowest effective dosage should be used to minimize rebound insomnia and avoid adverse effects on memory.

③ Benzodiazepine half-lives are prolonged in older patients, increasing the potential for drug accumulation and the incidence of CNS side effects. Prolonged sedation and cognitive and psychomotor impairment are concerns in the elderly. Benzodiazepine receptor agonists with long elimination half-lives are generally not first-line agents. There is an association between falls and hip fractures and the use of benzodiazepines with long elimination half-lives; thus flurazepam and quazepam should be avoided in elderly patients.²¹

Non-Benzodiazepine GABA_A Agonists

Zolpidem, zaleplon and eszopiclone are nonbenzodiazepine hypnotics that selectively bind to GABA_A receptors and effectively induce sleepiness. Zolpidem, an imidazopyridine chemically unrelated to benzodiazepines or barbiturates, has a duration of action of 6 to 8 hours.²² It is comparable in efficacy to benzodiazepine hypnotics, and is effective for reducing sleep latency and nocturnal awakenings and increasing total sleep time. It does not appear to have significant effects on next-day psychomotor performance. A sustained release formulation of zolpidem is now available that is effective at increasing total sleep time and reducing wakefulness after sleep onset without significant carryover sedation.

The safety and efficacy of zolpidem for insomnia is similar to that of the benzodiazepines. As with other sedative medications, treatment optimally should not exceed 4 weeks to minimize tolerance and dependence. Zolpidem is less disruptive of sleep stages than benzodiazepines. Adverse effects are dose related and can include drowsiness, amnesia, dizziness, headache, and gastrointestinal complaints.²² Several cases of brief psychotic reactions have been reported in women, and recent reports of sleep-eating during zolpidem therapy have caused significant weight gain.²² The recommended daily dose of zolpidem is 10 mg or 5 mg in elderly patients and those with hepatic impairment. The dosage can be increased to 20 mg per night.²² Because food decreases its absorption, zolpidem should be taken on an empty stomach.²³

Zaleplon is a pyrazolopyrimidine and has a rapid onset of action, a half-life of 1 hour, and is metabolized to inactive metabolites.²⁴ It is effective for decreasing time to sleep onset but not for reducing nighttime awakening or for increasing total sleep time.²⁵ Because of its short half-life, zaleplon has no effect on next-day psychomotor performance and can be best used as a sleep aid for middle-of-the-night awakenings.²⁶ The recommended dose is 10 mg in adults and 5 mg in the elderly.²⁴ The most common adverse effects with zaleplon are dizziness, headache, and somnolence. There are two drug interactions of note: zaleplon plasma levels are increased when combined with cimetidine and decreased with rifampin.²²

Eszopiclone is a pyrrolopyrazine hypnotic with a rapid onset of action and a half-life of 5 to 6 hours.²⁷ It is effective at reducing time to sleep onset, wake time after sleep onset, number of awakenings and increasing total sleep time and sleep quality. Eszopiclone's duration of action is up to 6 hours,²⁷ so it can be a better option for treatment of sleep maintenance insomnia or early morning awakenings than zaleplon. The most common adverse effects with eszopiclone are somnolence, unpleasant taste, headache, and dry mouth.²⁸ Eszopiclone is labeled for long-term use and may be taken nightly for up to 6 months.²⁸

Other Considerations

Rebound effects, withdrawal, and tolerance with prolonged use are minimal with zolpidem; however, theoretical concerns about abuse exist.²² Zaleplon does not appear to cause rebound insomnia, and development of tolerance does not appear to be significant.²² The incidence of rebound insomnia, tolerance, and withdrawal to eszopiclone has been reported to be minimal when taken nightly for 6 months.²⁸ In general, the nonbenzodiazepine hypnotics seem to be associated with less withdrawal, tolerance, and rebound insomnia than the benzodiazepine hypnotics. None of the GABA_A agonists has significant active metabolites.

EVALUATION OF THERAPEUTIC OUTCOMES

An algorithm for the evaluation and treatment of sleep disorders is shown in Figure 75–1. Patients with short-term or chronic insomnia should be evaluated after 1 week of therapy to assess for drug efficacy, adverse effects, and adherence to nonpharmacologic recommendations.

Patients should be instructed to keep a sleep diary. The diary requires daily recording of bedtime, wake time, latency of sleep onset, number and duration of awakenings, medication ingestion, naps, and an index of sleep quality. For patients with chronic insomnia, possible medical, psychiatric, and pharmacologic causes should be identified and managed.¹¹ Patients with insomnia should receive education about possible medication side effects and their management. Prescriptions for benzodiazepine receptor agonists should be accompanied by printed information and verbal counseling on precautions.

4 Clinicians should educate patients about the concepts of tolerance, withdrawal, and rebound insomnia. Tolerance and dependence can be avoided by using hypnotics at the lowest possible dose, intermittently, and for the shortest duration possible. Patients should receive instruction on the initiation of therapy about frequency of drug use and the expected duration of therapy, to help prevent development of dependence. Withdrawal symptoms can be diminished by tapering the dosage gradually.

SLEEP APNEA

Approximately 15 million Americans have sleep-disordered breathing.²⁹ The prevalence of sleep apnea in the U.S. adult population is 4% in males and 2% in females.³⁰ It appears to be more common in African Americans and less common in Asian populations. Sleep apnea also occurs in children and adolescents. It is characterized by repetitive episodes of cessation of breathing during sleep followed by brief arousal from sleep to restart breathing. Blood oxygen desaturation can occur with these apneic episodes. As a result, individuals with sleep apnea experience fragmented sleep, poor sleep architecture, and

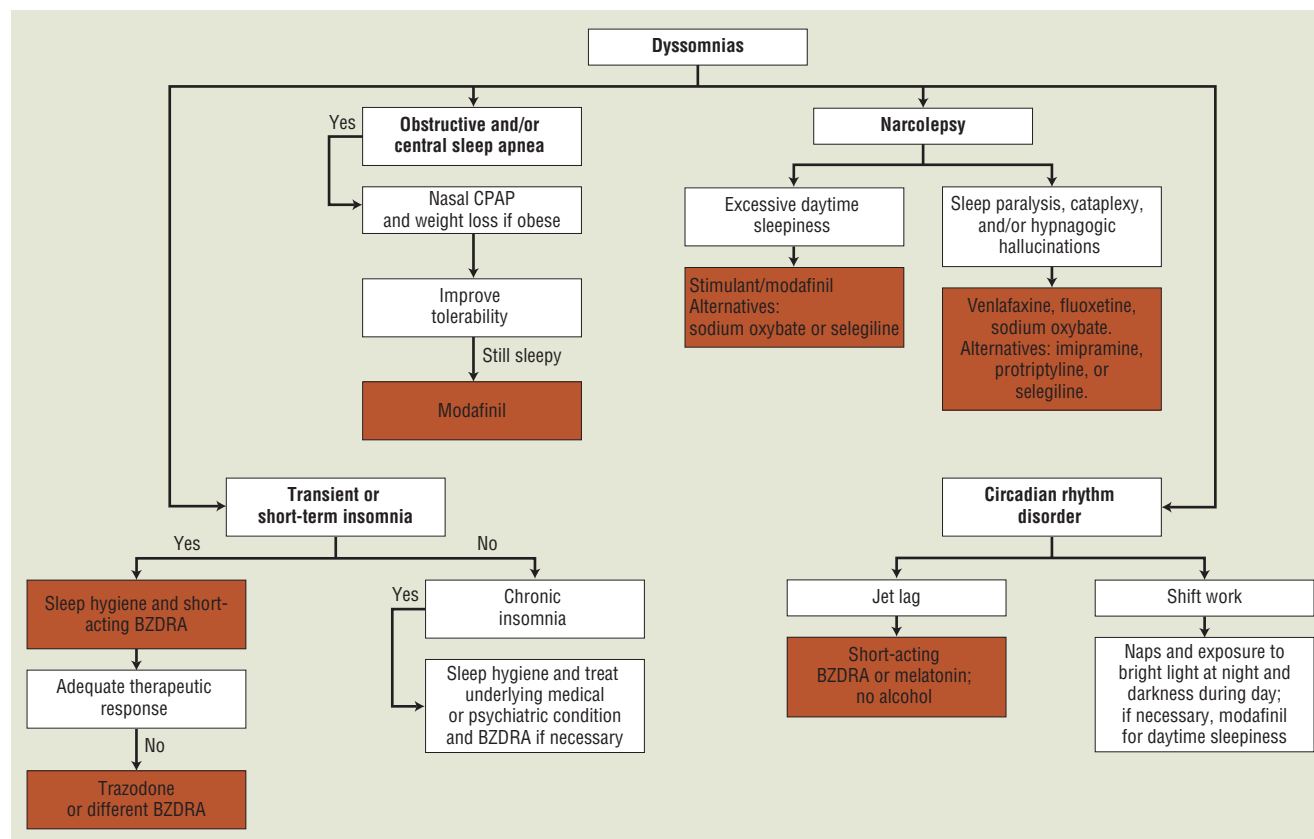

FIGURE 75-1. Algorithm for treatment of dyssomnias. (BZDRA, benzodiazepine receptor agonist; CPAP, continuous positive airway pressure.) (Adapted with permission from the American College of Clinical Pharmacy. Jermaine DM. Sleep Disorders. In: Carter BL, Angaren DM, Lake KD, Raebel MA, eds. *Pharmacotherapy Self-Assessment Program*, 2nd ed. Psychiatry module. Kansas City: American College of Clinical Pharmacy, 1995:139–154.)

periods of apnea and hypopnea. Polysomnography (PSG) is used to diagnose and quantify sleep apnea as central, obstructive, or mixed. Central sleep apnea (CSA) involves impairment of the respiratory drive, whereas obstructive sleep apnea (OSA) is caused by upper airway collapse and obstruction. Patients with mixed sleep apnea experience both central and obstructive sleep apnea. Severity of sleep apnea is determined by the number of apnea (total cessation of airflow) and hypopnea (partial airway closure with blood oxygen desaturation) episodes documented by PSG and is expressed by calculating the respiratory disturbance index (RDI). Mild sleep apneics have an RDI between 5 and 15 episodes per hour, moderate 15 to 30, whereas individuals with severe OSA can exhibit more than 30 episodes per hour.

Sleep apnea can affect behavior, cognitive abilities, and systemic disease.³¹ Neurocognitive sequelae are important factors in motor vehicle accidents, loss of work-related productivity, and personality changes.^{31,32} Alleviation of sleep disordered breathing can have a beneficial impact on both cardiovascular and neurobehavioral conditions.³³

OBSTRUCTIVE SLEEP APNEA

OSA is characterized by partial or complete closure of the upper airway, posterior from the nasal septum to the epiglottis, during inspiration. The reason for the loss of upper airway patency is not fully understood and is likely caused by several competing factors. Anatomical factors including neck obesity, narrow airway, and fixed upper airway lesions (e.g., polyps, enlarged tonsils) can narrow the upper airway. Intraluminal negative pressure generated during each inspiration also promotes collapse of the upper airway. Airway anatomy and intraluminal negative pressure that tend to collapse the airway compete with dilating forces, primarily the pharyngeal dilator muscle. Acromegaly, amyloidosis, hypothyroidism as well as neurologic conditions that impair upper airway muscle tone may cause OSA. The hallmarks of OSA are witnessed apneas, gasping, or both. Other recognized signs, symptoms, and considerations of sleep apnea include, obesity, snoring, hypertension, daytime sleepiness, and family history.

5 OSA is increasingly linked to cardiovascular and cerebrovascular morbidity and mortality, independent of other risk factors.^{33,34} Individuals with OSA are at risk for developing hypertension, and when hypertension is present, it is often resistant to drug therapy.³⁵ Alleviation of sleep disordered breathing (with nasal continuous positive airway pressure) can improve blood pressure and attenuate some of the potential hemodynamic and neurohumoral responses that may link OSA to systemic disease.^{36,37}

TREATMENT

Obstructive Sleep Apnea

Alleviation of sleep disordered breathing is the primary goal of treatment. Nonpharmacologic measures are the treatments of choice. There is no drug therapy for OSA. However, medications that worsen sleep should be avoided. Practice parameters for the treatment of OSA have been published by the American Academy of Sleep Medicine.³⁸

■ NONPHARMACOLOGIC THERAPY

Positive Airway Pressure

6 Nasal positive airway pressure (PAP) during sleep is the standard treatment for most patients with OSA. PAP produces a positive pressure column in the upper airway using room air to maintain patency. PAP can be continuous (CPAP) or bi-level PAP providing a

reduced applied pressure during expiration. During PSG, the pressure setting is increased until sleep-disordered breathing is eliminated. Each pressure setting (range 1 to 20 cm H₂O) is individualized. Barriers to PAP adherence, such as ill-fitted mask and nasal dryness, can be managed. Nonadherence for one night results in a complete reversal of the gains made in daytime alertness.³⁹ CPAP machines are small enough to be transportable and sit at the bedside. A flexible tube connects the CPAP machine to a mask that covers the nose.

Weight Reduction

Obesity can worsen sleep apnea, and weight management should be implemented for all overweight patients with OSA. OSA can itself predispose to weight gain and in obese patients with mild OSA weight loss alone can be effective.⁴⁰ Individuals who are morbidly obese and have severe OSA can undergo gastric stapling for weight loss.

Surgery

Surgical therapy (uvulopalatopharyngoplasty) opens the upper airway by removing the tonsils, trimming and reorienting the posterior and anterior tonsillar pillars, and removing the uvula and posterior portion of the palate. This is not a first-line option because it is invasive. In very severe cases tracheostomy can be necessary. This procedure can be indicated for select individuals that are morbidly obese, have severe facial skeletal deformity, experience severe drops in oxygen saturation (e.g., less than 70%), or have significant cardiac arrhythmias associated with their OSA.

Other Therapies

For individuals that experience OSA only during certain position (e.g. on their back) during sleep, positional therapies can be effective alone but usually are used in conjunction with PAP therapy. Oral appliances can be used to advance the lower jawbone and to keep the tongue forward to enlarge the upper airway.⁴¹

■ PHARMACOLOGIC THERAPY

The most important pharmacologic intervention is the avoidance of all CNS depressants (e.g., alcohol, hypnotics) and drugs that promote weight gain. Weight gain worsens OSA. CNS depressant use is potentially lethal as it reduces the brain's reflex ability to cause a mini-arousal and resume breathing. In addition, certain CNS depressants can relax airway muscles, promoting upper airway collapse.

There is no drug therapy for OSA. In clinical trials, serotonergic agents (e.g., fluoxetine, paroxetine), tricyclic antidepressants (TCAs) (i.e., imipramine, protriptyline), and clonidine have effects on sleep architecture or upper airway patency but do not clinically improve severity of OSA. Respiratory stimulants, including aminophylline and theophylline, have similarly failed to show clinical benefit. Medroxyprogesterone has proved disappointing in OSA and should be avoided as therapy. The effects of antihypertensive agents on sleep apnea are inconsistent.⁴²

Modafinil (Provigil) is a wake-promoting medication and is FDA approved to improve wakefulness in patients who have residual daytime sleepiness while treated with PAP. Initiation of wake-promoting medications should only be attempted after patients are using optimal PAP therapy to alleviate sleep disordered breathing. In patients with concurrent rhinitis, nasal steroids are recommended for use along with PAP therapy.

■ EVALUATION OF THERAPEUTIC OUTCOMES

Individuals with sleep apnea should be evaluated after 1 to 3 months of treatment for improvement in alertness and daytime symptoms

(improvement in memory and decreased irritability) and weight reduction. Individuals experiencing symptoms (e.g., daytime sleepiness, snoring) despite PAP therapy should have PSG repeated. Symptoms can recur if patients gain weight, requiring a higher pressure setting. Conversely, PAP pressure settings can be decreased if weight loss is achieved. Patient adherence to PAP therapy can be monitored by assessing the built-in compliance meter that measures the hours used at effective pressure.

CENTRAL SLEEP APNEA

CSA causes fragmented sleep and consequent daytime somnolence. However, unlike OSA, arousals from sleep are not required to initiate airflow. During PSG, there is an absence of airflow out of the mouth and nose with no activation of the inspiratory muscles. The prevalence of CSA is not well established and is less than OSA. CSA can be idiopathic but more commonly is caused by underlying autonomic nervous system lesions (e.g., cervical cordotomy), neurologic diseases (e.g., poliomyelitis, encephalitis, and myasthenia gravis), high altitudes, and congestive heart failure.⁴²

Potential underlying causes for CSA should be evaluated and treated. For example, worsening CSA in heart failure patients can signal the need to optimize heart failure therapies. Several medications for CSA have been studied. For example, acetazolamide induces a metabolic acidosis that stimulates respiratory drive. It has been shown to be beneficial in a small number of studies for high altitude, heart failure, and idiopathic CSA.^{43,44} Currently, the primary treatment approach for CSA is PAP therapy with or without supplemental oxygen.⁴⁵

NARCOLEPSY

Narcolepsy is a severely debilitating neurologic disease that affects approximately 140,000 Americans.⁴⁶ Despite the debilitating nature of the disease, it can be undiagnosed or misdiagnosed for years. Prevalence estimates differ between studies and range from 0.03% to 0.06% in the adult population.⁴⁶ It is equal or somewhat higher in men compared to women, and it has been noted in children and adolescents. However, it is commonly recognized in the second decade of life and increases in severity through the third and fourth decade.⁴⁶ Individuals with narcolepsy complain of excessive daytime sleepiness, with sleep attacks that last up to 30 minutes. In the sleep laboratory, individuals with narcolepsy exhibit impairment of both the onset and offset of REM and NREM sleep and have multiple arousals and disturbed sleep during the night.

Four characteristic symptoms differentiate narcolepsy from other sleep disorders and are known as the *narcolepsy tetrad*: sleep attacks, cataplexy, hypnagogic hallucinations, and sleep paralysis. Cataplexy, a sudden bilateral loss of muscle tone of varying severity and duration without the loss of consciousness, occurs in 70% to 80% of people with narcolepsy.⁴⁶ Patients can suffer subtle changes, such as jaw or head slumping, or severe weakness, such as knee buckling or collapsing to the ground. Cataplexy is often precipitated by situations characterized by high emotion (e.g., laughter, anger, excitement). Cataleptic episodes can be brief, lasting seconds or can last for several minutes. Sleep paralysis is an episodic loss of voluntary muscle tone that occurs when the individual is falling asleep or waking. Individuals are conscious but not able to move or speak. Hallucinations while falling asleep (i.e., hypnagogic) and on awakening (i.e., hypnopompic) are brief, dream-like experiences that intrude into wakefulness. Nearly 70% of narcoleptics experience these hallucinations. Unfortunately, these symptoms sometimes lead to an incorrect diagnosis of mental illness.⁴⁶ Cataplexy, sleep paralysis, and hypnagogic hallucinations can be caused by REM sleep disturbances.⁴⁷

TABLE 75-5 Drugs Used to Treat Narcolepsy

Generic Name	Trade Name	Daily Dosage Range (mg)
Excessive daytime somnolence		
Dextroamphetamine	Dexedrine	5–60
Dextroamphetamine/Amphetamine salts ^a	Adderall	5–60
Methamphetamine ^b	Desoxyn	5–15
Methylphenidate	Ritalin	30–80
Modafinil	Provigil	200–400
Sodium oxybate ^c	Xyrem	4.5–9 grams per night
Adjunct agents for cataplexy		
Fluoxetine	Prozac	20–80
Imipramine	Tofranil	50–250
Nortriptyline	Aventyl, Pamelor	50–200
Protriptyline	Vivacil	5–30
Selegiline	Eldepryl	20–40

^aDextroamphetamine sulfate, dextroamphetamine saccharate, amphetamine aspartate, and amphetamine sulfate.

^bNot available in some states.

^cAlso is effective at treating cataplexy.

Compiled from U.S. Modafinil in Narcolepsy Multicenter Study Group and Standard of Practice Committee of the American Sleep Disorders Association. Practice parameters for the use of stimulants in the treatment of narcolepsy. *Sleep* 1994;17:348–351.

The primary cause of narcolepsy is not known and can be caused by multiple external and internal factors. There can be a genetic component, as 3% of patients have a first-degree relative with the disorder.⁴⁷ The onset of disease in adolescence or adulthood, but not at birth, suggests that environmental influences might play a role. Molecular studies of human leukocyte antigen (HLA) have found a high prevalence of the HLA-DR2 and HLA-DQ6/DQB1 haplotypes in narcoleptics.⁴⁸ However, the HLA-DR2 haplotype is also common in the non-narcoleptic population and is not diagnostic.⁴⁷ The hypocretin-orexin neurotransmitter system has been implicated and can play a central role in narcolepsy. Neurons containing hypocretin-orexin are found in the lateral hypothalamus and project to various parts of the brain that are thought to regulate sleep. In 75% of narcoleptic patients, hypocretin-orexin is undetectable in cerebrospinal fluid.⁴⁸ Because narcoleptic patients have deficiencies in hypocretin-orexin-producing neurons,⁴⁹ an autoimmune process may be responsible for the destruction of hypocretin-producing cells.^{50,51}

TREATMENT

Narcolepsy

Nonpharmacologic management of narcolepsy includes counseling the patient and family concerning the illness to alleviate misconceptions around the individual's behavior. Good sleep hygiene should be encouraged as well as two or more scheduled daytime naps. Daytime naps lasting 15 minutes each can help the individual with narcolepsy stay refreshed for several hours.

7 Pharmacologic management of narcolepsy is focused on two primary areas: treatment of excessive daytime sleepiness (EDS) and cataplexy. Drug therapy for narcolepsy is summarized in Table 75–5.

CLINICAL PRESENTATION OF NARCOLEPSY

Symptoms

- Patients may complain of excessive daytime sleepiness and disrupted nighttime sleep; often they have some accompanying REM sleep abnormality, sleep paralysis, cataplexy, and/or hallucinations.

Laboratory Tests

- Although not routinely tested, there is a high incidence of HLA haplotypes DR2 and HLA-DQ6/DQB1 in narcolepsy.

Other Diagnostic Tests

- Narcolepsy is definitively diagnosed using the multiple sleep latency test (nap test). The patient takes four to five naps in a day, and narcolepsy is diagnosed if the patient falls asleep quickly (within less than 5 minutes) and goes into REM sleep in two of those nap periods.

Modafinil, a racemic compound unrelated to psychostimulants, is a recognized standard treatment for EDS.⁵² The precise mechanism of action of modafinil is not fully understood. It is readily absorbed, reaches peak plasma concentrations in 2 to 4 hours, and has a half-life of 15 hours. Common adverse effects are usually mild and include headache, nausea, nervousness, anxiety, and insomnia. The dose is between 200 and 400 mg/day.⁵³ Although modafinil is effective in treating EDS, it lacks efficacy for the treatment of cataplectic symptoms.⁵⁴

EDS can also be treated with stimulants to improve alertness and to increase daytime performance. Dextroamphetamine and methylphenidate also have FDA approval for the treatment of narcolepsy. Methamphetamine has also been used on an off-label basis. Methylphenidate and amphetamines have a fast onset of action and durations of 6 to 10 and 3 to 4 hours, respectively. The dose can range from 5 to 60 mg daily. Many clinicians prescribe both immediate-release and sustained-release stimulants to increase alertness throughout the day. Sustained-release stimulants are prescribed with scheduled administration times, and immediate release stimulants can be taken as needed when the patient requires alertness (e.g., driving, etc.).

Stimulants improve alertness, increase daytime performance, can elevate mood and prevent sleep. Side effects can include insomnia, hypertension, palpitations, and irritability. Tolerance to long-term stimulant therapy can occur, necessitating dosage increases. Amphetamine use is associated with more likelihood of abuse and tolerance, especially when prescribed in high doses.

The most effective treatments for cataplexy are TCAs, venlafaxine, and fluoxetine. The mechanism of antidepressants in relieving cataplexy, hypnagogic hallucinations, and sleep paralysis can be mediated through blockade of serotonin and norepinephrine reuptake in the locus coeruleus and raphe and subsequent suppression of REM sleep.⁵⁵ Imipramine, protriptyline, clomipramine, fluoxetine, and nortriptyline are effective in approximately 80% of patients. Selegiline improves hypersomnolence and cataplexy through REM suppression and an increase in REM latency. The cost of the medication is high, and experience with the high doses needed for narcolepsy is limited. Methylphenidate and amphetamines alone are usually ineffective for cataplexy.

Sodium oxybate (γ -hydroxybutyrate, Xyrem) improves symptoms of EDS and decreases episodes of sleep paralysis, cataplexy, and hypnagogic hallucinations. Nightly administration of sodium oxybate changes sleep architecture to resemble normal sleep. It increases slow-wave sleep, decrease nighttime awakenings, and increases REM efficiency.⁵⁶ Sodium oxybate is available only as a liquid and is taken as two doses; one is taken at bedtime and the second dose is taken 2.5 to 4 hours later. Sodium oxybate is a potent sedative hypnotic and should not be used concomitantly with any other sedating medications. The most common side effects include nausea, somnolence, confusion, dizziness, and incontinence.

■ EVALUATION OF THERAPEUTIC OUTCOMES

The primary objective of pharmacologic treatment of narcolepsy is to reduce symptoms that adversely impact quality of life. The goal is

to produce the fullest possible return of normal function for patients at work, school, home, and socially. Patients with narcolepsy should keep a diary of the frequency and severity of cataplexy, sleep paralysis, and sleep hallucinations. Patients should be evaluated regularly during medication titrations and then every 6 to 12 months to assess for adverse drug effects (e.g., sleep disturbances, and cardiovascular abnormalities). The health care provider should consider the benefit-to-risk ratio for the individual patient, the cost of medication, the convenience of administration, and cost of laboratory tests when selecting narcolepsy therapies.⁵² One wake-promoting agent can work better than another in an individual patient. If the first agent is not successful at adequate doses, a trial with another agent should be attempted.

CIRCADIAN RHYTHM DISORDERS

The sleep-wake cycle is under the circadian control of oscillators and can be disrupted by misalignment between an individual's biologic clock and external demands on the sleep cycle. Circadian rhythm sleep disorders usually present with either insomnia or hypersomnia, depending on the individual's performance requirements. Two commonly occurring circadian rhythm sleep disorders are jet lag and shift work sleep problems.

JET LAG

Jet lag occurs when a person travels across time zones, and the external environmental time is mismatched with the internal circadian clock. Sleep disturbances typically last for 2 to 3 days, but can last as long as 7 to 10 days if the time zone changes are greater than 8 hours. Compared to westward travel, eastward travel is associated with a longer duration of jet lag. Jet lag leads to increased incidence of gastrointestinal disturbances and a decrease in alertness and performance.

8 Treatment of jet lag includes nonpharmacologic approaches alone or in combination with drug therapy. Jet lag can be minimized in coast-to-coast travel in the United States if the duration is less than 7 days and the normal sleep-wake cycle is observed. For travel lasting longer than 7 days, jet lag severity can be lessened by 1- to 2-hour adjustments in sleep and wake times prior to departure to the destination time zone. Short-acting benzodiazepine receptor agonists or 0.5 to 5 mg melatonin taken at appropriate target bedtimes for east or west travel reduce jet lag and shorten sleep latency.⁵⁷

SHIFT WORK SLEEP DISORDER

Shift workers comprise approximately 20% of the work force.⁵⁸ Night shift work causes a misalignment in the sleep-wake cycle and circadian rhythm that is associated with a decrease in alertness, performance, and quality of daytime sleep. More than 65% of workers on rotating shifts complain of insomnia, compared with only 20% who work one shift.⁵⁸ Shift workers ultimately are at risk of developing shift work sleep disorder (SWSD). SWSD is a complaint of insomnia or excessive sleepiness that occurs because of working shifts during normal sleep time.^{7,59} Shift workers have a higher injury rate, rate of divorce, occurrence of on-the-job sleepiness, and incidence of substance use. Shift workers can also be at increased risk of developing peptic ulcers, heart disease, depression, breast cancer, and sleepiness-related accidents.⁵⁹⁻⁶¹ Night shift workers are usually in a state of permanent circadian misalignment because of the tendency to revert to conventional sleep schedules on their days off.⁵⁸

Treatment for shift work sleep problems includes optimizing sleep hygiene, extending daytime sleep by sleeping in the afternoon, scheduling a 2- to 3-hour nap on days off from work, or switching to a day shift job. Short-acting benzodiazepine receptor agonists can consolidate sleep during day sleep periods and reduce lost sleep time.

Modafinil is FDA approved to improve wakefulness in patients with excessive daytime sleepiness associated with SWSD. Scheduled exposure to bright lights at night and darkness in the daytime improves adaptation to night work and daytime sleep.⁵⁸ Melatonin has also been used successfully.

RESTLESS LEGS SYNDROME

Restless legs syndrome (RLS), or Ekbom syndrome, is characterized by paresthesias that are usually felt deep in the calf muscles but also can appear in the thighs and arms with the urge to keep limbs in motion. RLS occurs in both males and females, and occurs more frequently in the elderly. It has been associated with chronic kidney disease, iron deficiency anemia, and pregnancy. Caffeine, stress, alcohol, and fatigue can worsen symptoms. Recent data suggest that RLS can be caused by iron deficiency in the substantia nigra in the CNS.⁶² The diagnosis of RLS is based on patient or bed partner reported symptoms and specific diagnostic criteria. Criteria required to diagnose RLS are: (1) desire to move the limbs that is associated with paresthesias, (2) symptoms are worse in the evening or night, (3) symptoms are worsened by inactivity and are relieved by moving the affected limb, and (4) accompanying motor restlessness. The discomfort returns when the person tries to sleep, resulting in insomnia.⁶³

9 Dopamine agonists are effective for RLS and have replaced levodopa as first-line therapy.⁶⁴ Ropinirole and pramipexole are FDA approved for RLS, but rotigotine may also be effective.⁶⁴ Lower doses of dopamine agonists are used when treating RLS compared to Parkinson's disease. Levodopa therapy is associated with a high incidence of symptom augmentation and because of a short half-life, might not provide relief over the entire night. Augmentation is a worsening in symptom severity, increase in symptom distribution, or emergence of symptoms earlier in the evening. Sedative hypnotic agents can be effective in patients who have frequent awakenings from their RLS symptoms. Clonazepam at doses ranging from 0.5 mg to 2 mg has been most frequently studied, however, patients frequently experience carryover sedation because of its long duration of action. Shorter half-life sedative hypnotics (e.g., zolpidem, zaleplon, triazolam) can improve sleep and reduce daytime sleepiness without carryover sedation. Opiates such as methadone 5 to 20 mg, codeine 30 to 120 mg, and oxycodone 2.5 mg are very effective for patients with painful RLS. The potential for tolerance and dependence on opiate therapy should be considered. Gabapentin 300 to 900 mg near bedtime can also be considered for those with paresthetic or painful RLS symptoms.⁶⁵ Iron studies should be completed in patients with RLS and iron supplementation initiated in those that are iron deficient. In patients with ferritin concentrations less than 50 mcg/L, iron supplementation improves RLS symptoms. Patients with RLS or periodic limb movements of sleep should be evaluated regularly to monitor for excessive daytime somnolence, tolerance, efficacy, and adverse effects of the medication.

PERIODIC LEG MOVEMENTS OF SLEEP

RLS patients commonly have periodic limb movements during sleep (PLMS): approximately one-third of patients with PLMS have RLS.⁶⁴ PLMS are stereotypic, repetitive, periodic movements of the legs that occur during sleep every 20 to 40 seconds and last 10 minutes to several hours.⁶⁴ The movements usually involve the big toe, but the ankle, knee, and hip can also flex. They can be terminated by a violent kick or other body movement. Often patients will be unaware of these movements and only recognize consequent insufficient sleep and morning leg cramps. A bed partner can describe PLMS. PLMS is diagnosed in the sleep laboratory using electromyogram recordings. Bursts of muscle

activity lasting 0.5 to 5 seconds that reoccur at least 40 times within 8 hours of sleep is diagnostic.⁶⁴

PLMS can occur with RLS or alone because of systemic disease (e.g., renal failure) or drug therapy.⁶⁶ TCAs, SSRIs, dopaminergic antagonists, xanthines, nicotine, alcohol, and caffeine can all worsen PLMS. The treatment approach for PLMS is similar to that of RLS. If PLMS do not cause disruptions for the patient or bedpartner or daytime symptoms, they might not require treatment. Symptomatic or problematic PLMS should be treated with dopaminergic medications to suppress limb movements or sedative hypnotics to reduce awakenings and consolidate sleep.

PARASOMNIAS

Parasomnias are abnormal behavior or physiologic events that either occur during sleep or are exaggerated by sleep. Many of these disorders are considered to be disorders of partial arousal from various sleep stages. Parasomnias can be categorized as disorders of arousal (sleepwalking, sleep terrors), sleep-wake transition disorders (sleepwalking), rhythmic movement disorder, REM parasomnias (REM-behavior disorder), and miscellaneous parasomnias (enuresis, bruxism). Sleepwalking, sleep terrors and sleepwalking predominantly occur during NREM sleep whereas others (REM-behavior disorder) occur during REM sleep.

Sleepwalking and sleep terrors are found normally in children between the ages of 4 and 12 years and usually resolve in adolescence. These disorders are associated with psychopathology only if they persist into adulthood.⁶⁷ Sleep terrors can begin in adults between the ages of 20 and 30 years. Onset of sleepwalking in adults without a history of sleepwalking as children should prompt a search for a neurologic or substance-use condition.⁶⁷ Sleepwalking and sleep terror disorder involve intrusions of wakefulness into NREM sleep during the first third of the night. In sleepwalking, individuals become ambulatory, are difficult to awaken, and are amnesic for the event. Sleep terrors involve intense fear and autonomic arousal. Individuals are difficult to awaken, inconsolable, and amnesic for the event.⁶⁷

Treatment of sleepwalking involves protecting the individual from harm by putting safety latches on doors and windows, removing hazardous objects from bedrooms, and covering glass doors with heavy curtains. In adult patients, benzodiazepines, SSRIs, or TCAs can be beneficial therapies for sleepwalking or other NREM disorders of arousal.⁶⁸ Benzodiazepines can also be helpful in curtailing sleep terrors in adults.⁶⁷ Nightmares are anxiety-provoking dreams characterized by vivid recall. Treatment is directed at reducing stress, anxiety, and sleep deprivation. In extreme cases, low-dose benzodiazepines can be indicated. Clonazepam is the treatment of choice for REM behavior disorder. Melatonin (3–12 mg at bedtime) can also be an effective therapy for REM behavior disorder.⁶⁹

PHARMACOECONOMIC CONSIDERATIONS

Despite the prevalence of sleep disorders, most cases go undiagnosed and untreated. The direct cost of insomnia alone adds an estimated \$13.9 billion to the national health care bill each year.^{1,70} The direct and indirect costs of sleep disorders is estimated to be between \$92.5 and \$107.5 billion annually. Improvements in recognition and treatment can decrease the economic burden and prevent progression to both medical and psychiatric disorders.⁷⁰

Quality of life can be improved by appropriate treatment. For example, treatment of OSA with PAP improves the number of years of good health by 5.5 quality-adjusted life years. Hypnotic therapy has also been found to markedly improve both the disorder and quality of life in shift workers.⁷⁰

CONCLUSIONS

Disturbances of sleep affect approximately one-third of the population. Patients with sleep disorders should be accurately identified and diagnosed. Patients can have one or more concomitant sleep disorders. Unrecognized and poorly treated sleep disorders can worsen severity of and ability to effectively treat underlying systemic diseases. Effective management of sleep disorder(s) involves combined nonpharmacologic and pharmacologic treatment.

ACKNOWLEDGMENT

This chapter was authored by Cherry W. Jackson and Judy L. Curtis in the sixth edition of *Pharmacotherapy: A Pathophysiologic Approach*.

ABBREVIATIONS

CPAP: continuous positive airway pressure
 CNS: central nervous system
 CSA: central sleep apnea
 EDS: excessive daytime sleepiness
 EEG: electroencephalogram
 FDA: Food and Drug Administration
 GABA: γ -aminobutyric acid
 HLA: human leukocyte antigen
 NREM: nonrapid eye movement (sleep)
 OSA: obstructive sleep apnea
 PAP: positive airway pressure
 PLMS: periodic limb movement during sleep
 PSG: polysomnography
 RDI: respiratory disturbance index
 REM: rapid eye movement (sleep)
 RLS: restless legs syndrome
 SSRI: selective serotonin reuptake inhibitor
 SWSD: shift work sleep disorder
 TCA: tricyclic antidepressant

KEY CONCEPTS

- 1 Behavioral therapies, education, and pharmacologic treatment are complementary and should be integrated as part of a multimodal treatment approach in persons with developmental disabilities and concomitant behavioral issues.
- 2 Persons diagnosed with Down syndrome can be at increased risk for medical and psychiatric comorbidities.
- 3 When treating autism, objective and measurable outcome monitoring of psychoactive medication-responsive target behaviors is critical because of the variable response of individuals to medication therapy.
- 4 Many purported treatments for autism have limited or no evidence supporting their use. The use of such strategies should be discouraged, as many effective treatments exist.
- 5 Goals of treatment in persons with autism are to increase social interactions, improve verbal and nonverbal communication, and minimize the occurrence or impact of ritualistic repetitive behaviors and other related mood and behavior problems (e.g., overactivity, irritability, self-injury).
- 6 A structured approach to teaching, which focuses on increasing social communication and understanding and fosters integration with peers, is the treatment most highly correlated with improvement in persons with autism.
- 7 Although no medication has been shown to be universally effective, psychopharmacologic treatment in autism is effective and should be targeted at specific well-defined behavioral symptoms.
- 8 Rett's syndrome is characterized by the onset of developmental regression that occurs in four stages.

INTRODUCTION

Developmental disabilities and mental retardation can be identified in childhood or adolescence. Current criteria for a diagnosis of

mental retardation are based on deficiencies in intellectual and adaptive functioning with an onset prior to 18 years of age.^{1,2} This diagnosis is made regardless of the presence or absence of concomitant medical or psychiatric disorders. In the case of mild mental retardation, deficiencies may not be initially apparent. Problems can be noted when the chronologic age of the child and the developmental milestones achieved by peers with similar backgrounds, cultures, and socioeconomic and psychosocial settings differ significantly.¹ These gaps widen as the individual ages.

1 Adaptive functioning deficits pose a number of challenges in treating those with a developmental disability (DD). This population can be four to five times more likely to experience mental health problems compared to the general population.³ Until recently, little attention was given to this population and the need to evaluate them for psychiatric illnesses, leading to underrecognition of psychopathology. This oversight is a function of several factors, including limited, population-specific training for clinicians and a general lack of clinical contact with developmentally disabled individuals during training.³ Additional barriers are patient-related deficits in expressive and receptive language, combined with a lack of mental health screening and diagnostic testing instruments specific to developmentally disabled adults.³

Those with developmental disabilities often have fewer social interactions and less integration into the community. In the absence of stimulation and interaction with peers that typically shapes behaviors in persons with normal intellect, a different set of coping skills can functionally evolve. An example is self-talk, which can represent such a coping mechanism in some persons with DD. This behavior can be misinterpreted by some as psychosis. Another potential problem for the clinician assessing persons with DD is a significant deficit between receptive language skills and expressive language skills. If not readily recognized, intellectual capabilities can be overestimated, and coping skills can be inadequate to deal with demands placed on the individual. This can result in anxiety-induced decompensation.³

In the general population, features of psychiatric illnesses are more readily identifiable, and the clinician is able to interview and evaluate the patient, as indicated. The term “diagnostic overshadowing” has been used to refer to clinician perception of behavioral problems thought to be secondary to mental retardation, which can actually be caused by a mental illness. Diagnostic overshadowing can therefore result in underestimating the clinical significance of the emotional and behavioral presentation as the deficits are inaccurately associated with a diagnosis of mental retardation.³ This chapter will focus on three syndromes that are commonly seen in persons with developmental disabilities: Down syndrome, autistic disorder, and Rett's syndrome. In discussing these three syndromes, a broader perspective of issues encountered in persons with DD will be reviewed.

ENDOCRINOLOGIC DISORDERS

CHAPTER

77

Diabetes Mellitus

CURTIS L. TRIPLITT, CHARLES A. REASNER, AND WILLIAM L. ISLEY

KEY CONCEPTS

- 1 Diabetes mellitus is a group of metabolic disorders of fat, carbohydrate, and protein metabolism that results from defects in insulin secretion, insulin action (sensitivity), or both.
- 2 The incidence of type 2 diabetes mellitus (DM) is increasing. This has been attributed in part to a Western style diet, increasing obesity, sedentary lifestyle, and an increasing minority population.
- 3 The two major classifications of DM are type 1 (insulin deficient) and type 2 (combined insulin resistance and relative deficiency in insulin secretion). They differ in clinical presentation, onset, etiology, and progression of disease. Both are associated with microvascular and macrovascular disease complications.
- 4 Diagnosis of diabetes is made by three criteria: fasting plasma glucose ≥ 126 mg/dL, a 2-hour value from a 75-g oral glucose tolerance test ≥ 200 mg/dL, or a casual plasma glucose level of ≥ 200 mg/dL with symptoms of diabetes; with results confirmed by any of the three criteria on a separate day.
- 5 Goals of therapy in diabetes mellitus are directed toward attaining normoglycemia, reducing the onset and progression of retinopathy, nephropathy, and neuropathy complications, intensive therapy for associated cardiovascular risk factors, and improving quality and quantity of life.
- 6 Metformin should be included in the therapy for all type 2 DM patients, if tolerated and not contraindicated, as it is the only oral antihyperglycemic medication proven to reduce the risk of total mortality, according to the United Kingdom Prospective Diabetes Study (UKPDS).
- 7 Intensive glycemic control is paramount for reduction of microvascular complications (neuropathy, retinopathy, and nephropathy) as evidenced by the Diabetes Control and Complications Trial (DCCT) in type 1 DM and the UKPDS in type 2 DM. The UKPDS also reported that control of hypertension in patients with diabetes will not only reduce the risk of retinopathy and nephropathy but also reduce cardiovascular risk.
- 8 Knowledge of the patient's quantitative and qualitative meal patterns, activity levels, pharmacokinetics of insulin preparations, and pharmacology of oral and injected antihyperglycemic agents are essential to individualize the treatment plan and optimize blood glucose control while minimizing risks for hypoglycemia and other adverse effects of pharmacologic therapies.
- 9 Type 1 treatment necessitates insulin therapy. Currently, the basal-bolus insulin therapy or pump therapy in motivated individuals often leads to successful glycemic outcomes. Basal-bolus therapy includes a basal insulin for fasting and postabsorptive control, and rapid-acting bolus insulin for mealtime coverage. Addition of pramlintide in patients with uncontrolled or erratic postprandial glycemia can be warranted, if the patient is willing to inject additional times before each meal.
- 10 Treatment of type 2 DM often necessitates use of multiple therapeutic agents (combination therapy), including oral and/or injected antihyperglycemics and insulin to obtain glycemic goals.
- 11 Aggressive management of cardiovascular disease risk factors in type 2 DM is necessary to reduce the risk for adverse cardiovascular events or death. Smoking cessation, use of antiplatelet therapy as a primary prevention strategy, aggressive management of dyslipidemia minimally toward a goal of low-density lipoprotein-cholesterol (LDLC) at <100 mg/dL and secondarily to increase high-density lipoprotein-cholesterol (HDL) to ≥ 40 mg/dL, and treatment of hypertension (again often requiring multiple drugs) minimally to attain a blood pressure of $<130/80$ mm Hg are vital.
- 12 Prevention strategies for type 1 DM have been unsuccessful. Prevention strategies for type 2 DM are established. Lifestyle changes, dietary restriction of fat, aerobic exercise for 30 minutes five times a week, and weight loss, form the backbone of successful prevention. No medication is currently FDA approved for prevention of diabetes, although several, including metformin and rosiglitazone, have evidence of potential delay of the onset of diabetes.

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

13 Patient education and ability to demonstrate self-care and adherence to therapeutic lifestyle and pharmacologic interventions are crucial to successful outcomes. Multidisciplinary teams of healthcare professionals including physicians (primary care, endocrinologists, ophthalmologists, and vascular surgeons), podiatrists, dietitians, nurses, pharmacists, social workers, behavioral health specialists, and certified diabetes educators are needed to optimize these outcomes in persons with diabetes mellitus.

1 DM is a group of metabolic disorders characterized by hyperglycemia. It is associated with abnormalities in carbohydrate, fat, and protein metabolism and results in chronic complications including microvascular, macrovascular, and neuropathic disorders. Nearly 20.8 million Americans have DM, yet only approximately two-thirds of them have been diagnosed.¹ The economic burden of DM approximated \$132 billion in 2002, including direct medical and treatment costs as well as indirect costs attributed to disability and mortality.¹ DM is the leading cause of blindness in adults aged 20 to 74 years, and the leading contributor to development of end-stage renal disease. It also accounts for approximately 82,000 lower extremity amputations annually.¹ Finally, a cardiovascular event is responsible for two-thirds of deaths in individuals with type 2 DM.¹

Although efforts to control hyperglycemia and associated symptoms are important, the major challenges in optimally managing the patient with DM are targeted at reducing or preventing complications, and improving life expectancy and quality of life. Research and drug development efforts over the past several decades have provided valuable information that applies directly to improving outcomes in patients with DM and have expanded the therapeutic armamentarium. Additionally, interventions in an attempt to prevent disease in high-risk populations have been reported for type 1 and 2 DM.

EPIDEMIOLOGY

Typical type 1 DM is an autoimmune disorder developing in childhood or early adulthood, although some latent forms do occur. Type 1 DM accounts for 5% to 10% of all cases of DM and is likely initiated by the exposure of a genetically susceptible individual to an environmental agent.² Candidate genes and environmental factors are reportedly prevalent in the general population, but development of β -cell autoimmunity occurs in less than 10% of the genetically susceptible population and progresses to type 1 DM in less than 1% of the population.³

The prevalence of β -cell autoimmunity appears proportional to the incidence of type 1 DM in various populations. For instance, the countries of Sweden, Sardinia, and Finland have the highest prevalence of islet cell antibody (3% to 4.5%) and are associated with the highest incidence of type 1 DM, 22 to 35 per 100,000.⁴

Markers of autoimmunity have been detected in 14% to 33% of persons with type 2 DM in some populations and manifest with early failure of oral agents and insulin dependence. This type of DM has also been referred to as latent autoimmune diabetes of adults (LADA).⁴

Type 1 DM idiopathic is a nonimmune form of diabetes frequently seen in minorities with intermittent insulin requirements.⁵ The prevalence of type 1 DM has been increasing over the last 100 years.⁶ Maturity-onset diabetes of youth (MODY), which can be caused by one of at least six genetic defects, and endocrine disorders such as acromegaly and Cushing syndrome, can be secondary causes of DM.⁷ These unusual etiologies, however, only account for 1% to 2% of the total cases of type 2 DM. See the section on Other Specific Types of Diabetes later in this chapter for further discussion.

FIGURE 77-1. National Health and Nutrition Evaluation Survey (NHANES) prevalence of diabetes by race among adults ≥ 20 years of age: United States, 1988–1994 and 1999–2002. (Adapted from Cowie et al.⁹)

2 The prevalence of type 2 DM is increasing. Type 2 DM accounts for as much as 90% of all cases of DM, and the overall the prevalence of type 2 DM in the United States is approximately 9.6% in persons age 20 years or older. However, there is likely one person undiagnosed for every three persons currently diagnosed with the disease.¹ Multiple risk factors for the development of type 2 DM have been identified, including family history (i.e., parents or siblings with diabetes); obesity (i.e., $\geq 20\%$ over ideal body weight, or body mass index [BMI] ≥ 25 kg/m²); habitual physical inactivity; race or ethnicity; previously identified impaired glucose tolerance or impaired fasting glucose (see Diagnosis of Diabetes section); hypertension ($\geq 140/90$ mm Hg in adults); high-density lipoprotein (HDL) cholesterol ≤ 35 mg/dL and/or a triglyceride level ≥ 250 mg/dL; history of gestational DM (see Classification of Diabetes section) or delivery of a baby weighing >4 kg (9 lb); history of vascular disease; presence of acanthosis nigricans; and polycystic ovary disease.⁸ The prevalence of type 2 DM increases with age, it is more common in women than in men in the United States, and varies widely among various racial and ethnic populations, being especially increased in some groups of Native Americans, Hispanic American, Asian American, African American, and Pacific Island people⁹ (Fig. 77-1). Although the prevalence of type 2 DM increases with age (Fig. 77-2),⁹ the disorder is increasingly being recognized in adolescence. Much of the increase in adolescent type 2 DM is related to an increase in adiposity and sedentary lifestyle, in addition to an inheritable predisposition.¹⁰ Most cases of type 2 DM do not have a well-known cause; therefore it is uncertain whether it represents a few or many independent disorders manifesting as hyperglycemia.¹¹

Gestational diabetes mellitus (GDM) complicates roughly 7% of all pregnancies in the United States.¹² Most women will return to

FIGURE 77-2. National Health and Nutrition Evaluation Survey (NHANES) prevalence of diabetes mellitus in United States by age (≥ 20 years of age) 1988–1994 and 1999–2002. (Adapted from Cowie et al.⁹)

normoglycemia postpartum, but 30% to 50% will develop type 2 DM or glucose intolerance later in life.

PATHOGENESIS, DIAGNOSIS, AND CLASSIFICATION

CLASSIFICATION OF DIABETES

Diabetes is a metabolic disorder characterized by resistance to the action of insulin, insufficient insulin secretion, or both.¹³ The clinical manifestation of these disorders is hyperglycemia. The vast majority of diabetic patients are classified into one of two broad categories: type 1 diabetes caused by an absolute deficiency of insulin, or type 2 diabetes defined by the presence of insulin resistance with an inadequate compensatory increase in insulin secretion. Women who develop diabetes because of the stress of pregnancy are classified as having gestational diabetes. Finally, uncommon types of diabetes caused by infections, drugs, endocrinopathies, pancreatic destruction, and known genetic defects are classified separately (Table 77-1).

Type 1 Diabetes

3 This form of diabetes results from autoimmune destruction of the β cells of the pancreas. Markers of immune destruction of the β

cell are present at the time of diagnosis in 90% of individuals and include islet cell antibodies, antibodies to glutamic acid decarboxylase, and antibodies to insulin. Although this form of diabetes usually occurs in children and adolescents, it can occur at any age. Younger individuals typically have a rapid rate of β -cell destruction and present with ketoacidosis, whereas adults often maintain sufficient insulin secretion to prevent ketoacidosis for many years, which is often referred to as LADA.⁴

Type 2 Diabetes

3 This form of diabetes is characterized by insulin resistance and a relative lack of insulin secretion, with progressively lower insulin secretion over time. Most individuals with type 2 diabetes exhibit abdominal obesity, which itself causes insulin resistance. In addition, hypertension, dyslipidemia (high triglyceride levels and low HDL-cholesterol levels), and elevated plasminogen activator inhibitor type 1 (PAI-1) levels are often present in these individuals. This clustering of abnormalities is referred to as the *insulin resistance syndrome* or the *metabolic syndrome*. Because of these abnormalities, patients with type 2 diabetes are at increased risk of developing macrovascular complications. Type 2 diabetes has a strong genetic predisposition and is more common in all ethnic groups other than those of European ancestry. At this point the genetic cause of most cases of type 2 diabetes is not well defined.¹⁴

TABLE 77-1 Etiologic Classification of Diabetes Mellitus

1. Type 1 diabetes^a (β -cell destruction, usually leading to absolute insulin deficiency)	Drug- or chemical-induced
Immune mediated	Vacor (pyriminil)
Idiopathic	Pentamidine
2. Type 2 diabetes^a (can range from predominantly insulin resistance with relative insulin deficiency to a predominantly insulin secretory defect with insulin resistance)	Nicotinic acid
3. Other specific types	Glucocorticoids
Genetic defects of β -cell function	Thyroid hormone
Chromosome 20q, HNF-4 α (MODY1)	Diazoxide
Chromosome 7p, glucokinase (MODY2)	β -Adrenergic agonists
Chromosome 12q, HNF-1 β (MODY3)	Thiazides
Chromosome 13q, insulin promoter factor (MODY4)	Phenytoin
Chromosome 17q, HNF-1 β (MODY5)	Interferon alpha
Chromosome 2q, neurogenic differentiation 1/ β -cell e-box transactivator 2 (MODY6)	Others
Mitochondrial DNA	Infections
Others	Congenital rubella
Genetic defects in insulin action	Cytomegalovirus
Type 1 insulin resistance	Others
Leprechaunism	Uncommon forms of immune-mediated diabetes
Rabson-Mendenhall syndrome	"Stiff-man" syndrome
Lipoatrophic diabetes	Anti-insulin receptor antibodies
Others	Others
Diseases of the exocrine pancreas	Other genetic syndromes sometimes associated with diabetes
Pancreatitis	Down's syndrome
Trauma/pancreatectomy	Klinefelter's syndrome
Neoplasia	Turner's syndrome
Cystic fibrosis	Wolfram's syndrome
Hemochromatosis	Friedreich's ataxia
Fibrocalculous pancreatopathy	Huntington's chorea
Others	Laurence-Moon-Biedel syndrome
Endocrinopathies	Myotonic dystrophy
Acromegaly	Porphyria
Cushing's syndrome	Prader-Willi syndrome
Glucagonoma	Others
Pheochromocytoma	4. Gestational diabetes mellitus (GDM)
Hyperthyroidism	
Somatostatinoma	
Aldosteronoma	
Others	

^aPatients with any form of diabetes can require insulin treatment at some stage of their disease. Such use of insulin does not in itself classify the patient.

Adapted with permission from Report of the Expert Committee.¹³

Gestational Diabetes Mellitus

GDM is defined as glucose intolerance that is first recognized during pregnancy. Gestational diabetes complicates approximately 7% of all pregnancies. Clinical detection is important, as therapy will reduce perinatal morbidity and mortality.

Other Specific Types of Diabetes

Genetic Defects MODY is characterized by impaired insulin secretion with minimal or no insulin resistance. Patients typically exhibit mild hyperglycemia at an early age. The disease is inherited in an autosomal dominant pattern with at least six different loci identified to date. Genetic inability to convert proinsulin to insulin results in mild hyperglycemia and is inherited in an autosomal dominant pattern. Similarly, the production of mutant insulin molecules has been identified in a few families and results in mild glucose intolerance.

Several genetic mutations have been described in the insulin receptor and are associated with insulin resistance. Type A insulin resistance refers to the clinical syndrome of acanthosis nigricans, virilization in women, polycystic ovaries, and hyperinsulinemia. In contrast, type B insulin resistance is caused by autoantibodies to the insulin receptor. Leprechaunism is a pediatric syndrome with specific facial features and severe insulin resistance because of a defect in the insulin receptor gene. Lipodystrophic diabetes probably results from postreceptor defects in insulin signaling.

SCREENING

Type 1 Diabetes Mellitus

There is still a low prevalence of type 1 DM in the general population and because of the acuteness of symptoms, screening for type 1 DM is not recommended.⁸

Type 2 Diabetes Mellitus

Based on expert opinion, and not uniformly accepted by all guidance organizations, the American Diabetes Association (ADA) recommends screening for type 2 DM every 3 years in all adults beginning at age 45 years.⁸ Testing should be considered at an earlier age and more frequently in individuals with risk factors. The recommended screening test is the fasting plasma glucose (FPG). An oral glucose tolerance test (OGTT) (more costly, less convenient, less reproducible) can be performed alternatively or in addition to FPG when a high index of suspicion for the disease is present.⁵

Children and Adolescents

Despite a lack of clinical evidence to support widespread testing of children for type 2 DM, it is clear that more children and adolescents are developing type 2 DM. The ADA, by expert opinion, recommends that overweight (defined as BMI >85th percentile for age and sex, weight for height >85th percentile, or weight >120% of ideal [50th percentile] for height) youths with at least two of the following risk factors: a family history of type 2 diabetes in first- and second-degree relatives; Native Americans, African Americans, Hispanic Americans, and Asians/South Pacific Islanders; and those with signs of insulin resistance or conditions associated with insulin resistance (acanthosis nigricans, hypertension, dyslipidemia, or polycystic ovary syndrome) be screened. Testing should be done every 2 years starting at 10 years of age or at the onset of puberty if it occurs at a younger age.⁸

Gestational Diabetes

Risk assessment for GDM should occur at the first prenatal visit. Women at high risk (positive family history, history of GDM,

TABLE 77-2 Diagnosis of Gestational Diabetes Mellitus with a 100-g or 75-g Glucose Load

Time	Plasma Glucose
100-g Glucose load	
Fasting	≥95 mg/dL (5.3 mmol/L)
1 hour	≥180 mg/dL (10.0 mmol/L)
2 hours	≥155 mg/dL (8.6 mmol/L)
3 hours	≥140 mg/dL (7.8 mmol/L)
75-g Glucose load	
Fasting	≥95 mg/dL (5.3 mmol/L)
1 hour	≥180 mg/dL (10.0 mmol/L)
2 hours	≥155 mg/dL (8.6 mmol/L)

Two or more values must be met or exceeded for a diagnosis of diabetes to be made. The test should be done in the morning after an 8- to 14-hour fast.

marked obesity, or member of a high-risk ethnic group) should be screened as soon as feasible. If the initial screening is negative, they should undergo retesting at 24 to 28 weeks of gestation, as should all other pregnant women with the possible exception of low-risk primigravidas. Evaluation for GDM can be done in one of two ways. The one-step approach involves a 3-hour, 100 gram-OGTT and can be cost-effective in high-risk patient populations. The two-step approach uses a screening test to measure plasma or serum glucose concentration 1 hour after a 50 gram oral glucose load (glucose challenge test), followed by a diagnostic 3-hour OGTT on the subset of women exceeding a glucose threshold of either ≥140 mg/dL (80% sensitive) or ≥130 mg/dL (90% sensitive). The diagnosis of GDM is based on a 75-gram (not as well validated) or 100-gram OGTT. Criteria for diagnosis of GDM based on the OGTT are summarized in Table 77-2.

DIAGNOSIS OF DIABETES

4 The diagnosis of diabetes requires the identification of a glycemic cut point, which discriminates normal persons from diabetic patients (Table 77-3). The present cut points reflect the level of glucose above which microvascular complications have been shown to increase. Cross-sectional studies from Egypt, in Pima Indians, and in a representative sample from the United States have shown a consistent increase in the risk of developing retinopathy at a fasting glucose level above 99 to 116 mg/dL (5.5 to 6.4 mmol/L), at a 2-hour postprandial level above 125 to 185 mg/dL (6.9 to 10.3 mmol/L), and a hemoglobin A_{1c} (HbA_{1c}) above 5.9 to 6.0% (Fig. 77-3).^{13,15,16}

The ADA recommends using the fasting glucose test as the principal tool for the diagnosis of DM in nonpregnant adults. In addition, as shown in Table 77-4, they defined a new category of glycemia, impaired fasting glucose (IFG). IFG is a plasma glucose of at least 100 mg/dL (5.6 mmol/L) but less than 126 mg/dL (7.0

TABLE 77-3 Criteria for the Diagnosis of Diabetes Mellitus^a

Symptoms of diabetes plus casual ^b plasma glucose concentration ≥200 mg/dL (11.1 mmol/L)
or
Fasting ^c plasma glucose ≥126 mg/dL (7.0 mmol/L)
or
2-hour postload glucose ≥200 mg/dL (11.1 mmol/L) during an OGTT ^d

OGTT, oral glucose tolerance test.

^aIn the absence of unequivocal hyperglycemia, these criteria should be confirmed by repeat testing on a different day. The third measure is not recommended for routine clinical use.

^bCasual is defined as any time of day without regard to time since last meal. The classic symptoms of diabetes include polyuria, polydipsia, and unexplained weight loss.

^cFasting is defined as no caloric intake for at least 8 hours.

^dThe test should be performed as described by the World Health Organization, using a glucose load containing the equivalent of 75 g anhydrous glucose dissolved in water.

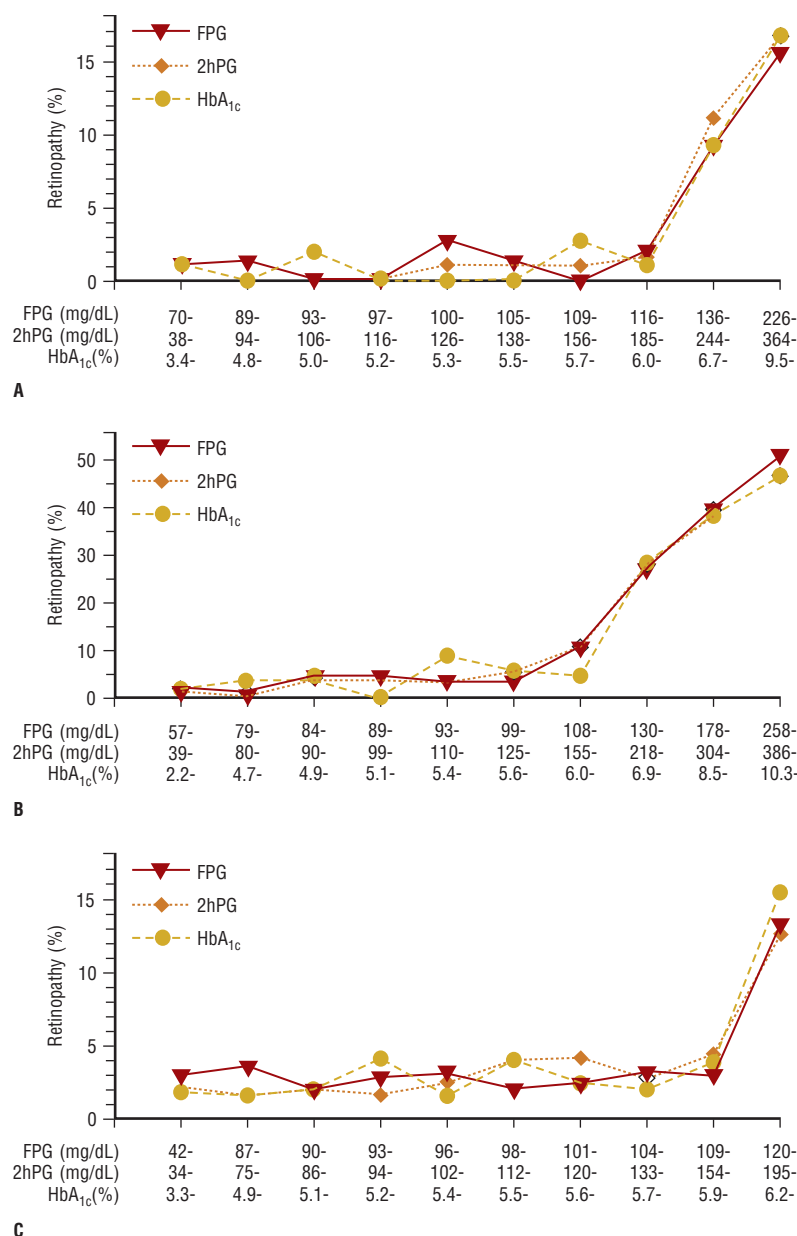

FIGURE 77-3. Prevalence of retinopathy by deciles of the distribution of fasting plasma glucose (FPG), 2-hour postprandial glucose (2-h PG), and hemoglobin A_{1c} (HbA_{1c}) in (A) Pima Indians,¹² (B) Egyptians,¹¹ and (C) in 40- to 74-year old participants in National Health and Nutrition Examination Survey (NHANES) III.¹³ The X-axis labels indicate the lower limit of each decile group. Note that these deciles and the prevalence rates of retinopathy differ considerably among the studies, especially the Egyptian study, in which diabetic subjects were oversampled. Retinopathy was ascertained by different methods in each study; therefore the absolute prevalence rates are not comparable between studies, but their relationships with FPG, 2-h PG, and HbA_{1c} are very similar within each population.

mmol/L). Impaired glucose tolerance (IGT), is defined as a 2-hour glucose value ≥ 140 mg/dL (7.8 mmol/L), but less than 200 mg/dL (11.0 mmol/L) during an OGTT. Patients with either IFG or IGT are now commonly referred to as having “prediabetes” because of a higher risk of developing diabetes in the future.

TABLE 77-4 Categorization of Glucose Status

<i>Fasting plasma glucose (FPG)</i>	
Normal	• FPG <100 mg/dL (5.6 mmol/L)
Impaired fasting glucose (IFG)	• 100–125 mg/dL (5.6–6.9 mmol/L)
Diabetes mellitus ^a	• FPG ≥ 126 mg/dL (7.0 mmol/L)
<i>2-Hour postload plasma glucose (oral glucose tolerance test)</i>	
Normal	• Postload glucose <140 mg/dL (7.8 mmol/L)
Impaired glucose tolerance (IGT)	• 2-hour postload glucose 140–199 mg/dL (7.8–11.1 mmol/L)
Diabetes mellitus ^a	• 2-hour postload glucose ≥ 200 mg/dL (11.1 mmol/L)

^aProvisional diagnosis of diabetes (diagnosis to be confirmed; see Table 77-3).

The fasting and postprandial glucose levels do not measure the same physiologic processes and do not identify the same individuals as having diabetes. The fasting glucose reflects hepatic glucose production, which depends on insulin secretory capacity of the pancreas. The postprandial glucose reflects uptake of glucose in peripheral tissues (muscle and fat) and depends on insulin sensitivity of these tissues.

The ADA recommends use of HbA_{1c} determinations to monitor glycemic control in known diabetic patients. Because there is no gold standard assay and several countries do not have ready access to the test, a HbA_{1c} determination is not recommended to diagnose diabetes at the present time.

PATHOGENESIS

Type 1 Diabetes Mellitus

Type 1 DM is characterized by an absolute deficiency of pancreatic β -cell function. Most often this is the result of an immune-mediated destruction of pancreatic β cells, but rare unknown or idiopathic processes can contribute. What is evident are four main features: (1) a long preclinical period marked by the presence of immune markers when β -cell destruction is thought to occur; (2) hypergly-

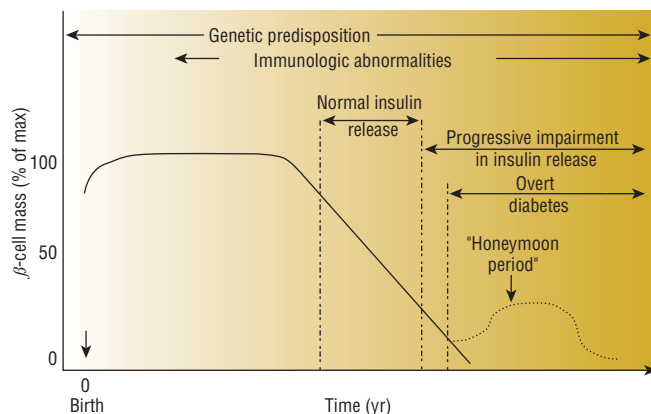

FIGURE 77-4. Scheme of the natural history of the β -cell defect in type 1 diabetes mellitus. (From ADA Medical Management of Type 1 Diabetes, 3rd ed. American Diabetes Association, Alexandria, VA, 1998.)

cemia when 80% to 90% of β cells are destroyed; (3) transient remission (the so-called *honeymoon* phase); and (4) established disease with associated risks for complications and death. Unknown is whether there is one or more inciting factors (e.g., cow's milk, or viral, dietary, or other environmental exposure) that initiate the autoimmune process (Fig. 77-4).²

The autoimmune process is mediated by macrophages and T lymphocytes with circulating autoantibodies to various β -cell antigens. The most commonly detected antibody associated with type 1 DM is the islet cell antibody. The test for islet cell antibody, however, is difficult to standardize across laboratories. Other more readily measured circulating antibodies include insulin autoantibodies, antibodies directed against glutamic acid decarboxylase, insulin antibodies against islet tyrosine phosphatase, and several others. More than 90% of newly diagnosed persons with type 1 DM have one or another of these antibodies, as will 3.5% to 4% of unaffected first-degree relatives. Preclinical β -cell autoimmunity precedes the diagnosis of type 1 DM by up to 9 to 13 years. Autoimmunity can remit in some perhaps less-susceptible persons, or can progress to β -cell failure in others. These antibodies are generally considered markers of disease rather than mediators of β -cell destruction. They have been used to identify individuals at risk for type 1 DM in evaluating disease-prevention strategies. Other nonpancreatic autoimmune disorders are associated with type 1 DM, most commonly Hashimoto thyroiditis, but the extent of organ involvement can range from no other organs to polyglandular failure.¹⁷

There are strong genetic linkages to the DQA and B genes, and certain human leukocyte antigens (HLAs) can be predisposing (DR3 and DR4) or protective (DRB1*04008-DQB1*0302 and DRB1*0411-DQB1*0302) on chromosome 6.¹⁷ Other candidate gene regions have been identified on several other chromosomes as well. Because twin studies do not show 100% concordance, environmental factors such as infectious agents, chemical agents, and dietary agents are likely contributing factors in the expression of the disease.

Destruction of pancreatic β -cell function causes hyperglycemia because of an absolute deficiency of both insulin and amylin.¹⁸ Insulin lowers blood glucose by a variety of mechanisms including: stimulation of tissue glucose uptake, suppression of glucose production by the liver, and suppression of free fatty acid release from fat cells.¹⁹ The suppression of free fatty acids plays an important role in glucose homeostasis. Increased levels of free fatty acids inhibit the uptake of glucose by muscle and stimulate hepatic gluconeogenesis.²⁰ Amylin, a glucoregulatory peptide hormone cosecreted with insulin, plays a role in lowering blood glucose by slowing gastric emptying, suppressing glucagon output from pancreatic α cells, and increasing satiety.²¹ In type 1 DM amylin production, caused by β -cell destruction, is very low.

Type 2 Diabetes Mellitus

Normal Insulin Action In the fasting state 75% of total body glucose disposal takes place in non-insulin-dependent tissues: the brain and splanchnic tissues (liver and gastrointestinal [GI] tissues).²² In fact, brain glucose uptake occurs at the same rate during fed and fasting periods and is not altered in type 2 diabetes.

The remaining 25% of glucose metabolism takes place in muscle, which is dependent on insulin.²³ In the fasting state approximately 85% of glucose production is derived from the liver, and the remaining amount is produced by the kidney.²²⁻²⁴ Glucagon, produced by pancreatic α cells, is secreted in the fasting state to oppose the action of insulin and stimulate hepatic glucose production. Thus, glucagon prevents hypoglycemia or restores normoglycemia if hypoglycemia has occurred.²⁵ In the fed state, carbohydrate ingestion increases the plasma glucose concentration and stimulates insulin release from the pancreatic β cells. The resultant hyperinsulinemia (1) suppresses hepatic glucose production and (2) stimulates glucose uptake by peripheral tissues.^{22,26} The majority (~80%–85%) of glucose that is taken up by peripheral tissues is disposed of in muscle,^{22,26} with only a small amount (~4%–5%) being metabolized by adipocytes. In the fed state, glucagon is suppressed.²⁵

Although fat tissue is responsible for only a small amount of total body glucose disposal, it plays a very important role in the maintenance of total body glucose homeostasis. Small increments in the plasma insulin concentration exert a potent antilipolytic effect, leading to a marked reduction in the plasma free fatty acid (FFA) level. The decline in plasma FFA concentration results in increased glucose uptake in muscle²⁷ and reduces hepatic glucose production.²⁸ Thus a decrease in the plasma FFA concentration lowers plasma glucose by both decreasing its production and enhancing the uptake in muscle.^{20,29}

Type 2 diabetic individuals are characterized by (1) defects in insulin secretion; and (2) insulin resistance involving muscle, liver, and the adipocyte. Insulin resistance is present even in *lean* type 2 diabetic individuals (Fig. 77-5).

Impaired Insulin Secretion The pancreas in people with a normal-functioning β cell is able to adjust its secretion of insulin to maintain normal glucose tolerance. Thus in nondiabetic individuals, insulin is increased in proportion to the severity of the insulin resistance, and glucose tolerance remains normal. Impaired insulin secretion is a uniform finding in type 2 diabetic patients and the evolution of β -cell dysfunction has been well characterized in diverse ethnic populations.

FIGURE 77-5. Whole body glucose disposal, a measure of insulin resistance, is reduced 40% to 50% in obese nondiabetic and lean type 2 diabetic individuals. Obese diabetic individuals are slightly more resistant than lean diabetic patients. (T2DM, type 2 diabetes mellitus.) (Copyright © 1988 American Diabetes Association. From *Diabetes*, Vol. 37, 1988;667–687. Reprinted with permission from The American Diabetes Association.)

FIGURE 77-6. The relationship between fasting plasma insulin and fasting plasma glucose in 177 normal weight individuals. Plasma insulin and glucose increase together up to a fasting glucose of 140 mg/dL. When the fasting glucose exceeds 140 mg/dL, the β cell makes progressively less insulin, which leads to an overproduction of glucose by the liver and results in a progressive increase in fasting glucose. (Adapted from DeFronzo,³⁰ with permission.)

DeFronzo and colleagues³⁰ measured the fasting plasma insulin concentration and performed OGTTs in 77 normal-weight type 2 diabetic patients and more than 100 lean subjects with normal or impaired glucose tolerance (Fig. 77-6). The relationship between the FPG concentration and the fasting plasma insulin concentration resembles an inverted U or horseshoe. As the FPG concentration increases from 80 to 140 mg/dL, the fasting plasma insulin concentration increases progressively, peaking at a value that is 2- to 2.5-fold greater than in normal weight nondiabetic controls. When the FPG concentration exceeds 140 mg/dL, the β cell is unable to maintain its elevated rate of insulin secretion, and the fasting insulin concentration declines precipitously. This decrease in fasting insulin leads to an increase in hepatic glucose production overnight, which results in an elevated FPG concentration.³⁰

In the type 2 diabetic patient, decreased postprandial insulin secretion is caused by both impaired pancreatic β -cell function and a reduced stimulus for insulin secretion from gut hormones. The role gut hormones play in insulin secretion is best shown by comparing the insulin response to an oral glucose load versus an isoglycemic intravenous glucose infusion.³¹ In nondiabetic control individuals 73% more insulin is released in response to an oral glucose load compared to the same amount of glucose given intravenously (Fig. 77-7, left panel). This increased insulin secretion in response to an oral glucose stimulus is referred to as *the incretin effect* and suggests

that gut derived hormones when stimulated by glucose lead to an increase in pancreatic insulin secretion. In type 2 diabetic patients this incretin effect is blunted, with the increase in insulin secretion to only 50% of that seen in nondiabetic control individuals (Fig. 77-7).³¹ It is now known that two hormones, glucagon-like peptide-1 (GLP-1) and glucose-dependent insulin-releasing peptide (GIP), are responsible for more than 90% of the increased insulin secretion seen in response to an oral glucose load. In patients with type 2 diabetes GLP-1 levels are reduced whereas GIP levels are increased.³²

GLP-1 is secreted from the L-cells in the distal intestinal mucosa in response to mixed meals. Because GLP-1 levels increase within minutes of food ingestion, neural signals initiated by food entry in the proximal gastrointestinal tract must stimulate GLP-1 secretion.³³ The insulinotropic action of GLP-1 is glucose-dependent, and for GLP-1 to enhance insulin secretion, glucose concentrations must be higher than 90 mg/dL.³² In addition to stimulating insulin secretion, GLP-1 suppresses glucagon secretion, slows gastric emptying and reduces food intake by increasing satiety. These effects of GLP-1 combine to limit postprandial glucose excursions. GIP is secreted by K-cells in the intestine and like GLP, increase insulin secretion.³⁴ However, GIP has no effect on glucagon secretion, gastric motility, or satiety.³⁵ The half-life of GLP-1 and GIP are short (<10 minutes). Both hormones are rapidly inactivated by removal of two N-terminal amino acids by the enzyme, dipeptidyl peptidase IV (DPP-IV).³⁶

Site of Insulin Resistance in Type 2 Diabetes

Liver In type 2 diabetic subjects with mild to moderate fasting hyperglycemia (140 to 200 mg/dL, 7.8 to 11.1 mmol/L), basal hepatic glucose production is increased by ~0.5 mg/kg per minute. Consequently, during the overnight sleeping hours the liver of an 80-kg diabetic individual with modest fasting hyperglycemia adds an additional 35 g of glucose to the systemic circulation. This increase in fasting hepatic glucose production is the cause of fasting hyperglycemia.²²

Following glucose ingestion, insulin is secreted into the portal vein and carried to the liver, where it suppresses glucagon secretion and reduces hepatic glucose output. Type 2 diabetic patients fail to suppress glucagon in response to a meal and can even have a paradoxical rise in glucagon levels.^{36,37} Thus, hepatic insulin resistance and hyperglucagonemia result in continued production of glucose by the liver. Therefore, type 2 diabetic patients have two sources of glucose in the postprandial state, one from the diet and one from continued glucose production from the liver. These sources of glucose in combination with a shortened gastric emptying time can result in marked hyperglycemia.

Peripheral (Muscle) Muscle is the major site of glucose disposal in man, and approximately 80% of total body glucose uptake occurs

FIGURE 77-7. The loss of the incretin effect in type 2 diabetes mellitus. The plasma insulin responses to oral and intravenous glucose in nondiabetic subjects (left figure), compared to patients with diabetes (right figure). (Adapted from Nauck M, Stockmann F, Ebert R, Creutzfeldt W. Reduced incretin effect in type 2 [non-insulin dependent] diabetes. *Diabetologia* 1986;29:46–52.)

in skeletal muscle.²² In response to a physiologic increase in plasma insulin concentration, muscle glucose uptake increases linearly, reaching a plateau value of 10 mg/kg per minute. In contrast, in lean type 2 diabetic subjects, the onset of insulin action is delayed for ~40 minutes, and the ability of insulin to stimulate leg glucose uptake is reduced by 50%. Therefore the primary site of insulin resistance in type 2 diabetic subjects resides in muscle tissue.

Peripheral (Adipocyte) In obese nondiabetic and diabetic humans, basal plasma FFA levels are increased and fail to suppress normally after glucose ingestion. FFAs are stored as triglycerides in adipocytes and serve as an important energy source during conditions of fasting. Insulin is a potent inhibitor of lipolysis, and restrains the release of FFAs from the adipocyte by inhibiting the hormone-sensitive lipase enzyme. It is now recognized that chronically elevated plasma FFA concentrations can lead to insulin resistance in muscle and liver,^{20,22,27,38} and impair insulin secretion.^{29,39,40} In addition to FFAs that circulate in plasma in increased amounts, type 2 diabetic and obese nondiabetic individuals have increased stores of triglycerides in muscle^{41,42} and liver,^{43,44} and the increased fat content correlates closely with the presence of insulin resistance in these tissues.

In summary, insulin resistance involving both muscle and liver are characteristic features of the glucose intolerance in type 2 diabetic individuals. In the basal state, the liver represents a major site of insulin resistance, and this is reflected by overproduction of glucose. This accelerated rate of hepatic glucose output is the primary determinant of the elevated FPG concentration in type 2 diabetic individuals. In the fed state, both decreased muscle glucose uptake and impaired suppression of hepatic glucose production contribute to the insulin resistance. In obese individuals and in the majority (>80%) of type 2 diabetic subjects, there is an expanded fat cell mass, and the adipocytes are resistant to the antilipolytic effects of insulin. Most obese and diabetic individuals are characterized by expanded visceral adiposity, discussed in detail later in the chapter, which is especially refractory to insulin effects and results in a high lipolytic rate. Not surprisingly, both type 2 diabetes and obesity are characterized by an elevation in the mean 24-hour plasma FFA concentration. Elevated plasma FFA levels, as well as increased triglyceride/fatty acyl coenzyme A (CoA) content in muscle, liver, and β cells, lead to the development of muscle/hepatic insulin resistance and impaired insulin secretion.

Cellular Mechanisms of Insulin Resistance

Insulin resistance and the components of the insulin resistance syndrome are described below.

Obesity and Insulin Resistance Weight gain leads to insulin resistance, and obese nondiabetic individuals have the same degree of insulin resistance as lean type 2 diabetic patients.⁴⁵ In 1,146 nondiabetic, normotensive individuals, Ferrannini and associates showed a progressive loss of insulin sensitivity when the BMI increased from 18 kg/m² to 38 kg/m².⁴⁶ The increase in insulin resistance with weight gain is directly related to the amount of visceral adipose tissue.^{47,48}

The term *visceral adipose tissue* (VAT) refers to fat cells located within the abdominal cavity and includes omental, mesenteric, retroperitoneal, and perinephric adipose tissue. VAT has been shown to correlate with insulin resistance and explain much of the variation in insulin resistance seen in a population of African Americans.⁴⁹ Visceral adipose tissue represents 20% of fat in men and 6% of fat in women. This fat tissue has been shown to have a higher rate of lipolysis than subcutaneous fat, resulting in an increase in FFA production. These fatty acids are released into the portal circulation and drain into the liver, where they stimulate the production of very-low-density lipoproteins and decrease insulin sensitivity in peripheral tissues.⁴⁷ VAT also produces a number of cytokines that cause insulin

resistance. These factors drain into the portal circulation and reduce insulin sensitivity in peripheral tissues.⁵⁰

The fat cell also has the capability of producing at least one hormone that improves insulin sensitivity: adiponectin. This factor is made in decreasing amounts as an individual becomes more obese.^{51,52} In animal models, adiponectin decreases hepatic glucose production and increases fatty acid oxidation in muscle.^{53,54}

The Metabolic Syndrome The association of insulin resistance with a clustering of cardiovascular risk factors including hyperinsulinemia, hypertension, abdominal obesity, dyslipidemia, and coagulation abnormalities has been referred to by a variety of names including “the insulin resistance syndrome,” “the metabolic syndrome,” “the dysmetabolic syndrome,” and “the deadly quartet,” to name a few. Since the description of the “insulin resistance syndrome” by Reaven in 1988,⁵⁵ the number of associated factors has continued to grow.

The most recent definition of the metabolic syndrome was adopted by the International Diabetes Federation (IDF) in 2005 (Table 77-5).⁵⁶

In the IDF definition of the metabolic syndrome, central obesity is recognized as an important causative factor and is a prerequisite component for the diagnosis. Central obesity can be easily assessed

TABLE 77-5 NCEP ATP III: Five Components of the Metabolic Syndrome (Individuals Having at Least Three Components Meet the Criteria for Diagnosis)

Risk Factor	Defining Level
Abdominal obesity	Waist circumference
Men	>102 cm (>40 in)
Women	>88 cm (>35 in)
Triglycerides	≥150 mg/dL
High-density-lipoprotein C	
Men	<40 mg/dL
Women	<50 mg/dL
Blood pressure	≥130/≥85 mm Hg
Fasting glucose	≥110 mg/dL
The 2005 IDF definition of metabolic syndrome	
For a person to be defined as having the metabolic syndrome they must have:	
Central obesity (defined as waist circumference >94 cm for Europid men and >80 cm for Europid women, with <i>ethnicity specific values for other groups</i>)	
Plus any two of the following four factors:	
1. Raised TG level: >150 mg/dL (1.7 mmol/L), or specific treatment for this lipid abnormality	
2. Reduced HDL cholesterol: <40 mg/dL (1.03 mmol/L) in males and <50 mg/dL (1.29 mmol/L) in females, or specific treatment for this lipid abnormality	
3. Raised blood pressure: systolic BP >130 or diastolic BP >85 mm Hg, or treatment of previously diagnosed hypertension	
4. Raised FPG >100 mg/dL (5.6 mmol/L), or previously diagnosed type 2 diabetes	
If above 5.6 mmol/L or 100 mg/dL, OGTT is strongly recommended but is not necessary to define the presence of the syndrome.	
Ethnic specific values for waist circumference	
Country/Ethnic Group	Waist Circumference
Europids	
Men	>94 cm
Women	>80 cm
South Asians, Chinese	
Men	>90 cm
Women	>80 cm
Japanese	
Men	>85 cm
Women	>90 cm

ASP III, Adult Treatment Panel III; BP, blood pressure; FPG, fasting plasma glucose; HDL, high-density lipoprotein; OGTT, oral glucose tolerance test; TG, triglyceride.

In the United States, the ATP III values (102 cm male, 88 cm female) are still being used. European cut points are recommended for sub-Saharan Africans and Eastern Mediterranean and Middle East (Arab) populations. South Asian values are recommended for South and Central Americans.

Reproduced from Expert Panel on Detection.¹⁵⁹

using waist circumference. The IDF has made a “first attempt” to provide ethnic group specific cut points for waist circumference. At the present time these are pragmatic estimates taken from various data sources. As more complete data becomes available these values can be modified. Table 77–5 lists the ethnic specific values for waist circumference.

The evolution of definitions of the metabolic syndrome is a result of accumulating data correlating degree of risk and specific metabolic abnormalities in various populations. As more robust data sets become available, future changes in the component cut points will be warranted.

Prevalence. Regardless of the definition used, large numbers of U.S. adults have the metabolic syndrome. The National Health and Nutrition Examination Survey (NHANES) 1999 to 2002 is the most scientifically rigorous sample of the U.S. population.⁵⁷ A total of 3,601 men and women aged >20 years were included in the survey. Using the National Cholesterol Education Program (NCEP) definition, the prevalence of metabolic syndrome was 33.7% of men and 35.4% of women. In comparison the prevalence using the IDF definition was 39.9% of men and 38.1% of women. The largest difference in prevalence was found in Mexican American men among whom the age-adjusted prevalence was 40.3% using the NCEP definition and 50.6% using the IDF definition. The percent agreement between the two definitions was 89.8% among men and 96% among women.

In a sample of 4,060 predominantly European adults from South Australia, the metabolic syndrome was present in 19.4% of men and 14.4% of women using the Adult Treatment Panel III (ATP III) definition.⁵⁸ Using the IDF definition, the metabolic syndrome was identified in 26.4% of men and 15.7% of women. In this population the IDF, using a smaller waist circumference, categorized 15 to 20% more individuals as having the metabolic syndrome. Although the prevalence of the metabolic syndrome in these surveys is staggering, these data are now more than 8 years old, and the prevalence has almost certainly increased as these populations age and become more obese.

The impact of treating the clinical components of the metabolic syndrome was demonstrated in the Steno-2 Study.⁵⁹ In this prospective study, 63 patients with diabetes and microalbuminuria were randomized to the usual therapy group, and 67 patients were treated intensively. Intensive therapy consisted of diet and exercise and pharmacologic intervention aimed at hyperglycemia, hypertension, dyslipidemia, microalbuminuria, and increased coagulopathy (aspirin therapy). Treatment goals for intensive therapy included a blood pressure <130/80 mm Hg, HbA_{1c} <6.5%, total cholesterol <175 mg/dL, and triglycerides <150 mg/dL. All patients in the intensive treatment group were given an aspirin and treated with an angiotensin-converting enzyme (ACE) inhibitor. Patients in the intensively treated group showed a 53% relative risk reduction in cardiovascular disease and a 61% relative risk reduction in nephropathy. In this small study, the magnitude of this reduction is greater than has been demonstrated with individual interventions, stressing the importance of targeting all the components of the metabolic syndrome. The study design did not allow conclusions regarding which interventions had the most impact.

CLINICAL PRESENTATION

The clinical presentations of type 1 DM and type 2 DM are very different (Table 77–6). Autoimmune type 1 DM can occur at any age. Approximately 75% will develop the disorder before age 20 years, but the remaining 25%, including relatives of index patients, develop the disease as adults. Individuals with type 1 DM are often thin and are prone to develop diabetic ketoacidosis if insulin is

TABLE 77-6 Clinical Presentation of Diabetes Mellitus^a

Characteristic	Type 1 DM	Type 2 DM
Age	<30 years ^b	>30 years ^b
Onset	Abrupt	Gradual
Body habitus	Lean	Obese or history of obesity
Insulin resistance	Absent	Present
Autoantibodies	Often present	Rarely present
Symptoms	Symptomatic ^c	Often asymptomatic
Ketones at diagnosis	Present	Absent ^d
Need for insulin therapy	Immediate	Years after diagnosis
Acute complications	Diabetic ketoacidosis	Hyperosmolar hyperglycemic state
Microvascular complications at diagnosis	No	Common
Macrovascular complications at or before diagnosis	Rare	Common

DM, diabetes mellitus.

^aClinical presentation can vary widely.

^bAge of onset for type 1 DM is generally <20 years of age but can present at any age. The prevalence of type 2 DM in children, adolescents, and young adults is increasing. This is especially true in ethnic and minority children.

^cType 1 can present acutely with symptoms of polyuria, nocturia, polydipsia, polyphagia, and weight loss.

^dType 2 children and adolescents are more likely to present with ketones but after the acute phase can be treated with oral agents. Prolonged fasting can also produce ketones in individuals.

withheld, or under conditions of severe stress with an excess of counterregulatory hormones.² Twenty to forty percent of patients with type 1 DM present with diabetic ketoacidosis after several days of polyuria, polydipsia, polyphagia, and weight loss. Occasionally, patients are diagnosed as short of “metabolic bankruptcy” when they have blood tests drawn for other reasons or for early symptoms. Because newly diagnosed patients with type 1 DM often have a small amount of residual pancreatic β -cell function, they can enter a “honeymoon” phase, when their blood glucose concentrations are relatively easy to control and small amounts of insulin are needed. Once this residual insulin secretion wanes, the patients are completely insulin deficient and tend to have more labile glycemia.

Patients with type 2 DM often present without symptoms, even though complications tell us that they may have had type 2 DM for several years.¹⁰ Often these patients are diagnosed secondary to unrelated blood testing. Lethargy, polyuria, nocturia, and polydipsia can be seen at diagnosis in type 2 diabetes, but significant weight loss at diagnosis is less common.

TREATMENT

DM

■ DESIRED OUTCOME

5 The primary goals of DM management are to reduce the risk for microvascular and macrovascular disease complications, to ameliorate symptoms, to reduce mortality, and to improve quality of life.⁸ Near-normal glycemia will reduce the risk for development of microvascular disease complications, but aggressive management of traditional cardiovascular risk factors (i.e., smoking cessation, treatment of dyslipidemia, intensive blood pressure control, and antiplatelet therapy) are needed to reduce the likelihood of development of macrovascular disease. Evidence-based guidelines, as published by the ADA, can help in the attainment of these goals (Table 77–7).

Hyperglycemia not only increases the risk for microvascular disease, but contributes to poor wound healing, compromises white blood cell function, and leads to classic symptoms of DM. Diabetic ketoacidosis and hyperosmolar hyperglycemic state are severe manifestations of poor diabetes control, invariably requiring hospitaliza-

TABLE 77-7 Selected American Diabetes Association Evidence-Based Recommendations^a

Recommendation Area	Specific Recommendation	Evidence Level ^a
Screening for diabetes	Screen overweight at 45 years old, repeat at 3-year intervals	E
	Screen with fasting plasma glucose or 2-hour 75-g OGTT	B
Monitoring	Home blood-glucose monitoring is needed if on insulin	A
	Subjects on other therapeutic interventions, including oral agents may need home blood glucose monitoring	E
	Quarterly HbA _{1c} in individuals not meeting glycemic goals, twice yearly in individuals meeting glycemic goals should be performed	E
Glycemic goals	HbA _{1c} goal for patients in general is <7%	B
	HbA _{1c} goal for individuals is as close to normal (<6%) as possible without significant hypoglycemia	E
Treatment		
Medical nutrition therapy	Weight loss is recommended for all insulin-resistant/overweight or obese individuals	A
	Saturated fat should be <7% of total calories	A
	Monitoring carbohydrate intake by carbohydrate counting or exchanges is recommended.	A
	Glycemic index can give modest benefits over total carbohydrate intake.	B
	Low-carbohydrate diets (<130 g of carbohydrate) are not currently recommended as long-term effects are unknown	B
Physical activity	150 min/wk of moderate intensity exercise is recommended or 90 minutes of vigorous exercise per week	A
	Resistance-train large muscle groups 3 times per week	A
Blood pressure	Systolic blood pressure should be treated to <130 mm Hg	C
	Diastolic blood pressure should be treated to <80 mm Hg	B
	Initial drug therapy should be with an ACE inhibitor, angiotensin receptor blocker, diuretic, β -blocker, or calcium channel blocker	A
Nephropathy	Type 1 DM with any degree of albuminuria—ACE inhibitor	A
	Type 2 DM with microalbuminuria—ACE inhibitor or angiotensin receptor blocker	A
	Type 2 DM with macroalbuminuria—angiotensin receptor blocker	A
Dyslipidemia	The primary goal is an LDL<100 mg/dL	A
	If 40 years of age or older, statin therapy to reduce LDL 30–40%, regardless of baseline LDL, is recommended	A
	LDL<70 mg/dL is an optional goal in individuals with overt cardiovascular (CV) disease	C
	Triglycerides should be lowered to <150 mg/dL	C
	Increase HDL to >40 mg/dL in men and >50 mg/dL in women	C
Antiplatelet	Use aspirin (75–162 mg daily) for secondary cardioprotection	A
	Use aspirin (75–162 mg) for primary prevention in type 2 DM if the subject is >40 years old or has additional CV risks	A
	Use aspirin (75–162 mg) for primary prevention in type 1 DM if the subject is >40 years old or has additional CV risks	C

ACE, angiotensin-converting enzyme; DM, diabetes mellitus; HbA_{1c}, glycosylated hemoglobin; HDL, high-density lipoprotein; LDL, low-density lipoprotein; OGTT, oral glucose tolerance test.

^aEvidence levels: A, Clear evidence from well-conducted, generalizable, randomized controlled trials that are adequately powered; B, supportive evidence from well-conducted cohort studies or well-conducted case-control study; C, supportive evidence from poorly controlled or uncontrolled studies or conflicting evidence with weight of evidence supporting intervention; and E, expert consensus or clinical experience. Based on American Diabetes Association Practice Recommendations.⁸

tion. Reducing the potential for microvascular complications is targeted at adherence to therapeutic lifestyle intervention (i.e., diet and exercise programs) and drug-therapy regimens, as well as at maintaining blood pressure as near normal as possible.

■ GENERAL APPROACH TO TREATMENT

Appropriate care requires goal setting for glycemia, blood pressure, and lipid levels, regular monitoring for complications, dietary and exercise modifications, medications, appropriate self-monitored blood glucose (SMBG), and laboratory assessment of the aforementioned parameters.⁸ Glucose control alone does not sufficiently reduce the risk of macrovascular complications in persons with DM.

■ GLYCEMIC GOAL SETTING AND THE HEMOGLOBIN A_{1c}

Controlled clinical trials provide ample evidence that glycemic control is paramount in reducing microvascular complications in both type 1 DM⁶⁰ and type 2 DM.⁶¹ HbA_{1c} measurements are the gold standard for following long-term glycemic control for the previous 2 to 3 months.⁶² Hemoglobinopathies, anemia, and red cell membrane defects can affect HbA_{1c} measurements. Other strategies such as measurement of fructosamine, which measures glycated plasma proteins and correlates to glucose control over the last 2 to 3 weeks, can be necessary to assess diabetes control in these patients. Unless the risk outweighs the benefit (as in elderly patients, patients with advanced complications, and patients with other advanced disease), a HbA_{1c} target of <7% is appropriate (Table 77–8), and

lower values should be targeted if significant hypoglycemia and/or weight gain can be avoided.⁸

■ MONITORING COMPLICATIONS

The ADA recommends initiation of complications monitoring at the time of diagnosis of DM.⁸ Current recommendations continue to advocate yearly dilated eye examinations in type 2 DM, and an initial eye examination in the first 3 to 5 years in type 1 DM, then yearly thereafter. Less frequent testing (every 2 to 3 years) can be implemented on the advice of an eye care specialist. The feet should be examined and the blood pressure assessed at each visit. A urine test for microalbumin once yearly is appropriate. Yearly testing for lipid abnormalities, and more frequently if needed to achieve lipid goals, is recommended.

TABLE 77-8 Glycemic Goals of Therapy

Biochemical Index	ADA	ACE and AACE
Hemoglobin A _{1c}	<7% ^a	≤6.5%
Preprandial plasma glucose	90–130 mg/dL (5.0–7.2 mmol/L)	<110 mg/dL
Postprandial plasma glucose	<180 mg/dL ^b (<10 mmol/L)	<140 mg/dL

ADA, American Diabetes Association; ACE, American College of Endocrinology; AACE, American Association of Clinical Endocrinologists; DCCT, Diabetes Control and Complications Trial.

^aReferenced to a nondiabetic range of 4.0–6.0% using a DCCT-based assay. More stringent glycemic goals (i.e., a normal HbA_{1c}, <6%) can further reduce complications at the cost of increased risk of hypoglycemia (particularly in those with type 1 diabetes).

^bPostprandial glucose measurements should be made 1–2 hours after the beginning of the meal, generally the time of peak levels in patients with diabetes.

■ SELF-MONITORING OF BLOOD GLUCOSE

The advent of SMBG in the early 1980s revolutionized the treatment of DM, enabling patients to know their blood glucose concentration at any moment easily and relatively inexpensively. Frequent SMBG is necessary to achieve near-normal blood glucose concentrations and to assess for hypoglycemia, particularly in patients with type 1 DM.⁶² The more intense the pharmacologic regimen is, the more intense the SMBG needs to be (four or more times daily in patients on multiple insulin injections or pump therapy). The optimal frequency of SMBG for patients with type 2 DM is unresolved. Frequency of monitoring in type 2 DM should be sufficient to facilitate reaching glucose goals. The role of SMBG in improving glycemic control in type 2 DM patients is controversial but has shown to reduce the HbA_{1c} ~0.4%.⁶³ What is clear is that patients must be empowered to change their therapeutic regimen (lifestyle and medications) in response to test results, or no meaningful glycemic improvement is likely to be effected.

CLINICAL CONTROVERSY

SMBG improves glycemic control when insulin is used, but few well-conducted studies have shown significant glycemic reductions with increasing use of home blood-glucose testing for type 2 DM patients not on insulin. In a recent review, the average HbA_{1c} reduction with use of SMBG in type 2 DM patients not on insulin was 0.4%, although others have reported no glycemic improvement.⁶³ Patients must be empowered to change their therapeutic regimen (lifestyle and medications) in response to test results, or no meaningful glycemic improvement is likely to be effected, and thus the money spent on the strip is wasted.

■ NONPHARMACOLOGIC THERAPY

Diet

Medical nutrition therapy is recommended for all persons with DM.⁶⁴ Paramount for all medical nutrition therapy is the attainment of optimal metabolic outcomes and the prevention and treatment of complications. For individuals with type 1 DM, the focus is on regulating insulin administration with a balanced diet to achieve and maintain a healthy body weight. A meal plan that is moderate in carbohydrates and low in saturated fat (<7% of total calories), with a focus on balanced meals is recommended. The amount (grams) and type (via the glycemic index, although controversial) of carbohydrates, whether accounted for by exchanges or carbohydrate counting, should be considered.⁶⁴ It is imperative that patients understand the connection between carbohydrate intake and glucose control. In addition, patients with type 2 DM often require caloric restriction to promote weight loss. Rather than a set diabetic diet, advocate a diet using foods that are within the financial reach and cultural milieu of the patient. As most patients with type 2 DM are overweight or obese, bedtime and between-meal snacks are not needed if pharmacologic management is appropriate.

CLINICAL CONTROVERSY

The recommended daily carbohydrate intake for type 2 DM, and even type 1 DM, has become controversial since low-carbohydrate diets such as the Atkins, South Beach, and Carbohydrate Addict's Diets have become exceptionally popular. Currently, the ADA recommends that approximately 45% to 65% of daily caloric intake should come from carbohydrates and does not recommend restricting diets to <130 grams of carbohydrate a day. Many clinicians are trying to increase the monounsaturated

fat percentage and decrease the carbohydrate percentage in a patient's diet to accomplish improved glycemic control. Recent studies have documented short-term success for weight loss on low-carbohydrate diets (~6 months), without deleterious effects on the lipid panel. Weight loss can reduce cardiovascular risk factors in type 2 DM.

Activity

In general, most patients with DM can benefit from increased activity.⁶⁵ Aerobic exercise improves insulin resistance and glycemic control in the majority of individuals, and reduces cardiovascular risk factors, contributes to weight loss or maintenance, and improves well-being. The patient should choose an activity that she or he is likely to continue. Start exercise slowly in previously sedentary patients. Older patients, patients with long-standing disease (age >35 years, or >25 years with DM ≥10 years), patients with multiple cardiovascular risk factors, presence of microvascular disease, and patients with previous evidence of atherosclerotic disease should have a cardiovascular evaluation, probably including an electrocardiogram and graded exercise test with imaging, prior to beginning a moderate to intense exercise regimen. In addition, several complications (autonomic neuropathy, insensate feet, and retinopathy) can require restrictions on the activities recommended. Physical activity goals include at least 150 minutes/week of moderate (50%–70% maximal heart rate) intensity exercise. In addition, resistance training, in patients without retinal contraindications, is recommended for 30 minutes three times per week.

■ PHARMACOLOGIC THERAPY

Until 1995, only two options for pharmacologic treatment were available for patients with diabetes; sulfonylureas (for type 2 DM only) and insulin (for type 1 or 2). Since 1995, a number of new oral agents, injectables, and insulins have been introduced in the United States.

Currently, six classes of oral agents are approved for the treatment of type 2 diabetes: α -glucosidase inhibitors, biguanides, meglitinides, peroxisome proliferator-activated receptor γ -agonists (which are also commonly identified as thiazolidinediones [TZDs] or glitazones), DPP-IV inhibitors, and sulfonylureas. Oral antidiabetic agents are often grouped according to their glucose-lowering mechanism of action. Biguanides and TZDs are often categorized as insulin sensitizers because of their ability to reduce insulin resistance. Sulfonylureas and meglitinides are often categorized as insulin secretagogues because they enhance endogenous insulin release.

New options for implementation of insulin therapy are now available. Detemir has given an additional option for choice of basal insulin for type 1 and 2 DM patients. Exubera, the first inhaled prandial insulin, was FDA approved, but has been withdrawn from the market due to poor sales. The subsequent sections describe the current antidiabetic medications that are available to treat type 1 and type 2 DM.

Drug Class Information

Insulin Pharmacology. Insulin is an anabolic and anticatabolic hormone. It plays major roles in protein, carbohydrate, and fat metabolism. For a complete review of insulin action, the reader is referred to a diabetes physiology text.⁶⁶ Endogenously produced insulin is cleaved from the larger proinsulin peptide in the β cell to the active peptide of insulin and C-peptide, which can be used as a marker for endogenous insulin production. All commercially available insulin preparations contain only the active insulin peptide.

TABLE 77-9 Available Injectable and Insulin Preparations

Trade/Generic Name	Manufacturer	Analog ^a	Administration Options	Room Temperature ^b Expiration
Rapid-acting insulins				
Humalog (insulin lispro)	Lilly	Yes	Insulin pen 3-mL, vial, and 3-mL pen cartridge	28 days
NovoLog (insulin aspart)	Novo-Nordisk	Yes	Insulin pen 3-mL, vial, or 3-mL pen cartridge	28 days
Apidra (insulin glulisine)	Sanofi-Aventis	Yes	3-mL, pen cartridge or Opticlick pen system	28 days
Exubera (inhaled human insulin)	Pfizer	No	1 and 3-mg blister packs	3 months once foil overwrap opened
Short-acting insulins				
Humulin R (regular; human insulin rDNA)	Lilly	No	100 units, 10-mL vial 500 units, 20-mL vial	28 days
Novolin R (regular; human insulin rDNA)	Novo-Nordisk	No	Insulin pen, vial, or 3-mL pen cartridge, and InnoLet ^d	Vial: 30 days; others: 28 days
Intermediate-acting insulins				
NPH				
Humulin N	Lilly	No	Vial, prefilled pen	Vial: 28 days; pen: 14 days

NPH, neutral protamine Hagedorn.

^aAll insulins available in the United States are now made by human recombinant DNA technology. An insulin analog is a modified human insulin molecule that imparts particular pharmacokinetic advantages.

^bRoom temperature defined as 15–30°C (59–86°F).

^cInnoLet: A prefilled insulin pen with a “kitchen timer” type of dial for determining the number of insulin units. Can be useful in patients with impaired eyesight or dexterity.

Adapted from the Texas Diabetes Council.

Characteristics. Characteristics that are commonly used to categorize insulins include source, strength, onset, and duration of action. Additionally, insulins can be characterized as analogs, defined as insulins that have had amino acids within the insulin molecule modified to impart particular physiochemical and pharmacokinetic advantages. Table 77–9 summarizes available insulin preparations.

The strengths of injectable insulin currently available in the United States are 100 units/mL (U-100) and 500 units/mL (U-500). For individuals who require large doses of insulin to control their diabetes, 500 units/mL regular insulin is available. In the United States, all other insulins are available only in 100 units/mL strength. For some type 1 diabetes patients who require extremely low doses of insulin, dilution of 100 units/mL insulin to obtain accurate insulin doses can be necessary. Diluents and empty bottles can be obtained from the manufacturers for dilution.

Historically, insulin came from either beef or pork sources. Beef insulin differs by three amino acids and pork by one amino acid when compared to human insulin. Manufacturers in the United States have discontinued production of beef and pork source insulins as of December 2003, and now exclusively use recombinant DNA (rDNA) technology to manufacture insulin. Eli Lilly, Pfizer, and Sanofi-Aventis currently use a non-disease-producing strain of *Escherichia coli* for synthesis of insulin, whereas Novo Nordisk uses *Saccharomyces cerevisiae*, or bakers' yeast, for synthesis.

Purity of insulin refers to the amount of proinsulin and other impurities present in a given insulin product. Prior to 1980, most insulin contained enough impurities (300 to 10,000 ppm) to cause local reactions on injection, as well as systemic adverse effects from antibody production. Modern technology has provided less expensive techniques to purify insulin. As a result, all insulin products contain ≤ 10 ppm of proinsulin, with purified preparations (all rDNA human insulin and insulin analogs) containing < 1 ppm of proinsulin.

Regular crystalline insulin naturally self-associates into a hexameric (six insulin molecules) structure when injected subcutaneously. Before absorption through a blood capillary can occur, the hexamer must dissociate first to dimers, and then to monomers. This principle is the premise for additives such as protamine and zinc described below, and modification of amino acids for insulin analogs. Lispro, aspart, and glulisine insulins dissociate rapidly to monomers, thus absorption is rapid. Lispro (B-28 lysine and B-29 proline human insulin; monomeric) insulin with two amino acids transposed, aspart (B-28 aspartic acid human insulin; mono- and dimeric) insulin with replacement of one amino acid, and glulisine (B-3 lysine and B-29 glutamic acid) are rapidly absorbed, peak faster, and have shorter durations of action when compared to regular insulin. In comparison to human insulin, with an isoelectric point of 5.4, the analog glargine insulin (A-21 glycine, B-30a-arginine, B-30a L-arginine, and B-30b L-arginine human insulin) has an isoelectric point of 6.8. In the bottle,

glargine is buffered to a pH of 4, a level at which it is completely soluble, resulting in a clear colorless solution. When injected into the neutral pH of the body, it rapidly forms microprecipitates that slowly dissolve into monomers and dimers which are then subsequently absorbed. The result is a long-acting, peakless, 24-hour duration insulin analog. Detemir, in contrast, attaches a C14 fatty acid (a 14 carbon fatty acid) at the B-29 position and removes the B-30 amino acid. This allows the fatty acid side chain to bind to interstitial albumin at the subcutaneous injection site. Also, the formulation allows stronger hexamer (six molecules of insulin associated together) associations, which prolong absorption. Once detemir dissociates from the interstitial albumin, it is free to enter a capillary, where it is again bound to albumin. It then travels to a site of action and interacts, after dissociation from albumin, with insulin receptors.

Insulin analogs are modified human insulin molecules, and safety is paramount for FDA approval. Key factors that should be considered in the approval process include local injection reactions, antigenicity, efficacy compared to human insulin, insulin receptor binding affinity, and insulin-like growth factor 1–receptor affinity (which is compared to that of human insulin to determine mitogenic potential).

Pharmacokinetics. Subcutaneous injection kinetics are dependent on onset, peak, and duration of action, and are summarized in Table 77–10. The pharmacokinetic considerations for Exubera will be discussed later in the section. Absorption of insulin from a subcutaneous depot is dependent on several factors, including: source of insulin, concentration of insulin, additives to the insulin preparations (e.g., zinc, protamine, etc.), blood flow to the area (rubbing of injection area, increased skin temperature, and exercise in muscles near the injection site can enhance absorption), and injection site. Regular or neutral protamine Hagedorn (NPH) insulin is commonly injected in (from most rapid to slowest absorption): abdominal fat, posterior upper arms, lateral thigh area, and superior buttocks area. Insulin analogs, unlike regular or NPH insulin, appear to retain their kinetic profile at all sites of injection. When compared to 100 units/mL insulin, 500 units/mL regular insulin has a delayed onset, peak, and a longer duration of action. Addition of protamine (NPH, insulin lispro protamine [NPL], and aspart protamine suspension) or excess zinc (historically lente or ultralente insulin) will delay onset, peak, and duration of the insulin's effect. Variability in absorption, inconsistent suspension of the insulin by the patient or healthcare provider when drawing up a dose, and inherent insulin action based on the pharmacokinetics of the products can all contribute to a labile glucose response. NPH should be inverted or rolled gently at least 10 times to fully resuspend the insulin prior to each use.

As detemir has a unique mechanism to prolong absorption, it should not be surprising that its pharmacokinetics are unique. The onset of detemir is consistent across doses, but the peak is delayed slightly with higher dosing. Also, at low dose (0.2 units/kg) the duration of action is approximately 14 hours, whereas at higher doses it is close to 24 hours.

The half-life of an intravenous (IV) injection of regular insulin is approximately 9 minutes. Thus the effective duration of action of a single IV injection is short, and changes in IV insulin rates will reach steady state in approximately 45 minutes. Intravenous pharmacokinetics of other soluble insulins (lispro, aspart, glulisine, and even glargine) appear similar to IV regular insulin, but they have no advantages over IV regular insulin and are more expensive.

Insulin is degraded in the liver, muscle, and kidney. Liver deactivation is 20% to 50% in a single passage. Approximately 15% to 20% of insulin metabolism occurs in the kidney. This can partially explain the lower insulin dosage requirements in patients with end-stage renal disease.

Human Insulin (rDNA Origin) Inhalation Powder (Exubera)

Due to poor sales, Exubera was recently discontinued, and subjects were asked to be switched to alternative treatments. Exubera was the first inhaled insulin, and was formulated to easily reach the alveolar space. Bronchial tubes are impermeable to insulin, but it is easily absorbed across the alveoli. The onset and peak of Exubera insulin after inhalation is similar to rapid-acting insulin analogs, but the duration of action is similar to regular insulin (see Table 77–10). Exubera consists of blister packets labeled as 1 mg or 3 mg of human insulin inhalation powder, which are administered using the Exubera inhaler. After an Exubera blister is inserted into the inhaler, the patient pumps the handle of the inhaler. When the patient presses a “fire” button, the insulin blister is pierced and the insulin inhalation powder is dispersed into the chamber, allowing inhalation. Normally, up to 45% of the 1 mg blister contents and up to 25% of the 3 mg blister contents can be retained in the blister. The 1 mg blister packet is equal to ~3 units of subcutaneously injected insulin and the 3 mg blister packet is equal to ~8 units. One puff of a 3 mg blister is not equivalent to three 1 mg blisters, which will deliver a higher dose of insulin than the one 3 mg blister. Human insulin inhalation powder should be given as prandial insulin, and the efficacy is equivalent to rapid-acting injected insulin analogs. Human insulin inhalation powder can be used in type 1 or type 2 DM, though the smallest increment between inhaled doses is equivalent to 2 to 3 units injected subcutaneously. This can restrict the usefulness in many patients with type 1 DM, who may have large reductions in glucose with a single unit of insulin. The following patient populations have relative contraindications to Exubera: chronic smoking in last 6 months, which increases

TABLE 77-10 Pharmacokinetics of Various Insulins Administered Subcutaneously or Inhaled

Type of Insulin	Onset (Hours)	Peak (Hours)	Duration (Hours)	Maximum Duration (Hours)	Appearance
Rapid-acting					
Aspart	15–30 min	1–2	3–5	5–6	Clear
Lispro	15–30 min	1–2	3–4	4–6	Clear
Glulisine	15–30 min	1–2	3–4	5–6	Clear
Inhaled human insulin	15–30 min	1–2	6	8	Powder

NPH, neutral protamine Hagedorn.

^aLente and ultralente insulin has been discontinued.

^bSee text for further discussion.

Adapted from the Texas Diabetes Council.

absorption two- to fivefold when compared to nonsmokers; chronic passive smoke, which reduces absorption of insulin inhalation; asthma, which decreases Exubera absorption, but bronchodilator use prior to insulin inhalation can increase absorption; chronic obstructive pulmonary disease (COPD), which increases the absorption of insulin inhalation; and other chronic lung diseases. A dry cough near inhalation, increased sputum, and dyspnea are the three most common drug-related side effects. Hypoglycemia rates are similar to regular insulin. There was a small, but statistically significant decrease in forced expiratory volume in the first second of expiration (FEV₁) and diffusing capacity of the lung for carbon monoxide (DLCO) in type 1 DM (T1DM) patients treated with Exubera. Two-year safety data indicate that in both T1DM and type 2 DM (T2DM) changes in FEV₁ and DLCO are small (<1%–2% from baseline), occur within the first 3 months of initiation, and the defect is reversible with discontinuation of therapy. A decline in FEV₁ or DLCO of $\geq 20\%$ occurred in 1.5% versus 1.3%, and 5.1% versus 3.6% for Exubera and the comparator group, respectively. Pulmonary function testing is recommended at baseline, after 6 months of therapy, and annually thereafter, even if no symptoms are present. If the FEV₁ or DLCO declines by $\geq 20\%$ on followup testing, the test should be repeated, and if confirmed, Exubera should be discontinued other inhaled insulin systems are in development.⁶⁷ Other inhaled insulin systems are in development.

Efficacy. The efficacy of traditional insulins (e.g., regular and NPH insulins) is unequivocal. Insulin analog efficacy is measured via the same ways as traditional insulins. Insulin analogs in most studies have not shown superior HbA_{1c} levels when compared to traditional insulins but are often preferred by patients and practitioners because of their ability to more closely mimic normal insulin secretion profiles. Lispro, aspart, glulisine, and Exubera are advantageous because of the ability to administer within 10 minutes of a meal, as compared to the recommendation to inject regular insulin approximately 30 minutes prior. Rapid-acting analogs have shown superior postprandial lowering of glucose when compared to regular insulin. Both detemir and glargine insulin injected at bedtime have shown significantly less nocturnal hypoglycemia when compared to NPH injected at bedtime.

An educated patient in conjunction with a skilled practitioner can achieve excellent glycemic control with insulin therapy. Efficacy with insulin therapy is related to achieving glycemic control while minimizing the risk of potential side effects, specifically hypoglycemia and weight gain. Insulin is recommended in patients with: extremely high FPG levels (>280 to 300 mg/dL) or HbA_{1c}, patients with ketonuria or ketonemia, symptomatic patients (weight loss with polyuria, polydipsia, and/or nocturia), GDM, and if deemed appropriate by the clinician and patient.^{68–71}

Microvascular Complications. Insulin has been shown to be as efficacious as any oral agent for treating DM. The UKPDS, which used sulfonylureas or insulin, showed equal efficacy in lowering the risk of microvascular events in newly diagnosed type 2 DM.⁶¹ Similarly, in type 1 DM the DCCT showed efficacy in reducing microvascular complications.⁶⁰

Macrovascular Complications. The connection between high insulin levels (hyperinsulinemia), insulin resistance, and cardiovascular events incorrectly leads some clinicians to believe that insulin therapy can cause macrovascular complications. The UKPDS and DCCT found no differences in macrovascular outcomes with intensive insulin therapy. One study, the Diabetes Mellitus, Insulin Glucose Infusion in Acute Myocardial Infarction study,⁷² reported reductions in mortality with insulin therapy. This group assessed the effect of an insulin-glucose infusion in type 2 DM patients who had experienced an acute myocardial infarction. Those randomized to insulin infusion followed by intensive insulin therapy lowered their absolute mortality risk by 11% over a mean followup period of

approximately 3 years. This was most evident in subjects who were insulin-naïve or had a low cardiovascular risk prior to the acute myocardial infarction.⁷² The importance of glycemic control in hospitalized patients is covered later in the chapter.

Adverse Effects. The most common adverse effects reported with insulin are hypoglycemia and weight gain. Hypoglycemia is more common in patients on intensive insulin therapy regimens versus those on less-intensive regimens. Also, patients with type 1 DM tend to have more hypoglycemic events compared to type 2 DM patients. In the UKPDS, performed over 10 years, the percentage of diabetic patients who needed assistance (third-party or hospitalization) because of a hypoglycemic reaction was 2.3%. The UKPDS reported a rate of 36.5% for risk of any hypoglycemic event, including mild, self-treated events. In the DCCT, tighter control produced a risk three times higher for severe hypoglycemia compared to conventional therapy. Glycemic goals should incorporate hypoglycemic risk versus the benefit of lowering the glucose when HbA_{1c} levels are near normal, especially in type 1 DM.

Minimization of risk for patients on insulin should include education about the signs and symptoms of hypoglycemia, proper treatment of hypoglycemia, and blood glucose monitoring. Blood glucose monitoring is essential for those on insulin, and is particularly of value in patients with hypoglycemia unawareness. Patients with hypoglycemia unawareness do not experience the normal sympathetic symptoms of hypoglycemia (tachycardia, tremulousness, and often, sweating). Initial hypoglycemia symptoms are neuroglycopenic in nature (confusion, agitation, loss of consciousness, and/or progression to coma). Patients with hypoglycemia unawareness often should at least temporarily raise their glycemic goals (requiring a reduction in insulin dose) and check their blood glucose level prior to any activities that can be dangerous with a low blood sugar (e.g., driving and certain sports, among others). Proper treatment of hypoglycemia dictates ingestion of carbohydrates, with glucose being preferred. Unconsciousness is an indication for either IV glucose, or glucagon injection, which increases glycogenolysis in the liver. Glucagon use would be appropriate in any situation in which the patient does not have or cannot have ready IV access for glucose administration. Education for reconstitution and injection of glucagon is recommended for close friends and family of a patient who has recurrent neuroglycopenic events. The patient and close contacts should be informed that it can take 10 to 15 minutes for the injection to start increasing glucose levels, and patients often vomit during this time. Proper positioning to avoid aspiration should be emphasized.

Weight gain is predominantly from increased truncal fat, and tends to be related to daily dose and plasma insulin levels present. Weight gain is undesirable in most type 2 DM patients, but can be seen as beneficial in underweight patients with type 1 DM. Weight gain appears to be related to intensive insulin therapy, and can be somewhat minimized by physiologic replacement of insulin.

Two forms of lipodystrophy, although much less common today in people with diabetes, still occur. Lipohypertrophy is caused by many injections into the same injection site. Because of insulin's anabolic actions, a raised fat mass is present at the injection site with resultant variable insulin absorption. Lipoatrophy, in contrast, is thought to be caused by insulin antibodies, with destruction of fat at the site of injection. Injection away from the site with more purified insulin is recommended, although several reports of lipoatrophy with lispro have been reported.

Drug-Drug Interactions. There are no significant drug-drug interactions with injected insulin, although other medications that can affect glucose control can be considered. Detemir does not appear to have albumin binding interactions, as it occupies only a small percent of albumin binding sites. Table 77–11 lists common medications known to affect blood glucose levels.

TABLE 77-11 Medications That Can Affect Glycemic Control^a

Drug	Effect on Glucose	Mechanism/Comment
Angiotensin-converting enzyme inhibitors	Slight reduction	Improves insulin sensitivity
Alcohol	Reduction	Reduces hepatic glucose production
Interferon alfa	Increase	Unclear
Diazoxide	Increase	Decreases insulin secretion, decreases peripheral glucose use
Diuretics	Increase	Can increase insulin resistance
Glucocorticoids	Increase	Impairs insulin action
Nicotinic acid	Increase	Impairs insulin action, increases insulin resistance
Oral contraceptives	Increase	Unclear
Pentamidine	Decrease, then increase	Toxic to β cells; initial release of stored insulin, then depletion
Phenytoin	Increase	Decreases insulin secretion
β -Blockers	Can increase	Decreases insulin secretion
Salicylates	Decrease	Inhibition of I-kappa-B kinase-beta (IKK-beta) (only high doses, e.g., 4–6 g/day)
Sympathomimetics	Slight increase	Increased glycogenolysis and gluconeogenesis
Clozapine and olanzapine	Increase	Decrease insulin sensitivity; weight gain

^aThis list is not inclusive of all medications reported to cause glucose changes.

Dosing and Administration. The dose of insulin for any person with altered glucose metabolism must be individualized. In type 1 DM, the average daily requirement for insulin is 0.5 to 0.6 units/kg, with approximately 50% being delivered as basal insulin, and the remaining 50% dedicated to meal coverage. During the honeymoon phase it can fall to 0.1 to 0.4 units/kg. During acute illness or with ketosis or states of relative insulin resistance, higher dosages are warranted. In type 2 DM a higher dosage is required for those patients with significant insulin resistance. Dosages vary widely depending on underlying insulin resistance and concomitant oral insulin sensitizer use. Strategies on how to initiate and monitor insulin therapy will be described later in the therapeutics section.

Storage. It is recommended that unopened injectable insulin be refrigerated (2.2° to 7.7°C [36° to 46°F]) prior to use. The manufacturer's expiration date printed on the insulin is used for unopened, refrigerated insulin. Once the insulin is in use, the manufacturer-recommended expiration dates will vary based on the insulin and delivery device. Table 77-9 outlines manufacturer-recommended expiration dates for room temperature (15° to 30°C [59° to 86°F]) insulin, including Exubera. For financial reasons, patients can attempt to use insulins longer than their expiration dates, but careful attention must be paid to monitoring for glycemic control deterioration and signs of insulin decay (clumping, precipitates, discoloration, etc.) if this is attempted.

Exenatide Pharmacology. Exendin-4 is a 39-amino acid peptide isolated from the saliva of the Gila monster (*Heloderma suspectum*) and shares approximately 50% amino acid sequence with human GLP-1. Exenatide is the synthetic analog to exendin-4. Exenatide (Byetta) has been shown to bind to GLP-1 receptors in many parts of the body including the brain and pancreas. Exenatide and GLP-1 have common glucoregulatory actions. Exenatide enhances glucose dependent insulin secretion while suppressing inappropriately high postprandial glucagon secretion in the presence of elevated glucose concentrations, resulting in a reduction in hepatic glucose production. Exenatide reduces food intake, which can result in weight loss, and slows gastric emptying so that the rate of glucose appearance into the plasma better matches the glucose

disposition. Unlike GLP-1, exenatide does not increase gastric secretions.

Pharmacokinetics. Exenatide concentrations are detectable in plasma within 10 to 15 minutes after subcutaneous injection, and the drug has a time of maximal concentration (t_{max}) of ~2 hours and a plasma half life of ~3.3 to 4.0 hours. Exenatide plasma concentrations increase in a dose-dependent manner and plasma exenatide concentrations are detectable for up to 10 hours postinjection, although pharmacodynamically, effects last for approximately 6 hours. Bioavailability of exenatide after injection in the abdomen, upper arm, or the thigh is similar. Elimination of exenatide is primarily by glomerular filtration with subsequent proteolytic degradation. When exenatide is administered to subjects with worsening degrees of renal insufficiency, there is a progressive prolongation of the half-life, and in dialysis patients, plasma clearance of exenatide is markedly reduced. The incidence of GI side effects appears to be increased in individuals with impaired renal function, possibly because of higher plasma levels, thus caution is advised.

No significant differences in exenatide pharmacokinetics have been observed with obesity, race, gender, or advancing age (up to 73 years old).

Efficacy. The average HbA_{1c} reduction is approximately 0.9% with exenatide, although, similar to oral agents, it is dependent on the baseline HbA_{1c} values. Three phase III trials reported similar HbA_{1c} reduction in patients on metformin, sulfonylureas, or both. Exenatide significantly decreases postprandial glucose excursions but has only a modest effect on FPG values. If a patient has significant elevations in FPG levels, these should be corrected with other agents, and the exenatide added on. Exenatide can allow some patients to lose weight. The average weight loss in controlled trials was 1 to 2 kg over 30 weeks, without dietary advice being given to the patients, although long-term, open-label followup on 10 mcg twice daily shows continued weight loss for at least 2.5 years. Exenatide, through decreasing appetite and slowing gastric emptying, can reduce the number of calories a patient eats at a meal.

Microvascular Complications. Exenatide reduces the HbA_{1c} level, which have been shown to be related to the risk of microvascular complications.

Macrovascular Complications. No published clinical trials have examined the effect of exenatide on cardiovascular outcomes. However, improvements in several cardiovascular risk factors have been reported. Plasma triglycerides (-37 ± 10 mg/dL) decreased and, plasma HDL cholesterol ($+4.5 \pm 0.4$ mg/dL) increased on exenatide 10 mcg twice daily. Nonsignificant reductions in systolic and diastolic blood pressure were observed. The greatest improvement in cardiovascular risk factors was seen in subjects who had the greatest weight loss.⁷³

Adverse Effects. The most common adverse effects associated with exenatide are GI in nature. Nausea occurs in ~40% of subjects on 5 mcg, and ~45% to 50% of subjects on 10 mcg twice daily. Vomiting or diarrhea occurs in approximately 10% of patients placed on exenatide. GI adverse effects appear to decrease over time, but approximately 1 in 20 patients can have prolonged problems with one of the above side effects, possibly requiring discontinuation. As these adverse effects appear to be dose-related, the patient should be started on 5 mcg twice daily and titrated to 10 mcg twice daily only if the adverse effects are mostly gone. Also, when the patient is increased to the 10 mcg twice daily dose, these adverse effects can recur for a short period of time. Many episodes of nausea would be better characterized as stomach fullness, and patients should be instructed to eat slow and stop eating when full, or risk nausea and vomiting. Also, weight loss appears not to be related to adverse effects but rather to a reduction in calories consumed. Exenatide

provides glucose-dependent insulin secretion, thus hypoglycemic rates when combined with metformin or a TZD are not increased, but when combined with a sulfonylurea or insulin, significant hypoglycemia can occur. Although exenatide reduces glucagon when the glucose is high, no suppression of counter-regulatory hormones has been noted during hypoglycemia. Exenatide antibodies can occur, but generally decrease over time and do not affect glycemic control. In approximately 5% of patients, titers can increase over time, resulting in a blunting of glycemic control in approximately one-half of these patients.

Drug Interactions. Exenatide delays gastric emptying, thus it can delay the absorption of other medications. Examples of medications that can be affected include oral pain medications and antibiotics dependent on threshold levels for efficacy. If rapid absorption of the medication is necessary, it is best to take the medication 1 hour before, or at least 3 hours after the injection of exenatide. In addition, if the patient has gastroparesis, exenatide is not recommended.

Dosing and Administration. Exenatide dosing should be started with 5 mcg twice daily, and titrated to 10 mcg twice daily in 1 month or when tolerability allows and if warranted. Exenatide should be injected 0 to 60 minutes before the morning and evening meals. If the patient does not eat breakfast, they can take the first injection of the day at lunch. The peak effect of exenatide is at approximately 2 hours, so anecdotally the patient can get better appetite suppression if injected 30 minutes to 1 hour prior to the meal. Storage and dosage availability information can be found in Table 77–9.

Pramlintide Pharmacology. Pramlintide (Symlin) is an anti-hyperglycemic agent used in patients currently treated with insulin. Pramlintide is a synthetic analog of amylin (amylinomimetic), a neurohormone co-secreted from the β cells with insulin. Pramlintide suppresses inappropriately high postprandial glucagon secretion, reduces food intake, which can result in weight loss, and slows gastric emptying so that the rate of glucose appearance into the plasma better matches the glucose disposition.

Pharmacokinetics. The absolute bioavailability of pramlintide after subcutaneous injection is 30% to 40%. The t_{\max} is approximately 20 minutes, but the maximal drug concentration (C_{\max}) is dose dependent and appears to be linear. The half-life ($t_{1/2}$) is approximately 45 minutes, thus the pharmacodynamic duration of action is approximately 3 to 4 hours. Pramlintide does not extensively bind to albumin, and should not have significant binding interactions. Metabolism is primarily by the kidneys, and one active metabolite (2–37 pramlintide) has a similar half-life as the parent compound. No accumulation has been seen in renal insufficiency, but caution is advised. Injection into the arm can increase exposure and variability of absorption, so injection into the abdomen or thigh is recommended.

Efficacy. The average HbA_{1c} reduction is approximately 0.6% with pramlintide, although optimization of the insulin and pramlintide doses can result in further drops in HbA_{1c} . If the 120 mcg dose is used in type 2 DM patients on insulin, it can also result in 1.5 kg weight loss. In type 1 DM patients, the average reduction in HbA_{1c} was 0.4% to 0.5%. Pramlintide decreases prandial glucose excursions but has little effect on the FPG concentration. The main advantage of pramlintide is in type 1 DM, where it helps to stabilize wide postprandial glycemic swings. The average weight loss in controlled trials was 1 to 2 kg, without dietary advice being given to the patients. Pramlintide, through decreasing appetite and slowing gastric emptying, can reduce the number of calories a patient eats at a meal.

Microvascular Complications. Pramlintide reduces the HbA_{1c} level, which has been shown to be related to the risk of microvascular complications.

Macrovascular Complications. No published clinical trials have examined the effect of pramlintide on cardiovascular outcomes.

Adverse Effects. The most common adverse effects associated with pramlintide are GI in nature. Nausea occurs in ~20% of type 2 DM patients, and vomiting or anorexia occurs in approximately 10% of type 1 or type 2 DM patients. Nausea is more common in type 1 DM, occurring in ~40% to 50% of patients. GI adverse effects appear to decrease over time and are dose related, thus starting at a low dose and slowly titrating as tolerated is recommended. Pramlintide alone does not cause hypoglycemia, but it is indicated for use in patients on insulin, thus hypoglycemia can occur. The risk of severe hypoglycemia early in therapy is higher in type 1 DM than in type 2 DM patients. A twofold increase in severe hypoglycemic reactions in type 1 DM patients has been reported.

Drug Interactions. Pramlintide delays gastric emptying, thus it can delay the absorption of other medications. Examples of medications that can be affected include oral pain medications and antibiotics dependent on threshold levels for efficacy. If rapid absorption of the medication is necessary, it is best to take the medication 1 hour before, or at least 3 hours after the injection of pramlintide.

Dosing and Administration. Pramlintide dosing varies in type 1 and type 2 DM. It is imperative that the prandial insulin dose, if used, be reduced 30% to 50% when pramlintide is started to minimize severe hypoglycemic reactions. Basal insulin may need to be adjusted only if the FPG is close to normal. In type 2 DM, the starting dose is 60 mcg prior to major meals, and can be titrated to the maximally recommended 120 mcg dose as tolerated and warranted based on postprandial plasma glucose concentrations. In type 1 DM dosing starts at 15 mcg prior to each meal and can be titrated up to a maximum of 60 mcg prior to each meal if tolerated and warranted. Pramlintide comes in a vial, allowing individualization of titration at even smaller increments (by units) than the package insert recommends. Each 2.5 units on a 100 units/mL insulin syringe equals 15 mcg of pramlintide. In addition, pramlintide has a pH of 4, and it is not recommended that pramlintide be mixed with any other insulin, thus this potentially adds two to four additional injections a day. Storage information can be found in Table 77–9.

Sulfonylureas Pharmacology. The primary mechanism of action of sulfonylureas is enhancement of insulin secretion. Sulfonylureas bind to a specific sulfonylurea receptor (SUR) on pancreatic β cells. Binding closes an adenosine triphosphate-dependent potassium ion (K^+) channel, leading to decreased potassium efflux and subsequent depolarization of the membrane. Voltage-dependent calcium ion (Ca^{+2}) channels open and allow an inward flux of Ca^{+2} . Increases in intracellular Ca^{+2} cause translocation of secretory granules of insulin to the cell surface and resultant exocytosis of the granule of insulin. Elevated secretion of insulin from the pancreas travels via the portal vein and subsequently suppresses hepatic glucose production.

Classification. Sulfonylureas are classified as first-generation and second-generation agents. The classification scheme is largely derived from differences in relative potency, relative potential for selective side effects, and differences in binding to serum proteins (i.e., risk for protein-binding displacement drug interactions). First-generation agents consist of acetohexamide, chlorpropamide, tolazamide, and tolbutamide. Each of these agents is lower in potency relative to the second-generation drugs: glimepiride, glipizide, and glyburide (Table 77–12). It is important to recognize that all sulfonylureas are equally effective at lowering blood glucose when administered in equipotent doses.

Pharmacokinetics. All sulfonylureas are metabolized in the liver; some to active, others to inactive metabolites (see Table 77–12).

TABLE 77-12 Oral Agents for the Treatment of Type 2 Diabetes Mellitus

Generic Name (generic version available? Y = yes, N = no)	Brand	Dose (mg)	Recommended Starting Dosage (mg/day)		Equivalent Therapeutic Dose (mg)	Maximum Dose (mg/day)	Duration of Action	Metabolism or Therapeutic Notes
			Nonelderly	Elderly				
<i>Sulfonylureas</i>								
Acetohexamide (Y)	Dymelor	250, 500	250	125–250	500	1,500	Up to 16 hours	Metabolized in liver; metabolite potency equal to parent compound; renally eliminated
Chlorpropamide (Y)	Diabinese	100, 250	250	100	250	500	Up to 72 hours	Metabolized in liver; also excreted unchanged renally
Tolazamide (Y)	Tolinase	100, 250, 500	100–250	100	250	1,000	Up to 24 hours	Metabolized in liver; metabolite less active than parent compound; renally eliminated
Tolbutamide (Y)	Orinase	250, 500	1,000–2,000	500–1,000	1,000	3,000	Up to 12 hours	Metabolized in liver to inactive metabolites that are renally excreted
Glipizide (Y)	Glucotrol	5, 10	5	2.5–5	5	40	Up to 20 hours	Metabolized in liver to inactive metabolites
Glipizide (Y)	Glucotrol XL	2.5, 5, 10, 20	5	2.5–5	5	20	24 hours	Slow-release form; do not cut tablet
Glyburide (Y)	DiaBeta Micronase	1.25, 2.5, 5	5	1.25–2.5	5	20	Up to 24 hours	Metabolized in liver; elimination 1/2 renal, 1/2 feces
Glyburide, micronized (Y)	Glynase	1.5, 3, 6	3	1.5–3	3	12	Up to 24 hours	Equal control, but better absorption from micronized preparation
Glimepiride (Y)	Amaryl	1, 2, 4	1–2	0.5–1	2	8	24 hours	Metabolized in liver to inactive metabolites
<i>Short-acting insulin secretagogues</i>								
Nateglinide (N)	Starlix	60, 120	120 with meals	120 with meals	NA	120 mg three times a day	Up to 4 hours	Metabolized by cytochrome P450 (CYP450), CYP2C9, and CYP3A4 to weakly active metabolites; renally eliminated
Repaglinide (N)	Prandin	0.5, 1, 2	0.5–1 with meals	0.5–1 with meals	NA	16	Up to 4 hours	Metabolized by CYP3A4 to inactive metabolites; excreted in bile
<i>Biguanides</i>								
Metformin (Y)	Glucophage	500, 850, 1,000	500 mg twice a day	Assess renal function	NA	2,550	Up to 24 hours	No metabolism; renally secreted and excreted
Metformin extended-release (Y)	Glucophage XR	500, 750, 1,000 mg	500–1,000 mg with evening meal	Assess renal function	NA	2,550	Up to 24 hours	Take with evening meal or may split dose; can consider trial if intolerant to immediate-release
<i>Thiazolidinediones</i>								
Pioglitazone (N)	Actos	15, 30, 45	15	15	NA	45	24 hours	Metabolized by CYP2C8 and CYP3A4; two metabolites have longer half-lives than parent compound
Rosiglitazone (N)	Avandia	2, 4, 8	2–4	2	NA	8 mg/day or 4 mg twice a day	24 hours	Metabolized by CYP2C8 and CYP2C9 to inactive metabolites that are renally excreted
<i>α-Glucosidase inhibitors</i>								
Acarbose (N)	Precose	25, 50, 100	25 mg one to three times a day	25 mg one to three times a day	NA	25–100 mg three times a day	1–3 hours	Eliminated in bile
Miglitol (N)	Glyset	25, 50, 100	25 mg one to three times a day	25 mg one to three times a day	NA	25–100 mg three times a day	1–3 hours	Eliminated renally
<i>Dipeptidyl peptidase-IV inhibitors (DPP-IV inhibitors)</i>								
Sitagliptin (N)	Januvia	25, 50, 100	100 mg daily	25 to 100 mg daily based on renal function	NA	100 mg daily	24 hours	50 mg daily if: creatinine clearance >30 to <50 mL/minute 25 mg if: creatinine clearance < 30 mL/min
<i>(continued)</i>								

TABLE 77-12 Oral Agents for the Treatment of Type 2 Diabetes Mellitus (continued)

Generic Name (generic ver- sion available? Y = yes, N = no)	Brand	Dose (mg)	Recommended Starting Dosage (mg/day)		Equivalent Therapeutic Dose (mg)	Maximum Dose (mg/day)	Duration of Action	Metabolism or Therapeutic Notes
			Nonelderly	Elderly				
Combination products								
Glyburide/met- formin (Y)	Glucovance	1.25/250 2.5/500 5/500	2.5–5/500 twice a day	1.25/250 twice a day; assess renal function	NA	20 of glyburide, 2,000 of met- formin	Combina- tion medi- cation	Use as initial therapy: 1.25/ 250 mg twice a day
Glipizide/met- formin (N)	Metaglip	2.5/250 2.5/500 5/500	2.5–5/500 twice a day	2.5/250; assess renal function	NA	20 of glipizide, 2,000 of met- formin	Combina- tion medi- cation	Use as initial therapy: 2.5/ 250 mg twice a day
Rosiglitazone/ metformin (N)	Avandamet	1/500 2/500 4/500 2/1,000 4/1,000	1–2/500 twice a day	1/500 twice a day; assess renal function	NA	8 of rosiglitazone; 2,000 of met- formin	Combina- tion medi- cation	Past manufacturing prob- lems but recently reintro- duced to market. Can use as initial therapy
Rosiglitazone/ glimepiride (N)	Avandaryl	4/1 4/2 4/4	4/1 or 4/2 once a day	4/1 daily	NA	8 mg of rosiglita- zone, 8 mg of glimepiride	Combina- tion medi- cation	Recent labeling that it can increase cardiovascular events in patients with concomitant heart fail- ure—caution
Pioglitazone/ metformin (N)	ACTOplus Met	15/500 15/850	15/500 to 15/850 once or twice daily	15/500 daily to twice daily; assess renal function	NA	45 mg of pioglitazone, 2,550 mg of metformin	Combina- tion medi- cation	
Pioglitazone/ glimepiride (N)	Duetact	30/2 30/4	30/2 or 30/4 daily	30/2 daily to avoid hypoglycemia	NA	45 mg pioglitazone, 8 mg glimepiride	Combina- tion medi- cation	Maximum dose cannot be given of either medication because of formulations available
Sitagliptin/met- formin (N)	Janumet	50/500 50/1,000	50/500 twice daily with meals up to 50/ 1,000twice daily with meals	Either given twice daily; assess renal function prior to use	NA	100 mg sitagliptin daily	Combina- tion medi- cation	Follow renal precautions for metformin.

Data from Gerich JE. Oral hypoglycemic agents. *N Engl J Med* 1989;321:1231–1245.

Cytochrome P450 (CYP) 2C9 is involved with the hepatic metabolism of the majority of sulfonylureas. Agents with active metabolites or parent drug that are renally excreted require dosage adjustment or use with caution in patients with compromised renal function. The half-life of the sulfonylurea also relates directly to the risk for hypoglycemia. The hypoglycemic potential is therefore higher with chlorpropamide and glyburide. The long duration of effect of chlorpropamide can be particularly problematic in elderly individuals, whose renal function declines with age, and therefore it has great potential for accumulation, resulting in severe and protracted hypoglycemia. Individuals at high risk for hypoglycemia (e.g., elderly individuals and those with renal insufficiency or advanced liver disease) should be started at a very low dose of a sulfonylurea with a short half-life. Hypoglycemia on low-dose sulfonylureas can dictate a short-acting insulin secretagogue (nateglinide or repaglinide) in lieu of a sulfonylurea.

Efficacy. As mentioned earlier, when given in equipotent doses, all sulfonylureas are equally effective at lowering blood glucose. On average, HbA_{1c} will decrease 1.5% to 2%, with FPG reductions of 60 to 70 mg/dL. A majority of patients will not reach glycemic goals with sulfonylurea monotherapy. Patients who fail sulfonylurea usually fall into two groups: Those with low C-peptide levels and high (>250 mg/dL) FPG levels. These patients are often primary failures on sulfonylureas (<30 mg/dL drop of FPG) and have significant glucose toxicity or slow-developing type 1 DM. The other group is those with a good initial response (>30 mg/dL drop of FPG), but which is insufficient to

reach their glycemic goals. More than 75% of patients fall into the second group. Factors that portend a positive response include newly diagnosed patients with no indicators of type 1 DM, high fasting C-peptide levels, and moderate fasting hyperglycemia (<250 mg/dL). If glycemic goals are met, a secondary failure rate of approximately 5% to 7% per year can be expected.

Microvascular Complications. Sulfonylureas showed a reduction of microvascular complications in type 2 DM patients in the UKPDS.⁶¹ A more in-depth discussion follows later in the chapter.

Macrovascular Complications. In the largest study to date, the UKPDS, no significant benefit or harm was seen in newly diagnosed type 2 DM patients given sulfonylureas over 10 years. The University Group Diabetes Program study documented higher rates of coronary artery disease in type 2 patients given tolbutamide, when compared to patients given insulin or placebo, although this study has been widely criticized.^{74,75} Some sulfonylureas bind to the SUR-2A receptor that is found in cardiac tissue. Binding to the SUR-2A receptor has been implicated in blocking ischemic preconditioning via K⁺ channel closure in the heart. Ischemic preconditioning is the premise that prior ischemia in cardiac tissue can provide greater tolerance of subsequent ischemia. Thus patients with heart disease potentially have one compensatory mechanism to protect the heart from ischemia blocked. Conclusions are controversial, and readers are referred to the pertinent articles for further discussion.^{76–78}

Adverse Effects. The most common side effect of sulfonylureas is hypoglycemia. The pretreatment FPG is a strong predictor of hypoglycemic potential. The lower the FPG is on initiation, the higher the potential for hypoglycemia. Also, in addition to the high-risk individuals outlined in the pharmacokinetics section, those who skip meals, exercise vigorously, or lose substantial amounts of weight are also more likely to experience hypoglycemia.

Hyponatremia (serum sodium <129 mEq/L) is reportedly associated with tolbutamide, but it is most common with chlorpropamide and occurs in as many as 5% of individuals treated. An increase in antidiuretic hormone secretion is the mechanism for hyponatremia. Risk factors include age >60 years, female gender, and concomitant use of thiazide diuretics.

Weight gain is common with sulfonylureas. In essence, patients who are no longer glycosuric and who do not reduce caloric intake with improvement of blood glucose will store excess calories. Other notable, although much less common, adverse effects of sulfonylureas are skin rash, hemolytic anemia, GI upset, and cholestasis. Disulfiram-type reactions and flushing have been reported with tolbutamide and chlorpropamide when alcohol is consumed.

Drug Interactions. Several drugs are thought to interact with sulfonylureas, and Table 77-13 summarizes them by proposed mechanisms of action.⁷⁹ Drug interactions from protein-binding changes should occur shortly after the interacting medication is given, as the concentration of free (thus active) sulfonylurea will acutely increase. First-generation sulfonylureas, which bind to proteins ionically, are more likely to cause drug-drug interactions than second-generation sulfonylureas, which bind nonionically.⁸⁰ The clinical importance of protein-binding interactions has been questioned, as the majority of these drug interactions have been found to truly be caused by hepatic metabolism. Drugs that are inducers or inhibitors of CYP2C9 should be monitored carefully when used with a sulfonylurea. Additionally, other drugs known to alter blood glucose should be considered (see Table 77-11).

Dosing and Administration. The usual starting dose and maximum dose of sulfonylureas are summarized in Table 77-12. Lower dosages are recommended for most agents in elderly patients and those with compromised renal or hepatic function. The dosage should be titrated every 1 to 2 weeks (use a longer interval with chlorpropamide) to achieve glycemic goals. This is possible because of the rapid increase of insulin secretion in response to the sulfonylurea. Of note, immediate-release glipizide's maximal dose is 40 mg/day, but its maximal effective dose is about 10 to 15 mg/day. The maximal effective dose of sulfonylureas tends to be approximately 60% to 75% of their stated maximum dose.

Short-Acting Insulin Secretagogues Pharmacology. Although the binding site is adjacent to the binding site of sulfonylureas, nateglinide and repaglinide stimulate insulin secretion from the β cells of the pancreas, similarly to sulfonylureas. Repaglinide, a benzoic acid derivative, and nateglinide, a phenylalanine amino acid derivative, both require the presence of glucose to stimulate insulin

secretion. As glucose levels diminish to normal, stimulated insulin secretion diminishes.

Pharmacokinetics. Both nateglinide and repaglinide are rapid-acting insulin secretagogues that are rapidly absorbed (~0.5 to 1 hour) and have a short half-life (1 to 1.5 hours). Nateglinide is highly protein-bound, primarily to albumin, but also to α_1 -acid glycoprotein. Nateglinide is predominantly metabolized by CYP2C9 (70%) and CYP3A4 (30%) to less active metabolites. Glucuronide conjugation then allows rapid renal elimination. Repaglinide is mainly metabolized by the CYP3A4 system to inactive metabolites that are excreted in the bile.

Efficacy. In monotherapy, both significantly reduce postprandial glucose excursions and reduce HbA_{1c} levels. Repaglinide, dosed 4 mg three times a day, when compared to glyburide in diet-treated drug-naïve patients reduced HbA_{1c} levels less (1% vs. 2.4%, from baseline, respectively).⁸¹ Nateglinide, dosed 120 mg three times a day in a similar population reduced HbA_{1c} values by 0.8%.⁸² The lower efficacy of these agents versus sulfonylureas should be considered when patients are >1% above their HbA_{1c} goal. These agents can be used to provide increased insulin secretion during meals, when it is needed, in patients close to glycemic goals. Also, it should be noted that addition of either agent to a sulfonylurea will not result in any improvement in glycemic parameters.

Adverse Effects. Hypoglycemia is the main side effect noted with both agents. Hypoglycemic risk appears to be less than with sulfonylureas. In part, this is because of the glucose-sensitive release of insulin. If the glucose concentration is normal, less glucose-stimulated release of insulin will occur. In two separate studies, nateglinide rates of hypoglycemia were 3% and repaglinide 15% versus glyburide and glipizide rates of 15% and 19%, respectively. Weight gain of 2 to 3 kg has been noted with repaglinide, whereas weight gain with nateglinide appears to be <1 kg.

Drug Interactions. Glycemic control and hypoglycemia should be closely monitored when inducers or inhibitors of CYP3A4 are given with repaglinide. Gemfibrozil, a common medication used to treat hypertriglyceridemia in DM, more than doubles the half-life of repaglinide and has resulted in prolonged hypoglycemic reactions. Nateglinide appears to be a weak inhibitor of CYP2C9 based on tolbutamide metabolism, although no significant drug-drug interactions have been reported.

Dosing and Administration. Nateglinide and repaglinide should be dosed prior to each meal (up to 30 minutes prior). The recommended starting dose for repaglinide is 0.5 mg in subjects with HbA_{1c} <8% or treatment-naïve patients, increased weekly to a total maximum daily dose of 16 mg (see Table 77-12). The maximal effective dose of repaglinide is likely 2 mg with each meal, as a dose of 1 mg prior to each meal provides approximately 90% of the maximal glucose-lowering effect. Nateglinide should be dosed at 120 mg prior to meals, and does not require titration. A 60-mg dose is available, but the HbA_{1c} decrement is small (0.3% to 0.5%). If a meal is skipped, the medication can be skipped, and meals extremely low in carbohydrate content may not need a dose. Both agents can be used in patients with renal insufficiency and offer an excellent alternative in patients experiencing hypoglycemia with low-dose sulfonylurea. Caution is advised for patients with moderate to severe hepatic impairment, as nateglinide has not been studied and the half-life is prolonged with use of repaglinide.

Biguanides Pharmacology. Metformin is the only biguanide available in the United States. Metformin has been used clinically for 45 years and has been approved in the United States since 1995. Metformin enhances insulin sensitivity of both hepatic and peripheral (muscle) tissues. This allows for an increased uptake of glucose

TABLE 77-13 Drug Interactions with Sulfonylureas

Interaction	Drugs
Displacement from protein binding sites ^a	Warfarin, salicylates, phenylbutazone, sulfonamides
Alters hepatic metabolism (cytochrome P450)	Chloramphenicol, monoamine oxidase inhibitors, cimetidine, rifampin ^b
Altered renal excretion	Allopurinol, probenecid

^aMany of these drug interactions may be metabolism-based.

^bInducer.

Reproduced from Gerich.⁷⁹

into these insulin-sensitive tissues. The exact mechanisms of how metformin accomplishes insulin sensitization are still being investigated, although adenosine 5-monophosphate-activated protein kinase activity, tyrosine kinase activity enhancement, and glucose transporter-4 all play a part. Metformin has no direct effect on the β cells, although insulin levels are reduced, reflecting increases in insulin sensitivity.

Pharmacokinetics. Metformin has approximately 50% to 60% oral bioavailability, low lipid solubility, and a volume of distribution that approximates body water. Metformin is not metabolized and does not bind to plasma proteins. Metformin is eliminated by renal tubular secretion and glomerular filtration. The average half-life of metformin is 6 hours, although pharmacodynamically, metformin's antihyperglycemic effects last >24 hours.

Efficacy. Metformin consistently reduces HbA_{1c} levels by 1.5% to 2.0%, FPG levels by 60 to 80 mg/dL, and retains the ability to reduce FPG levels when they are extremely high (>300 mg/dL). The sulfonylureas' ability to stimulate insulin release from β cells at extremely high glucose levels is often impaired, a concept commonly referred to as *glucose toxicity*. Metformin also has positive effects on several components of the insulin resistance syndrome. Metformin decreases plasma triglycerides and LDL-C by approximately 8% to 15%, as well increasing HDL-C very modestly (2%). Metformin reduces levels of plasminogen activator inhibitor-1 and causes a modest reduction in weight (2 to 3 kg).

Microvascular Complications. Metformin ($n = 342$) was compared to intensive glucose control with insulin or sulfonylureas in the UKPDS. No significant differences were seen between therapies with regard to reducing microvascular complications.

6 Macrovascular Complications. Although normal weight type 2 DM subjects may not receive benefit, metformin reduced macrovascular complications in obese subjects in the UKPDS.⁸³ Metformin significantly reduced all-cause mortality and risk of stroke versus intensive treatment with sulfonylureas or insulin. Metformin also reduced diabetes-related death and myocardial infarctions as opposed to the conventional treatment arm of the UKPDS. Metformin should be included in the therapy for all type 2 DM patients, if tolerated and not contraindicated, as it is the only oral antihyperglycemic medication proven to reduce the risk of total mortality and is generic.

Adverse Effects. Metformin causes GI side effects, including abdominal discomfort, stomach upset, and/or diarrhea in approximately 30% of patients. Anorexia and stomach fullness is likely part of the reason loss of weight is noted with metformin. These side effects are usually mild and can be minimized by slow titration. GI side effects also tend to be transient, lessening in severity over several weeks. If encountered, make sure patients are taking metformin with or right after meals and reduce the dose to a point at which no GI side effects are encountered. Increases in the dose can be tried again in several weeks. Anecdotally, extended-release metformin (Gluco-phage-XR) can lessen some of the GI side effects. Metallic taste, interference with vitamin B₁₂ absorption, and hypoglycemia during intense exercise have been documented but are clinically uncommon.

Metformin therapy rarely (3 cases per 100,000 patient-years) causes lactic acidosis. Any disease state that can increase lactic acid production or decrease lactic acid removal can predispose to lactic acidosis. Tissue hypoperfusion, such as that caused by congestive heart failure, hypoxic states, shock, or septicemia, via increased production of lactic acid; and severe liver disease or alcohol, through reduced removal of lactic acid in the liver, all increase the risk of lactic acidosis. The clinical presentation of lactic acidosis is often nonspecific flu-like symptoms, thus the diagnosis is usually made by laboratory confirmation. Metformin use in renal insufficiency, defined as a

serum creatinine of 1.4 mg/dL in women and 1.5 mg/dL in men or greater, is contraindicated, as it is renally eliminated. Elderly patients, who often have reduced muscle mass, should have their glomerular filtration rate estimated by a 24-hour urine creatinine collection. If the estimated glomerular filtration rate is less than 70 mL/min, metformin should not be given. Because of the risk of acute renal failure during intravenous dye procedures, metformin therapy should be withheld starting the day of the procedure and resumed in 2 to 3 days, after normal renal function has been documented.

Drug Interactions. Cimetidine competes for renal tubular secretion of metformin and concomitant administration leads to higher metformin serum concentrations. At least one case report of lactic acidosis with metformin therapy implicates cimetidine. Other cationic drugs may interact similarly such as procainamide, digoxin, quinidine, trimethoprim, and vancomycin.⁸⁴

Dosing and Administration. Metformin immediate-release is usually dosed 500 mg twice a day with the largest meals to minimize GI side effects. Metformin can be increased by 500 mg weekly until glycemic goals or 2,000 mg/day is achieved (see Table 77–12). Metformin 850 mg can be dosed daily and then increased every 1 to 2 weeks to the maximum dose of 850 mg three times a day (2,550 mg/day). Approximately 80% of the glycemic-lowering effect can be seen at 1,500 mg, and 2,000 mg/day is the maximal effective dose.

Extended-release metformin can be initiated at 500 mg a day with the evening meal and titrated weekly by 500 mg as tolerated to a single evening dose of 2,000 mg/day. Twice daily to three times a day dosing of extended-release metformin can help minimize GI side effects and improve glycemic control. Metformin extended-release 750 mg tablets can be titrated weekly to the maximum dose of 2,250 mg/day, although as stated above, 1,500 mg/day provides the majority of the glycemic-lowering effect.

Thiazolidinediones Pharmacology. Thiazolidinediones are also referred to as TZDs or glitazones. Pioglitazone and rosiglitazone are the two currently approved TZDs for the treatment of type 2 DM (see Table 77–12). TZDs work by binding to the peroxisome proliferator-activated receptor- γ (PPAR- γ), which are primarily located on fat cells and vascular cells. The concentration of these receptors in the muscle is very low; thus this is unlikely to be the main site of action. TZDs enhance insulin sensitivity at muscle, liver, and fat tissues indirectly. TZDs cause preadipocytes to differentiate into mature fat cells in subcutaneous fat stores. Small fat cells are more sensitive to insulin and more able to store FFAs. The result is a flux of FFAs out of the plasma, visceral fat, and liver into subcutaneous fat, a less insulin-resistant storage tissue. Muscle intracellular fat products, which contribute to insulin resistance, also decline. TZDs also affect adipokines, (e.g., angiotensinogen, tissue necrosis factor- α , interleukin-6, plasminogen activator inhibitor-1), which can positively affect insulin sensitivity, endothelial function, and inflammation. Of particular note, adiponectin is reduced with obesity and/or diabetes but is increased with TZD therapy, which improves endothelial function, insulin sensitivity, and has a potent antiinflammatory effect.

Pharmacokinetics. Pioglitazone and rosiglitazone are well absorbed with or without food. Both are highly (>99%) protein bound to albumin. Pioglitazone is primarily metabolized by CYP2C8, and to a lesser extent by CYP3A4 (17%), with the majority being eliminated in the feces. Rosiglitazone is metabolized by CYP2C8, and to a lesser extent by CYP2C9, then conjugated with two-thirds found in urine and one-third in feces. The half-life of pioglitazone and rosiglitazone is 3 to 7 hours and 3 to 4 hours, respectively. Two active metabolites of pioglitazone with longer half-lives deliver the majority of activity at steady state. Both medications have a duration of antihyperglycemic action of more than 24 hours.

Efficacy. Pioglitazone and rosiglitazone, given for approximately 6 months, reduce HbA_{1c} values ~1.5% and reduce FPG levels by approximately 60 to 70 mg/dL at maximal doses. Glycemic-lowering onset is slow, and maximal glycemic-lowering effects may not be seen until 3 to 4 months of therapy. It is important to inform patients of this fact and that they should not stop therapy even if minimal glucose lowering is initially encountered. The efficacy of both drugs is dependent on sufficient insulinemia. If there is insufficient endogenous insulin production (β -cell function) or exogenous insulin delivery via injections, neither will lower glucose concentrations efficiently. Interestingly, patients who are more obese, or who gain weight on either medication tend to have a larger reduction in HbA_{1c} values. Pioglitazone consistently decreases plasma triglyceride levels by 10% to 20%, whereas rosiglitazone tends to have a neutral effect. LDL-C concentrations tend to increase with rosiglitazone 5% to 15% but do not significantly increase with pioglitazone. Both appear to convert small, dense low-density lipoprotein (LDL) particles, which have been shown to be highly atherogenic, to large, fluffy LDL particles that are less dense. Large, fluffy LDL particles may be less atherogenic, but any increase in LDL must be of concern. Both drugs increase HDL similarly, up to 3 to 9 mg/dL. TZDs also affect several components of the insulin resistance syndrome. PAI-1 levels are decreased, and many other adipocytokines are affected, endothelial function improves, and blood pressure can decrease slightly.

Microvascular Complications. TZDs reduce HbA_{1c} levels, which have been shown to be related to the risk of microvascular complications.

Macrovascular Complications. Macrovascular complications with TZDs are controversial. In the Prospective Pioglitazone Clinical Trial in Macrovascular Events (PROactive) study, pioglitazone 45 mg was added to standard therapy in patients who had experienced a macrovascular event or had peripheral vascular disease.⁸⁵ The two groups were well matched at baseline, and the reported average observation time period was approximately 3 years. The primary end point (reduction in death, myocardial infarction, stroke, acute coronary syndrome, coronary revascularization, leg amputation, and leg revascularization) was reduced 10% ($P = 0.095$). The main secondary end point (all-cause mortality, nonfatal myocardial infarction, or stroke) was reduced 16% ($P = 0.027$). The seemingly dichotomous results relate to the inclusion of leg revascularization, which were increased in the pioglitazone group. Reasons for the increase are speculative, but can relate to more testing and inspection because of peripheral edema. Also of note, the pioglitazone group had 209 nonadjudicated admissions for heart failure occur versus 153 in the placebo group ($P = 0.007$), although fatal heart failure was not increased. Several nonpublished meta-analyses of rosiglitazone reported higher myocardial infarction rates with rosiglitazone. Recently, a hazard ratio of 1.43 (95% confidence intervals 1.03–1.98; $P = 0.03$) for the risk of a myocardial infarction with rosiglitazone versus other oral agents was reported, but has been widely criticized.⁸⁶ A prospective cardiovascular outcome trial with rosiglitazone is underway, but the FDA will likely require a black box warning about cardiovascular events with rosiglitazone.

Adverse Effects. Troglitazone, the first TZD approved, caused idiosyncratic hepatotoxicity and had 28 deaths from liver failure, which prompted removal from the U.S. market in March, 2000. Approximately 1.9% of patients placed on troglitazone had alanine aminotransferase (ALT) levels more than three times the upper limit of normal. The incidence, using these criteria for elevated liver enzymes, with pioglitazone (0.25%) and rosiglitazone (0.2%) has been low. No evidence of hepatotoxicity was reported in an analysis of more than 5,000 patients given rosiglitazone or pioglitazone.⁸⁷ Several case reports of hepatotoxicity with rosiglitazone or pioglitazone have been reported, but improvement in ALT was consistently noted when the drug was discontinued. Prior to therapy, it is

recommended that an ALT be checked. ALT monitoring vigilance has been lowered, and it is now recommended that the ALT be checked periodically at the practitioner's discretion. Patients with ALT levels >2.5 times the upper limit of normal should not start either medication, and if the ALT is >3 times the upper limit of normal the medication should be discontinued.

Retention of fluid leads to many different possible side effects with rosiglitazone and pioglitazone. The etiology of the fluid retention has not been fully elucidated but appears to include peripheral vasodilation and/or improved insulin sensitization with a resultant increase in renal sodium and water retention. A reduction in plasma hemoglobin (2% to 4%), attributed to a 10% increase in plasma volume, can result in a dilutional anemia, which does not require treatment. Edema is also commonly (4% to 5% in mono- or combination therapy) reported. When a TZD is used in combination with insulin, the incidence of edema (~15%) is increased. TZDs are contraindicated in patients with New York Heart Association class III and IV heart failure, and great caution should be exercised when given to patients with class I and II heart failure or other underlying cardiac disease, as pulmonary edema and heart failure have been reported. Edema tends to be dose related and if not severe, a reduction in the dose as well as use of diuretics (anecdotally spironolactone appears to help selected patients) will allow the continuation of therapy in the majority of patients.⁸⁸ In addition, rarely, TZDs have been reported to worsen macular edema in the eye.

Weight gain, which is also dose related, can be seen with both rosiglitazone and pioglitazone. Mechanistically, both fluid retention and fat accumulation play a part in explaining the weight gain. TZDs, besides stimulating fat cell differentiation, also reduce leptin levels, which stimulate appetite and food intake. Average weight gain varies, but a 1.5- to 4-kg weight gain is not uncommon. Rarely, a patient will gain large amounts of weight in a short period of time, and this may necessitate discontinuation of therapy. Weight gain positively predicts a larger HbA_{1c} reduction but must be balanced with the well documented effects of long-term weight gain.

TZDs have also been associated with an increased fracture rate in the upper and lower limbs in postmenopausal women, but not men. As opposed to comparative diabetes therapy, TZDs can double the risk of fracture in this population. The underlying pathophysiology is speculative but can relate to the effect of TZD in bone marrow, with a reduction in osteoblast activity and an increase in bone marrow fat. It would be prudent to consider a patient's risk factors for fractures if prescribed a TZD and possibly have a lower threshold for additional assessment in postmenopausal women.

As a caution, anovulatory patients can resume ovulation on TZDs. Adequate pregnancy and contraception precautions should be explained to all women capable of becoming pregnant, as both agents are pregnancy category C.

Drug Interactions. No significant drug interactions have been noted with either medication. Neither pioglitazone nor rosiglitazone appear to be inhibitors or inducers of CYP3A4 and CYP2C8 or CYP2C8 and CYP2C9, respectively, although drugs that are strong inhibitors or inducers of these pathways (e.g., gemfibrozil or rifampin) necessitate close monitoring.

Dosing and Administration. The recommended starting dosages of pioglitazone and of rosiglitazone are 15 to 30 mg once daily and 2 to 4 mg once daily, respectively. Dosages can be increased slowly based on therapeutic goals and side effects. The maximum dose and maximum effective dose of pioglitazone is 45 mg, and rosiglitazone is 8 mg once daily, although 4 mg twice a day can reduce HbA_{1c} by 0.2% to 0.3% more as opposed to 8 mg once daily.

α -Glucosidase Inhibitors Pharmacology. Currently, there are two α -glucosidase inhibitors available in the United States (acarbose and miglitol). α -Glucosidase inhibitors competitively inhibit

enzymes (maltase, isomaltase, sucrase, and glucoamylase) in the small intestine, delaying the breakdown of sucrose and complex carbohydrates.^{89,90} They do not cause any malabsorption of these nutrients. The net effect from this action is to reduce the postprandial blood glucose rise.

Pharmacokinetics. The mechanism of action of α -glucosidase inhibitors is limited to the luminal side of the intestine. Some metabolites of acarbose are systemically absorbed and renally excreted, whereas the majority of miglitol is absorbed and renally excreted unchanged.

Efficacy. Postprandial glucose concentrations are reduced (40 to 50 mg/dL), whereas fasting glucose levels are relatively unchanged (~10% reduction). Efficacy on glycemic control is modest (average reductions in HbA_{1c} of 0.3% to 1%), affecting primarily postprandial glycemic excursions. Thus patients near target HbA_{1c} levels with near-normal FPG levels, but high postprandial levels, might be candidates for therapy.

Microvascular Complications. α -Glucosidase inhibitors modestly reduce HbA_{1c} levels, which have been shown to be related to the risk of microvascular complications.

Macrovascular Complications. The Study to Prevent Non-Insulin-Dependent Diabetes Mellitus (STOP-NIDDM), in subjects with impaired glucose tolerance, reported a significant reduction in the risk of cardiovascular events, although the total number of events were small.^{91,92} No large cardiovascular study confirming these preliminary results has been done in prediabetes or diabetes patients.

Adverse Effects. The GI side effects, such as flatulence, bloating, abdominal discomfort, and diarrhea, are very common and greatly limit the use of α -glucosidase inhibitors. Mechanistically, these side effects are caused by distal intestinal degradation of undigested carbohydrate by the microflora, which results in gas (carbon dioxide [CO₂] and methane) production. α -Glucosidase inhibitors should be initiated at a low dose and titrated slowly to reduce GI intolerance. Beano, an α -glucosidase enzyme, can help to decrease GI side effects but can decrease efficacy slightly.⁹³

If a patient develops hypoglycemia within several hours of ingesting an α -glucosidase inhibitor, oral glucose is advised because the drug will inhibit the breakdown of more complex sugar molecules. Milk, with lactose sugar, can be used as an alternative when no glucose is available, as acarbose only slightly (10%) inhibits lactase.

Rarely, elevated serum aminotransferase levels have been reported with the highest doses of acarbose. It appeared to be dose and weight related and is the premise for the weight-based maximum doses.

Dosing and Administration. Dosing for both miglitol and acarbose are similar. Initiate with a very low dose (25 mg with one meal a day); increase very gradually (over several months) to a maximum of 50 mg three times a day for patients ≤ 60 kg or 100 mg three times a day for patients > 60 kg (see Table 77-12). Both α -glucosidase inhibitors should be taken with the first bite of the meal so that drug may be present to inhibit enzyme activity. Only patients consuming a diet high in complex carbohydrates will have significant reductions in glucose levels. α -Glucosidase inhibitors are contraindicated in patients with short-bowel syndrome or inflammatory bowel disease, and neither should be administered in patients with serum creatinine > 2 mg/dL, as this population has not been studied.

DPP-IV inhibitors Sitagliptin is currently approved for use in the United States, whereas vildagliptin has received an approvable letter from the FDA.

Pharmacology. DPP-IV inhibitors prolong the half-life of an endogenously produced glucagon-like peptide-1 (GLP-1). It has

clearly been shown that in type 2 DM, GLP-1 levels are deficient. DPP-IV inhibitors partially reduce the inappropriately elevated glucagon postprandially and stimulate glucose-dependent insulin secretion. As these agents block nearly 100% of the DPP-IV enzyme activity for at least 12 hours, near normal, nondiabetic GLP-1 levels are achieved. These drugs do not alter gastric emptying.

Pharmacokinetics. Sitagliptin appears to have rapid absorption, with t_{\max} and C_{\max} of approximately 1.5 hours. Absolute bioavailability after oral intake is approximately 87%. The $t_{1/2}$ of sitagliptin is approximately 12 hours, and 79% of the dose of sitagliptin is excreted unchanged in the urine by active tubular secretion. Sitagliptin exposure is increased by approximately 2.3-, 3.8-, and 4.5-fold relative to healthy subjects for patients with moderate renal insufficiency (creatinine clearance 30 to < 50 mL/min), severe renal insufficiency (creatinine clearance < 30 mL/min), and end-stage renal disease (on dialysis), respectively. Pharmacodynamically, DPP-IV inhibition appeared to mirror directly the plasma concentration of sitagliptin. Doses of 50 mg produced at least 80% inhibition of DPP-IV enzyme activity at 12 hours, and 100 mg produced 80% inhibition of DPP-IV enzyme activity at 24 hours. Food had no effect on absorption kinetics of sitagliptin or vildagliptin.

Vildagliptin is rapidly and almost completely (85%) absorbed after oral intake. Within 1 to 2 hours, t_{\max} is achieved. The plasma $t_{1/2}$ varies with dose and is approximately 1.5 to 4.5 hours over a range or 25 mg to 200 mg. Approximately 55% of the drug is metabolized by hydrolysis, with the majority of the remaining drug eliminated unchanged by the kidneys. Vildagliptin dose-dependently inhibits the DPP-IV enzyme activity, approximately a 70% inhibition at 50 mg and 90% inhibition at 100 mg at 12 hours, with a continued 40% inhibition at 24 hours.

Efficacy. The average reduction in HbA_{1c} with vildagliptin or sitagliptin is approximately 0.7% to 1% at a dose of 100 mg a day. The HbA_{1c} decrement is dependent on the baseline value, with a larger reduction being seen with a higher baseline HbA_{1c}. As they are well tolerated, adjustment in the dose for adverse effects is unlikely.

Microvascular and Macrovascular Complications. HbA_{1c} levels are reduced, which have been related to a reduction in microvascular complications, but no outcome data are available to date.

Drug-Drug Interactions. Both are unlikely to have significant drug-drug interactions. Sitagliptin is metabolized approximately 20% by CYP3A4 with some CYP2C8 involvement but is neither an inhibitor nor inducer of any CYP450 enzyme system. Sitagliptin is a p-glycoprotein substrate, but had negligible effects on digoxin kinetics, and cyclosporine A increased the area under the curve (AUC) by only 30%. Neither drug is extensively plasma protein bound. Vildagliptin is neither an inhibitor nor inducer of CYP450 enzymes.

Adverse Effects. Both drugs are very well tolerated, weight neutral, and do not cause GI side effects. Mild hypoglycemia appears to be the only significant adverse effect, and the rate is similar to metformin. No significant increases in peripheral edema, hypertension, or cardiac outcomes have been noted to date. In regards to long-term safety, DPP-IV enzymes metabolize a wide variety of peptides (peptide YY [PYY], neuropeptide Y, growth hormone releasing hormone, and vasoactive intestinal polypeptide, and others) potentially affecting other regulatory systems. DPP-IV (also known as CD26) plays an important role for T-cell activation and theoretically the inhibition of DPP-IV could be associated with adverse immunologic reactions. Additionally DPP-8/9 inhibition in animals produced multiple toxicities. Both compounds have explored their binding to DPP-8/9, and have found minimal binding to these subtypes. Long-term safety data is still limited, but to date no adverse effects have been clearly linked to this issue.

Dosing and Administration. Vildagliptin will be dosed orally, likely at 50 mg to 100 mg daily. Sitagliptin is dosed orally at 100 mg daily unless renal insufficiency is present. The 50 mg dose is recommended if the creatinine clearance is 30 to less than 50 mL/min, or 25 mg if less than 30 mL/min. Equivalent serum creatinine levels are: sitagliptin 50 mg daily in men, greater than 1.7 to 3.0 mg/dL, women, greater than 1.5 to 2.5 mg/dL; 25 mg daily in men, greater than 3.0 mg/dL, women, greater than 2.5 mg/dL. No short-term adverse effects have been noted with increased exposure. Because of their excellent tolerability profile and a fairly flat dose-response curve, it seems logical that these drugs should be maximally dosed, unless cautions exist.

■ PIVOTAL TRIALS

Diabetes Control and Complications Trial

7 Much of the last century in diabetes care was dominated by the debate over whether glycemic control actually was causative in complications of DM. Animal studies and some human studies suggested that the worse the glycemia the greater the risk of complications. But “the glucose hypothesis” was not ultimately accepted as proven until the publication of the DCCT in 1993.⁶⁰ One thousand four hundred forty-one patients with type 1 DM were divided into two groups: those without complications (726 subjects, primary prevention), and those with early microvascular complications (715 subjects, secondary prevention). These two groups were then again divided into two groups, one randomized to receive conventional therapy (one or two shots of insulin daily and infrequent SMBG with no attempt to change therapy based on home blood glucose readings), and the other to receive intensive therapy (three or more injections of insulin daily or insulin pump, with frequent SMBG and alteration of insulin therapy based on SMBG results, plus frequent contact with a health professional). After 6.5 years mean followup with a difference in HbA_{1c} between the two groups being ~2% (~9% vs. ~7%), retinopathy was decreased by 76% in the primary prevention cohort, with retinopathy progression reduced 54% in the secondary prevention group. Neuropathy was decreased by 60% in both groups combined. Microalbuminuria was decreased 39%, whereas macroproteinuria was reduced 54% with intensive therapy. Hypoglycemia was more common and weight gain greater with intensive therapy. A nonstatistically significant reduction in coronary events was seen in the intensively treated group as compared to the conventional group. Followup studies 8 years after the DCCT ended continued to show an advantage of good glycemic control over what was previously considered conventional therapy.⁹⁴ The DCCT revolutionized therapy of DM, demanding that stricter glycemic control be the goal. Long-term followup of former DCCT subjects in the Epidemiology of Diabetes Interventions and Complications (EDIC) trial reported that, despite similar HbA_{1c} values 11 years later, renal and cardiovascular outcomes continued to be lower in intensively treated subjects from the DCCT as opposed to those who received conventional treatment.⁹⁵

Implications of the United Kingdom Prospective Diabetes Study

The UKPDS was a landmark study for the care of patients with type 2 DM, confirming the importance of glycemic control for reducing the risk of microvascular complications.⁶¹ More than 5,000 patients with newly diagnosed type 2 DM were entered into the study. Patients were followed for an average of 10 years. The major portion of the study assessed “conventional therapy” (no drug therapy unless the patient was symptomatic or had FPG >270 mg/dL), versus intensive therapy starting with either sulfonylureas or insulin, aimed at keeping the FPG <108 mg/dL. A subset of obese patients was studied using metformin as the primary therapeutic agent.

CLINICAL CONTROVERSY

Preservation of β -cell function, and thus arresting the progression of type 2 diabetes, appears to be the future goal of treatment. The UKPDS clearly showed that sulfonylureas, metformin, and insulin are ineffective in stopping the progressive β -cell failure. In animal models TZDs, exenatide, and DPP-IV inhibitors have been able to arrest β -cell failure, and in humans, short-term indirect β -cell function measures have improved. Confirmatory human data showing arrest or delay of the progressive β -cell decline in type 2 DM is needed. Rosiglitazone data in prediabetes and newly diagnosed diabetes, although measured by the homeostatic model assessment (HOMA)- β , has not shown significant preservation of β -cell function. Long-term data is underway with incretin based therapies.

Significant findings from the study include:

- Microvascular complications (predominantly the need for laser photocoagulation on retinal lesions) are reduced by 25% when median HbA_{1c} is 7% as compared to 7.9%.⁵³
- A continuous relationship exists between glycemia and microvascular complications, with a 35% reduction in risk for each 1% decrement in HbA_{1c}. No glycemic threshold for microvascular disease exists.⁹⁶
- Glycemic control has minimal effect on macrovascular disease risk.⁶¹ Excess macrovascular risk appears to be related to conventional risk factors such as dyslipidemia and hypertension.⁹⁷
- Sulfonylureas and insulin therapy do not increase macrovascular disease risk.⁶¹
- Metformin reduces macrovascular risk in obese patients.⁸⁴
- Vigorous blood pressure control reduces microvascular and macrovascular events.⁹⁷ There was no evidence for a threshold systolic blood pressure above 130 mm Hg for protection against complications. β -Blockers and ACE inhibitors appear to be equally efficacious.⁹⁸

■ THERAPEUTICS

8 Knowledge of the patient’s quantitative and qualitative meal patterns, activity levels, pharmacokinetics of insulin preparations and other injectables, and pharmacology of oral and antidiabetic agents for type 2 DM are essential to individualize the treatment plan and optimize blood glucose control while minimizing risks for hypoglycemia and other adverse effects of pharmacologic therapies.

Type 1 DM

The choice of therapy for type 1 DM is simple: All patients need insulin. However, how that insulin is delivered to the patient is a matter of considerable practice difference among patients and clinicians. Historically, after the discovery of insulin by Banting and Best in 1921, frequent injections of regular insulin (initially the only insulin available) were given. Modifications of insulin led to longer-acting insulin suspensions and the use by many patients of one or two shots of longer-acting insulin each day. Because SMBG and HbA_{1c} testing were not available at that time, patients and practitioners had no idea how well their patients’ blood glucose concentrations were controlled, other than a vague sense from an indirect method, measurement of glucose in the urine. Although the renal threshold for glucose is relatively predictable in young healthy subjects, it is highly variable in older patients and patients with renal disease. The advent of SMBG and HbA_{1c} testing in the 1980s revolutionized the care of diabetes, enabling patients and practitioners to directly access blood glucose for assessment, and enabling

the patient to make instantaneous changes in the insulin regimen if need be. Modern diabetes management would be impossible without these two tools.

Contemporary management of type 1 DM attempts to match carbohydrate intake with glucose-lowering processes, most commonly insulin, as well as with exercise. Diet is still the cornerstone of diabetes therapy, but unlike in previous years, attempts are made to allow the patient to live as normal a life as possible. Understanding the principles of glucose input and glucose egress from the blood will allow the practitioner and the patient great latitude in the management of patients with type 1 DM.

Simply speaking, one can break down normal insulin secretion into a relatively constant background level of insulin (*basal*) for the fasting and postabsorptive period, and prandial spikes of insulin after eating (*bolus*) (Fig. 77–8).⁹⁹ Insulin sensitivity and insulin secretion are not constant throughout the day, rendering the basal concept inaccurate. However, in most clinical situations, this approach provides a useful paradigm for understanding and applying insulin treatment for type 1 DM. The other basic principle to consider is that the timing of insulin onset, peak, and duration of effect must match meal patterns and exercise schedules to achieve near-normal blood glucose values throughout the day.

Historically, complexity of insulin regimens has usually been related to the number of injections of insulin administered per day.

This is a reasonable classification. Clearly one injection of any insulin preparation daily will in no way mimic normal physiology, and therefore is unacceptable. Similarly, two injections of any insulin daily will fail to replicate normal insulin release patterns. Injection regimens that begin to approximate physiologic insulin release start with “split-mixed” injections of a morning dose of NPH and regular insulin before breakfast, and again before the evening meal. The presumption is made that the morning NPH insulin gives basal insulin for the day and covers the midday meal, the morning regular insulin covers breakfast, the evening NPH insulin gives basal insulin for the rest of the day, and the evening regular covers the evening meal. If patients are very compulsive about consistency of timing of their injections and meals and intake of carbohydrate, such a strategy can be successful. However, most patients are not sufficiently predictable in their schedule and food intake to allow “tight” glucose control with such an approach.

The first modification that is frequently made to such a regimen is the movement of the evening NPH to bedtime (now three total injections per day) because the fasting glucose in the morning is too high. This approach improves glycemic control and reduces hypoglycemia, sufficiently intensifying the insulin therapy for some patients.¹⁰⁰ However, many patients need a more intense approach that also allows greater flexibility in their lifestyle.

9 The basal-bolus concept is an attempt to replicate normal insulin physiology with a combination of intermediate- or long-acting insulin to give the basal component, and short-acting insulin to give the bolus component. Various strategies have been used for the former, including once- or twice-daily NPH or detemir, or once-daily insulin glargine. Most type 1 DM patients require two shots of all of the above insulins except insulin glargine. Also, all of the above insulins, with the exception of insulin glargine, have some degree of peak effect that must be considered in planning meals and activity. Insulin glargine or insulin detemir is a feasible basal insulin supplement for most patients with type 1 DM. The bolus insulin component is given before meals with regular insulin, insulin lispro, insulin aspart, or insulin glulisine. The rapid onset of action and short time course of rapid-acting insulin analogs more closely replicate normal physiology. This approach allows the patient to vary the amount of insulin injected, depending on the preprandial SMBG level, the anticipated activity (upcoming exercise can reduce insulin requirement), and anticipated carbohydrate intake. Most patients will have a prescribed dose of insulin preprandially that they vary by use of a *sliding scale*. This type of adjusted scale insulin is intended to optimize the insulin regimen. In light of the negative connotation of the term *sliding scale* (usually referring to giving insulin only after the blood glucose increases, rather than treating the underlying disorder), a better descriptor for the adjusted-dose insulin is *variable-dose prandial insulin*, *correction factor*, or *insulin algorithm*. A rough correction factor can be calculated by taking 1,500 divided by the total daily dose of insulin. This gives the approximate glucose lowering (mg/dL) effect of one unit of insulin. Carbohydrate counting is a very effective tool for determining the amount of insulin to be injected preprandially. Although general algorithms give rough guidelines, each patient will have to adjust the prescribed preprandial insulin dosage to achieve optimal glucose control. A rough estimate of how much carbohydrate (grams) one unit of rapid-acting insulin will cover is to divide 500 by the total daily dose of insulin.

Empirically, patients can begin on ~0.6 unit/kg per day with basal insulin 50% of total dose and prandial insulin 20% of total dose prebreakfast, 15% prelunch, and 15% presupper. Type 1 DM patients generally require between 0.5 and 1 unit/kg per day. The need for significantly higher amounts of insulin suggests the presence of insulin antibodies or insulin resistance (coexistent endocrinopathy or type 2 DM).

Intensive insulin therapy regimens

	7AM	11AM	5PM	Bedtime
1. 2 doses, ^a R or rapid acting + N	R, L, A, E, GLU + N	R, L, A, E, GLU + N	R, L, A, E, GLU + N	
2. 3 doses, R or rapid acting + N	R, L, A, E, GLU + N	R, L, A, E, GLU + N	R, L, A, E, GLU + N	
3. 4 doses, R or rapid acting + N	R, L, A, E, GLU + N	R, L, A, E, GLU + N	R, L, A, E, GLU + N	N
4. 4 doses R or rapid acting + N	R, L, A, E, GLU + N	R, L, A, E, GLU + N	R, L, A, E, GLU + N	N
5. 4 doses, ^b R or rapid acting + long acting	R, L, A, E, GLU + N	R, L, A, E, GLU + N	R, L, A, E, GLU + N	G or D ^b (G may be given anytime every 24 hours)
6. CS-II pump	Bolus	Bolus	Bolus	

^aMany clinicians may not consider this intensive insulin therapy

^bMay be given BID in type 1 DM= 5 doses

FIGURE 77-8. Relationship between insulin and glucose over the course of a day and how various insulin regimens could be given. (A, aspart; CS-II, continuous subcutaneous insulin infusion; D, detemir; E, Exubera; G, glargine; GLU, glulisine; L, lispro; N, NPH; R, regular.)

Obviously, insulin pump therapy (continuous subcutaneous insulin infusion [CSII], generally using lispro or aspart insulin to diminish aggregation) is the most sophisticated form of basal bolus insulin delivery system. CSII can be slightly more efficacious in achieving good glycemic control than multiple-dose insulin injections.^{101,102} Extensive discussion of this mode of therapy is beyond the scope of this text.¹⁰³ Nevertheless, the basic principles for implementation are the same. The one advantage of pump therapy is that the basal insulin dose can be varied, consistent with changes in insulin requirements throughout the day. In selected patients, this feature will allow greater glycemic control with CSII. However, insulin pumps require even greater attention to detail and frequency of SMBG than four injections daily.¹⁰⁴ In appropriately selected patients willing to pay sufficient attention to detail of SMBG and insulin administration, CSII can be a very useful form of therapy.

Intensive therapy (basal-bolus) to all adult patients with type 1 DM at the time of diagnosis is recommended to reinforce the importance of glycemic control from the outset rather than change strategies over time after lack of control. Occasional patients with an extended honeymoon period may need less intense therapy initially but should be converted to basal-bolus therapy at the onset of glycemic lability. For patients insisting on two injections daily, NPH and regular insulin (starting at 0.6 units/kg with two-thirds in the morning, two-thirds of morning dose as NPH, and one-half of evening dose as NPH) may be sufficient. Regardless of the regimen chosen, gross adjustments in the total insulin dose can be made based on HbA_{1c} measurements and symptoms such as polyuria, polydipsia, and weight gain or loss. Finer insulin adjustments can be determined on the basis of the results of frequent SMBG.

All patients receiving insulin should have extensive education in the recognition and treatment of hypoglycemia. Yearly (or more often) questioning about the recognition of hypoglycemia is warranted. Documentation of frequency of hypoglycemia, particularly that requiring assistance of another person, visit to an emergent or urgent care facility, or hospitalization, should be recorded. In type 1 DM, the development of hypoglycemia unawareness is common. It can result from progression of disease with autonomic neuropathy. Loss of adrenergic warning signs in such a situation is a relative contraindication to intensive insulin therapy. More commonly, type 1 DM patients have loss of warning signs because of a presumed lower set point for release of counterregulatory hormones as a result of frequent episodes of hypoglycemia (“hypoglycemia begets hypoglycemia”).¹⁰⁵ In such situations, more normal hypoglycemia awareness can be restored by reduction or redistribution of the insulin dose to eliminate significant hypoglycemic episodes. A recent publication has found that short-term treatment with theophylline will improve hypoglycemia awareness.¹⁰⁶ This therapy should not routinely be employed but can be considered in refractory cases.

Children and pubescent adolescents are relatively protected from microvascular complications and must be managed with consideration of what is practical. Therefore it is not unreasonable to use less intense management (two shots per day, premixed insulins) until the patient is postpubertal.¹⁰⁷

Occasional patients have antibodies to injected insulin, but the significance of the antibodies is usually minimal.¹⁰⁸ Human insulin therapy has not totally eliminated insulin allergies, although most patients have a local reaction that will dissipate over time. If the allergic reaction does not improve or is systemic, insulin desensitization can be carried out.¹⁰⁹ Protocols for desensitization are available from major insulin manufacturers. Although more common in the animal insulin era, lipohypertrophy is still seen in some patients with long-standing type 1 DM. Such patients give their insulin injections in the same site to minimize discomfort. Because insulin absorption from an area of lipohypertrophy is unpredictable, avoidance of injections into these areas is mandatory.

Several common errors can occur in the therapy of patients with type 1 DM, causing erratic glucose fluctuations:

- Failure to take into account peaks of insulin action when using a peaking insulin and planning meals and/or activity. Eating should be planned around the peaks of the insulin.
- Random rotation of insulin injection sites. There is sufficient variability of insulin absorption from site to site that this practice alone can cause wide glucose swings. The most consistent absorption of insulin is from the abdominal wall. We try to get our patients to take all their injections in the abdomen. If the patient is unable or unwilling to follow this advice, then systematic site rotation is the next preferable option. The patient always gives the insulin injection in the same region of the body the same time of the day each day. For instance, the arms are always used every morning. Needless to say, the patient would not inject in a limb and then go out and exercise that limb, increasing blood flow and insulin absorption.
- Overinsulinization is a very common problem. The answer to all high blood glucose is not necessarily more insulin, as the patient may be insulinopenic, or may be “rebounding” from a previous low glucose and treating it with excessive amounts of carbohydrate. Fastidious SMBG, particularly during the night (or selected use of continuous glucose monitoring) will help sort this out. Also, practitioners sometimes do not adequately differentiate type 1 DM from type 2 DM when using insulin. Patients with type 1 DM are insulinopenic but have normal insulin sensitivity. Patients with type 2 DM have varying degrees of insulin resistance. Therefore one unit change in the dose of insulin for a patient with type 1 DM can have a dramatic effect on glucose concentrations, whereas in some patients with type 2 DM 10 to 20 times that amount of insulin can have little effect on glucose. Large changes in insulin dose in patients with type 1 DM are not usually indicated unless the patient’s blood glucose control is very poor. Widely erratic SMBG results and/or weight gain often suggest overinsulinization.
- When in doubt, always double check the patient’s technique for insulin dosing, insulin injection, and SMBG. Sometimes the simplest of errors results in miserable glycemic control.

Pramlintide in type 1 DM patients who continue to have erratic postprandial control despite consideration or implementation of the above strategies can be appropriate. It is imperative at initiation of therapy with pramlintide that each dose of prandial insulin (rapid acting analog or regular insulin) be reduced by 30% to 50%, or severe hypoglycemic reactions have occurred. Pramlintide should be judiciously titrated based on GI adverse effects and postprandial glycemic goals. As pramlintide is not recommended for mixing, you are adding an additional prandial injection at each meal. A patient who is cognizant of the hypoglycemic risk, GI side effects, and effective strategies to reduce both is needed.

Islet cell and whole pancreas transplantation are occasionally used in patients, usually renal transplants, who require immunosuppressive therapy for other reasons.¹¹⁰ There has been considerable interest in islet cell transplantation since investigators in Edmonton reported success without using glucocorticoids as immunosuppressive agents.¹¹¹ Some of these patients are able to come off insulin altogether.

Type 2 DM

Pharmacotherapy for type 2 DM has changed dramatically in the last few years with the addition of several new drug classes and recommendations to achieve more stringent glycemic control. Symptomatic patients may initially require treatment with insulin or combination oral therapy to reduce glucose toxicity (which can reduce β -cell

insulin secretion and worsen insulin resistance). Patients with HbA_{1c} $\sim 7\%$ or less are usually treated with therapeutic lifestyle measures and an agent that will not cause hypoglycemia. Those with $HbA_{1c} > 7\%$ but $< 8\%$ could be initially treated with single oral agents, or low dose combinations. Patients with higher initial HbA_{1c} can benefit from initial therapy with two oral agents, or even insulin.

10 Depending on patient motivation and adherence to therapeutic lifestyle changes, most patients with HbA_{1c} greater than 9% to 10% will likely require therapy with two or more agents to reach glycemic goals. Treatment of type 2 DM often necessitates use of multiple therapeutic agents (combination therapy), to obtain glycemic goals.

The best initial oral therapy for patients with type 2 DM is widely debated. Based on the results of the UKPDS and safety record, obese patients ($> 120\%$ ideal body weight) without contraindications should be started on metformin titrated to $\sim 2,000$ mg/day.¹¹² Near-normal weight patients can be treated with insulin secretagogues. Failure of initial therapy should result in addition rather than substitution (reserve substitution for intolerance to a drug because of side effects) of another class of drug. For cost and glycemic efficacy reasons, metformin and an insulin secretagogue are often first- and second-line therapy, although combination with other agents for potential cardioprotection or potential β -cell preservation may be preferred. Initial oral combination therapy for patients with $HbA_{1c} > 9\%$ to 10% should be considered, and several oral combination products are available. Oral combination agents that have metformin in combination with a sulfonylurea are often very effective in lowering initially high HbA_{1c} levels. Figure 77-9 is an algorithm developed by the Texas Diabetes Council for glycemic control. TZDs can be substituted in situations in which a patient is

intolerant of, or has a contraindication to, metformin as an insulin sensitizer, understanding that TZDs should be used with caution in heart failure.

The paradigm of treatment is slowly changing, as potentially preserving β -cell function, thus arresting the progressive nature of type 2 DM, is becoming a priority. In the UKPDS, insulin, metformin, or sulfonylureas did not halt β -cell failure. TZDs, exenatide, vildagliptin, and sitagliptin can potentially preserve β -cell function.^{113,114} Despite long-term success at preventing diabetes or treating newly diagnosed diabetes, HOMA- β measures have not shown β -cell benefit with rosiglitazone. Long-term β -cell studies with pioglitazone are underway. If positive human results are found long-term, any of these medications could become potential first-line therapy. For dual therapy, HbA_{1c} reductions vary according to the medication added to the current therapy (Table 77-14). After a patient has inadequate control on two drugs, adding a third drug can be considered. Triple therapy with a TZD is often instituted, but a significant number of patients either have inadequate glycemic improvement or significant side effects. An alternative is to add exenatide, DPP-IV inhibitor, basal insulin, or even the prandial inhaled insulin, Exubera. Therapy should be guided by the HbA_{1c} , FPG, cost, additional benefits (such as weight loss), and avoidance of contraindications and side effects. If the HbA_{1c} is $> 8.5\%$ to 9% on multiple therapies, insulin therapy should be considered first. If the patient is obese and the HbA_{1c} is $\leq 8.5\%$, addition of exenatide or potentially a DPP-IV inhibitor can be considered. Sulfonylureas are often stopped when insulin is added, but continuing the sulfonylurea is permissible until multiple daily injections are started, at which time it should definitely be discontinued.

Exenatide and DPP-IV inhibitors add a new mechanistic way to lower blood glucose. Exenatide is advantageous because it can allow weight loss in type 2 DM patients, but is a twice-a-day injection and has some GI adverse effects. DPP-IV inhibitors are advantageous because they are orally active, weight neutral, and are very well tolerated but lack long-term safety data. It should be remembered that both classes work mainly to lower postprandial glucose excursions

and have only a modest effect on the FPG. Thus, if the patient's fasting glucose is significantly elevated, additional therapy to lower the FPG will often be needed. Metformin, sulfonylureas, repaglinide, TZDs, and basal insulin all effectively lower the FPG.

Virtually all patients with type 2 DM ultimately become relatively insulinopenic and will require insulin therapy. Insulin therapy for type 2 DM has changed dramatically in the last few years. Specifically, patients are often "transitioned" to insulin by using a bedtime injection of an intermediate- or long-acting insulin, and using oral agents primarily for control during the day.^{115,116} This strategy leads to less hyperinsulinemia during the day and is associated with less weight gain than the more traditional insulin strategies. Because most patients are insulin resistant, insulin sensitizers are commonly used with insulin therapy. Patients with type 2 DM are usually well buffered against hypoglycemia. Patients should be monitored for hypoglycemia by asking about nocturnal sweating, nightmares (both indicative of nocturnal hypoglycemia), palpitations, tremulousness, and neuroglycopenic symptoms, as well as SMBG. When bedtime insulin plus daytime oral medications fail to achieve glycemic goals, a conventional multiple daily dose insulin regimen while continuing the insulin sensitizers is often tried. Alternatively, off-label use of exenatide for prandial control can be considered, if covered by insurance. Concerns and problems with insulin administration as addressed in the section on type 1 DM generally relate to the therapy of type 2 DM. However, patients with type 2 DM rarely have hypoglycemia unawareness. Also, the variability of insulin resistance means that insulin doses can range from 0.7 to 2.5 units/kg or more. Figure 77-10 is an algorithm for insulin therapy options in type 2 diabetes developed by the Texas Diabetes Council.

The availability of short-acting insulin secretagogues, rapid-acting insulin analogs, human insulin inhalation powder, exenatide, DPP-IV inhibitors, and α -glucosidase inhibitors, all of which target postprandial glycemia, has reminded practitioners that glycemic control is a function of fasting and preprandial glycemia and postprandial glycemic excursions.¹¹⁷ Therefore postprandial glucose measurements may need more emphasis if the HbA_{1c} is near the glycemic goal. Currently, it remains controversial whether targeting after-meal glucose excursions will have more of an effect on complications risk than more conventional strategies. Importantly, postprandial excursions proportionally contribute more than the FPG to the HbA_{1c} percentage when the HbA_{1c} nears goals, and thus will need to be targeted for optimal glycemic control in many patients. Also controversial are the American College of Endocrinology/American Association of Clinical Endocrinologists postprandial glycemic goals (see Table 77–8). These guidelines use epidemiologic studies with post-glucose challenge glucose measurements in diabetic and nondiabetic subjects to state that postprandial glycemia is a better predictor of macrovascular disease risk in DM.¹¹⁸ In contrast, the ADA continues to recommend peak postprandial blood glucose levels less than 180 mg/dL.

■ SPECIAL POPULATIONS

Children and Adolescents with Type 2 DM

Type 2 DM is increasing in adolescence.¹⁰ Obesity and physical inactivity seem to be particular culprits in the pathogenesis of this disease. Given the many years that the patient will have to live with diabetes, and recent evidence that the timeline for complications may mimic that of older adults, extraordinary efforts should be expended on lifestyle modification measures in an attempt to normalize glucose levels. Failing that strategy, the only labeled oral agent for use in children (10 to 16 years of age) is metformin, although sulfonylureas are also commonly used in therapy. TZDs have not been studied in children, but studies to ascertain safety and efficacy are currently underway. Off-label use of exenatide, as it potentially helps the child to lose weight, is also increasing, but the long-term effects of this therapeutic modality are unknown. In adolescent females, the possibility of future pregnancy should be considered in the prescription of any drug regimen.

Elderly Patients with DM

Elderly patients with newly diagnosed DM (almost always type 2 DM) present a different therapeutic challenge. Consideration of the risks of hypoglycemia in this population and the probable life span should help determine if less-stringent glycemic goals should be set. Thinner, older patients can primarily be treated with shorter-acting insulin secretagogues, low-dose sulfonylureas (preferably not long-acting ones), DPP-IV inhibitors, or α -glucosidase inhibitors. The risk for lactic acidosis, which increases with older age and the age-related decline in renal function, makes metformin therapy more problematic. In a patient whom weight gain or loss may not be unwelcome, TZDs or exenatide, respectively, can be considered. DPP-IV inhibitors or α -glucosidase inhibitors can be advantageous because of low risk of hypoglycemia. Simple insulin regimens such as an injection of basal insulin daily can be appropriate for glycemic control in elderly patients with newly diagnosed DM.

Gestational DM

GDM is diagnosed as previously described. Dietary therapy to minimize wide fluctuations in blood glucose is of paramount importance.⁵ Intensive educational efforts are usually necessary. Pregnant women without DM maintain plasma glucose concentrations between 50 and 130 mg/dL. Frequent SMBG is needed to tell

whether dietary interventions are successful. If FPG is >105 mg/dL, or 1-hour postprandial plasma glucose levels are >155 mg/dL, or if 2-hour postprandial plasma glucose levels are >130 mg/dL, insulin therapy is usually begun. One shot of NPH or a mixture of NPH and regular insulin in a 2:1 ratio given before breakfast may be adequate to reach glucose targets. Titration of insulin and switching to more complicated regimens is guided by SMBG results. Use of basal insulins other than NPH is still debated, but with the ease of use of detemir or glargine insulin, their use in GDM will likely increase. In addition, pump therapy for the duration of the pregnancy is often instituted, as it can obtain excellent glycemic control and is quickly adjustable. In spite of the long-standing labeling of sulfonylureas as contraindicated in pregnancy, one randomized, open-label, controlled trial evaluated the efficacy of glyburide as compared to insulin initiated after 11 weeks' gestation.¹¹⁹ Adequate control of blood glucose was achieved as compared to traditional insulin therapy, with less hypoglycemia in the glyburide group. No evidence of any difference in complications, specifically cord-serum insulin concentrations, incidence of macrosomia (birth weight of 4 kg or more), cesarean delivery, or neonatal hypoglycemia between regimens were noted. Glyburide was not detected in the cord serum of any infant. As the study limited enrollment beyond 11 weeks' gestation, no conclusions regarding teratogenicity can be made from this study. The ADA cites this study in a position paper and mentions its usefulness, but also warns that it is not a labeled use of the drug and suggests further studies are needed to establish its safety.¹² Patients with GDM should be evaluated 6 weeks after delivery to ensure that normal glucose tolerance has returned. Because these patients' long-term risk for the development of type 2 DM is considerable, periodic assessment after that is warranted.

■ SPECIAL SITUATIONS

Sick Days

Acute self-limited illness rarely presents a major problem for patients with type 2 DM but can be a significant challenge for insulinopenic type 1 DM patients.¹²⁰ Although caloric intake generally declines, insulin sensitivity also decreases, meaning that it can take greater amounts of insulin to control blood glucose concentrations. Patients need to be adept at frequent SMBG, checking urine ketones, use of short-acting insulin, and understanding that sugar intake in this situation is not “bad” but can be necessary to “cover” the insulin therapy given to keep the patient out of diabetic ketoacidosis. We encourage patients to continue their usual insulin regimen and to use supplemental rapid-acting insulin based on SMBG results, with further additional insulin given if ketonuria develops. Sugar and electrolyte solutions, such as sports drinks, can be used to maintain hydration, to provide needed electrolytes if there are significant GI or urinary losses, and to provide sugar to keep the patient from developing hypoglycemia because of the extra insulin that is usually needed. In contrast, type 2 patients may need to switch to sugar-free drinks if blood glucose levels are continually elevated. Most patients can be taught how to sufficiently manage sick days and avoid hospitalization.

Diabetic Ketoacidosis and Hyperosmolar Hyperglycemic State

Diabetic ketoacidosis and hyperosmolar hyperglycemic state are true diabetic emergencies.^{121,122} A comprehensive discussion of their treatment is beyond the scope of this chapter. In patients with known diabetes, diabetic ketoacidosis is usually precipitated by insulin omission in type 1 DM, and intercurrent illness, particularly infection, in both type 1 and type 2 DM. However, patients with type 1 or type 2 DM (the latter being usually nonwhites or Hispan-

ics) can present at initial presentation.¹²³ It is possible that some of the patients deemed to have type 2 DM actually have type 1 idiopathic DM. Patients with diabetic ketoacidosis can be alert, stuporous, or comatose at presentation. The hallmark diagnostic laboratory values include hyperglycemia, anion gap acidosis, and large ketonemia or ketonuria. Afflicted patients have fluid deficits of several liters and sodium and potassium deficits of several hundred milliequivalents. Restoration of intravascular volume acutely with normal saline, followed by hypotonic saline to replace free water, potassium supplements, and constant infusion insulin restore the patient's metabolic status relatively quickly. A flow sheet is often helpful in tracking the fluid and insulin therapies and laboratory parameters in these patients. Bicarbonate administration is generally not needed and may be harmful, especially in children.¹²⁴ Treatment of the inciting medical condition is also vital. Hourly bedside monitoring of glucose and frequent monitoring (every 2 to 4 hours) of potassium is essential. Metabolic improvement is manifested by an increase in the serum bicarbonate or pH. Serum phosphorus usually starts high and plummets to lower-than-normal levels, although replacing phosphorus, although not unreasonable, is of questionable benefit in most patients. Fluid administration alone will reduce the glucose concentration, so a decrement in glucose values does not necessarily mean that the patient's metabolic status is improving. Rare patients will require larger amounts of insulin than those usually given (5 to 10 units/h). We double the patient's insulin dose if the serum bicarbonate has not improved after the first 4 hours of insulin therapy. Constant infusion of a fixed dose of insulin and the administration of intravenous glucose when the blood glucose level decreases to <250 mg/dL is preferable to titration of the insulin infusion based on the glucose level. The latter strategy may delay clearance of the ketosis and prolong treatment. The insulin infusion should be continued until the urine ketones clear and the anion gap closes. Long-acting insulin should be given 1 to 3 hours prior to discontinuing the insulin infusion. Intramuscular regular insulin or subcutaneous insulin lispro or aspart given every 1 to 2 hours can be used rather than an insulin infusion in patients without hypoperfusion. Patients can develop hyperchloremic metabolic acidosis with treatment if they have been given large volumes of normal saline in the course of their treatment. Such a situation does not require any specific treatment.

Hyperosmolar hyperglycemic state usually occurs in older patients with type 2 DM, at times undiagnosed, or in younger patients with prolonged hyperglycemia and dehydration or significant renal insufficiency. Large ketonemia is usually not seen, as residual insulin secretion suppresses the production of ketones. Infection or another medical illness is the usual precipitant. Fluid deficits are usually greater and blood glucose concentrations higher (at times >1,000 mg/dL) in these patients than in patients with diabetic ketoacidosis. Blood glucose levels should be lowered very gradually with hypotonic fluids and low-dose insulin infusions (1 to 2 units/h). Rapid correction of the glucose levels, a drop greater than 75 to 100 mg/dL per hour, is not recommended, as it can result in cerebral edema. This is especially true for children with diabetic ketoacidosis. Mortality is high with the hyperosmolar hyperglycemic state.

Hospitalization for Intercurrent Medical Illness

Patients on oral agents can need transient therapy with insulin to achieve adequate glycemic control. In patients requiring insulin, patients should receive scheduled doses of insulin with additional short-acting insulin. "Sliding-scale" insulin is to be discouraged, as it is notorious for not controlling glucose and for sometimes resulting in therapeutic misadventures, with wide swings in the blood glucose as the patient "bounces" from hypoglycemia to hyperglycemia.¹²⁵ In-hospital mortality is increased in many hyperglycemic conditions. At least one study documented a reduction in

mortality in type 2 diabetes patients with acute myocardial infarctions¹²⁶ who receive constant intravenous insulin during the acute phase of the event to maintain near-normal glucose concentrations. Similar mortality results have been documented in some intensive care unit settings using intravenous insulin and tight glucose control.^{127,128} Currently the American College of Endocrinology recommends preprandial levels <110 mg/dL, and postprandial level <180 mg/dL, but the ADA lists these data as evidence based level B.¹²⁹ Many protocols for IV insulin infusion are currently available, and implementation for an inpatient setting should use a well established protocol. It is prudent to stop metformin in all patients who arrive in acute care settings until full elucidation of the reason for presentation can be ascertained, as contraindications to metformin are prevalent in hospitalized patients.¹³⁰

Perioperative Management

Surgical patients can experience worsening of glycemia for reasons similar to those listed above for intercurrent medical illness.¹³¹ Patients on oral agents can need transient therapy with insulin to control blood glucose. In patients requiring insulin, scheduled doses of insulin or continuous insulin infusions are preferred. For patients who can eat soon after surgery, the time-honored approach of giving one-half of the usual morning NPH insulin dose with dextrose 5% in water intravenously is acceptable, with resumption of scheduled insulin, perhaps at reduced doses, within the first day. For patients requiring more prolonged periods without oral nutrition and for major surgery, such as coronary artery bypass grafting and major abdominal surgery, constant infusion intravenous insulin is preferred. Use of intravenous insulin infusion has been shown to reduce deep sternal wound infections in patients undergoing coronary artery bypass grafting. Metformin should be discontinued temporarily after any major surgery until it is clear that the patient is hemodynamically stable and normal renal function is documented.

Reproductive-Age Women and Preconception Care for Women

An increasing prevalence of DM has been noted in reproductive-age women.^{132,133} Prepregnancy planning is absolutely mandatory, as organogenesis is largely completed within 8 weeks, so good glycemic control should be obtained prior to conception. Unfortunately, major congenital malformations because of poor glucose control remain the leading cause of mortality and serious morbidity in infants of mothers with type 1 or type 2 diabetes. For women with DM controlled by lifestyle measures alone, conversion to insulin as soon as the pregnancy is confirmed is appropriate. For women with polycystic ovary disease who ovulate and become pregnant with insulin sensitizer therapy, conversion to insulin is mandatory as soon as pregnancy is confirmed. Insulin is the only acceptable pharmacologic therapy during pregnancy for women with DM in the United States. In Europe, metformin and glyburide are sometimes used in pregnancy for type 2 DM, but their use is controversial in the United States. Patients previously treated with insulin can need intensification of their regimen to achieve therapeutic goals. Normal pregnancy is associated with a decrease in the blood glucose concentration as fuel is diverted to the fetus. Pregnant patients will be ingesting both meals and snacks daily. SMBG is generally intensified to try to reach glycemic targets and reduce fetal and maternal morbidity. Whether preprandial or postprandial glucose concentrations should be the target of therapy is hotly debated. Ketosis should be avoided, requiring urine monitoring for ketones in the morning and if the blood sugar is >200 mg/dL.

There has been some concern about the safety of insulin analogs in pregnancy, both for fetal development and advancement of microvascular complications. One study has shown no increase in

retinopathy or progression of same with the use of insulin lispro in pregnancy.¹³⁴

■ SPECIAL TOPICS

Prevention of DM

12 Efforts to prevent type 1 DM with immunosuppressives¹³⁵ or injected¹³⁶ or oral insulin therapy¹³⁷ have been unsuccessful. The Diabetes Prevention Program¹³⁸ confirmed that modest weight loss in association with exercise can have a dramatic impact on insulin sensitivity and the conversion from impaired glucose tolerance to type 2 diabetes. In this study approximately 2,000 individuals with impaired glucose tolerance were randomized to lifestyle changes (diet, exercise, and weight loss) as opposed to usual care. The study, which was originally planned to be ongoing for 5 years, was stopped after 2.8 years because the results were so conclusive. The usual care group developed diabetes at the rate of 11% each year. The lifestyle arm developed diabetes at a rate of 5% per year, a 58% reduction in the risk of developing diabetes.¹³⁸ Surprisingly, a modest amount of diet and exercise yielded impressive results. The exercise program in the lifestyle group was walking 30 minutes, 5 days each week. The mean weight loss over the 2.8 year study period was only 3.6 kg (8 lb). Similar results were seen in the Finnish Diabetes Study.¹³⁹ In the Diabetes Prevention Program¹³⁸ discussed above, approximately 1,000 of the study patients were randomized to metformin therapy. The metformin-treated patients showed a 1.8-kg (4-lb) weight loss.¹³⁸ Interestingly, young and overweight individuals on metformin had a greater reduction in the risk of developing diabetes than normal weight and older study patients.¹³⁸

Metformin and acarbose⁹² appear to mostly be treating early diabetes, because when the drugs were stopped, diabetes rates were close to the conversion rates for placebo. In contrast, the Troglitazone in the Prevention of Diabetes (TRIPOD) study¹⁴⁰ evaluated the ability of troglitazone to prevent the development of diabetes in women with a history of gestational diabetes. The rate of development of diabetes in the placebo arm of the study was approximately 12% per year, compared to about 5% in the treatment group. Total preservation of β -cell function was demonstrated over a 5-year period in women who had near normal β -cell function at baseline and who initially responded to the drug.¹⁴⁰ The preservation of β -cell function was observed for at least 8 months after the drug had been discontinued. The Diabetes Reduction Assessment with Ramipril and Rosiglitazone Medication (DREAM) trial evaluating rosiglitazone and/or ramipril treatment for the delay or prevention of type 2 DM in impaired glucose tolerant subjects was recently published.^{141,142} Rosiglitazone 8 mg daily, over approximately 3 years, reduced the incidence of type 2 diabetes by 60%. In addition, a 37% nonsignificant increase in cardiovascular events was reported. Ramipril 15 mg daily did not significantly prevent the conversion to diabetes. It is possible that longer exposure could have made a difference, but the study was stopped prematurely. It should be noted that no pharmacologic agents are currently FDA approved or recommended for prevention of type 2 diabetes, though the ADA recommends metformin in conjunction with lifestyle changes if the patient is younger, obese, has a family history of diabetes, dyslipidemia, hypertension, or a HbA_{1c} above 6%.¹⁴³ Prevention studies are still underway using pioglitazone, nateglinide, and valsartan.

effective, with a 58% lower relative risk of progression to diabetes, metformin 850 mg twice a day reduced the risk by 31%, and was essentially as effective as diet and exercise in young/obese subjects. Rosiglitazone, acarbose, and even orlistat all have, to one extent or another, been able to delay the onset of type 2 DM. Despite these data, there are no FDA-approved drugs for the delay or prevention of diabetes. The ADA-recommended medications, in conjunction with lifestyle, for the delay or prevention of type 2 DM include metformin. It should be remembered that medications require monitoring and can have serious side effects. Many feel they are simply treating diabetes early, as β -cell dysfunction can be documented in early impaired glucose tolerant subjects. Other than troglitazone, which is not on the market, no medication has clearly shown β -cell preservation. It is logical to try to use medications if they alter the decline of β -cell function, but this is currently off-label use and any attempt to use medication in these situations should be clearly and frankly discussed with the patient.

Patient Education

13 It is not satisfactory to give patients with DM brief instructions with a few pamphlets and expect them to manage their disease adequately. Thinking that diabetes education is limited to one or two encounters is misguided; education is a lifetime exercise. Successful treatment of DM involves lifestyle changes for the patient (e.g., medical nutrition therapy, physical activity, self-monitoring of blood glucose and possibly of urine for ketones, and taking prescribed medications). The patient must be involved in the decision-making process and must learn as much about the disease and associated complications as possible. Emphasis should be placed on the evidence that indicates that complications can be prevented or minimized with glycemic control and management of risk factors for cardiovascular disease. Recognition of the need for proper patient education to empower them into self-care has generated programs for certification in diabetes education. Certified diabetes educators must document their patient education hours and sit for a certification examination that assesses the knowledge, tasks, and skills of an educator in order to become certified. An increasing number of nurses, pharmacists, dietitians, and physicians are becoming certified diabetes educators to document to the public that they meet a minimum standard for diabetes education and to fulfill quality initiatives in meeting guidelines for education recognition.¹⁴⁴

■ TREATMENT OF CONCOMITANT CONDITIONS AND COMPLICATIONS

Retinopathy

Patients with established retinopathy should see an ophthalmologist or optometrist trained in diabetic eye disease.¹⁴⁵ A dilated eye examination is required to fully evaluate diabetic eye disease. Early background retinopathy can reverse with improved glycemic control. More advanced retinopathy will not regress with improved glycemia and can actually worsen with short-term improvements in glycemia. Studies are underway to determine whether medical therapy independent of glucose control will prevent the development of advanced retinopathy. Laser photocoagulation has markedly improved sight preservation in diabetic patients.

Neuropathy

Peripheral neuropathy is the most common complication seen in type 2 DM patients in outpatient clinics.¹⁴⁶ Paresthesias, numbness, or pain can be the predominant symptom. The feet are involved far more often than the hands. Improved glycemic control can alleviate some of

CLINICAL CONTROVERSY

DM is associated with a substantially higher risk of morbidity and mortality. Pharmacologic prevention or delay of type 2 DM has been widely discussed since the release of the Diabetes Prevention Program results. Although lifestyle changes were

the symptoms. If neuropathy is painful, symptomatic therapy is empiric, including low-dose tricyclic antidepressants, anticonvulsants (gabapentin, pregabalin, carbamazepine, and maybe phenytoin), duloxetine, venlafaxine, topical capsaicin, and various pain medications, including tramadol and nonsteroidal antiinflammatory drugs. Recently, another anticonvulsant, topiramate, has shown promise in the reduction of symptoms, with the positive side effect of weight loss in type 2 diabetes patients, although tolerability is problematic. The numb variant of peripheral neuropathy is not treated with medication. Clinical manifestations of diabetic autonomic neuropathy include resting tachycardia, exercise intolerance, orthostatic hypotension, constipation, gastroparesis, erectile dysfunction, sudomotor dysfunction (anhidrosis, heat intolerance, gustatory sweating, and/or dry skin), impaired neurovascular function, and hypoglycemic autonomic failure. Gastroparesis can be a severe and debilitating complication of DM. Improved glycemic control, discontinuation of medications that slow gastric motility, and the use of metoclopramide (preferably for only a few weeks at a time) or erythromycin can be helpful. Gastric pacemakers as therapeutic hardware are rarely used, although available. Orthostatic hypotension can require pharmacologic management with mineralocorticoids or adrenergic agonist agents. In severe cases, supine hypertension is extreme, mandating that the patient sleep in a sitting or semirecumbent position. Patients with cardiac autonomic neuropathy are at a higher risk for silent myocardial infarction and mortality. The hallmark of diabetic diarrhea is its nocturnal occurrence. Diabetic diarrhea frequently responds to a 10- to 14-day course of an antibiotic such as doxycycline or metronidazole. In more unresponsive cases, octreotide can be useful. Erectile dysfunction is common in diabetes, and initial treatment should include a trial of one of the oral medications currently available to treat erectile dysfunction. People with diabetes often require the highest doses of these medications to have an adequate response. Sudomotor dysfunction, as earlier defined, results in loss of sweating and resultant dry, cracked skin. Use of hydrating creams and ointments is needed.

Microalbuminuria and Nephropathy

DM, and particularly type 2 DM, is the biggest contributor statistically to the development of end-stage renal disease in the United States.¹⁴⁷ The ADA recommends a screening urinary analysis for albumin at diagnosis in persons with type 2 DM. Precise onset of type 2 DM can rarely be ascertained, and patients will often present at diagnosis with microvascular complications. In type 1 DM, microalbuminuria rarely occurs with short duration of disease or before puberty. Screening individuals with type 1 DM should begin with puberty and after 5 years' disease duration. There are three methods for assessing microalbuminuria: (1) measurement of the urine albumin-to-creatinine ratio in a random spot collection (preferably the first morning void); (2) 24-hour timed collection; and (3) timed (e.g., 4-hour or 10-hour overnight) collection. Microalbuminuria on a spot urine specimen is defined as a ratio of 30 to 300 mg/g albumin-to-creatinine. On timed collections, microalbuminuria is defined as 30 to 300 mg/24 hours or an albumin excretion rate of 20 to 200 mcg/min. Because of day-to-day variability, microalbuminuria should be confirmed on at least two of three samples over 3 to 6 months. Additionally, when assessing urine protein or albumin, conditions that can cause transient elevations in urinary albumin excretion should be excluded. These conditions include: intense exercise, recent urinary tract infections, hypertension, short-term hyperglycemia, heart failure, and acute febrile illness.¹⁴⁷

In type 2 DM, the presence of microalbuminuria is a strong risk factor for macrovascular disease and is frequently present at the time of diagnosis. Microalbuminuria is a weaker predictor for future kidney disease in type 2 versus type 1 DM.

Glucose and blood pressure control are most important for the prevention of nephropathy, and blood pressure control is the most

important for retarding the progression of established nephropathy. ACE inhibitors and angiotensin receptor blockers, considered first-line recommended treatment modalities, have shown efficacy in preventing the clinical progression of renal disease in patients with type 2 DM.^{148–150} Diuretics frequently are necessary because of the volume-expanded state of the patient and are recommended second-line therapy. The ADA and the National Kidney Foundation blood pressure goal of <130/80 mm Hg can be difficult to achieve. Three or more antihypertensives are often needed to treat to goal blood pressures.

Peripheral Vascular Disease and Foot Ulcers

Claudication and nonhealing foot ulcers are common in type 2 DM patients.¹⁵¹ Smoking cessation, correction of lipid abnormalities, and antiplatelet therapy are important strategies in treating claudicants. Pentoxifylline or cilostazol can be useful in selected patients. Revascularization is successful in selected patients. Local débridement and appropriate footwear and foot care are vitally important in the early treatment of foot lesions. In more advanced lesions, topical treatments can be of benefit. Diabetic foot care is an excellent example of the adage, “an ounce of prevention is worth a pound of cure.”

Coronary Heart Disease

■ The risk for coronary heart disease (CHD) is two to four times greater in diabetic patients than in nondiabetic individuals. CHD is the major source of mortality in patients with DM. Recent studies suggest that multiple risk-factor intervention (lipids, hypertension, smoking cessation,¹⁵² and antiplatelet therapy)¹⁵³ will reduce the burden of excess macrovascular events. Epidemiologic data suggest that CHD prevention guidelines for type 2 DM apply equally to patients with type 1 DM.¹⁵⁴ β -Blocker therapy supplies an even greater protection from recurrent CHD events in diabetic patients than in nondiabetic subjects. Masking of hypoglycemic symptoms is a greater problem in type 1 DM patients than in patients with type 2 DM.

Lipids The Collaborative Atorvastatin Diabetes Study (CARDS) randomized diabetes subjects with no documented cardiovascular disease to atorvastatin 10 mg daily ($n = 1,428$) or placebo ($n = 1,410$). The trial was stopped 2 years early (mean duration of followup was 3.9 years) after meeting the primary efficacy end point of major cardiovascular events, which were reduced by 37% ($P = 0.001$). All-cause death was reduced 27% ($P = 0.059$) and potentially could have had its significance influenced by the early stoppage of the trial.¹⁵⁵ The Heart Protection Study randomized 5,963 patients age >40 years with diabetes and total cholesterol >135 mg/dL. A significant 22% reduction (95% confidence interval [CI], 13–30) in the event rate for major cardiovascular events was seen with simvastatin 40 mg per day. This was evident even at lower LDL levels (<116 mg/dL), and suggests that ~30% reduction in LDL levels regardless of starting LDL levels can be appropriate.¹⁵⁶ The proper use of fibrates in diabetes continues to be controversial. The diabetic subgroup in the Veterans Administration HDL Intervention Trial (VA-HIT) of CHD patients with low HDL-C and low LDL-C showed approximately 22% reduction in CHD events in diabetic patients with known CHD when HDL-C was increased by approximately 6% by gemfibrozil.¹⁵⁷ The Fenofibrate Intervention and Event Lowering in Diabetes (FIELD) was conducted in 9,795 subjects (22% with previously documented cardiovascular disease) with type 2 DM given fenofibrate 200 mg daily or placebo. A relative reduction of 11% ($P = 0.16$) was seen in any coronary event in conjunction with a slight increase in the risk of all-cause mortality. (0.7%, $P = 0.18$). Reasons for this have been speculated on, including the increased use of statins in the placebo group, but it continues to be controversial.¹⁵⁸

The National Cholesterol Education Program Adult Treatment Panel III (NCEP-ATP III)¹⁵⁹ guidelines classify the presence of DM

TABLE 77-15 Classification of Lipid and Lipoprotein Levels in Adults

Parameter	Goal	Treatment (in order of preference)
LDL cholesterol	<100 mg/dL <70 mg/dL ^a	Lifestyle; HMG-CoA reductase inhibitors; cholesterol absorption inhibitor; niacin or fenofibrate
HDL cholesterol	Men >40 mg/dL Women >50 mg/dL	Lifestyle; nicotinic acid; fibric acid derivatives
Triglycerides	<150 mg/dL	Lifestyle; glycemic control; fibric acid derivatives; high-dose statins (in those with high LDL)

HDL, high-density lipoprotein; HMG-CoA, 3-hydroxy-3-methylglutaryl coenzyme A; LDL, low-density lipoprotein.

^aCan be optimal goal in patients with preexisting cardiovascular disease.

Data from American Diabetes Association. *Dyslipidemia management in adults with diabetes. Diabetes Care* 2004;27:568–571.

as a CHD risk equivalent, and therefore recommend that LDL-C be lowered to <100 mg/dL. An optional LDL goal in high-risk DM patients, such as those who already have CHD, has been updated to be <70 mg/dL.¹⁶⁰ Unlike previous guidelines, more consideration is now given to HDL-C and triglycerides. The primary target is the treatment of LDL-C. After the LDL-C goal is reached (usually with a statin), triglycerides are possibly considered for pharmacologic management, assuming unresponsiveness to glycemic control efforts, weight management, and exercise. In such situations, a non-HDL-C goal is established (a surrogate for all apolipoprotein B-containing particles). The non-HDL-C goal for patients with DM is <130 mg/dL. Niacin or a fibrate can be added to reach that goal if triglycerides are 201 to 499 mg/dL. Niacin or a fibrate can also be added if the LDL-C goal is reached, but the patient has low HDL-C (<40 mg/dL). Patients with marked hypertriglyceridemia (≥500 mg/dL) are at risk for pancreatitis. Efforts to reduce triglycerides with glycemic control, elimination of other secondary causes (including medications), and drug therapy (fibrate and/or niacin) are effective treatment strategies. The ADA also recommends similar LDL goals but places raising HDL as the second priority (Table 77–15). The definitive role of pharmacologic therapy of HDL-C and/or hypertriglyceridemia in type 2 DM patients (beyond that seen with statin therapy) has yet to be proven in clinical trials.

Hypertension

The role of hypertension in increasing microvascular and macrovascular risk in patients with DM has been confirmed in the UKPDS⁹⁷ and Hypertension Optimization Treatment¹⁶¹ trials. The ADA recommends aggressive goals for blood pressure (<130/80 mm Hg) in patients with DM.⁸ ACE inhibitors and angiotensin receptor blockers are generally recommended for initial therapy. The National Kidney Foundation also suggests that the blood pressure goal be less than 130/80 mm Hg, as well as recommending diuretics as second-line therapy in patients with diabetic kidney disease.¹⁶² Many patients require multiple agents, on average three agents, to obtain goals, so diuretics, calcium channel blockers, and β -blockers frequently are useful as second and third agents. Blood pressure goals are generally more difficult to achieve than glycemic goals or lipid goals in most diabetic patients.¹⁶³

their well documented renoprotective effects. Currently, angiotensin receptor blockers have less robust data to support cardiovascular reduction compared to other therapeutic choices, yet the data that exists appears to be positive in patients with type 2 DM. Also, in the diabetic subset of the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT), diuretics have shown equivalent results to an ACE inhibitor. The ADA currently recommends the use of any class (ACE inhibitors, angiotensin receptor blockers, β -blockers, diuretics, or calcium channel blockers) of antihypertensive medication that has shown benefit in prevention of poor cardiovascular outcomes. Choice of monotherapy may not be important, as an average of two to three antihypertensive medications are needed to reach blood pressure goals.

Transplantation

Whole pancreas and islet cell transplantation are still relatively experimental procedures in patients with type 1 DM; those with end-stage renal disease also receive kidney transplantation.¹⁶⁴

PHARMACOECONOMIC CONSIDERATIONS

As described in the introduction, the direct and indirect costs of DM are substantial. Much of the indirect costs are related to loss of productivity because of the significant morbidity (hospitalizations, loss of vision, lower extremity amputations, kidney failure, and cardiovascular events) associated with the disease. For a disease that affects about 9% of the population, it is responsible for 11% to 12% of health expenditures. With evidence from the DCCT and UKPDS to support intensive blood glucose control to reduce the risk of complications, the question of cost effectiveness comes into play.

An economic model based on the DCCT approximates that 120,000 persons in the United States would meet criteria for intensive intervention. The cost of implementing intensive therapy over the lifetime of the population is estimated at \$4 billion dollars. The benefits of this strategy are net gains of 920,000 years of sight, 691,000 years free from end-stage renal disease, and 678,000 years free from lower extremity amputations. The incremental cost per year of life gained is \$28,661.¹⁶⁵ This is well within the limits of a cost-effective strategy and compares favorably to treatment of high blood pressure or hypercholesterolemia.

Economic analysis of intensive therapy for type 2 DM is more complex. Outcomes must also factor in the burden of cardiovascular disease as the major cause of mortality. One model analyzed the health benefits and economics of treating type 2 DM with the goal of achieving normoglycemia but using outcomes based on the DCCT trial results. Accounting for the prevalence of cardiovascular disease in type 2 DM, an estimate of \$16,002 incremental cost per quality-adjusted life year gained was obtained. The limitation of this analysis is that although the UKPDS did demonstrate an improvement in diabetes-related outcomes, the overall efficacy on microvascular disease complications was not mirrored by the DCCT.

Two economic analyses were performed on data generated from the UKPDS, one assessing cost effectiveness of an intensive blood glucose control policy in type 2 DM, and the other assessing improved blood pressure control in hypertensive patients with type 2 DM. In the first analysis, outcome was measured as the incremental cost per event-free year gained within the trial. Based on trial outcomes and assumptions, the incremental cost in the intensive treatment group per event-free year gained is \$1,366. Although intensive treatment costs were higher, the cost per event-free year gained appears cost-effective. The second analysis showed the incremental cost per extra year free from microvascular and macrovascu-

CLINICAL CONTROVERSY

Initial therapy choices for hypertension in DM usually include ACE inhibitors or an angiotensin receptor blocker because of

lar end points from intensive blood pressure control in a standard clinical practice model to be \$1,498. The incremental cost per life year gained was estimated at \$619, again demonstrating the cost-effectiveness of intensive intervention.^{166,167}

EVALUATION OF THERAPEUTIC OUTCOMES

MONITORING OF THE PHARMACEUTICAL CARE PLAN

A comprehensive pharmaceutical care plan for the patient with DM will integrate considerations of goals to optimize blood glucose control and protocols to screen for, prevent, or manage microvascular and macrovascular complications. In terms of standards of care for persons with DM, one can review the document published by the ADA that outlines initial and ongoing assessments for patients with DM.⁸ For quality-of-care measures, one can refer to the National Diabetes Quality Improvement Alliance website at www.nationaldiabetesalliance.org, whose members include many of the governmental and physician organizations concerned with diabetes quality-of-care measures.

The major performance measures, such as Health Plan Employer Data and Information Set (HEDIS), should assess the ability to meet current standards of care and recognize the minimal treatment goals for glycemia, lipids, and hypertension, and provide targets for monitoring and adjusting pharmacotherapy as discussed in various sections above. Publicly reported quality measures continue to move closer to current guidelines. Glycemic control (percentage of patients with HbA_{1c} <7%), lipid (percentage of patients with LDL <100 mg/dL), and hypertension (percentage of patients with blood pressure <130/80 mm Hg) are now quality measures congruent with the current goals recommended by the ADA. Glycemic control is paramount in managing type 1 or type 2 DM but as readily identified from the above discussion, it requires frequent assessment and adjustment in diet, exercise, and pharmacologic therapies. Minimally, HbA_{1c} should be measured twice a year in patients meeting treatment goals on a stable therapeutic regimen. Quarterly assessments are recommended for those whose therapy has changed or who are not meeting glycemic goals. Fasting lipid profiles should be obtained as part of an initial assessment and thereafter at each followup visit if not at goal, annually if stable and at goal, or every 2 years if the lipid profile suggests low risk. Documenting regular frequency of foot exams (each visit), urine albumin assessment (annually), dilated ophthalmologic exams (yearly or more frequently with identified abnormalities), and office visits for followup are also important. Assessment for pneumococcal vaccine administration, annual administration of influenza vaccine, and routine assessment for and management of other cardiovascular risks (i.e., smoking and antiplatelet therapy) are components of preventive medicine strategies. The multiplicity of assessments for each patient visit are likely to be better facilitated using an integrative computer program and electronic medical record, standardized progress note forms, or flow sheets, which assist the clinician in identifying whether the patient has met standards of care in the frequency of monitoring and achievement of defined targets of therapy.

ABBREVIATIONS

ACE: angiotensin-converting enzyme

ADA: American Diabetes Association

ALLHAT: Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial

ALT: alanine aminotransferase

BMI: body mass index

CHD: coronary heart disease

CSII: continuous subcutaneous insulin infusion

CYP450: cytochrome P450

DCCT: Diabetes Control and Complications Trial

DM: diabetes mellitus

DPP-IV: dipeptidyl peptidase IV

DREAM: Diabetes Reduction Assessment with Ramipril and Rosiglitazone Medication (study)

FFA: free fatty acid

GDM: gestational diabetes mellitus

GIP: glucose-dependent insulin-releasing peptide

GLP-1: glucagon-like peptide-1

HbA_{1c}: hemoglobin A_{1c}

HDLC: high-density lipoprotein cholesterol

IFG: impaired fasting glucose

IGT: impaired glucose tolerance

LADA: latent autoimmune diabetes in adults

LDLC: low-density lipoprotein cholesterol

MODY: maturity onset diabetes of youth

NCEP-ATP: National Cholesterol Education Program Adult Treatment Panel

NHANES III: The Third National Health and Nutrition Evaluation Survey

NPH: neutral protamine Hagedorn

OGTT: oral glucose tolerance test

PAI-1: activator-1 plasminogen-inhibitor

PPAR- γ : peroxisome proliferator activator receptor- γ

PROactive: Prospective Pioglitazone Clinical Trial in Macrovascular Events

SMBG: self-monitored blood glucose

STOP-NIDDM: Study to Prevent Non-Insulin-Dependent Diabetes Mellitus

SUR: sulfonylurea receptor

TRIPOD: Troglitazone in the Prevention of Diabetes

TZD: thiazolidinedione

UKPDS: United Kingdom Prospective Diabetes Study

VAT: visceral adipose tissue

STEVEN I. SHERMAN AND ROBERT L. TALBERT

KEY CONCEPTS

- 1 The molecular biology of the thyroid hormones and their receptors has provided an in-depth understanding of the various mutations that give rise to hyper- and hypothyroidism.
- 2 Thyrotoxicosis is most commonly caused by Graves' disease, which is an autoimmune disorder in which thyroid-stimulating antibody (TSAb) directed against the thyrotropin receptor elicits the same biologic response as thyroid-stimulating hormone (TSH).
- 3 Hyperthyroidism can be treated with antithyroid drugs such as propylthiouracil (PTU) or methimazole (MMI), radioactive iodine (RAI; e.g., iodine-131 [^{131}I]), or surgical removal of the thyroid gland; selection of the initial treatment approach is based on patient characteristics such as age, concurrent physiology (e.g., pregnancy), comorbidities (e.g., chronic obstructive lung disease), and convenience.
- 4 PTU and MMI reduce the synthesis of thyroid hormones and are similar in efficacy and adverse effects, but their dosing ranges differ by 10-fold.
- 5 Response to PTU and MMI is seen in 4 to 6 weeks with a maximal response in 4 to 6 months; treatment usually continues for 1 to 2 years, and therapy is monitored by clinical signs and symptoms and by measuring the serum concentrations of TSH and free thyroxine (T_4).
- 6 Many patients choose to have ablative therapy with ^{131}I rather than undergo repeated courses of PTU or MMI; most receiving RAI eventually become hypothyroid and require thyroid hormone supplementation.
- 7 Adjunctive therapy with β -blockers controls the adrenergic symptoms of thyrotoxicosis but does not correct the underlying disorder; iodine can also be used adjunctively in preparation for surgery and acutely for thyroid storm.
- 8 Hypothyroidism is most often caused by an autoimmune disorder known as Hashimoto's thyroiditis, and the drug of choice for replacement therapy is levothyroxine.
- 9 Monitoring of levothyroxine replacement therapy is done by clinical signs and symptoms and by measuring the TSH (elevated for under-replacement, suppressed for overreplacement).

Learning objectives, review questions, and other resources can be found at
www.pharmacotherapyonline.com.

Thyroid hormones affect the function of virtually every organ system. In the child, thyroid hormone is critical for normal growth and development. In the adult, the major role of thyroid hormone is to maintain metabolic stability. Substantial reservoirs of thyroid hormone in the thyroid gland and blood provide constant thyroid hormone availability. In addition, the hypothalamic-pituitary-thyroid axis is exquisitely sensitive to small changes in circulating thyroid hormone concentrations, and alterations in thyroid hormone secretion maintain peripheral free thyroid hormone levels within a narrow range. Patients seek medical attention for evaluation of symptoms because of abnormal thyroid hormone levels or because of diffuse or nodular thyroid enlargement.

THYROID HORMONE PHYSIOLOGY

THYROID HORMONE SYNTHESIS

The thyroid hormones thyroxine (T_4) and triiodothyronine (T_3) are formed on thyroglobulin, a large glycoprotein synthesized within the thyroid cell (Fig. 78–1). Because of the unique tertiary structure of this glycoprotein, iodinated tyrosine residues present in thyroglobulin are able to bind together to form active thyroid hormones.¹

Iodide is actively transported through the basolateral membrane via a sodium/iodide (Na^+/I^-) symporter from the extracellular space into the thyroid follicular cell against an electrochemical gradient, driven by the coupled transport of sodium.² Structurally related anions such as thiocyanate (SCN^-), perchlorate (ClO_4^-), and pertechnetate (TcO_4^-) are competitive inhibitors of iodine transport.³ In addition, bromine, fluorine, and lithium block iodide transport into the thyroid (Table 78–1). Inorganic iodide that enters the thyroid follicular cell is ushered through the cell to the apical membrane, where it is transported into the follicular lumen by at least two efflux channels.^{4,5} Located on the luminal side of the apical membrane, thyroid peroxidase oxidizes iodide and covalently binds the organified iodide to tyrosine residues of thyroglobulin (Fig. 78–2). It is interesting that although salivary glands and the gastric mucosa are able to actively transport iodide, they are unable to effectively incorporate iodide into proteins given the lack of similar oxidizing machinery. Similarly, when tyrosine molecules are iodinated on proteins other than thyroglobulin, they lack the proper tertiary structure needed to allow the formation of active thyroid hormones.

The iodinated tyrosine residues monoiodotyrosine (MIT) and diiodotyrosine (DIT) combine to form iodothyronines (Fig. 78–3). Thus, two molecules of DIT combine to form T_4 , whereas MIT and DIT constitute T_3 . In addition to its role in iodine organification, the hemoprotein thyroid peroxidase also catalyzes the formation of iodothyronines (coupling).

Iodine deficiency causes an increase in the ratio of MIT to DIT in thyroglobulin and leads to a relative increase in the production of T_3 .⁶ Because T_3 is more potent than T_4 , the increase in T_3 production in

FIGURE 78-1. Structure of thyroid hormones.

iodine-depleted areas can be beneficial. The thionamide drugs used to treat hyperthyroidism inhibit thyroid peroxidase and thus block thyroid hormone synthesis.

Thyroglobulin is stored in the follicular lumen and must reenter the cell, where the process of proteolysis liberates thyroid hormone into the bloodstream. Thyroid follicles active in hormone synthesis are identified histologically by columnar epithelial cells lining follicular lumens, which are depleted of colloid. Inactive follicles are lined by cuboidal epithelial cells and are replete with colloid. Both iodide and lithium block the release of preformed thyroid hormone through poorly understood mechanisms.

T_4 and T_3 are transported in the bloodstream primarily by three proteins: thyroxine-binding globulin (TBG), transthyretin (TTR), and albumin.⁷ It is estimated that 99.96% of circulating T_4 and 99.5% of T_3 are bound to these proteins. However, only the unbound (free) thyroid hormone is able to diffuse into the cell, elicit a biologic effect, and regulate thyroid-stimulating hormone (TSH; also known as thyrotropin) secretion from the pituitary. Multiple functions have been ascribed to these transport proteins, including (1) assuring minimal urinary loss of iodide, (2) providing a mechanism for uniform tissue distribution of free hormone, and (3) transport of hormone into the central nervous system.

Whereas T_4 is secreted solely from the thyroid gland, less than 20% of T_3 is produced in the thyroid. The majority of T_3 is formed from the breakdown of T_4 catalyzed by the enzyme 5-monodeiodinase found in extrathyroidal peripheral tissues. Because the binding affinity of nuclear thyroid hormone receptors is 10 to 15 times higher for T_3 than T_4 , the deiodinase enzymes play a pivotal role in determining overall metabolic activity. Three different monodeiodinase enzymes are present in the body.⁸ Of the enzymes that catalyze 5'-monodeiodination, type I enzymes are present in peripheral tissues, whereas type II enzymes are found in the central nervous system, pituitary, and thyroid. Type III enzymes, found in the placenta, skin, and developing brain, inactivate T_4 and T_3 by deiodinating the inner ring at the 5'-position. The principal characteristics of these enzymes are listed in Table 78-2. T_4 may also be acted on by the enzyme 5'-monodeiodinase to form reverse T_3 , but this accounts for a small component of hormone metabolism. Reverse T_3 has no known significant biologic activity. T_3 is removed from the body by deiodinative degradation

TABLE 78-1 Thyroid Hormone Synthesis and Secretion Inhibitors

Mechanism of Action	Substance
Blocks iodide transport into the thyroid	Bromine
	Fluorine
	Lithium
Impairs organification and coupling of thyroid hormones	Thionamides
	Sulfonyleureas
	Sulfonamide (?)
	Salicylamide (?)
	Antipyrine (?)
Inhibits thyroid hormone secretion	Lithium iodide (large doses)

FIGURE 78-2. Thyroid hormone synthesis. Iodide is transported from the plasma, through the cell, to the apical membrane where it is organified and coupled to the thyroglobulin (TG) synthesized within the thyroid cell. Hormone stored as colloid reenters the cell through endocytosis and moves back toward the basal membrane, where T_4 is secreted. (T_4 , thyroxine.)

and through the action of sulfotransferase enzyme systems to T_3 sulfate and 3,3'-diiodothyronine sulfates, thus facilitating enterohepatic clearance.

The growth and function of the thyroid are stimulated by activation of the thyrotropin receptor by TSH.⁹ The receptor belongs to the family of G-protein-coupled receptors. The thyrotropin receptor is coupled to the α subunit of the stimulatory guanine-nucleotide-binding protein (G_s), activating adenylate cyclase and increasing the accumulation of cyclic adenosine monophosphate. Through this mechanism, TSH stimulates the expression of thyroglobulin and thyroid peroxidase genes as well as increases apical iodide efflux. Somatic activating mutations in the receptor are commonly seen in autonomously functioning thyroid nodules.¹⁰ Rarely, germline activating mutations of the TSH receptor have been reported in kindreds with Leclère's syndrome, and thyrotoxicosis can also result from germline-activating mutations in G protein signaling in McCune-

FIGURE 78-3. Scheme of coupling reactions. After tyrosine is iodinated to form monoiodotyrosine (MIT) or diiodotyrosine (DIT) (organification of the iodine), MIT and DIT combine to form triiodothyronine (T_3), or two molecules of DIT form thyroxine (T_4).

TABLE 78-2 Properties of Iodothyronine 5'-Deiodinase Isoforms

Property	Type I	Type II	Type III
Effect of propylthiouracil	Increase	Decrease	Increase
Tissue localization	Thyroid, liver, kidney	Pituitary, thyroid, CNS, brown adipose tissue	Placenta, developing brain, skin
Preferred substrate	$rT_3 > T_4 > T_3$	$T_4 > T_3$	$T_3 \text{ (sulfate)} > T_4$
Physiologic role	Extracellular T_3 production for peripheral tissue	Intracellular T_3 production, especially for brain in hypothyroidism or iodine deficiency	Inactivation of T_4 and T_3
Developmental expression	Expressed latest in development; predominant deiodinase in adult	Expressed second; especially high in brain and brown adipose tissue	Expressed first; high in developing brain; may be important for fetal thyroid hormone metabolism

rT_3 , reverse T_3 ; T_3 , triiodothyronine; T_4 , thyroxine.

Albright's syndrome.^{9,11–13} Conversely, thyrotropin resistance would result from point mutations that prevent TSH binding, leading to abnormalities in the thyrotropin receptor–adenylate cyclase system and congenital hypothyroidism.^{14,15} Individuals with this abnormality have high levels of TSH, but decreased thyroglobulin levels and a normal or small gland.

Thyroid hormone receptors regulate the transcription of target genes in the presence of physiologic concentrations of T_3 .¹⁶ Unlike most other nuclear receptors, thyroid hormone receptors also actively regulate gene expression in the absence of hormone, typically resulting in an opposite effect. Thyroid receptors translocate from the cytoplasm to the nucleus, interact in the nucleus with T_3 , and target genes and other proteins required for basal and T_3 -dependent gene transcription. Thyroid receptors exist in three isoforms, $TR\beta$, $TR\beta_1$, and $TR\alpha_1$, with variation in the expression of each in differing tissues.

The production of thyroid hormone is regulated in two main ways. First, thyroid hormone is regulated by TSH secreted by the anterior pituitary. The secretion of TSH is itself under negative feedback control by the circulating level of free thyroid hormone and the positive influence of hypothalamic thyrotropin-releasing hormone (TRH). Second, extrathyroidal deiodination of T_4 to T_3 is regulated by a variety of factors including nutrition, nonthyroidal hormones, drugs, and illness.

THYROTOXICOSIS

Thyrotoxicosis results when tissues are exposed to excessive levels of T_4 , T_3 , or both.¹⁷ In the National Health and Nutrition Examination Survey III (NHANES III), 0.7% of those surveyed who were not taking thyroid medications and had no history of thyroid disease had subclinical hyperthyroidism (TSH <0.1 mIU/L; and T_4 normal), and 0.5% had “clinically significant” hyperthyroidism (TSH <0.1 mIU/L; and $T_4 >13.2$ mcg/dL).¹⁸ The prevalence of suppressed TSH peaked in people aged 20 to 39 years, declined in those 40 to 79 years of age, and increased again in those 80 years of age or older. Abnormal TSH levels were more common among women than among men.

CLINICAL PRESENTATION OF THYROTOXICOSIS

General

- Patients can have symptoms for an extended time period before the diagnosis of hyperthyroidism is made.

Symptoms

- The typical clinical manifestations of thyrotoxicosis include nervousness, anxiety, palpitations, emotional lability, easy fatigability, menstrual disturbances, and heat intolerance. A cardinal symptom is loss of weight concurrent with an increased appetite.

Signs

- A variety of physical signs can be elicited including warm, smooth, moist skin, exophthalmos (in Graves' disease only),

pretibial myxedema (in Graves' disease only), and unusually fine hair. Separation of the end of the fingernails from the nail beds (onycholysis) may be noted. Ocular signs that result from thyrotoxicosis include retraction of the eyelids and lagging of the upper lid behind the globe when the patient looks downward (lid lag). Physical signs of a hyperdynamic circulatory state are common and include tachycardia at rest, a widened pulse pressure, and a systolic ejection murmur. Gynecomastia is sometimes noted in men. Neuromuscular examination often reveals a fine tremor of the protruded tongue and outstretched hands. Deep tendon reflexes are generally hyperactive. Thyromegaly is usually present.

Diagnosis

- Low TSH serum concentration. Elevated free and total T_3 and T_4 serum concentrations, particularly in more severe disease.
- Elevated radioactive iodine uptake (RAIU) by the thyroid gland when hormone is being overproduced; suppressed RAIU in thyrotoxicosis caused by thyroid inflammation (thyroiditis)

Other Tests

- Thyroid stimulating antibodies (TSAb)
- Thyroglobulin
- Thyrotropin receptor antibodies
- Thyroid biopsy
- Thyroperoxidase antibodies (TPO antibodies)

In the elderly (>65 years old) patient and in the patient with very severe disease, anorexia can be present as well. Elderly patients are also more likely to develop atrial fibrillation with thyrotoxicosis than younger patients. The frequency of bowel movements can increase, but frank diarrhea is unusual. Palpitations are a prominent and distressing symptom, particularly in the patient with preexisting heart disease. Proximal muscle weakness is common and is noted on climbing stairs or in getting up from a sitting position. Women might note their menses are becoming scanty and irregular. Extremely thyrotoxic (thyrotoxic storm) patients can have tachycardia, heart failure, psychosis, hyperpyrexia, and coma.¹⁹

DIFFERENTIAL DIAGNOSIS

If the clinical history and examination do not provide pathognomonic clues to the etiology of the patient's thyrotoxicosis, measurement of the RAIU is critical in the evaluation (Table 78–3). The normal 24-hour RAIU ranges from 10% to 30% with some regional variation because of differences in iodine intake. An elevated RAIU indicates true hyperthyroidism, that is, the patient's thyroid gland is actively overproducing T_4 , T_3 , or both. Conversely, a low RAIU, in the absence of iodine excess, indicates that high levels of thyroid hormone are not a consequence of thyroid gland hyperfunction but likely caused by thyroiditis or hormone ingestion. The importance

TABLE 78-3 Differential Diagnosis of Thyrotoxicosis

Increased RAIU	Decreased RAIU
TSH-induced hyperthyroidism	Inflammatory thyroid disease
TSH-secreting tumors	Subacute thyroiditis
Selective pituitary resistance to T_4	Painless thyroid
Thyroid stimulators other than TSH ^a	Ectopic thyroid tissue
TSAb (Graves' disease)	Struma ovarii
hCG (trophoblastic diseases)	Metastatic follicular carcinoma
Thyroid autonomy	Exogenous sources of thyroid hormone
Toxic adenoma	Medication
Multinodular goiter	Food

hCG, human chorionic gonadotropin; RAIU, radioactive iodine uptake; TSAb, thyroid-stimulating antibodies; TSH, thyroid-stimulating hormone; T_3 , triiodothyronine; T_4 , thyroxine.

^aThe RAIU can be decreased if the patient has been recently exposed to excess iodine.

of differentiating true hyperthyroidism from other causes of thyrotoxicosis lies in the widely different prognosis and treatment of the diseases in these two categories. Therapy of thyrotoxicosis associated with thyroid hyperfunction is mainly directed at decreasing the rate of thyroid hormone synthesis, secretion, or both. Such measures are ineffective in treating thyrotoxicosis that is not the result of true hyperthyroidism, because hormone synthesis and regulated hormone secretion are already at a minimum.

CAUSES OF THYROTOXICOSIS ASSOCIATED WITH ELEVATED RAIU

TSH-Induced Hyperthyroidism

To better understand these syndromes we must first review TSH biosynthesis and secretion. TSH is synthesized in the anterior pituitary as separate α - and β -subunit precursors. The α subunits from luteinizing hormone (LH), follicle-stimulating hormone (FSH), human chorionic gonadotropin (hCG), and TSH are similar, whereas the β subunits are unique and confer immunologic and biologic specificity. Free β -subunits are devoid of receptor binding and biologic activity and require combination with an α -subunit to express their activity. Criteria for the diagnosis of TSH-induced hyperthyroidism include (1) evidence of peripheral hypermetabolism, (2) diffuse thyroid gland enlargement, (3) elevated free thyroid hormone levels, and (4) elevated or inappropriately "normal" serum immunoreactive TSH concentrations. Because the pituitary gland is extremely sensitive to even minimal elevations of free T_4 , a "normal" or elevated TSH level in any thyrotoxic patient indicates the inappropriate production of TSH.

TSH-Secreting Pituitary Adenomas

TSH-secreting pituitary tumors occur sporadically and release biologically active hormone that is unresponsive to normal feedback control.²⁰ The mean age at diagnosis is approximately 40 years of age, with women being diagnosed more commonly than men (8:7). These tumors can cosecrete prolactin or growth hormone; therefore the patients can present with amenorrhea/galactorrhea or signs of acromegaly. Most patients present with classic symptoms and signs of thyrotoxicosis. Visual-field defects can be present because of impingement of the optic chiasm by the tumor. Tumor growth and worsening visual-field defects have been reported following treatment of thyrotoxicosis, because of loss of feedback inhibition from high thyroid hormone levels.

Diagnosis of a TSH-secreting adenoma should be made by demonstrating lack of TSH response to TRH stimulation, inappropriate TSH levels, elevated α -subunit levels, and radiologic imaging; given the lack of routine availability of TRH, the other three criteria are essential. Note that some small tumors are not identified by

magnetic resonance imaging (MRI). Moreover, 10% of "normal" individuals can have pituitary tumors or other benign focal lesions noted on pituitary imaging.

Transsphenoidal pituitary surgery is the treatment of choice for TSH-secreting adenomas. Pituitary gland irradiation is often given following surgery to prevent tumor recurrence. Bromocriptine and octreotide have been used to treat tumors, especially those that cosecrete prolactin.

Pituitary Resistance to Thyroid Hormone

Pituitary resistance to thyroid hormone (PRTH) refers to selective resistance of the pituitary thyrotrophs to thyroid hormone.²¹ Approximately twice as many women as men have been reported with this rare, probably familial syndrome. Multiple abnormalities have been reported in the initial 50 reported cases including schizophrenia (three patients), mental retardation (two patients), short fourth metacarpals (one patient), and Marfanoid habitus (one patient). Approximately 90% of patients studied have an appropriate increase in TSH in response to TRH; conversely, the TSH will be suppressed by T_3 administration.

Patients with PRTH require treatment to reduce their elevated thyroid hormone levels. Determining the appropriate serum T_4 level is difficult because TSH cannot be used to evaluate adequacy of therapy. Any reduction in thyroid hormone carries the risk of inducing thyrotroph hyperplasia. Ideally, agents that suppress TSH secretion could be used to treat these individuals. Glucocorticoid, dopaminergic drugs, somatostatin and its analog, and thyroid hormone analogs with reduced metabolic activity have all been tried; given the ability of retinoid X receptor ligands to inhibit TSH production, drugs such as bexarotene can have therapeutic benefit in PRTH.²²

THYROID STIMULATORS OTHER THAN TSH

Graves' Disease

Graves' disease is an autoimmune syndrome that usually includes hyperthyroidism, diffuse thyroid enlargement, and exophthalmos, and less commonly pretibial myxedema and thyroid acropachy (Fig. 78-4).^{17,23,24} Graves' disease is the most common cause of hyperthyroidism, with a prevalence estimated to be 3 per 1,000 in the U.S. population. Hyperthyroidism results from the action of TSABs, which are directed against the thyrotropin receptor on the surface of the thyroid cell.^{14,15} When these immunoglobulins bind to the receptor, they activate downstream G-protein signaling and adenylate cyclase in the same manner as TSH. Autoantibodies that react with orbital muscle and fibroblast tissue in the skin are responsible for the extrathyroidal manifestations of Graves' disease, and these autoantibodies are encoded by the same germline genes that encode for other autoantibodies for striated muscle and thyroid peroxidase.²⁵ Clinically, the extrathyroidal disorders might not appear at the same time that hyperthyroidism develops.

There is now compelling evidence that heredity predisposes the susceptible individual to development of clinically overt autoimmune thyroid disease in the setting of appropriate environmental and hormonal triggers. A role for gender in the emergence of Graves' disease is suggested by the fact that hyperthyroidism is approximately eight times more common in women than men. Other lines of evidence support a role for heredity. First, there is a well-recognized clustering of Graves' disease within some families. Twin studies in Graves' disease have revealed that a monozygotic twin has a 35% likelihood of ultimately developing the disease compared with a 3% likelihood for a dizygotic twin, resulting in estimation that the 79% of the predisposition to Graves' disease is genetic.²⁶ Second, the occurrence of other autoimmune diseases, including Hashimoto's thyroiditis, is also increased in families of patients with Graves' disease. Third, several

FIGURE 78-4. Features of Graves' disease. (A) Facial appearance in Graves' disease; lid retraction, periorbital edema, and proptosis are marked. (B) Thyroid dermopathy over the lateral aspects of the shins. (C) Thyroid acropachy. (Reproduced with permission from Kasper DL, et al, eds. *Harrison's Principles of Internal Medicine*, 16th ed. New York: McGraw-Hill, 2005:2114.)

studies have demonstrated an increased frequency of certain human leukocyte antigens (HLAs) in patients with Graves' disease. Differing HLA associations have been identified in the various ethnic groups studied. In whites, for example, the relative risk of Graves' disease in carriers of the HLA-DR3 haplotype is between 2.5 and 5, whereas lesser associations have been reported for HLA-B8 and the HLA-DQA*0501 allele.^{27,28} As with other autoimmune conditions, certain polymorphisms of the T-cell immunoregulatory protein CTLA-4 have also been associated with Graves' disease. Despite these statistical associations, however, even detailed molecular genetic linkage studies have failed to identify specific genes responsible for the disease.²⁹

The thyroid gland is diffusely enlarged in the majority of patients and is commonly 40 to 60 g (two to three times the normal size). The surface of the gland is either smooth or bosselated, and the consistency varies from soft to firm. In patients with severe disease, a thrill may be felt and a systolic bruit may be heard over the gland, reflecting the increased intraglandular vascularity typical of hyperplasia. Whereas the presence of any of the extrathyroidal manifestations of this syndrome, including exophthalmos, thyroid acropachy, or pretibial myxedema, in a thyrotoxic patient is pathognomonic of Graves' disease, most patients can be diagnosed on the basis of their history and examination of their diffuse goiter (see Fig. 78-4). An important clinical feature of Graves' disease is the occurrence of spontaneous remissions, albeit uncommon. The abnormalities in TSA_b production can decrease or disappear over time in many patients.

The results of laboratory tests in thyrotoxic Graves' disease include an increase in the overall hormone production rate with a dispropor-

tionate increase in T_3 relative to T_4 (Table 78-4). In an occasional patient, the disproportionate overproduction of T_3 is exaggerated, with the result that only the serum T_3 concentration is increased (T_3 toxicosis). The saturation of TBG is increased because of the elevated levels of serum T_4 and T_3 , which is reflected in elevated values for the T_3 resin uptake. As a result, the concentration of free T_4 , free T_3 , and the free T_4 and T_3 indices are increased to an even greater extent than are the measured serum total T_4 and T_3 concentrations. The TSH level will be undetectable because of negative feedback by elevated levels of thyroid hormone at the pituitary.

In the patient with manifest disease, measurement of the serum free T_4 concentration (or total T_4 and T_3 resin uptake), total T_3 , and the TSH value will confirm the diagnosis of thyrotoxicosis. If the patient is not pregnant, a 24-hour RAIU should be obtained if there is any diagnostic uncertainty, for example, recent onset of symptoms or other factors suggestive of thyroiditis. An increased RAIU documents that the thyroid gland is inappropriately using the iodine to produce more thyroid hormone at a time when the patient is thyrotoxic.

Hypokalemic periodic paralysis is a rare complication of hyperthyroidism more commonly observed in Asian and Hispanic populations.³⁰ It presents as recurrent proximal muscle flaccidity ranging from mild weakness to total paralysis. The paralysis can be asymmetric and usually involves muscle groups that are strenuously exercised before the attack. Cognition and sensory perception are spared, whereas deep tendon reflexes are commonly markedly diminished. Hypokalemia results from a sudden shift of potassium from extracellular to intracellular sites, rather than reduced total body potassium.

TABLE 78-4 Thyroid Function Test Results in Different Thyroid Conditions

	Total T_4	Free T_4	Total T_3	T_3 Resin Uptake	Free Thyroxine Index	TSH
Normal	4.5–10.9 mcg/dL	0.8–2.7 ng/dL	60–181 ng/dL	22% to 34%	1.0–4.3 units	0.5–4.7 mIU/L
Hyperthyroid	↑↑	↑↑	↑↑↑	↑	↑↑↑	↓↓
Hypothyroid	↓↓	↓↓	↓	↓↓	↓↓↓	↑↑
Increased TBG	↑	Normal	↑	↓	Normal	Normal

TBG, thyroid-binding globulin; TSH, thyroid-stimulating hormone; T_3 , triiodothyrene; T_4 , thyroxine.

High carbohydrate loads and exercise provoke the attacks. Treatment includes correcting the hyperthyroid state, potassium administration, spironolactone to conserve potassium, and propranolol to minimize intracellular shifts.

Trophoblastic Diseases

Human chorionic gonadotropin (hCG) is a stimulator of the TSH receptor and can cause hyperthyroidism.³¹ The basis for the thyrotropic effect of hCG is the structural similarity of hCG to TSH (similar α -subunits and unique β subunits). In hyperthyroid patients with very high hCG levels, serum TSH can be inappropriately undetectable because of the weak cross-reactivity of hCG in the radioimmunoassay for TSH. In patients with hyperthyroidism caused by trophoblastic tumors, serum hCG levels usually exceed 300 units/mL and always exceed 100 units/mL. The mean peak hCG level in normal pregnancy is 50 units/mL. On a molar basis, hCG has only 1/10,000 the activity of pituitary TSH in mouse bioassays. Nevertheless, this thyrotropic activity can be very substantial in patients with trophoblastic tumors, whose serum hCG concentrations can reach 2,000 units/mL.

THYROID AUTONOMY

Toxic Adenoma

An autonomous thyroid nodule is a discrete thyroid mass whose function is independent of pituitary and TSH control.³² The prevalence of toxic adenoma ranges from about 2% to 9% of thyrotoxic patients, and depends on iodine availability and geographic location. Toxic adenomas arise from gain-of-function somatic mutations of the TSH receptor, or less commonly the $G_s\alpha$ protein; more than a dozen TSH receptor mutations have been described.¹⁰ These nodules can be referred to as a toxic adenoma or a “hot” nodule because of their persistent uptake on a radioiodine thyroid scan, despite suppressed uptake in the surrounding non-nodular gland (Fig. 78–5). The amount of thyroid hormone produced by an autonomous nodule is mass related. Therefore hyperthyroidism usually occurs with larger nodules (i.e., those >3 cm in diameter). Older patients (>60 years of age) are more likely (up to 60%) to be thyrotoxic from autonomous nodules than are younger (<60 years of age) patients (12%). There are many reports of isolated elevation of serum T_3 in patients with autonomously functioning nodules. Therefore if the T_4 level is normal, a T_3 level must be measured to rule out T_3 toxicosis.

If autonomous function is suspected, but the TSH is normal, the diagnosis can be confirmed by a failure of the autonomous nodule to decrease its iodine uptake during exogenous T_3 administration sufficient to suppress TSH. Surgical resection, thionamides, percutaneous ethanol injection, and RAI ablation are treatment options, but as thionamides do not halt the proliferative process in the nodule, definitive therapies are recommended.³³ Ethanol ablation can be associated with pain and damage to surrounding extrathyroidal tissues, limiting its acceptance in the United States. It has been hypothesized that sublethal radiation doses received by the surrounding non-nodular thyroid tissue during RAI therapy of toxic nodules can lead to induction of thyroid cancer, and excess thyroid cancer mortality has recently been associated with RAI therapy of toxic nodular disease. Thus, an autonomously functioning nodule, if not large enough to cause thyrotoxicosis, can often be observed conservatively without therapy.

Multinodular Goiters

In multinodular goiters (MNGs; Plummer's disease), follicles with autonomous function coexist with normal or even nonfunctioning follicles.³² The pathogenesis of MNG is thought to be similar to that of toxic adenoma: diffuse hyperplasia caused by goitrogenic stimuli, leading to mutations and clonal expansion of benign neoplasms.³⁴ The functional status of the nodule(s) depends on the nature of the underlying mutations, whether activating such as TSH-receptor mutations or inhibitory such as ras mutations. Thyrotoxicosis in a MNG occurs when a sufficient mass of autonomous follicles generates enough thyroid hormone to exceed the needs of the patient. It is not surprising that this type of hyperthyroidism develops insidiously over a period of several years and predominantly affects older individuals with long-standing goiters. The patient's complaints of weight loss, depression, anxiety, and insomnia might be attributed to old age. Any unexplained chronic illness in an elderly patient presenting with a MNG calls for the exclusion of hidden thyrotoxicosis.³⁵ Third-generation TSH assays and T_3 suppression testing can be useful in detecting subclinical hyperthyroidism.³⁶

A thyroid scan will show patchy areas of autonomously functioning thyroid tissue intermixed with hypofunctioning areas. When the patient is euthyroid, therapy is based on the need to reduce goiter size because of mass-related symptoms such as dysphagia. Doses of thyroid hormone sufficient to suppress TSH levels can slow goiter growth or cause some degree of shrinkage, but in general suppression

FIGURE 78-5. Radioiodine thyroid scans. (A) Normal to increased thyroid uptake of iodine-125 (^{125}I). (B) Thyroid with marked decrease in ^{125}I uptake in a large palpable mass. (C) Increased ^{125}I uptake isolated to a single nodule, the “hot nodule.” (D) Decreased thyroid ^{125}I uptake in an isolated region, the “cold nodule.” (Reproduced with permission from Molina PE. *Endocrine Physiology*, 2nd ed. New York: McGraw-Hill, 2006:90. Images courtesy of Dr. Luis Linares, Memorial Medical Center, New Orleans, LA.)

therapy for nodular disease is inadequate to address mass effect.³⁷ The preferred treatment for toxic MNG is RAI or surgery. Surgery is usually selected for younger (<60 years old) patients and patients in whom large goiters impinge on vital organs. Alternatively, percutaneous injection of 95% ethanol has also been used to destroy single or multinodular adenomas with a 5-year success rate approaching 80%.

CAUSES OF THYROTOXICOSIS ASSOCIATED WITH SUPPRESSED RAIU

Inflammatory Thyroid Disease

Subacute Thyroiditis Painful subacute (granulomatous or de Quervain's) thyroiditis often develops after a viral syndrome but rarely has a specific virus been identified in thyroid parenchyma.³⁸ A genetic predisposition exists with markedly higher risk for developing subacute thyroiditis in patients with HLA-Bw35. Systemic symptoms often accompany the syndrome, including fever, malaise, and myalgia, in addition to those symptoms caused by thyrotoxicosis. Typically, patients complain of severe pain in the thyroid region, which often extends to the ear on the affected side.³⁹ With time, the pain can migrate from one side of the gland to the other. On physical examination, the thyroid gland is firm and exquisitely tender. Signs of thyrotoxicosis are present.

Thyroid function tests typically run a triphasic course. Initially, serum T₄ levels are elevated because of release of preformed thyroid hormone from disrupted follicles. The 24-hour RAIU during this time is less than 2% because of thyroid inflammation and TSH suppression by the elevated T₄ level. As the disease progresses, intrathyroidal hormone stores are depleted, and the patient can become mildly hypothyroid with an appropriately elevated TSH level. During the recovery phase thyroid hormone stores are replenished, and serum TSH elevation gradually returns to normal. Recovery is generally complete within 2 to 6 months. Most patients remain euthyroid, and recurrences of painful thyroiditis are extremely rare. The patient with painful thyroiditis should be reassured that the disease is self-limited and is unlikely to recur. Thyrotoxic symptoms can be relieved with β -blockers. Aspirin (650 mg orally every 6 hours) will usually relieve the pain. Occasionally, prednisone (20 mg orally three times a day) must be used to suppress the inflammatory process. Antithyroid drugs are not indicated because they do not decrease the release of preformed thyroid hormone.

Painless Thyroiditis Since its description in 1975, painless (silent, lymphocytic) thyroiditis has been recognized as a common cause of thyrotoxicosis and can represent up to 15% of cases of thyrotoxicosis in North America.⁴⁰ In the setting of development of lymphocytic thyroiditis during the first 12 months after the end of pregnancy, the condition is also called "postpartum thyroiditis."⁴¹ The etiology is not fully understood and may be heterogeneous, but evidence indicates that autoimmunity underlies most cases. There is an increased frequency of HLA-DR3 and DR5 in patients with subacute thyroiditis; nonendocrine autoimmune diseases are also more common. Histologically, diffuse lymphocytic infiltration is generally identified. The triphasic course of this illness mimics that of subacute thyroiditis. Most patients present with mild thyrotoxic symptoms. Lid retraction and lid lag are present, but exophthalmos is absent. The thyroid gland can be diffusely enlarged, but thyroid tenderness is absent.

The 24-hour RAIU will typically be suppressed to less than 2% during the thyrotoxic phase of painless thyroiditis. Antithyroglobulin and antimicrosomal antibody levels are elevated in more than 50% of patients. Patients with mild hyperthyroidism and painless thyroiditis should be reassured that they have a self-limited disease, although patients with postpartum thyroiditis can experience recurrence of the disease with subsequent pregnancies. As with other thyrotoxic syndromes, adrenergic symptoms can be ameliorated

with propranolol or metoprolol. Antithyroid drugs, which inhibit new hormone synthesis, are not indicated because they do not decrease the release of preformed thyroid hormone.

Ectopic Thyroid Tissue

Struma Ovarii Struma ovarii is a teratoma of the ovary that contains differentiated thyroid follicular cells and is capable of making thyroid hormone.⁴² This extremely rare cause of thyrotoxicosis is suggested by the absence of thyroid enlargement in a thyrotoxic patient with a suppressed RAIU in the neck and no findings to suggest thyroiditis. The diagnosis is established by localizing functioning thyroid tissue in the ovary with whole-body radioactive iodine (¹³¹I) scanning. Interestingly, struma ovarii without associated hyperthyroidism is much more common than struma ovarii associated with hyperthyroidism. Because the tissue is neoplastic and potentially malignant, combined surgical and radioiodine treatment of malignant struma ovarii for both monitoring and therapy of relapse is the recommended treatment.

Follicular Cancer In widely metastatic differentiated papillary or follicular carcinomas with relatively well-preserved function, sufficient thyroid hormone can be synthesized and secreted to produce thyrotoxicosis.^{43,44} In most instances, a previous diagnosis of thyroid malignancy has been made. The diagnosis can be confirmed by whole-body ¹³¹I scanning. Treatment with ¹³¹I is generally effective at ablating functioning thyroid metastases.

Exogenous Sources of Thyroid Hormone

Thyrotoxicosis factitia is produced by the ingestion of exogenous thyroid hormone.⁴⁵ Obesity is the most common nonthyroidal disorder for which thyroid hormone is inappropriately used, but thyroid hormone has been used for almost every conceivable problem from menstrual irregularities and infertility to hypercholesterolemia and baldness. Despite there being little evidence to suggest that these patients benefit from treatment with thyroid hormone, the physician or patient can gradually increase the dose of hormone employed in an attempt to gain the desired effect. Obviously, thyrotoxicosis factitia can also occur when too large a dose of thyroid hormone is employed for conditions in which it is likely to be beneficial, such as differentiated thyroid carcinoma. Rarely, thyrotoxicosis factitia is caused by the purposeful and secretive ingestion of thyroid hormone by disturbed patients (usually with a medical background) who wish to obtain attention or lose weight.

Thyrotoxicosis factitia should be suspected in a thyrotoxic patient without evidence of increased hormone production, thyroidal inflammation, or ectopic thyroid tissue. The RAIU uptake is at low levels because the patient's thyroid gland function is suppressed by the exogenous thyroid hormone.⁴⁶ Measurement of plasma thyroglobulin (TG) is a valuable laboratory aid in the diagnosis of thyrotoxicosis factitia. TG is normally secreted in small amounts by the thyroid gland; however, when thyroid hormone is taken orally, very low amounts of thyroglobulin are detectable in the plasma. In other entities characterized by a low RAIU, such as thyroiditis, leakage of preformed thyroid hormone results in elevated thyroglobulin levels. If a history of thyroid hormone ingestion is elicited or deduced, exogenous thyroid hormone should be withheld for between 4 and 6 weeks and thyroid function tests repeated to document that the euthyroid state has been restored. Rarely, thyroid hormone analogues or metabolites can be the drug of abuse, specific detection of which can be difficult with standard thyroid hormone assays. For example, tiratricol (3,5,3-triiodothyroacetic acid [TRIAC]), an endogenous metabolite of T₃ that has been used for weight loss and paradoxically by body builders, will suppress TSH at high enough doses and may cross-react in many T₃ immunoassays; thus, thyrotoxicosis factitia because of tiratricol abuse can be misinterpreted as T₃-toxicosis.⁴⁷

Amiodarone can induce thyrotoxicosis (2% to 3% of patients), hypothyroidism, or euthyroid hyperthyroxinemia, depending on the underlying thyroid pathology or lack thereof.⁴⁸ Because amiodarone contains 37% iodine by weight, approximately 6 mg/day of iodine is released for each 200 mg of amiodarone, 1,000 times greater than the recommended daily amount of iodine of 200 mcg/day. As a result of this iodine overload, iodine-exacerbated thyroid dysfunction commonly occurs among those patients with preexisting thyroid disease: thyrotoxicosis in patients with hyperthyroidism or euthyroid nodular autonomy, and hypothyroidism in patients with autoimmune thyroid disease. In contrast to hyperthyroidism induced by amiodarone (type I), destructive thyroiditis with loss of thyroglobulin and thyroid hormones also occurs (type II), typically among individuals with otherwise normal glands. The two types of amiodarone-induced thyrotoxicosis can be differentiated using color flow Doppler ultrasonography. Such distinction is critically important, given the therapeutic implications of the two syndromes: type I amiodarone-induced hyperthyroidism responds somewhat to thionamides, whereas type II can require glucocorticoids or iopanoic acid.^{49–51} Obviously, RAI therapy is inappropriate, in type I because of the drug-induced iodine excess and in type II because of lack of increased hormone synthesis. The manifestations of amiodarone-induced thyrotoxicosis can be atypical symptoms such as ventricular tachycardia and exacerbation of underlying chronic obstructive pulmonary disease, both of which are even more significant given the severe underlying cardiac pathology which led to the use of the drug in the first place. Amiodarone also directly interferes with type I 5'-deiodinase, leading to reduced conversion of T_4 to T_3 and hyperthyroxinemia without thyrotoxicosis.

TREATMENT

Hyperthyroidism

■ DESIRED OUTCOMES

③ Three common treatment modalities are used in the management of hyperthyroidism: surgery, antithyroid medications, and RAI (Table 78–5). The overall therapeutic objectives are to eliminate the excess thyroid hormone and minimize the symptoms and long-term consequences of hyperthyroidism. Therapy must be individualized based on the type and severity of hyperthyroidism, patient age and gender, existence of nonthyroidal conditions, and response to previous therapy.^{52,53} Clinical guidelines for the treatment of hyperthyroidism have been published by various groups.^{54–56}

■ NONPHARMACOLOGIC THERAPY

Surgical removal of the hypersecreting thyroid gland became feasible in 1923 when Plummer discovered that iodine reduced the gland's vascularity, making this definitive procedure possible. Surgery should be considered in patients with a large thyroid gland (>80 g), severe ophthalmopathy, and a lack of remission on antithyroid drug treatment. In case of cosmetic or pressure symptoms, the choice in MNG stands between surgery, which is still the first choice, and radioiodine if uptake is adequate (hot). In addition to surgery, the solitary nodule, whether hot or cold, can be treated with percutaneous ethanol injection therapy. If hot, radioiodine is the therapy of choice.⁵⁷ Traditional preparation of the patient for thyroidectomy includes PTU or MMI until the patient is biochemically euthyroid (usually 6 to 8 weeks), followed by the addition of iodides (500 mg/day) for 10 to 14 days before surgery to decrease the vascularity of the gland. Levothyroxine can be added to maintain the euthyroid state while the thionamides are continued. Iodine supplementation in iodine-deficient areas of the country can lead to a greater reduction in remnant volume in nontoxic goiter.⁵⁸ Propranolol for several weeks preoperatively and 7 to 10 days after surgery has also been used to maintain a pulse rate of less than 90 beats/min. Combined pretreatment with propranolol and 10 to 14 days of potassium iodide also has been advocated.

The overall morbidity rate with surgery is 2.7%. Hyperthyroidism persists or recurs in 0.6% to 17.9% of patients after thyroidectomy for Graves' disease and is more common in children. The most common complications of surgery include hypothyroidism (up to about 49%), hypoparathyroidism (up to 3.9%), and vocal cord abnormalities (up to 5.4%). The frequent occurrence of hypothyroidism following surgery requires periodic followup for identification and treatment of these patients.^{59,60}

■ PHARMACOLOGIC THERAPY

Antithyroid Medications

Thiourea Drugs Two drugs within this category, PTU and MMI, are approved for the treatment of hyperthyroidism in the United States.⁶¹ They are classified as thioureylenes (thionamides), which incorporate a N—C—S = N group into their ring structures.

Mechanism of Action. PTU and MMI share several mechanisms to inhibit the biosynthesis of thyroid hormone.¹⁷ These drugs serve as preferential substrates for the iodinating intermediate of thyroid peroxidase and divert iodine away from potential iodination sites in thyroglobulin. This prevents subsequent incorporation of iodine into

TABLE 78-5 Treatments for Hyperthyroidism Caused by Graves' Disease

Treatment	Advantages	Disadvantages	Comment
Antithyroid drugs	Noninvasive Lower initial cost Low risk of permanent hypothyroidism Possible remissions because of immune effects	Low cure rate (30–80%; average 40–50%) Adverse drug reactions Drug compliance	First-line treatment in children, adolescents, and in pregnancy Initial treatment in severe cases or preoperative preparation
Radioactive iodine (¹³¹ I)	Cure of hyperthyroidism Most cost effective	Permanent hypothyroidism almost inevitable Might worsen ophthalmopathy Pregnancy must be deferred for 6–12 months; no breast-feeding Small potential risk of exacerbation of hyperthyroidism	Best treatment for toxic nodules and toxic multinodular goiter
Surgery	Rapid, effective treatment, especially in patients with large goiters	Most invasive Potential complications (recurrent laryngeal nerve damage, hypoparathyroidism) Most costly Permanent hypothyroidism Pain, scar	Potential in pregnancy if major side-effect from antithyroid Useful when coexisting suspicious nodule present Option for patients who refuse radioiodine

iodotyrosines and ultimately iodothyronine (*organification*). Second, they inhibit coupling of monoiodotyrosine and diiodotyrosine to form T_4 and T_3 . The coupling reaction can be more sensitive to these drugs than the iodination reaction. Experimentally, these drugs exhibit immunosuppressive effects, although the clinical relevance of this finding is unclear. In patients with Graves' disease, antithyroid drug treatment has been associated with lower TSAb titers and restoration of normal suppressor T-cell function. However, perchlorate, which has a different mechanism of action, also decreases TSABs, suggesting that normalization of the thyroid hormone level can itself improve the abnormal immune function. PTU inhibits the peripheral conversion of T_4 to T_3 . This effect is acutely dose related and occurs within hours of PTU administration. MMI does not have this effect. Over time, depletion of stored hormone and lack of continuing synthesis of thyroid hormone results in the clinical effects of these drugs.

Pharmacokinetics. Both antithyroid drugs are well absorbed (80% to 95%) from the gastrointestinal tract, with peak serum concentrations approximately 1 hour after ingestion. The plasma half-life ranges of PTU and MMI are 1 to 2.5 hours and 6 to 9 hours, respectively, and are not appreciably affected by thyroid status. Urinary excretion is approximately 35% for PTU and less than 10% for MMI. These drugs are actively concentrated in the thyroid gland, which can account for the disparity between their relatively short plasma half-lives and the effectiveness of once-daily dosing regimens even with PTU. Approximately 60% to 80% of PTU is bound to plasma albumin, whereas MMI is not protein-bound. MMI readily crosses the placenta and appears in breast milk. Older studies suggested that PTU crosses the placental membranes only one-tenth as well as MMI; however, these studies were done in the course of therapeutic abortion early in pregnancy. Newer studies show little difference between fetal concentrations of PTU and MMI, and both are associated with elevated TSH in approximately 20% and low T_4 in approximately 7% of the fetuses.⁶²

Dosing and Monitoring. PTU is available as 50-mg tablets and MMI as 5- and 10-mg tablets. MMI is approximately 10 times more potent than PTU. Initial therapy with PTU ranges from 300 to 600 mg daily, usually in three or four divided doses. MMI is given in three divided doses totaling 30 to 60 mg/day. Although the traditional recommendation is for divided doses, evidence exists that both drugs can be given as single daily doses. Patients with severe hyperthyroidism can require larger initial doses, and some might respond better at these larger doses if the dose is divided. The maximal blocking doses of PTU and MMI are 1,200 and 120 mg daily, respectively. Once the intrathyroidal pool of thyroid hormone is reduced, and new hormone synthesis is sufficiently blocked, clinical improvement should ensue. Usually within 4 to 8 weeks of initiating therapy, symptoms are diminished, and circulating thyroid hormone levels are returning to normal. At this time the tapering regimen can be started. Changes in dose for each drug should be made on a monthly basis, because the endogenously produced T_4 will reach a new steady-state concentration in this interval. Typical ranges of daily maintenance doses for PTU and MMI are 50 to 300 mg and 5 to 30 mg, respectively.

If the objective of therapy is to induce a long-term remission, the patient should remain on continuous antithyroid drug therapy for 12 to 24 months. Antithyroid drug therapy induces permanent remission rates of 10% to 98%, with an overall average of about 40% to 50%.⁶³ This is much higher than the remission rate seen with propranolol alone, which is reported to range from 22% to 36%. Patient characteristics for a favorable outcome include older patients (>40 years of age), low ratio of T_4 to T_3 (<20), a small goiter (<50 g), short duration of disease (<6 months), no previous history of relapse with antithyroid drugs, duration of therapy 1 to 2 years or longer, and low TSAb titers at baseline or a reduction with treatment.¹⁷ It is important that patients be followed every 6 to 12 months after remission occurs.

6 If a relapse occurs, alternate therapy with RAI is preferred to a second course of antithyroid drugs. Relapses seem to plateau after approximately 5 years, and eventually 5% to 20% of patients will develop spontaneous hypothyroidism.

Concurrent administration of T_4 with thionamide therapy for thyrotoxicosis and subclinical hyperthyroidism can reduce autoantibodies directed toward the thyroid gland and improve the remission rate; however, these effects have not been consistently observed in all studies.^{63,64} In a Japanese study, adjunctive treatment with T_4 was associated with a 20-fold reduction in the recurrence rate of Graves' disease compared with the recurrence rate seen in patients treated with antithyroid drugs alone. Attempts to reproduce these results in American and European patients with Graves' disease have failed to show any delay or reduction in the recurrence of Graves' disease with T_4 administration.⁶⁵

Adverse Effects. Minor adverse reactions to PTU and MMI have an overall incidence of 5% to 25% depending on the dose and the drug, whereas major adverse effects occur in 1.5% to 4.6% of patients receiving these drugs.^{61,66} Pruritic maculopapular rashes (sometimes associated with vasculitis based on skin biopsy), arthralgias, and fevers occur in up to 5% of patients and can occur at greater frequency with higher doses and in children. Rashes often disappear spontaneously, but if persistent, can be managed with antihistamines.

Perhaps one of the most common side effects is a benign transient leukopenia characterized by a white blood cell (WBC) count of less than 4,000/mm³. This condition occurs in up to 12% of adults and 25% of children, and sometimes can be confused with mild leukopenia seen in Graves' disease. This mild leukopenia is not a harbinger of the more serious adverse effect of agranulocytosis, so therapy can usually be continued. If a minor adverse reaction occurs with one antithyroid drug, the alternate thiourea can be tried, but cross-sensitivity occurs in approximately 50% of patients.⁶¹

Agranulocytosis is the most serious adverse effect of thiourea drug therapy and is characterized by fever, malaise, gingivitis, oropharyngeal infection, and a granulocyte count less than 250/mm³.⁶¹ These drugs are concentrated in granulocytes, and this reaction can represent a direct toxic effect rather than hypersensitivity. This toxic reaction has occurred with both thioureas, and the incidence varies from 0.5% to 6%. It is higher in patients older than age 40 years receiving a MMI dose greater than 40 mg/day or the equivalent dose of PTU, and is linked to HLA class II genes containing the DRB1*08032 allele.⁶⁷ Agranulocytosis almost always develops in the first 3 months of therapy. Because the onset is sudden, routine monitoring is not recommended. Colony-stimulating factors have been used with some success to restore cell counts to normal, but it is unclear how effective this form of therapy is to routine supportive care.^{68,69} Peripheral lymphocytes obtained from patients with PTU-induced agranulocytosis undergo transformation in the presence of other thioamides, suggesting that these severe reactions are immunologically mediated, and patients should not receive other thionamides. Aplastic anemia has been reported with MMI and can be associated with an inhibitor to colony-forming units. Once antithyroid drugs are discontinued, clinical improvement is seen over several days to weeks. Patients should be counseled to discontinue therapy and contact their physician when flu-like symptoms such as fever, malaise, or sore throat develop.

Arthralgias and a lupus-like syndrome (sometimes in the absence of antinuclear antibodies) have been reported in 4% to 5% of patients. This generally occurs after 6 months of therapy. Uncommonly, polymyositis, presenting as proximal muscle weakness and elevated creatine phosphokinase, has been reported with PTU administration. Gastrointestinal intolerance is also reported to occur in 4% to 5% of patients. Hepatotoxicity, which usually occurs within the first 3 months of therapy, can be seen with both MMI and PTU with a prevalence of approximately 1.3%.⁷⁰ In mice, MMI undergoes

epoxidation of the C-4,5 double bond by cytochrome P450 enzymes, and after being hydrolyzed, the resulting epoxide is decomposed to form *N*-methylthiourea, a proximate toxicant.⁷¹ At moderate doses, some authors have found that initial enzyme elevations eventually normalize in most patients with continued therapy.⁷² High doses of PTU are more likely to produce severe hepatitis and even death. Discontinuation of therapy usually results in complete resolution of hepatitis. Patients receiving interferon products for hepatitis C or other disorders can develop hyper- or hypothyroidism along with liver enzyme abnormalities.⁷³ Although older reports suggested that congenital skin defects (aplasia cutis) can be caused by MMI and carbimazole, a registry review from the Netherlands could not find an association between maternal use of these drugs and skin defects.⁷⁴ Hypoprothrombinemia is a rare complication of thionamide therapy. Patients who have experienced a major adverse reaction to one thiourea drug should not be converted to the alternate drug because of cross-sensitivity.

Iodides Iodide was the first form of drug therapy for Graves' disease. Its mechanism of action is to acutely block thyroid hormone release, inhibit thyroid hormone biosynthesis by interfering with intrathyroidal iodide use (the Wolff-Chaikoff effect), and decrease the size and vascularity of the gland. This early inhibitory effect provides symptom improvement within 2 to 7 days of initiating therapy, and serum T_4 and T_3 concentrations can be reduced for a few weeks. Despite the reduced release of T_4 and T_3 , thyroid hormone synthesis continues at an accelerated rate, resulting in a gland rich in stored hormones. The normal and hyperfunctioning thyroid soon escapes from this inhibitory effect within 1 to 2 weeks by decreasing the active transfer of iodide into the gland. Iodides are often used as adjunctive therapy to prepare a patient with Graves' disease for surgery, to acutely inhibit thyroid hormone release and quickly attain the euthyroid state in severely thyrotoxic patients with cardiac decompensation, or to inhibit thyroid hormone release following radioactive iodine therapy. However, large doses of iodine can exacerbate hyperthyroidism or indeed precipitate hyperthyroidism in some previously euthyroid individuals (Jod-Basedow's disease).⁷⁵ This Jod-Basedow's phenomenon is most common in iodine-deficient areas, particularly in patients with preexisting non-toxic goiter. Iodide is contraindicated in toxic MNG.

Potassium iodide is available either as a saturated solution (saturated solution of potassium iodide [SSKI]), which contains 38 mg of iodide per drop, or as Lugol solution, which contains 6.3 mg of iodide per drop. The typical starting dose of SSKI is 3 to 10 drops daily (120 to 400 mg) in water or juice. There is no documented advantage to using doses in excess of 6 to 8 mg/day. When used to prepare a patient for surgery, it should be administered 7 to 14 days preoperatively. As an adjunct to RAI, SSKI should not be used before, but rather 3 to 7 days after RAI treatment, so that the radioactive iodine can concentrate in the thyroid. The most frequent toxic effect with iodide therapy is hypersensitivity reactions (skin rashes, drug fever, rhinitis, and conjunctivitis); salivary gland swelling; "iodism" (metallic taste, burning mouth and throat, sore teeth and gums, symptoms of a head cold, and sometimes stomach upset and diarrhea); and gynecomastia.

Other compounds containing organic iodide have also been used therapeutically for hyperthyroidism. These include various radiologic contrast media that share a triiodo- and monoaminobenzene ring with a propionic acid chain (e.g., iopanoic acid and sodium ipodate). The effect of these compounds is a result of the iodine content inhibiting thyroid hormone release as well as competitive inhibition of 5'-monodeiodinase conversion related to their structures, which resemble thyroid analogs.⁷⁶

Adrenergic Blockers 7 Because many of the manifestations of hyperthyroidism are mediated by β -adrenergic receptors, β -blockers

(especially propranolol) have been used widely to ameliorate thyrotoxic symptoms such as palpitations, anxiety, tremor, and heat intolerance. Although β -blockers are quite effective for symptom control, they have no effect on the urinary excretion of calcium, phosphorus, hydroxyproline, creatinine, or various amino acids, suggesting a lack of effect on peripheral thyrotoxicosis and protein metabolism. Furthermore, β -blockers do not reduce TSAb nor prevent thyroid storm. Propranolol and nadolol partially block the conversion of T_4 to T_3 , but this contribution to the overall therapeutic effect is small in magnitude. Inhibition of conversion of T_4 to T_3 is mediated by *d*-propranolol, which is devoid of β -blocking activity, and *l*-propranolol, which is responsible for the antiadrenergic effects and has little effect on the conversion.

β -Blockers are usually used as adjunctive therapy with antithyroid drugs, RAI, or iodides when treating Graves' disease or toxic nodules; in preparation for surgery; or in thyroid storm. The only conditions for which β -blockers are primary therapy for thyrotoxicosis are thyrotoxicosis and iodine-induced hyperthyroidism. The dose of propranolol required to relieve adrenergic symptoms is variable, but an initial dose of 20 to 40 mg four times daily is effective (heart rate <90 beats/min) for most patients. Younger or more severely toxic patients can require as much as 240 to 480 mg/day because there seems to be an increased clearance rate in these patients. β -Blockers are contraindicated in patients with decompensated heart failure unless it is caused solely by tachycardia (high output). Nonselective agents and those lacking intrinsic sympathomimetic activity should be used with caution in patients with asthma and bronchospastic chronic obstructive lung disease. β -Blockers that are cardioselective and have intrinsic sympathomimetic activity may have a slight margin of safety in these situations. Other patients in whom contraindications exist are those with sinus bradycardia, those receiving monoamine oxidase inhibitors or tricyclic antidepressants, and those with spontaneous hypoglycemia. β -Blockers can also prolong gestation and labor during pregnancy. Other side effects include nausea, vomiting, anxiety, insomnia, light-headedness, bradycardia, and hematologic disturbances.

Antiadrenergic agents such as centrally acting sympatholytics and calcium channel antagonists may have some role in the symptomatic treatment of hyperthyroidism. These drugs might be useful when contraindications to β -blockade exist. When compared to nadolol 40 mg twice daily, clonidine 150 mcg twice daily reduced plasma catecholamines, whereas nadolol increased both epinephrine and norepinephrine after 1 week of treatment. Diltiazem 120 mg given every 8 hours reduced heart rate by 17%; fewer ventricular extrasystoles were noted after 10 days of therapy, and diltiazem has been shown to be comparable to propranolol in lowering heart rate and blood pressure.

Radioactive Iodine Although other radioisotopes have been used to ablate thyroid tissue, sodium iodide 131 (^{131}I) is considered to be the agent of choice for Graves' disease, toxic autonomous nodules, and toxic MNGs.^{77,78} RAI is administered as a colorless and tasteless liquid that is well absorbed and concentrates in the thyroid. Sodium iodide 131 is a β - and γ -emitter with a tissue penetration of 2 mm and a half-life of 8 days. Other organs take up ^{131}I , but the thyroid gland is the only organ in which organification of the absorbed iodine takes place. Initially, RAI disrupts hormone synthesis by incorporating into thyroid hormones and thyroglobulin. Over a period of weeks, follicles that have taken up RAI and surrounding follicles develop evidence of cellular necrosis, breakdown of follicles, development of bizarre cell forms, nuclear pyknosis, and destruction of small vessels within the gland, leading to edema and fibrosis of the interstitial tissue. Pregnancy is an absolute contraindication to the use of RAI.

β -Blockers can be given any time without compromising RAI therapy, accounting for their role as a mainstay of adjunctive therapy to RAI treatment. If iodides are administered, they should be given 3 to 7 days after RAI to prevent interference with the uptake of RAI in the thyroid gland. Because thyroid hormone levels

will transiently increase following RAI treatment because of release of preformed thyroid hormone, patients with cardiac disease and elderly patients are often treated with thionamides prior to RAI ablation. Occasionally, in patients with underlying cardiac disease, it can be necessary to reinstitute antithyroid drug therapy following radioactive iodine ablation. The standard practice is to withdraw the thionamide 4 to 6 days prior to RAI treatment and to reinstitute it 4 days after therapy is concluded. Administering antithyroid drug therapy following RAI treatment can result in a higher rate of posttreatment recurrence or persistent hyperthyroidism.⁷⁸

Corticosteroid administration will blunt and delay the increase in antibodies to the TSH receptor, thyroglobulin, and thyroid peroxidase while reducing T_3 and T_4 concentrations following RAI. Bartalena and associates found no progression in ophthalmopathy in patients receiving prednisone after RAI compared with MMI (2% to 3% worsened), or no other treatment (5% with persistent worsening).⁴⁶ Theoretically, if shared thyroïdal and orbital antigen is involved in the pathogenesis of Graves' ophthalmopathy, antigen released with RAI treatment could aggravate preexisting eye disease. Note also that thyroid ablation can decrease eye disease in the long term by removing the source of antigen, but it is unclear if RAI differs from surgery or thionamide for the risk of worsening eye disease.⁷⁹

Destruction of the gland attenuates the hyperthyroid state, and hypothyroidism commonly occurs months to years following RAI.⁸⁰ The goal of therapy is to destroy overactive thyroid cells, and a single dose of 4,000 to 8,000 rads results in a euthyroid state in 60% of patients at 6 months or less. The remaining 40% become euthyroid within 1 year, requiring two or more doses. It is advisable that a second dose of RAI be given 6 months after the first RAI treatment if the patient remains hyperthyroid. Variables that influence the outcome of RAI include gender (men are less likely to develop hypothyroidism), race (blacks are more resistant to ^{131}I), the size of the thyroid, severity of disease, and perhaps the level of TSAb. The acute, short-term side effects of ^{131}I therapy are minimal and include mild thyroïdal tenderness and dysphagia. Concern over the development of thyroid carcinoma and leukemia and increased risk of mutations and congenital defects now appears to be unfounded because long-term followup studies have not revealed increased risk for these complications.⁸¹ Although RAI is very effective in the treatment of hyperthyroidism, long-term followup from Great Britain suggests that among patients with hyperthyroidism treated with RAI, mortality from all causes and mortality resulting from cardiovascular and cerebrovascular disease and fracture are increased.⁸²

A common approach to Graves' hyperthyroidism is to administer a single dose of 5 to 15 mCi (80 to 200 microCi/g of tissue).⁷⁸ The optimal method for determining ^{131}I treatment doses for Graves' hyperthyroidism is unknown, and techniques have varied from a fixed dose to more elaborate calculations based on gland size, iodine uptake, and iodine turnover. In a trial of 88 patients with Graves' disease, no difference in outcome was seen among high or low, fixed or adjusted doses.⁸³ Thyroid glands estimated to weigh >80 g can require larger doses of RAI. Larger doses are likely to induce hypothyroidism and are seldom given outside the United States because of the imposition of stringent safety restrictions. For example, in the United Kingdom, a nursery school teacher is advised to stay out of school for 3 weeks following a 15-mCi dose of ^{131}I .⁸⁴

EVALUATION OF THERAPEUTIC OUTCOMES: HYPERTHYROIDISM

After therapy (surgery, thionamides, or RAI) for hyperthyroidism has been initiated, patients should be evaluated on a monthly basis until they reach a euthyroid condition. Clinical signs of continuing thyrotoxicosis (tachycardia, weight loss, and heat intolerance, among others) or the development of hypothyroidism (bradycardia, weight gain,

and lethargy, among others) should be noted. β -Blockers can be used to control symptoms of thyrotoxicosis until the definitive treatment has returned the patient to a euthyroid state. Once T_4 replacement is initiated, the goal is to maintain both the free T_4 level and the TSH concentration in the normal range. Once a stable dose of T_4 is identified, the patient can be followed up every 6 to 12 months.

Finally, a common, potentially confusing clinical situation should be mentioned. Why are the TSH concentrations suppressed in some patients who are clinically hypothyroid and who have a low free T_4 level? In patients with long-standing hyperthyroidism, the pituitary thyrotrophs responsible for making TSH become atrophic. The average amount of time required for these cells to resume normal functioning is 6 to 8 weeks.⁸⁵ Therefore if a thyrotoxic patient has his or her free T_4 concentration lowered rapidly, before the thyrotrophs resume normal function, a period of "transient central hypothyroidism" will be observed.

SPECIAL CONDITIONS

Graves' Disease and Pregnancy⁸⁶

Inappropriate production of hCG is a cause of abnormal thyroid function tests during the first half of pregnancy, and hCG can cause either subclinical (normal T_4 , suppressed TSH) or overt hyperthyroidism.^{87,88} This is because of the homology of hCG and TSH, leading to hCG-mediated stimulation through the TSH receptor. Hyperthyroidism during pregnancy is almost solely caused by Graves' disease, with approximately 0.1% to 0.4% of pregnancies affected. Although the increased metabolic rate is usually well tolerated in pregnant women, two symptoms suggestive of hyperthyroidism during pregnancy are failure to gain weight despite good appetite, and persistent tachycardia. There is no increase in maternal mortality or morbidity in well-controlled patients; however, postpartum thyroid storm has been reported in about 20% of untreated individuals. Fetal loss is also more common, because spontaneous abortion and premature delivery are more common in untreated pregnant women, as are low-birth-weight infants and eclampsia. Transplacental passage of thyroid-stimulating antibodies can occur, causing fetal as well as neonatal hyperthyroidism.⁸⁹ An uncommon cause of hyperthyroidism is molar pregnancy; women present with a large-for-date uterus, and evacuation of the uterus is the preferred management approach.⁹⁰

Because RAI is contraindicated in pregnancy and surgery is usually not recommended (especially during the first trimester), antithyroid drug therapy is usually the treatment of choice. MMI readily crosses the placenta and appears in breast milk.

PTU is considered to be the drug of choice in pregnancy, with the lowest possible doses used to maintain the maternal T_4 level in the high-normal range, but as described previously, there appears to be little difference between PTU and MMI.^{89,91} To prevent fetal goiter and suppression of fetal thyroid function, PTU is usually prescribed in daily doses of 300 mg or less and tapered to 50 to 150 mg daily after 4 to 6 weeks. PTU doses of less than 200 mg daily are unlikely to produce fetal goiter.⁹¹ Thioamide doses should be adjusted to maintain free T_4 within 10% of the upper normal limit of the nonpregnant reference range.⁸⁶ During the last trimester, TSABs fall spontaneously, and some patients will go into remission so that antithyroid drug doses can be reduced. A rebound in maternal hyperthyroidism occurs in approximately 10% of women and can require more intensive treatment postpartum than in the last trimester of pregnancy.⁸⁹

Neonatal and Pediatric Hyperthyroidism

Following delivery, some babies will be hyperthyroid because of placental transfer of TSABs, which stimulates thyroid hormone production in utero and postpartum.^{92,93} This is likely if the maternal TSAB titers were quite high. The disease is usually expressed 7 to 10

days postpartum, and treatment with antithyroid drugs (PTU 5 to 10 mg/kg per day or MMI 0.5 to 1 mg/kg per day) can be needed for as long as 8 to 12 weeks until the antibody is cleared (immunoglobulin G half-life is approximately 2 weeks). Iodide (potassium iodide 1 drop/day or Lugol solution 1 to 3 drops/day) and sodium ipodate can be used for the first few days to acutely inhibit hormone release.

Childhood hyperthyroidism is usually managed with either PTU or MMI. Long-term followup studies suggest that this form of therapy is quite acceptable, with 25% of a cohort experiencing remission every 2 years.⁹⁴

Thyroid Storm

Thyroid storm is a life-threatening medical emergency characterized by decompensated thyrotoxicosis, high fever (often >39.4°C [103°F]), tachycardia, tachypnea, dehydration, delirium, coma, nausea, vomiting, and diarrhea.¹⁹ Although Graves' disease and less commonly toxic nodular goiter are usually the underlying thyrotoxic pathology, at least two cases of subacute thyroiditis leading to thyroid storm have been reported.^{95–97} Precipitating factors for thyroid storm include infection, trauma, surgery, RAI treatment, and withdrawal from antithyroid drugs. Although the duration of clinical decompensation lasts for an average duration of 72 hours, symptoms can persist up to 8 days. With aggressive treatment, the mortality rate has been lowered to 20%. The following therapeutic measures should be instituted promptly: (1) suppression of thyroid hormone formation and secretion, (2) antiadrenergic therapy, (3) administration of corticosteroids, and (4) treatment of associated complications or coexisting factors that precipitated the storm. Specific agents used in thyroid storm are outlined in Table 78–6. PTU in large doses is the preferred thionamide because it interferes with the production of thyroid hormones and blocks the peripheral conversion of T₄ to T₃. If patients are unable to take medications orally, the tablets can be crushed into suspension and instilled by gastric or rectal tube.⁹⁸ Iodides, which rapidly block the release of preformed thyroid hormone, should be administered after PTU is initiated to inhibit iodide use by the overactive gland. If iodide is administered first, it could theoretically provide substrate for even higher levels of hormone.

Antiadrenergic therapy with the short-acting agent esmolol is preferred, both because it can be used in the patient with pulmonary disease or at risk for cardiac failure and because its effects can be rapidly reversed.⁹⁹ Corticosteroids are generally recommended, although there is no convincing evidence of adrenocortical insufficiency in thyroid storm, and the benefits derived from steroids can be caused by their antipyretic action and their effect of stabilizing blood pressure.¹⁹ General supportive measures, including acetaminophen as

an antipyretic (do not use aspirin or other nonsteroidal antiinflammatory agents because they can displace bound-thyroid hormone), fluid and electrolyte replacement, sedatives, digitalis, antiarrhythmics, insulin, and antibiotics should be given as indicated. Plasmapheresis and peritoneal dialysis have been used to remove excess hormone (and to remove thyroid-stimulating immunoglobulins in Graves' disease) when the patient has not responded to more conservative measures, although these measures do not always work.¹⁰⁰

HYPOTHYROIDISM

Hypothyroidism is defined as the clinical and biochemical syndrome resulting from decreased thyroid hormone production.¹⁰¹ Overt hypothyroidism occurs in 1.5% to 2% of women and 0.2% of men, and its incidence increases with age. In the Third National Health and Nutrition Examination Survey, levels of serum TSH and total T₄ were measured in a representative sample of adolescents and adults (age 12 years or older). Among 16,533 people who neither were taking thyroid medication nor reported histories of thyroid disease, 3.9% had subclinical hypothyroidism (serum TSH >4.5 mIU/L; and T₄ normal), and 0.2% had "clinically significant" hypothyroidism (TSH >4.5 mIU/L; and T₄ <4.5 mcg/dL).¹⁸ The vast majority of patients have primary hypothyroidism because of thyroid gland failure caused by chronic autoimmune thyroiditis. Special populations with higher risk of developing hypothyroidism include postpartum women, individuals with a family history of autoimmune thyroid disorders and patients with previous head and neck or thyroid irradiation or surgery, other autoimmune endocrine conditions (e.g., type 1 diabetes mellitus, adrenal insufficiency, and ovarian failure), some other nonendocrine autoimmune disorders (e.g., celiac disease, vitiligo, pernicious anemia, Sjögren's syndrome, and multiple sclerosis), primary pulmonary hypertension, and Down's and Turner's syndromes. Secondary hypothyroidism caused by pituitary failure is uncommon, but should be suspected in a patient with decreased levels of T₄ and inappropriately normal or low TSH levels. Most patients with secondary hypothyroidism because of inadequate TSH production will have clinical signs of more generalized pituitary insufficiency, such as abnormal menses and decreased libido, or evidence of a pituitary adenoma, such as visual field defects, galactorrhea, or acromegaloid features, but isolated TSH deficiency can be congenital or acquired as a result of autoimmune hypophysitis.¹⁰² Generalized (peripheral and central) resistance to thyroid hormone is extremely rare.

Thyroid hormone is essential for normal growth and development during embryonic life. Uncorrected thyroid hormone deficiency during fetal and neonatal development results in mental retardation and/or cretinism. There is loss of physical and mental activity, as well as of cardiovascular, gastrointestinal, and neuromuscular function.

TABLE 78-6 Drug Dosages Used in the Management of Thyroid Storm	
Drug	Regimen
Propylthiouracil	900–1200 mg/day orally in four or six divided doses
Methimazole	90–120 mg/day orally in four or six divided doses
Sodium iodide	Up to 2 g/day IV in single or divided doses
Lugol solution	5–10 drops three times a day in water or juice
Saturated solution of potassium iodide	1–2 drops three times a day in water or juice
Propranolol	40–80 mg every 6 h
Dexamethasone	5–20 mg/day orally or IV in divided doses
Prednisone	25–100 mg/day orally in divided doses
Methylprednisolone	20–80 mg/day IV in divided doses
Hydrocortisone	100–400 mg/day IV in divided doses

CLINICAL PRESENTATION OF HYPOTHYROIDISM

General

- Hypothyroidism can lead to a variety of end-organ effects with a wide range of disease severity, from entirely asymptomatic individuals to patients in coma with multisystem failure. In the adult, manifestations of hypothyroidism are varied and non-specific. In the child, thyroid hormone deficiency can manifest as growth or intellectual retardation.

Symptoms

- Common symptoms of hypothyroidism include dry skin, cold intolerance, weight gain, constipation, and weakness. Complaints of lethargy, depression, fatigue or loss of ambition and energy are also common but are less specific. Muscle cramps, myalgia, and stiffness are frequent complaints of hypothyroid patients. Menorrhagia and infertility can present commonly in women.

Signs

- Objective weakness is common, with proximal muscles being affected more than distal muscles. Slow relaxation of deep tendon reflexes is common. The most common signs of decreased levels of thyroid hormone include coarse skin and hair, cold or dry skin, periorbital puffiness, and bradycardia. Speech is often slow as well as hoarse. Reversible neurologic syndromes such as carpal tunnel syndrome, polyneuropathy, and cerebellar dysfunction can also occur. Galactorrhea can be found in women.

Diagnosis

- In primary hypothyroidism, TSH serum concentration should be elevated. In secondary hypothyroidism, TSH levels can be within or below the reference range; when TSH bioactivity is altered, the levels reported by immunoassay can even be elevated.
- Free and/or total T_4 and T_3 serum concentrations should be low.

Other Tests
