The most cost-effective choice of treatment for allergic rhinitis is an individualized decision. Seasonal allergic rhinitis patients who see improvement and can tolerate nonprescription and/or generic antihistamines will experience the least impact on out-of-pocket medical and drug expenses. If these are ineffective, the economic picture becomes more complicated. Choices should follow the logical path based on symptoms, tolerance, and efficacy, as described earlier in this chapter. Knowledge of an individual patient's drug coverage or lack of drug coverage may drive drug choices.

EVALUATION OF THERAPEUTIC OUTCOMES

With allergic rhinitis, the major outcomes issues include the effect of the disease on a patient's life, the efficacy and tolerability of treatment, and patient satisfaction. Consideration must be given to how the condition is affecting the patient's job or school performance, family and social interactions, and other aspects of quality of life. The drug therapy should prevent or minimize symptoms with minimal or no adverse effects. The patient should not have difficulty obtaining needed medication for financial or other reasons. Patients should be questioned about their satisfaction with the management of their allergic rhinitis. The management should result in minimal disruption to their lives.

Both the Medical Outcomes Study 36-Item Short Form Health Survey and the Rhinoconjunctivitis Quality of Life Questionnaire have been used to evaluate outcomes of treatment for seasonal and perennial allergic rhinitis.^{57–59} These tools go beyond measuring improvement in symptoms and include such items as sleep quality,

nonallergic symptoms (e.g., fatigue, poor concentration, and others), emotions, and participation in a variety of activities. How well each of the current treatment modalities performs and how they compare in improving patient outcomes remain to be determined.

Clinicians caring for allergic rhinitis patients should develop a comprehensive pharmaceutical care plan that addresses several areas. Discuss and agree on therapeutic end points for allergic rhinitis, including the patient's acceptable level of symptom relief, onset of symptom relief expectations, and seasonal starts and stops. Discuss adverse drug reaction self-monitoring and prevention based on treatment selection. Assess patient attitude toward adherence to and persistence with oral, ocular, intranasal, or immunologic therapies. Ensure proper matching of treatment to symptoms and intervene with the prescriber if necessary. Conduct seasonal or annual review with patient.

The therapeutic goal for all patients with allergic rhinitis is to minimize or prevent symptoms. Evaluation of success is accomplished primarily through the discussions with the patient, in whom both relief of symptoms and tolerance of drug therapy must be discussed.

CONCLUSIONS

Allergic rhinitis is a common disease with symptoms ranging from mild to severe. If avoidance measures are unsuccessful, it should be treated to improve quality of life and prevent long-term complications. Timing of treating is essential. Treatment regimens should be individualized based on patient symptoms and response.

ABBREVIATION

IgE: immunoglobulin E

SECTION 14

DERMATOLOGIC DISORDERS

CHAPTER

99

Dermatologic Drug Reactions and Self-Treatable Skin Disorders

NINA H. CHEIGH

KEY CONCEPTS

- 1 Pharmacists are often expected to offer advice regarding skin, hair, and nail conditions. Proper assessment includes not only identification of the condition, but also to identification of patients who need further referral.
- 2 In attempting to make a proper assessment, the healthcare professional must assess factors such as patient age, hormonal status, subjective complaints, and history, as well as examine the lesions.
- 3 Dermatitis is one of the most common reasons why patients seek advice. Symptomatic control, as well as identification of the offending agent, is typically the mainstay of therapy.
- 4 Goals of treating seborrheic dermatitis include loosening and removing scales, preventing yeast colonization, controlling any secondary infections, and reducing itching and erythema.
- 5 Maculopapular eruptions are the most common manifestation of drug-induced skin reactions. Lesions tend to resemble those of measles, often involving the trunk or pressure areas, and are frequently symmetrical.
- 6 A fixed-drug reaction appears as a round or oval pigmented lesion and typically reappears with a rechallenge within 30 minutes to 8 hours.
- 7 Sun- or hormonal-induced hyperpigmentation can be treated with skin bleaching agents such as hydroquinone or kojic acid.
- 8 Lesions that have the following: asymmetry, border irregularity, changes in color, and changes in diameter should be further evaluated by a dermatologist for possible melanoma.

As the largest organ of the body, the skin, also known as the integumentary system, is the site of a vast number of pathologic conditions.

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

Patients present with insults to and infections of the skin in a variety of primary care settings ranging from community pharmacies to the emergency department, requesting evaluation of and advice about skin lesions.

In a survey of patients about the sources of advice they use for skin conditions, pharmacists ranked second just behind physicians. Interestingly, the advice sought seemed to depend on the nature of the condition, in that patients sought more pharmacists for advice on conditions such as dermatitis, psoriasis, skin cancer, and acne.¹ To properly assess a patient, pharmacists and other primary care providers must not only understand clinical presentations of common skin disorders, but also be able to quickly identify patients who may need referral for further evaluation by a physician.

1 In this chapter, skin disorders that are self-treatable and dermatologic reactions to medications are presented from the primary care perspective of a pharmacist or other healthcare professional who primarily recommends nonprescription therapies or refers patients to prescribers or physician specialists. Skin infections are mentioned here but discussed in detail in Chap. 114.

SKIN STRUCTURE AND FUNCTION

The skin has many important functions. Its three layers—the epidermis, dermis, and hypodermis (subcutaneous tissue)—provide a barrier, prevent dehydration, and protect from external injury or microorganisms, maintain body temperature, and even express emotions through dilation or constriction of blood vessels. The dermal layer contains most of the structural components of skin, such as mast cells, fibroblasts, collagen, elastic fibers, sweat glands, sebaceous glands, pigment-producing melanin cells, and vasculature.

The hair and nails are considered appendages of the skin. Hair, comprising keratinized epithelial cells, is protein bound and grows in cycles. Scalp hair grows at a rate of approximately 35 mm/day, but this can be affected by various medications and hormones. The nails, also comprising keratinized cells, have different anatomic components. The nail plate is the main part of the nail, and is highly adherent to the nail bed, which grows underneath. Generally, toenails tend to grow at a much slower rate than fingernails. Several factors affect the growth of the nails, including genetics, age, and weather.²

PATIENT ASSESSMENT

2 Before a treat-or-refer recommendation can be made, the pharmacist or other healthcare professional must make a reasoned assessment of the problem and make a presumptive diagnosis (or at least rule out some of the many skin disorders). Several factors play into this decision, including patient age and hormonal status, patient complaint and history, and lesion assessment.

AGE AND HORMONAL STATUS

A primary factor to consider in evaluation is the age of the patient. Changes in the anatomy and physiology of skin and its appendages relate closely to patient age and for women, hormonal status.

Geriatric Considerations

In addition to wrinkling and dryness, expected age-related skin changes include an increase in uneven pigmentation and thinning of the protective layers, thus predisposing the skin to external injuries. Langerhans cells are reduced by 50% in number, reducing natural immunity to skin cancers. The vascularity of the skin declines, and thus older patients tend to look pale (pallor), feel cold to the touch, and develop certain conditions such as psoriasis, seborrhea, pemphigoid, and candidiasis. Changes in the skin appendages can also occur in the elderly, such as thinning, graying, and balding of the scalp. Women can develop facial hair as a result of the reduction of estrogen. The thickness of the nails is reduced, and nails change in color.

Pediatric Considerations

Certain dermatologic conditions, such as atopic dermatitis, are most likely to occur in children. Also, the rate and amount of absorption of medications through the skin are higher in children. Infants may not be able to safely metabolize or excrete medications because of immaturity of their hepatic and renal systems. They also have immature sebaceous gland activity, and thus present frequently with seborrheic dermatitis on the scalp, also known as “cradle cap.”

In adolescence, hair appears in new places: the face in boys, and the pubic and other areas in both boys and girls. Sweating and sebaceous gland activity is greater, thus resulting in increased body odor and skin conditions such as acne (see Chap. 100).

Hormone-Related Considerations

Variations in progesterone and estrogen can result in dermatologic disorders as women go through changes and events of their lives.

Menopausal women tend to develop brown hyperpigmentation, or melasma. Women who are on hormone-replacement therapy or oral contraceptives also develop these nonspecific brown discolorations on their skin.

Pregnant women develop many changes, including hyperpigmentation of the areola and genitalia. These women can also develop melasma, commonly known as the “mask of pregnancy.” Most pregnant women develop stretch marks, or striae gravidarum around the abdomen, thighs, breasts, and buttocks. They can also develop disorders such as pruritic urticarial papules and plaques of pregnancy, referred to by clinicians as its acronym, PUPPS. Women who are pregnant also typically notice changes in their hair, whether it be thinner or thicker, straighter or curlier.

SUBJECTIVE QUESTIONING

In addition to clues offered by patient age and special conditions such as pregnancy, several key questions can provide insights into

the patient’s skin disorder or injury. Getting an accurate history and other information from the patient is critical for ensuring optimal treatment and avoiding undue complications.

Interview

When interviewing the patient, the healthcare professional should make note of the interaction. Questions that are helpful in assessment include the following:

- *Are you having other symptoms—difficulty breathing, fever, or nausea/vomiting?* When patients present with a rash or skin lesion, the first thought should be any potential anaphylaxis or angioedema. Many medications can be responsible for these reactions, and these must be ruled out. If a patient has a severe reaction, with difficulty breathing, the patient may require immediate or even emergent referral to an emergency care facility to obtain proper care. Epinephrine, intravenous corticosteroids, or oral prednisone may be needed immediately.
- *Where did the problem first appear? Where are you affected? Did it spread?* Asking where the skin lesions are is of importance, as most likely, the entire skin is not visible to the healthcare professional, and the source of the infection may be covered. For example, although the arms and legs can demonstrate a rash, it would be pertinent to determine if the trunk is also affected, leading to more of a systemic cause, as opposed to an unaffected trunk, which would likely indicate a nonsystemic cause.
- *If not visible, what do the lesions look like?* The patient can be asked whether the lesion is painful or itching, and can thus can be assessed for any infection requiring immediate treatment. For example, if the area is oozing, erythematous, and warm to the touch, it is most likely infected. Alternatively, if the lesion is not painful and no other symptoms are present, other conditions are likely present. The lesions, if appropriate, can be assessed by the pharmacist for color, texture, size, and temperature. Also, it is important to note any symmetrical differences (e.g., present on only one side of the body).
- *How long have the lesions been present?* Some patients present after having had a skin condition for quite sometime without seeking any advice. This information is also helpful if to the lesions’ appearance was after the start of a certain suspected medication.
- *Have the lesions changed in size, shape, color, or consistency?* This question is important in determining any changes that might have occurred with the condition. Most importantly, this question enables evaluation of the patient’s melanoma risk. Typically, any skin lesion that changes in these elements should be further examined by a physician.
- *What do you think the problem may be?* Many patients have some thought as to what the source of their problem may be. It is helpful to ask this question, and get their opinion and observation.
- *Obtain general medical/allergy history.* After questioning the patient, a pharmacist or other healthcare professional may be able to rule out recently started drugs or new diseases as causes of the patient’s reaction.

LESION ASSESSMENT

If appropriate and acceptable to the patient, the healthcare professional should make a quick visual assessment of the skin lesions. The skin surface should be examined, preferably in natural light. As proper diagnosis is based on pattern recognition, the pharmacist or other health professional must understand and demonstrate com-

A.

B.

FIGURE 99-1. Macules are circumscribed, flat lesions of any shape or size that differ from surrounding skin because of their color. A. Macules may be the result of hyperpigmentation (A), hypopigmentation, dermal pigmentation (B), vascular abnormalities, capillary dilation (erythema) (C), or purpura (D). B. The clinical appearance of a drug reaction that has produced an eruption consisting of multiple, well-defined red macules of varying size that blanch upon pressure (diascopy) and are thus a result of inflammatory vasodilation. (Reprinted with permission from Stewart MI, Bernhard JD, Cropley TG, Fitzpatrick TB. *The structure of skin lesions and fundamentals of diagnosis*. In: Freedberg IM, Eisen AZ, Wolff K, et al., eds. *Fitzpatrick's Dermatology in General Medicine*, 6th ed. New York: McGraw-Hill, 2003:18.)

petence in assessing the lesion (Figs. 99-1 through 99-6).³ In addition, when referral is needed, the pharmacist or other health-care professional should describe lesions to dermatologists or other physicians in a consistent manner.

Site Distribution and Arrangement

Note the area involved (e.g., face, trunk, arms, legs) and number of lesions present (single or multiple). Identifying the arrangement of the lesions is helpful, such as stating that the lesions are linear (in a

line), grouped, annular (limited to one lesion), or serpiginous (resembling a snake). Symmetry or asymmetry should be noted; in skin cancer, lesions are typically asymmetrical.

Surface Texture

Unless the lesions are oozing or appear to be infectious (see Fig. 99-6B), they should be palpated with caution. Palpation helps the healthcare professional determine whether the lesion is smooth or rough, firm or soft, or scaly or crusting.

Type of Lesions

The size of lesions should be measured. Typically, lesions are demarcated as being less than or greater than 0.5 cm in diameter. A *macule* (see Fig. 99-1A) or a *papule* (see Fig. 99-2A) is typically 1 cm or less in diameter, while the term *patch* is sometimes used for larger flat macules (see Fig. 99-1B).

Border

Poorly circumscribed lesions are those for which it is hard to tell where the “normal” skin begins and ends (see Fig. 99-3B), whereas well-defined lesions have clearer demarcations between healthy skin and lesions (see Fig. 99-4B).

Lesions and Skin Color

Lesions should be examined for variations from the patient's predominant skin color. Increased pigmentation (brownish color), loss of pigmentation, redness (erythema), pallor, cyanosis, and yellowing should be noted. Color can be very indicative of an underlying systemic diseases. For example, anemia and reduced blood flow can result in decreased skin redness. Cyanosis can indicate reduced heart blood flow or lung disease. Jaundice can suggest liver disease.

Other Features

An assessment of the nails, hair, and mucous membranes should also be performed as needed and appropriate.

Once the healthcare professional identifies the specific questions to ask and can provide a reasonable description of the lesion, referral or appropriate therapies can be recommended. As there are hundreds of varieties of dermatologic disorders, this chapter focuses on the common conditions most frequently encountered by the pharmacist and other primary care professionals, with an emphasis on skin disorders that are often treated with nonprescription medications, and on drug-induced skin disorders. Infectious skin conditions are discussed in detail in Chap. 114.

SKIN DISORDERS

DERMATITIS

The term *dermatitis* is a general word denoting an inflammatory, erythematous rash. Many types of dermatitis have been described, with the most common ones being atopic dermatitis (see Chap. 102 for a complete discussion) and contact dermatitis. Although atopic dermatitis can occur at any age, it is most common in infants and children; consequently, age can be a critical identifier in distinguishing between atopic and contact dermatitis. Atopic dermatitis is also frequently associated with elevated immunoglobulin E levels and family history of atopic disease such as dermatitis, allergic rhinitis, and asthma.⁴

Contact Dermatitis

Contact dermatitis is an acute (Fig. 99-7) or chronic (Fig. 99-8) inflammatory skin condition that results from contact of a triggering

A.

C.

B.

FIGURE 99-2. Papules are small, solid, elevated lesions that are usually less than 1 cm in diameter. The major portion of a papule projects above the plane of the surrounding skin. A. Papules may result, for example, from metabolic deposits in the dermis (A), from localized dermal cellular infiltrates (B), and from localized hyperplasia of cellular elements in the dermis and epidermis (C). Papules with scaling are referred to as papulosquamous lesions, as in psoriasis (see Chap. 101). B. Clinical examples of papules. The examples are two well-defined and dome-shaped papules of firm consistency and brownish color, which are dermal melanocytic nevi. C. Multiple, well-defined, and coalescing papules of varying size are seen. Their violaceous color, glistening surface, and flat tops are characteristic of lichen planus. (Reprinted with permission from Stewart MI, Bernhard JD, Cropley TG, Fitzpatrick TB. *The structure of skin lesions and fundamentals of diagnosis*. In: Freedberg IM, Eisen AZ, Wolff K, et al., eds. *Fitzpatrick's Dermatology in General Medicine*, 6th ed. New York: McGraw-Hill, 2003:18.)

factor with the skin. Typically, contact dermatitis can be further divided into two major subgroups, allergic or irritant, depending on whether the cause is an antigen (allergen) or irritant, such as an organic substance. Irritant contact dermatitis accounts for 80% of cases of contact dermatitis. In allergies, the antigenic substance triggers the Langerhans cells, and their immunologic responses produce the allergic skin reaction, sometimes several days later. Irritant contact dermatitis is more likely to be the result of a reaction within a few hours of exposure. Although symptoms of either type of contact dermatitis (erythematous vesicles with pruritus) are generally similar, the allergic type can result in more serious erosions or oozing pustules. Table 99-1 lists common offending agents for contact dermatitis.⁵

3 When patients present with symptoms of contact dermatitis, pharmacists and other primary care providers should initially ask key questions about exposure to potentially offending substances.

Initial treatment of contact dermatitis should always focus on identification and removal of the offending agent. When this is not possible, the patient should be advised to avoid exposure to those agents considered most likely responsible.

TABLE 99-1 Common Allergens Producing Contact Dermatitis Among People in the United States	
Fragrances	Lanolin (wool)
Flavorings	Neomycin sulfate
Rubber	Nickel (jewelry)
Metals	Paraben mix
Adhesives	Thimerosal
Glues	Urushiol (resin found in poison ivy, oak, sumac)
Plastics	Preservatives
Formaldehyde (clothing, nail polish)	

A.

C.

B.

FIGURE 99-3. A. Plaque is a mesa-like elevation that occupies a relatively large surface area in comparison with its height above the skin surface. B. Well-defined, reddish, scaling plaques can coalesce to cover large areas of the back and buttocks, with some regression in the center as is common in psoriasis (see Chap. 101). C. Lichenification, a thickening of the skin and accentuation of skin, can result from repeated rubbings. It develops frequently in patients with atopy, and also occurs in eczematous dermatitis or other conditions associated with pruritus. Lesions of lichenification are not as well defined as most plaques and often show signs of scratching, such as in excoriations and crusts. (Reprinted with permission from Stewart MI, Bernhard JD, Cropley TG, Fitzpatrick TB. *The structure of skin lesions and fundamentals of diagnosis*. In: Freedberg IM, Eisen AZ, Wolff K, et al., eds. *Fitzpatrick's Dermatology in General Medicine*, 6th ed. New York: McGraw-Hill, 2003:18.)

The second goal of treatment is the relief of symptoms. Products that relieve itching, rehydrate the skin, and decrease weeping of the lesions will provide some immediate relief. The dosage form of topical preparations is determined by the stage of inflammation. In the acute stage, wet dressings are preferred because ointments and creams further irritate the tissue. Astringents such as aluminum acetate, Burrow solution, or witch hazel decrease weeping from lesions, “dry out” the skin, and provide relief from itching. These agents are applied as wet dressings and should not be used for more than 7 days.

For chronic dermatitis, lubricants, emollients, or moisturizers should be applied after bathing. Soap-free (or mild) cleansers and products containing colloidal oatmeal also contribute to alleviating itch and soothing the skin. If the patient's reaction does not subside

within a few days, or further spread occurs, the patient should be referred for prescriber or specialist followup and for prescription therapy with stronger topical corticosteroids and possibly oral corticosteroid bursts.

Seborrheic Dermatitis

The prevalence of seborrheic dermatitis peaks during infancy, and then again during the fourth to seventh decades of life, affecting 3% to 5% of adults in the United States. In infants, seborrheic dermatitis is commonly referred to as “cradle cap.” Typically, this condition occurs around the areas of skin rich in sebaceous follicles, such as the face (Fig. 99–9), ears, scalp, and upper trunk (Fig. 99–10), although

A.

B.

C.

FIGURE 99-4. Nodules are palpable, solid, round or ellipsoidal lesions. Depth of involvement and/or substantive palpability rather than diameter differentiates a nodule from a papule. A. Nodules may be located in the epidermis (B) or extend into the dermis or subcutaneous tissue (A). B. This photograph shows a well-defined, firm nodule with a smooth and glistening surface through which telangiectasia (dilated capillaries) can be seen; there is central crusting indicating tissue breakdown and thus incipient ulceration (nodular basal cell carcinoma). C. Multiple nodules of varying size can be seen (melanoma metastases). (Reprinted with permission from Stewart MI, Bernhard JD, Cropley TG, Fitzpatrick TB. *The structure of skin lesions and fundamentals of diagnosis*. In: Freedberg IM, Eisen AZ, Wolff K, et al., eds. *Fitzpatrick's Dermatology in General Medicine*, 6th ed. New York: McGraw-Hill, 2003:18.)

it is not classified as a disease of the sebaceous glands per se.⁶ Little is known about its etiology, although factors such as hormone levels, fungal infections (often caused by *Malassezia furfur*), and various nutritional deficits can be associated with the condition. Adult and adolescent seborrheic dermatitis usually starts as mild, greasy scaling of the scalp with erythema and possible scaling of the nasolabial folds. It typically appears oily and occurs in areas of increased sebaceous gland activity (nose, eyebrows, beard area). Adults may develop seborrheic dermatitis on the chest that can appear as small, reddish-brown papules with greasy scales. Infants can have scalp ("cradle cap"), forehead, and ear involvement that typically look like white to yellow scales. Generalized seborrheic dermatitis is uncommon in healthy children, so those who have this should be evaluated for immunodeficiencies.⁷

Therapy of seborrheic dermatitis has four major goals: to loosen and remove scales, prevent yeast colonization, control any secondary infections, and reduce itching and erythema. 4 Interestingly, the disease typically seems to improve with warmer weather and worsens when the air is colder.

Many topical agents are used to manage seborrheic dermatitis. Depending on what area of the body is affected, the pharmacist or other healthcare professional can assist in selection of proper vehicles (i.e., solutions or shampoos for scalp). Adults with seborrheic dermatitis of the scalp can be treated with twice daily topical corticosteroids. This is often used in conjunction with a shampoo containing selenium sulfide, coal tar, or salicylic acid to help loosen the scales. Topical calcineurin inhibitors such as tacrolimus ointment and pimecrolimus cream have fungicidal and antiinflammatory properties and can be used for the scalp or face.^{8,9}

Diaper Dermatitis

Diaper dermatitis, or diaper rash, is an acute, inflammatory dermatitis of the buttocks, genital, and perineum region. Commonly seen in infants in diapers, this condition resulting in erythematous patches, erosion of skin, vesicles, and ulcerations can be seen in adults who might wear diapers for incontinence. This reaction is a

C.

FIGURE 99-5. A. Wheals are rounded or flat-topped papules or plaques that are characteristically evanescent, disappearing within hours. An eruption consisting of wheals is termed urticaria and usually itches. B. Wheals may be tiny papules 3 to 4 mm in diameter, as in cholinergic urticaria. C. Alternatively, wheals may present as large, coalescing plaques, as in allergic reactions to penicillin, other drug, or alimentary allergens. (Reprinted with permission from Stewart MJ, Bernhard JD, Cropley TG, Fitzpatrick TB. *The structure of skin lesions and fundamentals of diagnosis*. In: Freedberg IM, Eisen AZ, Wolff K, et al., eds. *Fitzpatrick's Dermatology in General Medicine*, 6th ed. New York: McGraw-Hill, 2003:18.)

type of contact dermatitis, as it results from direct fecal and moisture contact to the skin in an occlusive environment.

Treatment of diaper dermatitis includes frequent diaper changes and keeping the area dry. Lukewarm water and mild soap can be used to cleanse the area thoroughly, which is then allowed to dry. Occlusive agents—such as zinc oxide, titanium dioxide, petrolatum, or any combination of these—should be generously applied to the area before the diaper is applied.

DRUG-INDUCED SKIN DISORDERS

Approximately 2% to 3% of hospitalized patients experience an adverse cutaneous drug reaction, with a higher incidence in older individuals. Almost every commonly used drug has been implicated in producing local and/or systemic drug reactions (Table 99-2). Typically, these reactions are unpredictable, ranging from mild, self-

limiting episodes to more severe, life-threatening ones. Some reactions are nonallergic, but drug-induced skin reactions tend to be immunologic in origin and relate to hypersensitivity.

Pharmacists and other primary care providers should develop an organized and thorough approach to evaluation of patients with potential drug-induced skin disorders. This process begins with a comprehensive drug history, including episodes of previous drug allergies, and is based on an understanding the mechanisms involved in drug reactions.

CUTANEOUS DRUG REACTIONS

Maculopapular eruptions are the most common manifestation of drug-induced skin reactions. Lesions tend to resemble those of measles, often involving the trunk or pressure areas, and are frequently symmetrical. **5** These eruptions are classified as either early, appearing within a few hours to 3 days after ingestion of the

TABLE 99-2 Types of Drug-Induced Skin Eruptions

Clinical Presentation	Pattern and Distribution of Skin Lesions	Mucous Membrane Involvement	Implicated Drugs	Treatment
Erythema multiforme	Target lesions, limbs	Absent	Anticonvulsants (including lamotrigine), sulfonamide antibiotics, allopurinol, nonsteroidal antiinflammatory drugs, dapsone	Supportive ^a
Stevens-Johnson syndrome	Atypical targets, widespread	Present	As above	Intravenous immunoglobulins, cyclosporine
Toxic epidermal necrolysis	Epidermal necrosis with skin detachment	Present	As above	Supportive ^a
Pseudoporphyria	Skin fragility, blister formation in photodistribution	Absent	Tetracycline, furosemide, naproxen	Supportive ^a
Liver immunoglobulin A disease	Bullous dermatosis	Present or absent	Vancomycin, lithium, diclofenac, piroxicam, amiodarone	Supportive ^a
Pemphigus	Flaccid bullae, chest	Present or absent	Penicillamine, captopril, piroxicam, penicillin, rifampin	Supportive ^a
Bullous pemphigoid	Tense bullae, widespread	Present or absent	Furosemide, penicillamine, penicillins, sulfasalazine, captopril	Supportive ^a

^aSupportive care includes administration of systemic glucocorticoids until all symptoms of active disease disappear.

Reprinted with permission from Freedberg IM, Eisen AZ, Wolff K, et al, eds. *Fitzpatrick's Dermatology in General Medicine*, 6th ed. New York: McGraw-Hill, 2003:1199.

drug, or late, appearing up to 9 days after the exposure. Most reactions disappear within a few days after discontinuing the agent, and thus symptomatic control of the affected area is the primary intervention. Topical corticosteroids and oral antihistamines can relieve pruritus. In severe eruptions, a short course of systemic corticosteroids may be warranted.

6 A fixed-drug reaction, typically presenting as an erythematous or hyperpigmented round or oval lesion, usually ranges from a few millimeters to 20 cm in diameter.¹⁰ Although the lesion can appear anywhere, the oral mucosa or genitalia regions are the most common sites. If the patient takes the agent again, the drug reaction tends to recur within 30 minutes to 8 hours after rechallenge in the exact same location; this is highly indicative of the fixed-drug reaction (lesions may also occur in other locations).¹¹ The pathogenesis of fixed drug reactions is not well understood.

Treatment of fixed-drug reactions involves removal of the offending agent. Rechallenge should be avoided when possible. Other therapeutic measures include the use of corticosteroids, antihistamines to relieve itch, and perhaps cool water compresses to the affected area.¹¹

Sun-induced drug eruptions tend to appear similar to a sunburn, and present with erythema, papules, edema, and sometimes vesicle formations. They also appear in areas that tend to be most susceptible to sunlight, such as the ears, nose, cheeks, forearms, and hands. Photosensitivity is subdivided into phototoxicity, which is defined as a nonimmunologic reaction, and photoallergic reaction, which involves an immunologic mechanism and is far less common.¹² Common medications associated with photosensitivity reactions include fluoroquinolones, nonsteroidal antiinflammatory drugs, phenothiazines, antihistamines, estrogens, progestins, sulfonamides, sulfonylureas, thiazide diuretics, and tricyclic antidepressants.² Typically, patients can achieve symptom resolution by discontinuing the medication.

Patients with photosensitivity reactions should be treated much as a burn victim would be. Management of the “burn” is of primary importance. Some patients benefit from topical corticosteroids and oral antihistamines, but these are relatively ineffective. Systemic corticosteroids, typically with oral prednisone at 1 mg/kg per day tapered over 3 weeks, is more effective for these patients. Pharmacists and other healthcare professionals should provide proper sunscreen use counseling and recommend a protective product that covers ultraviolet A and B rays.¹³

HYPERPIGMENTATION

Many medications can cause changes in skin color. These can be caused by the medication or by disturbances in melanin production or formation. Depending on the medication, the site of hyperpigmentation can vary. For example, patients receiving anticonvulsants such as phenytoin, phenobarbital, and carbamazepine report a brown patchy lesion in sun-exposed areas.¹⁰ Patients who receive anticonvulsant therapy for longer than 1 year are at a 10% risk of developing some form of hyperpigmentation related to the medication.¹⁴ Women on oral contraceptives frequently report melasma, or brown, irregularly shaped macules on the cheeks, forehead, or upper lip. Hormonal changes in estrogen and progesterone, as well as sun exposure, are attributed with the increase in melanin deposition.¹⁵ Other medications commonly associated with skin hyperpigmentation include antimalarial agents, phenothiazines, tetracyclines,¹⁶ and amiodarone (Fig. 99–11).¹⁷

Patients with drug-induced hyperpigmentation can use skin-bleaching creams and/or cosmetic agents that help to even out skin tone. Many such products have been marketed. Hydroquinone or kojic acid are most commonly found in cosmetic agents to aid in bleaching the darkened area of skin. **7** Many times, these agents are formulated in conjunction with α -hydroxy acids, which help to slowly slough off the outermost layer of skin. Those patients who are using bleaching creams absolutely must use sunscreen, as areas being treated with these creams tend to be even more sun-sensitive.

SKIN CANCERS

Actinic keratoses (AKs) are abnormal keratinocytes that develop in response to prolonged exposure to ultraviolet radiation. These lesions can develop into squamous cell or basal cell carcinomas, and the presence of suspicious lesions is one of the top reasons that patients seek medical attention for dermatologic disorders.

AK usually presents as a small (2- to 6-mm), erythematous papule that feels flat, rough, or scaly when palpated (Fig. 99–12). It tends to be found in chronically sun-exposed areas, such as the top of the hands, head, neck, and forearms. Patients with AKs are frequently elderly and have fair skin, light-colored eyes, freckles, and a history of significant sun exposure and sunburning easily. Because AKs are likely caused by

B.

FIGURE 99-6. Vesicles and bullae are the technical terms for blisters. Vesicles are circumscribed lesions that contain fluids, while bullae are vesicles that are larger than 0.5 cm in diameter. A. Subcorneal vesicles (A) result from fluid accumulation just below the stratum corneum, whereas spongiotic vesicles (B) result from intercellular edema. B. Multiple translucent subcorneal vesicles are extremely fragile, collapse easily, and thus lead to crusting (arrows). These lesions are staphylococcal impetigo. (Reprinted with permission from Stewart MJ, Bernhard JD, Cropley TG, Fitzpatrick TB. *The structure of skin lesions and fundamentals of diagnosis*. In: Freedberg IM, Eisen AZ, Wolff K, et al., eds. *Fitzpatrick's Dermatology in General Medicine*, 6th ed. New York: McGraw-Hill, 2003:18.)

ultraviolet radiation, sun-preventive measures, particularly in childhood, are of utmost importance.¹⁸ Most commonly, AKs are treated with liquid nitrogen, which will remove the affected AK. Another frequently used therapy is topical 5-fluorouracil. Patients who are prescribed topical 5-fluorouracil should be properly counseled, as significant erythema, erosion, crusting, and even ulceration normally occur during treatment.

Squamous cell carcinoma (SCC) is a cutaneous malignancy, with estimates of approximately 200,000 cases in the United States in 2001. SCC seems to be more common in advanced age, and twice as common in men than in women. Because of their susceptibility to the negative effects of long-term sun exposure, patients of Celtic ancestry and those with blue/green eyes, red hair, and fair complexion are at

FIGURE 99-7. Acute dermatitis caused by poison ivy. Note the linear arrangement of lesions typical of phyto dermatitis acquired by inadvertent contact with the plant. The severe vesiculobullous reaction is typical for urushiol, an oily poisonous irritant found in *Toxicodendron* spp. (Reprinted with permission from Belsito DV. *Allergic contact dermatitis*. In: Freedberg IM et al., eds. *Fitzpatrick's Dermatology in General Medicine*, 6th ed. New York: McGraw-Hill, 2003:1167.)

the greatest risk of developing SCC.¹⁹ Other risk factors include precursor lesions, such as AKs, long-term immunosuppression, and ultraviolet radiation. SCC can appear in many areas, but mainly occurs in sun-exposed areas such as the head, neck, and dorsal aspect of the hands. Most SCCs appear as a firm, flesh-colored, or erythematous papule or plaque (Fig. 99-13). Some resemble an ulcer. Treatment for SCC is determined by the tumor risk for metastasis, but commonly involves some form of surgical excision.

Basal cell carcinoma is the most common cancer in humans, with an estimated 900,000 cases per year in the United States.¹⁹ Basal cell carcinomas can occur anywhere on the body, but they appear most commonly on the head and neck, usually as a nodular, pigmented lesion (Fig. 99-14). Treatment varies depending on the histology of the lesion, but frequently requires Mohs micrographic surgery, surgical excision, and possible use of topical agents. Topical imiquimod is approved by the U.S. Food and Drug Administration for treating basal cell carcinoma of areas other than the face, and this agent resulted in some clearances in a phase II study.²⁰ Topical 5-fluorouracil has also been used, but needs further evaluation to warrant routine use.

8 The risk of malignant melanoma is increasing, with a prediction that prevalence could reach 1 in 50 by 2010.²¹ Most frequently, melanoma occurs on the back and extremities of white males and females, whereas in Asians and blacks, it tends to appear on mucous membranes and soles and palms. Risk factors include skin type, sun exposure and response to the sun (i.e., ability to tan), family history, and changing moles. Exposure to environmental radiation or chronic

B.

FIGURE 99-8. A. This patient has allergic chronic dermatitis involving the dorsal aspects of the hands and the distal forearms, but with minimal involvement of the palms. In this case, contact dermatitis is secondary to use of thiuram present in rubber gloves, prescribed for treatment of an irritant hand dermatitis. B. This patient, a florist, has allergic contact dermatitis as a consequence of exposure to tuliposide A, the allergen in Peruvian lilies (*Alstroemeria* spp.). Note the more prominent involvement of the palms of the dominant hand. (Reprinted with permission from Belsito DV. Allergic contact dermatitis. In: Freedberg IM et al., eds. *Fitzpatrick's Dermatology in General Medicine*, 6th ed. New York: McGraw-Hill, 2003:1167.)

immunosuppression can lead to an increased incidence of SCCs.²² The presence of any nonhealing lesion should raise the suspicion of skin cancer. In addition to assessing these risk factors, pharmacists can play a key role in examining the questionable lesion(s) and by assessing the lesion's asymmetry, border, color, diameter, and history, as when a mole has changed and led to the lesion (Fig. 99-15). Patients who fit these criteria should be further evaluated by a dermatologist.

LAURA SCUDERI, AND GIUSEPPE MICALI

KEY CONCEPTS

- 1 In the United States, acne vulgaris is the most common skin disorder, affecting up to 50 million people.
- 2 Four primary factors are identified as being involved in the formation of acne lesions: increased sebum production, sloughing of keratinocytes, bacterial growth, and inflammation.
- 3 Acne vulgaris is a disease of the pilosebaceous unit (i.e., the sebaceous glands and adjacent hair follicle).
- 4 Several types of lesions present at the same time in various stages of development, including noninflammatory and inflammatory lesions, scars, and residual hyperpigmentation.
- 5 Most therapeutic interventions function primarily to prevent the formation of new acne lesions and have minimal impact on existing lesions.
- 6 Because most treatments for acne reduce or prevent new eruptions, they can take up to 8 weeks for visible results.
- 7 *Mild acne* usually is managed with topical retinoids alone or with topical antimicrobials, salicylic acid, or azelaic acid. *Moderate acne* can be managed with topical retinoids in combination with oral antibiotics, and if indicated, benzoyl peroxide. *Severe acne* is often managed with oral isotretinoin.
- 8 Minocycline has more adverse effects than the other tetracyclines.
- 9 Acne is a common, chronic inflammatory disorder of the pilosebaceous unit in which a microcomedo develops as the initial condition. The most common form of acne is acne vulgaris. Other variants of acne are neonatal acne, adult acne, acne cosmetica, and acne mechanica. These descriptors refer to age of onset or causative factors.

Localization of acne vulgaris on the facial area, especially in an adolescent population, significantly impacts self-esteem. Although acne is self-limiting, it can persist for years and can result in disfigurement and scarring.¹ Acne can also be associated with anxiety, depression, and higher-than-average unemployment rates.² As the emotional impact of acne is not always easy to assess clinically, it is important for the healthcare professional to educate patients on causes of acne, discussing treatment regimens, and counseling on proper medication use.³

Learning objectives, review questions,
and other resources can be found at
www.pharmacotherapyonline.com.

EPIDEMIOLOGY

- 1 In the United States, acne vulgaris is the most common skin disorder, affecting up to 50 million people.⁴ Acne vulgaris affects approximately 80% of the population between the ages of 11 and 30 years,⁵ with no gender, race, or ethnicity prevalence.⁶

Acne age of onset varies but usually begins at puberty. A form of acne called *adult acne* can first occur after the mid-20s, affecting females more than males, and with lesions generally distributed in the lower facial area around the mouth, chin, and jaw line.⁷

ETIOLOGY

- 2 Four primary factors are identified as being involved in the formation of acne lesions: increased sebum production, sloughing of keratinocytes, bacterial growth, and inflammation.^{5,8,9}

INCREASED SEBUM PRODUCTION

Androgen stimulation is enhanced at puberty and sebaceous glands actively produce sebum. Testosterone, the predominant androgen, and its metabolites along with androstenedione, dehydroepiandrosterone, and dehydroepiandrosterone sulfate, are all increased in acne and apparently capable of enhancing sebaceous gland activity. Anatomic sites for acne tend to be more metabolically active in converting androgens to dihydrotestosterone.

Androgenic activity drives sebum production in the sebaceous glands; however, most acne patients do not have an endocrine abnormality. Acne-affected pilosebaceous units apparently have a hyperresponsiveness to circulating androgens.⁵ Increased sebum production per se is not necessarily responsible for acne but can rather be viewed as an underlying factor.

SLOUGHING OF KERATINOCYTES

A primary factor in the development of acne is the process of follicular keratinization. Sloughing of keratinocytes within the hair follicle is a normal process, but in acne, follicular keratinization more readily involves keratinocyte clumping and subsequent plugging of the hair follicle pore. Increased sloughing of keratinocytes correlates with comedo formation and can be related to influences such as local cytokine modulation, a decrease in sebaceous linoleic acid, and androgen stimulation.⁵ Abnormal follicular keratinization can be a primary event, or can be a secondary response to irritation or other factors.

BACTERIAL GROWTH AND COLONIZATION

The mix of “trapped” keratinocytes and sebum provide an environment for the normally occurring bacteria *Propionibacterium acnes* to

FIGURE 100-1. Principal influence in the formation of acne lesions. (*P. acnes*, *Propionibacterium acnes*.)

flourish.¹⁰ Although *P. acnes*, a partial anaerobe, resides in the follicle as normal flora, it triggers immune responses such that titers of antibodies to *P. acnes* are higher in patients with severe acne than in non-acne control subjects.

INFLAMMATION AND IMMUNE RESPONSE

Inflammation can be a consequence of increased sebum production, keratinocyte sloughing, and bacterial growth. Also, *P. acnes* can trigger inflammatory acne lesions by producing biologically active mediators and promoting proinflammatory cytokine release.¹¹

PATHOPHYSIOLOGY

3 Acne vulgaris is a disease of the pilosebaceous unit (i.e., the sebaceous gland and adjacent hair follicle). Sebaceous glands, predominant on the face, chest, and upper back, respond to androgen stimulation. These glands provide sebum to the follicular canal and eventually to the skin surface through the follicular opening (the pore). Follicular canal contents include keratinocytes, *P. acnes*, and free fatty acids.

Formation of the primary lesion, the comedo, can be thought of as a plugging of the pilosebaceous follicle. In acne, the follicular canal widens and an increase in cell production can be seen. Sebum mixes with excess loose cells in the follicular canal to form a keratinous plug. The resulting lesion appears as a “blackhead,” or open comedo. The brown or black color is not a result of dirt accumulation, but that of melanin (pigment). Inflammation or trauma to the follicle can lead to formation of a “whitehead,” or closed comedo. If the follicular wall is damaged or ruptured, the contents of the follicle can extrude into dermis and present clinically as a pustule. Closed comedones are of clinical importance as they can become larger, inflammatory lesions secondary to local *P. acnes* activity (Fig. 100–1).^{5,12} Acne lesions can take months to heal completely, and fibrosis associated with healing can lead to permanent scarring.¹³

CLINICAL PRESENTATION OF ACNE VULGARIS

4 Acne lesions typically occur on the face, back, upper chest, and shoulder area. Severity of the disease varies from a mild comedonal form to severe inflammatory necrotic acne.¹⁴ Acne vulgaris is described as mild, moderate, or severe, depending on the type and severity of lesions present. See Table 100–1 for descriptions of mild, moderate, and severe acne.

Symptoms

■ Generally, the diagnosis of acne vulgaris consists of findings that include a mixture of lesions of acne (e.g., comedones, pustules, papules, nodules, and cysts) on the face, back, or chest. Although there is no precise definition for acne, many practitioners consider the presence of 5 to 10 comedones to be diagnostic.

Signs

■ There can be more than one morphologic type of lesion present (see Table 100–1), in various stages of development, including noninflammatory and inflammatory lesions, scars, and residual hyperpigmentation.¹⁴

Noninflammatory Lesions

■ An open comedo or blackhead is a plug of sebum, keratinocytes, and microorganisms blocking a *dilated* hair follicle opening, whereas a closed comedone or whitehead is a similar plug blocking a *closed* hair follicle opening to the surface of the skin.

Inflammatory Lesions

- A papule is a well-defined, elevated, palpable, distinct area of skin generally less than 1 cm in diameter involving the epidermis and/or dermis. Papules may not have a change in skin color, but are always raised and can have variable textures.
- A pustule is an elevated, distinct, superficial cavity filled with purulent fluid, typically surrounding a hair follicle.
- A nodule is an elevated, firm, distinct, palpable, round or oval lesion up to 1 cm in diameter that occurs in the dermis and/or hypodermis.

TABLE 100-1 Predominance of Acne Lesion Type by Acne Severity

Acne Severity	Predominant Lesions	Typical Frequency of Lesion Type					
		Closed Comedones	Open Comedones	Papules	Pustules	Nodules	Scarring
Mild	Noninflammatory lesions (open and closed comedones)	Few to numerous	Few to numerous	Possible	Possible	None	None
Moderate	Inflammatory papules and pustules with some noninflammatory lesions	Few to numerous	Few to numerous	Numerous	Numerous	Few	Possible
Severe	Inflammatory lesions and scarring with some noninflammatory lesions	Few to numerous	Few to numerous	Extensive	Extensive	Extensive	Extensive

Scars

- Permanent scars can occur as a result of inflammatory acne lesions.

Residual Hyperpigmentation

- Inflammatory acne lesions can trigger noticeable hyperpigmentation that can persist weeks to months after resolution of the lesion.¹⁵

Laboratory Tests

- There are no laboratory tests to diagnose acne vulgaris.¹⁶ Diagnosis is based on clinical signs. Other dermatologic conditions, such as folliculitis, acne rosacea, and other various acneiform disorders, sometimes can be confused with acne vulgaris.¹⁷

TREATMENT**Acne Vulgaris**

5 Most therapeutic interventions function primarily to prevent the formation of new acne lesions and have minimal impact on existing lesions. Among the factors that can affect acne are genetics, climate, diet, environment, stress, and physical activity.

Stress seems to aggravate, but not induce, acne.¹⁸ In response to stress, immunoreactive nerve fibers can stimulate sebaceous gland activity and provoke inflammatory reactions via mast cells.¹⁹

The ingestion of iodine can exacerbate acne or induce acneiform lesions.⁸ Dietary factors in acne are controversial.

CLINICAL CONTROVERSY

An observational study has concluded that the incidence of acne in Western and non-Western societies is greatly different and suggests that it is not because of genetic influence alone, but most likely occurs because of differences in diet. These authors thought that a non-Westernized diet, representing a substantially low glycemic index, influenced a dramatically lower incidence of acne.⁴ It is disputed whether this conclusion is accurate, as acne is influenced by multiple factors, and there are no data to support an effect of glycemic index on acne.^{20,21} Whether proven or not, some clinicians feel that diet is a factor in skin conditions, including acne, and needs to be further addressed.²²

GENERAL APPROACH TO TREATMENT

6 Severity, lesion types, scarring, and skin discoloration, as well as previous treatment history, helps to determine a treatment approach to acne vulgaris (see Table 100–1).^{5,9,23,24} Most treatments reduce or prevent new eruptions and can take up to 8 weeks to produce visible results. During the first few weeks of therapy, acne can appear to worsen as existing acne lesions can resolve more rapidly. Patients must understand the need to continue therapy for optimal outcome.

7 Patient education with emphasis on goals, realistic expectations, and dangers of overtreatment is important to optimize therapeutic outcomes. Treatment regimens are targeted to types of lesions and acne severity.^{5,14} Mild acne usually is managed with topical retinoids alone or with topical antimicrobials, salicylic acid, or azelaic acid. Moderate acne can be managed with topical retinoids in combination with oral antibiotics, and if indicated, benzoyl peroxide.²⁴ Severe acne is often managed with oral isotretinoin.

Initial treatment is aimed at reducing lesion count and will vary in duration from a few months to a few years, depending on severity and response to treatment. Once control is achieved, chronic indefinite treatment can be required. Therapy with both topical and systemic

antibiotics should be for the minimum duration necessary to achieve control of acne, to minimize the likelihood of resistance.^{5,23,24}

Topical treatment forms include creams, lotions, solutions, gels, and disposable wipes. Responses to different formulations can be dependent on skin type and individual preferences:

- Oily to normal skin types can tolerate gels, solutions, and lotions.
- Normal skin can tolerate gels, solutions, lotions, and creams.
- Normal to dry skin can tolerate lotions and creams.

Ointments are not typically included in topical acne therapy because of their occlusive nature and possible induction of acne cosmetica.

Systemic treatment is required in patients with moderate to severe acne, especially when acne scarring is a possibility.²⁵

Antibiotics such as tetracyclines and macrolides are the agents of choice for papulopustular acne. In severe papulopustular and nodulocystic/conglobate acne, oral isotretinoin is the treatment of choice. Hormonal therapy represents an alternative effective regimen in female patients.

NONPHARMACOLOGIC THERAPY

Scrubbing the skin with abrasive scrubs or excessive face washing does not necessarily open or cleanse pores. Follicular plugging originates too deeply to be affected by superficial epidermal scrubbing, which often leads to skin irritation.

Because surface cleansing with soap and water primarily affects sebum and bacteria on the surface of the skin and has minimal impact within the follicle, cleansing has a relatively small impact on the treatment of acne.

To avoid skin irritation and dryness during some acne therapies, it is important to use gentle, nondrying cleansing agents.

PHARMACOLOGIC THERAPY

Recently, worldwide consensus statements regarding management and treatment of acne have been widely distributed to improve and optimize outcomes. See Table 100–2 for highlights of consensus statements from the Global Alliance to Improve Outcomes in Acne.⁵ In addition, Table 100–3 shows the American Academy of Dermatology evidence basis for acne vulgaris treatment.¹⁶ Figure 100–2 provides acne treatment algorithms based on acne severity. See Table 100–4 for the mechanism of action of selected acne treatments.

Topical Agents: First-Line Therapies

Benzoyl Peroxide Superficial inflammatory acne is typically treated with benzoyl peroxide (BPO), a nonantibiotic antibacterial agent that is rapidly bacteriostatic and possibly bactericidal against *P. acnes*.²⁶ Its antibacterial mechanism of action is uncertain, although BPO is decomposed on the skin by cysteine, liberating free oxygen radicals that oxidize bacterial proteins.²⁷ BPO increases the sloughing rate of epithelial cells, loosens the follicular plug structure, and thus possesses some degree of comedolytic activity. An advantage to using topical BPO is that *P. acnes* resistance is not known to develop.^{5,24}

BPO is available in soaps, lotions, creams, washes, and gels, in concentrations ranging from 1% to 10%;⁵ 10% concentrations are not significantly more efficacious and can be more irritating. Gel formulations have better stability and are usually most potent, whereas lotions, creams, and soaps are weaker. Gels are usually based on alcohol, propylene glycol, or water; the alcohol-based preparations generally cause more dryness and irritation. The addition of a 10% urea to the vehicle is theorized to increase skin moisturization because of its humectant properties as well as to enhance the efficacy of BPO.²⁸ Fair or moist skin usually is more sensitive to irritation from BPO; thus patients should be advised to

TABLE 100-2 Treatment Guidelines for Acne Vulgaris

Therapy	Recommendations
Topical retinoids	<ul style="list-style-type: none">• Should be primary treatment for most forms of acne vulgaris• Use early for best results• Should be applied to the entire affected area• Combine with antimicrobial therapy when inflammatory lesions are present• Essential part of maintenance therapy
Hormonal therapy	<p>Excellent choice for women who also need oral contraceptives for gynecologic reasons</p> <ul style="list-style-type: none">• Use early in female patients with moderate to severe acne or with symptoms of seborrhea, acne, hirsutism, or alopecia• Useful as part of combination therapy in women with or without endocrine abnormalities• Sometimes used in women with late-onset acne
Oral isotretinoin	<p>Indications:</p> <ul style="list-style-type: none">• Severe nodulocystic acne• Severe acne variants• Inflammatory acne with scarring after conventional therapy has failed• Moderate to severe acne, especially frequently relapsing cases• Acne with severe psychological distress <p>Typical dose:</p> <ul style="list-style-type: none">• 0.5–1.0 mg/kg daily in two divided doses, with cumulative dose of 120–150 mg/kg per treatment course (4–6 months)• A lower dose (<0.5 mg/kg) can be used but is associated with a higher relapse rate
Combination therapy	<ul style="list-style-type: none">• Patient counseling is critical• Should be used when inflammatory lesions are present• Speeds clearing and provides greater resolution of both inflammatory lesions and comedones• Topical retinoid should be started at the initiation of antimicrobial therapy• Antibiotic should be discontinued when inflammatory lesions resolve adequately• If this is not possible, then switch to a combination agent with benzoyl peroxide plus an antibiotic• Continue use of topical retinoid to maintain remission of new acne lesions when antibiotic therapy is discontinued

Recommendations from Gollnick et al.⁵

apply medication to dry skin (at least 30 minutes after washing) to decrease irritation. Cleansing dosage forms (washes) that contain anti-acne ingredients such as α -hydroxy acids, BPO, or salicylic acid are available. BPO cleansers can be considered for adolescent boys, both to enhance compliance and to cover large skin areas such as the chest and back.⁵

Dryness and irritation from a primary irritant such as BPO can limit therapy in some patients; allergic contact dermatitis has also been reported.²⁹

To limit irritation and increase patient tolerance of BPO, one can initiate therapy with a low-potency formulation (2.5%), and increase either strength (5% to 10%) or application frequency (every other day, each day, and then twice a day). To minimize irritation potential, BPO should be applied to cool, clean, dry skin, no more frequently than twice daily. Use should be discontinued if excessive irritation or allergy occurs. One disadvantage is that BPO can bleach or discolor some fabrics (clothing, bed linen, or towels). Tolerability and effectiveness are enhanced when used in combination with other agents such as topical retinoids, clindamycin, and erythromycin.^{5,24,26,30,31}

Retinoids Topical retinoids—tretinoin, adapalene, tazarotene, and in some countries, topical isotretinoin, motretinide, retinaldehyde, and retinoyl- β -glucuronide⁵—can be used as first-line therapy for mild to moderate inflammatory acne and comedonal acne. They can also be viewed by some as preferred agents for maintenance therapy to minimize antibiotic use in acne therapy.⁵ To

TABLE 100-3 American Academy of Dermatology Evidence Basis for Acne Vulgaris Treatment

Therapy	Therapeutic Approach	Strength of Recommendation	Level of Evidence
Topical	Retinoids	A	I
	Benzoyl peroxide	A	I
	Antibiotics	A	I
	Other agents	A	I
Systemic antibiotics	Tetracyclines	A	I

Strength of recommendation: A, recommendation based on consistent and good-quality patient-oriented evidence; B, recommendation based on inconsistent or limited quality patient-oriented evidence; C, recommendation based on consensus, opinion, or case studies.
Level of evidence: I, good quality patient-oriented evidence; II, limited quality patient-oriented evidence; III, other evidence including consensus guidelines, extrapolations from bench research, opinion, or case studies.
Data from Strauss et al.¹⁶

optimize efficacy in moderate inflammatory acne, topical retinoids should be combined with topical antibiotics or BPO.^{24,32}

Tretinoin Tretinoin, a topical vitamin A analogue, is a comedolytic agent that increases cell turnover in the follicular wall and decreases cohesiveness of cells, leading to extrusion of existing comedones and inhibition of the formation of new comedones,²⁷ and can reduce the number of inflammatory acne lesions.²⁴ Tretinoin significantly decreases the number of cell layers in the stratum corneum from approximately 14 to approximately 5.²⁷

In a typical 12-week study of tretinoin, the reduction of lesion counts ranged from 32% to 81% for noninflammatory lesions, and 17% to 71% for inflammatory lesions (22% to 83% for the total lesion count).²⁴

Tretinoin is available as 0.05% solution (most irritating); 0.01% and 0.025% gels; and 0.025%, 0.05%, and 0.1% creams (least irritating).⁵ Treatment initiation with 0.025% cream usually is recommended for mild acne in patients with easily irritated and nonoily skin, 0.01% gel for moderate acne in easily irritated skin with oily complexion, and 0.025% gel for moderate acne with nonsensitive and oily skin. A “flare” of acne can appear suddenly after initiation of treatment, followed by clinical clearing in approximately 8 to 12 weeks.²⁷

Once control is established, therapy should be continued at the lowest effective concentration and at the maximum effective interval sufficient to minimize acne exacerbations.

Concomitant use of an antibacterial agent with tretinoin can decrease keratinization, inhibit *P. acnes*, and decrease inflammation. In addition, both BPO and tretinoin have shown additive or synergistic effects in the treatment of inflammatory acne.³³ A regimen of BPO each morning and tretinoin at bedtime can enhance efficacy and be less irritating than either agent used alone.³³ By slowly increasing application frequency from every other day, to daily, and then twice daily, tolerance to tretinoin can be increased. Increased sensitivity to sun exposure, wind, cold, and other irritants can also be evident in patients using tretinoin.

Acne Treatment Algorithms

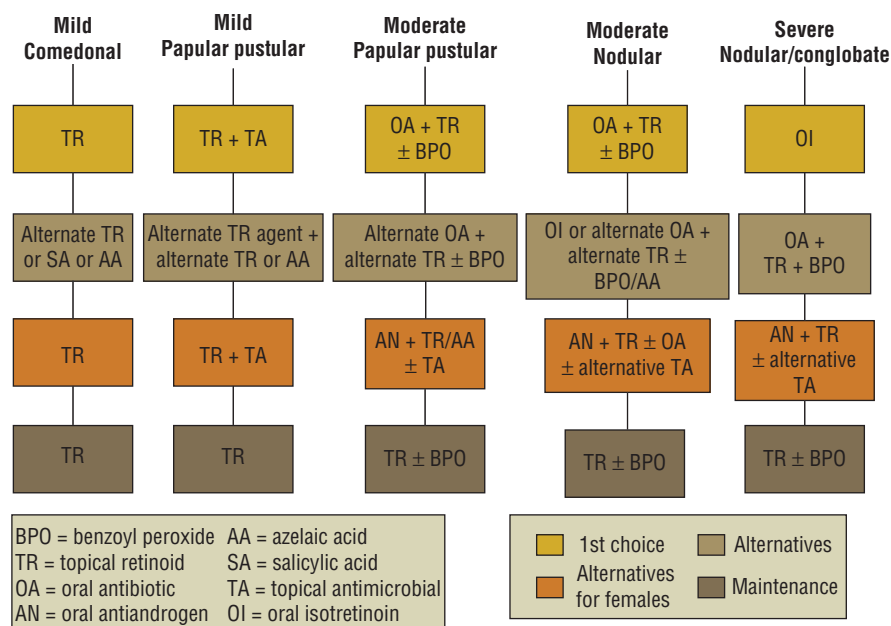

FIGURE 100-2. Algorithms for acne treatment.

Two reformulations of tretinoin include a porous bead (0.01% gel) (microspheres) and liquid polymer (0.025% cream and 0.025% gel). These are designed to be less irritating than standard vehicles for tretinoin and to release tretinoin in a sustained controlled manner.³⁴ In a topical gel formulation containing polyolprepolymer-2, tretinoin penetration is significantly reduced while epidermal deposition is enhanced, compared with a commercially available gel preparation at the same concentration. Polyolprepolymer-2 is designed to promote retention of drug molecules on the skin surface and in the upper layers of the skin.³⁴

A microsphere delivery system represents another formulation approach consisting of macroporous beads 10 to 15 micrometers in diameter that are loaded with tretinoin. Gradual release of active ingredient after topical application depends on mechanical rubbing, temperature, pH, and other factors.³⁵ Tretinoin 0.1% gel microsphere, tretinoin 0.025% gel, tazarotene 0.1% gel, and adapalene 0.1% gel all showed equivalent facial tolerability in a split-face study.³⁵ In another variation, a formulation of liposomally encapsulated tretinoin showed somewhat better tolerance than gel dosage forms, yet demonstrated equivalent efficacy.³⁶

Adverse reactions to tretinoin—such as skin irritation, erythema, and peeling—vary depending on individual skin type and dosage form used. Allergic contact dermatitis is rare and much less common than with BPO. Teratogenicity risk with topical retinoids remains controversial.

CLINICAL CONTROVERSY

During treatment with topical tretinoin, plasma tretinoin concentrations are typically less than endogenous levels, and apparently do not affect endogenous levels of tretinoin or its metabolites or alter plasma vitamin A levels. However, controversy continues with regard to teratogenicity and embryotoxicity risk-to-benefit issues in the use of topical retinoids during pregnancy.^{24,37}

Adapalene Adapalene, a third-generation retinoid,⁵ is a retinoid-mimetic compound (a naphthoic acid derivative), available as 0.1% gel, cream, alcoholic solution, and pledgets. Recently, a new 0.3% gel formulation of adapalene has been developed.³⁸ Adapalene has selective affinity for retinoic acid receptor (RAR) subtypes RAR-β and RAR-γ found in the epidermis,³⁹ and has comedolytic, keratolytic, and antiinflammatory activity.^{9,40,41} Vehicle-controlled and comparative studies have demonstrated the usefulness of adapalene in treatment of acne.^{40,41,42}

Adapalene is indicated for mild to moderate acne vulgaris. Adapalene 0.1% gel can be used as an alternative to tretinoin 0.025% gel to achieve better tolerability in some patients.^{39,42} Adapalene coadministered with a topical or oral antibiotic represents a rational therapy for moderate forms of acne.⁹

TABLE 100-4 Mechanism of Action of Selected Pharmacotherapeutic Agents in Acne

Treatment	Antimicrobial	Antiinflammatory	Decreased Sebum Production	Keratolytic/Comedolytic
Adapalene	+	++	—	+++
Antibacterial oral agents	+++	++	—	+
Antibacterial topical agents	+++	+	—	+
Azelaic acid	++	+	—	++
Benzoyl peroxide	+++	++	—	+
Oral isotretinoin	++	++	+++	+++
Oral contraceptives	—	—	+++	++
Salicylic acid	—	—	—	+
Spiroglactone	—	++	++	—
Topical retinoids	—	+	—	+++

—, No activity; +, low activity; ++, moderate activity; +++, high activity.

In a double-blind 12-week study, tretinoin microsphere gel demonstrated faster onset of action than adapalene, including a greater reduction in comedone counts at week 4. Yet reductions in acne lesions at 12 weeks were similar with the two drugs, and an increased incidence of dryness and peeling was associated with tretinoin.⁴³

Adapalene can also be an alternative in treating some patients of color as it produces less skin irritation and subsequent discoloration than the first-generation topical tretinoin products.⁹

Tazarotene Tazarotene, a prodrug and a synthetic acetylenic retinoid, is converted to its active form, tazarotenic acid, after topical application. This new-generation retinoid also selectively binds to RARs and can alter expression of genes involved in cell proliferation, cell differentiation, and inflammation.⁴⁴

Tazarotene is used in the treatment of mild to moderate acne vulgaris and has comedolytic, keratolytic, and antiinflammatory action. Tazarotene 0.1% and 0.05% gel and cream have been shown to be more effective than vehicle in the treatment of acne vulgaris.^{45,46} The 0.1% gel was slightly more effective than the 0.05% gel in decreasing lesion counts, with treatment success rates of 68% and 51% of patients, respectively.⁶

Clinical studies have shown that once-daily 0.1% tazarotene gel is more effective than 0.025% tretinoin gel and 0.1% tretinoin gel microsphere in reducing noninflammatory acne lesions.^{44,47} Once-daily 0.1% tazarotene gel is also more effective than once-daily adapalene 0.1% gel in reducing both noninflammatory and inflammatory acne lesions.^{44,48,49} However, the occurrence of perilesional irritation can limit the use of tazarotene.⁴⁸ Once-daily short contact applications significantly reduced irritation potential, yet maintained therapeutic equivalency to standard application regimens.⁵⁰ Also, when alternate-day therapy with tazarotene 0.1% gel was compared with once-daily adapalene 0.1% gel therapy, there were no clinically significant differences in improvement or tolerability.⁵¹

Both 0.1% and 0.05% concentrations had acceptable tolerability profiles, with no serious adverse events.⁴⁶ Dose-related local adverse effects include erythema, pruritus, stinging, and burning.⁵²

Erythromycin Erythromycin in topical form in concentrations of 1% to 4% with or without the addition of zinc is effective against inflammatory acne. Zinc combination products possibly enhance penetration of erythromycin into the pilosebaceous unit.⁵³

Combinations of erythromycin and BPO have shown greater efficacy in treating acne than a combination of erythromycin and tretinoin.³² Development of *P. acnes* resistance to erythromycin can be reduced by combination therapy with BPO.

Topical erythromycin, usually applied twice daily, is formulated as a gel, lotion, solution, and disposable pad. Reduction of the percentage of free fatty acids in sebum has been noted with the use of topical erythromycin.⁵³

Clindamycin Topical clindamycin inhibits *P. acnes* and provides comedolytic as well as antiinflammatory activity.⁵⁴ It is available in gel, lotion, solution, foam and disposable pad formulations, and is usually applied twice daily.⁴⁹ Combination with BPO increases efficacy.⁵⁵ Although rare, diarrhea and pseudomembranous colitis can occur secondary to topical clindamycin.⁵⁶

Azelaic Acid Azelaic acid has a dicarboxylic acid structure that confers antibacterial, antiinflammatory, and comedolytic activity.⁵⁴ Azelaic acid is useful for treating mild to moderate acne in patients who do not tolerate BPO. It is useful in treating postinflammatory hyperpigmentation as it also has skin-lightening properties.⁵⁷

Azelaic acid has no likelihood of bacterial resistance, systemic adverse effects, or photosensitivity reactions. Although uncommon, adverse effects, usually transient, include burning, pruritus, stinging, and tingling.^{5,24}

Azelaic acid is available in a 20% cream and 15% gel formulations.⁵⁸ Application is usually twice daily on clean, dry skin to acne prone areas.

Topical Agents: Second-Line Therapies

Motretinide Motretinide, available outside the United States, is a topical aromatic ester retinoid with an efficacy profile similar to low-dose tretinoin concentrations but with somewhat less irritant potential.²⁴

Retinaldehyde Retinaldehyde is biotransformed into all-*trans*-retinoic acid and induces biologic effects including comedolytic activity⁵⁹ similar to those of topical tretinoin when administered at comparatively lower concentrations.⁵

Retinaldehyde 0.1% cream combined with 6% glycolic acid vs placebo vehicle showed the active agent to be significantly more effective and well tolerated than placebo in the treatment of mild to moderate acne vulgaris.⁶⁰

Retinaldehyde 0.1% in combination with 6% glycolic acid cream was also studied to investigate the potential to prevent and treat acne scarring in patients previously treated for moderate acne vulgaris. Global scarring score, number of inflammatory lesions and comedones significantly improved in the patients using 0.1% retinaldehyde/6% glycolic acid cream compared to those using vehicle.^{59,61}

Retinoyl- β -Glucuronide Retinoyl- β -glucuronide is a naturally occurring, biologically active metabolite of vitamin A. It is a retinoid that possesses the biologic activity of all-*trans*-retinoic acid but with fewer adverse effects. Topically applied retinoyl- β -glucuronide is safe and effective for treatment of mild forms of acne.⁶²

Isotretinoin Isotretinoin is available outside the United States as a gel formulation; it does not significantly alter sebum secretion as does oral isotretinoin. Used topically, the effectiveness of isotretinoin is similar to that of other topical retinoids, but it causes somewhat less skin irritation.²⁰ It reduces noninflammatory lesions from 46% to 78% and inflammatory lesions from 24% to 55% after 12 to 14 weeks of treatment.²⁴

Keratolytic Agents In addition to keratolytic activity, salicylic acid, sulfur, and resorcinol are mildly antibacterial.

Salicylic acid has comedolytic and antiinflammatory action.²³ Also known as β -hydroxy acid, it is deemed a more effective comedolytic than most α -hydroxy acids.¹⁰ In addition, it increases penetration of other substances, and in low concentrations is bacteriostatic and fungistatic.²⁴

Although evidence for efficacy in the treatment of acne is conflicting, each agent has been classified as safe and effective by the FDA. Some combinations of these agents can be considered synergistic (e.g., sulfur and resorcinol, salicylic acid, BPO). Keratolytic products, in the concentration allowed, can be less irritating than BPO and tretinoin; however, they are not considered as effective comedolytic agents, as are BPO and tretinoin.

Disadvantages of these agents include the odor created by hydrogen sulfide on reaction of sulfur with the skin, the brown scale from use of resorcinol, and the possibility of salicylism from repeated and widespread use of sufficient concentrations of salicylic acid on highly permeable (inflamed and/or abraded) skin.⁵⁶

Corticosteroids Topical corticosteroids can be applied in very selected patients with very inflammatory acne for short periods of time. They may play a role in reducing flare-up reactions in severe conglobate acne and for reduction of granuloma pyogenicum-like lesions under systemic isotretinoin treatment.²⁴

Chemical Peeling Light chemical peels can be useful in some acne patients to reduce superficial scarring and hyperpigmentation.⁶³ Chemical peeling targets the interfollicular epidermis.²⁴

Some currently available substances for chemical peeling include: α -hydroxy acids (glycolic acid), salicylic acid, and trichloroacetic acid.⁶³ Salicylic acid is lipid soluble and can penetrate into sebum-laden follicles more readily than water-soluble α -hydroxy acids. Salicylic acid can also have some ability to reduce the inflammatory component of acne.^{5,23} Patients with sensitive skin types usually tolerate salicylic acid peels.⁶⁴

Dapsone Topical dapsone has both antibacterial and antiinflammatory properties. Topical dapsone 5% gel is FDA approved for use in the treatment of acne in patients older than 12 years of age.⁶⁵

Systemic Agents: First-Line Therapy—Severe Nodular/Conglobata

Isotretinoin As an oral retinoid, isotretinoin is the most effective sebosuppressive agent that affects all of the etiologic factors involved in inflammatory acne, including induction of atrophy of the sebaceous gland with decreased sebum production and change in sebum composition, inhibition of *P. acnes* growth within follicles, inhibition of inflammation, and altered patterns of keratinization within follicles (decreased size and increased differentiation).⁶⁶ These characteristics make it the treatment of choice in severe nodulocystic acne.^{16,67} It can be used in patients who have failed conventional treatment, those who have scarring acne, those who have chronic relapsing acne, and those who have acne with severe psychological distress.^{16,68}

Adverse effects from orally administered isotretinoin are numerous, frequent, and often dose related.⁶⁹ Approximately 90% of patients receiving isotretinoin therapy suffer from mucocutaneous effects. Drying of the mucosa of the mouth, nose, and eyes is the most common problem, with relatively rare involvement of the genito-anal mucosa. Cheilitis and skin desquamation occurs in more than 80% of patients. Less frequently, the conjunctiva and nasal mucosa are affected. Table 100-5 shows selected responses to some of the adverse effects of oral isotretinoin.

Disturbances in lipid metabolism also can occur, resulting in transitory increase of blood values for cholesterol and triglycerides.⁶⁸ Liver function and serum lipids should initially be monitored, typically at baseline and at weeks 4 and 8.⁷⁰ Serious adverse effects of isotretinoin therapy include: increased creatine phosphokinase and blood glucose, as well as photosensitivity, pseudotumor cerebri, excess granulation tissue, hepatomegaly with abnormal liver function tests, bone abnormalities, arthralgias, muscle stiffness, and headaches.⁷¹

TABLE 100-5 Principal Adverse Effects of Oral Isotretinoin

Adverse Effect	Recommendations for prevention
Teratogenicity	Contraindicated during pregnancy
Depression	Patient monitoring and counseling; antidepressants
Dryness	
Mouth	Sugar-free candy, lozenges, or gum
Eyes	Eyedrops; avoid contact lenses if possible during treatment course
Nose	Lubricant
Skin	Nondrying gentle skin cleansers; noncomedolytic moisturizers
Lips	Lip moisturizer with sunscreen
Muscle and joint pain	Nonsteroidal antiinflammatory drugs
Alopecia	Reversible when drug discontinued or dose decreased
Hypertriglyceridemia	Reversible when drug discontinued or dose decreased
Acne flare at start of therapy	Continue therapy
Photosensitivity	Use sunscreens (moisturizing), protective clothing, and sun avoidance

Hyperlipidemia, diabetes mellitus, and severe osteoporosis are relative contraindications for oral isotretinoin. The drug can very occasionally produce significant mood changes, depression, and other significant psychiatric adverse effects. Although relationship to drug therapy is controversial, current recommendations are that patients be counseled about and screened for depression during therapy.⁷²

Oral isotretinoin is a potent teratogen and therefore all patients must participate in the iPLEDGE program, which requires pregnancy tests and assurances by prescribers and pharmacists that they will follow certain procedures, in order to receive oral isotretinoin treatment. It is mandatory for all prescribers, patients, pharmacies, drug wholesalers, and manufacturers in the United States to register and comply with the iPLEDGE program.¹⁶

Isotretinoin dosing guidelines range from 0.5 to 1 mg/kg per day, but the cumulative dose taken by patients during a treatment course can be the major factor influencing long-term outcome. Optimal results generally have occurred when cumulative doses have attained a range of 120 to 150 mg/kg.¹⁶ One study using dosages of 0.3 to 0.4 mg/kg per day over 6 months found that lower doses over a longer period of time are effective in the treatment of moderate acne with a lower incidence of severe mucocutaneous side effects and laboratory abnormalities.⁷³

Although a 5-month course of therapy is sufficient for most patients, it has been observed that an initial dose of 1 mg/kg per day for 3 months, then reduced to 0.5 mg/kg per day, and if possible, to 0.2 mg/kg per day for 3 to 9 additional months can optimize the therapeutic outcome.²⁵ Generally, after 2 to 4 weeks of treatment, a 50% reduction in pustules can be expected. Pustules clear more rapidly than papules or nodules. Improvement continues during the posttreatment period. In female patients contraception is required because of teratogenicity, recommended to begin 1 month before therapy, continuing during the entire period of treatment, and for up to 3 months after discontinuation of isotretinoin.⁶⁹

Although costs of therapy with isotretinoin are greater in the first year, isotretinoin can be more cost effective than long-term antibiotic treatment.⁷⁴

Systemic Agents: First-Line Therapy—Moderate Papular Pustular/Nodular

Macrolide Antibiotics The macrolide antibiotics (erythromycin, azithromycin, and clindamycin) exhibit antiinflammatory properties in patients with acne.

Erythromycin can be used for patients who require systemic antibiotics but cannot tolerate tetracyclines, or who acquire bacterial strains resistant to tetracyclines.^{75,76} The dosage is usually 1 g/day with meals to minimize gastrointestinal intolerance. Zinc combination products possibly enhance penetration of erythromycin into the pilosebaceous unit.⁵³ The efficacy of erythromycin is similar to tetracycline, but it induces higher rates of bacterial resistance.^{75,76} Development of erythromycin resistance by *P. acnes* can be reduced by combination therapy with BPO.

Azithromycin, an azalide antibiotic and derivative of erythromycin, is a safe and effective alternate treatment of moderate to severe inflammatory acne. With a half-life of 68 hours, it can be intermittently dosed three times a week.⁷⁷ One study comparing 100 mg doxycycline daily in addition to topical 0.05% tretinoin cream to 500 mg azithromycin once a day for four days per month along with 0.05% topical tretinoin for a total of 12 weeks found that the monthly dose of azithromycin was as effective as daily doxycycline.⁷⁸ Adherence is high with this regimen, and phototoxicity and resistance have not been reported.⁷⁷

Although clindamycin is very effective in the treatment of acne, it is seldom used for long-term therapy because of the possible induction of pseudomembranous colitis.⁷⁹

Tetracyclines The tetracyclines are effective in reducing *P. acnes*.⁷⁹ In addition to their antibacterial effects, they reduce the amount of keratin in sebaceous follicles and have antiinflammatory properties inhibiting chemotaxis, phagocytosis, complement activation (by the alternate pathway), and cell-mediated immunity.^{80,81} Tetracyclines also appear to have an affinity for inflammatory cells and bacteria, resulting in higher drug concentration in areas of inflamed skin.

The recent discovery that tetracyclines have biologic actions affecting inflammation, proteolysis, angiogenesis, apoptosis, metal chelation, ionophoresis, and bone metabolism has led to the development of chemically modified tetracyclines, also known as inhibitors of multiple proteases and cytokines. These are tetracyclines modified by the removal of the dimethylamino group at carbon 4. This eliminates its antibiotic properties and enhances antiinflammatory properties.⁸¹ Incyclinide, one chemically modified tetracycline, is in initial trials for acne.

Adverse reactions involving the gastrointestinal tract can occur with the tetracyclines. Drawbacks to the use of tetracyclines include hepatotoxicity and predisposition to superinfections (vaginal candidiasis), and very rarely benign intracranial hypertension. All tetracyclines are photosensitizing, and a sun protection plan should be used. Also, these agents should not be used in children younger than 10 years of age or in pregnant women because the risk of tooth discoloration when used in children and inhibition of skeletal growth in the developing fetus and child. Emergence of resistant strains of *P. acnes*,⁷⁵ adverse events, and adherence issues associated with long-term systemic tetracycline use have led to new treatment approaches.

Moreover, adverse effects of tetracyclines include resistant bacteria, folliculitis, candidiasis, gastrointestinal upset, and phototoxic effects. Tetracyclines must not be combined with systemic retinoids because of the increased probability for development of intracranial hypertension. Tetracycline is used in the treatment of moderate to severe acne vulgaris. It is the least expensive of the tetracyclines and therefore often prescribed for initial therapy.²⁷ A common initial approach includes tetracycline 1 g daily (500 mg twice daily), 1 hour before meals; after 1 or 2 months, when marked improvement of inflammatory lesions is observed, the dose can be decreased to 500 mg every day, for another 1 or 2 months.⁷⁵ Drawbacks to the use of tetracycline include also a drug-food interaction with dairy products.

Doxycycline is commonly used in the treatment of moderate to severe acne vulgaris. It is more effective and produces less resistance than tetracycline. The initial dosage is usually 100 or 200 mg daily, followed after improvement by 50 mg/day as a maintenance dose; it can be taken with food even though it is more effective when taken 30 minutes before meals. Subantimicrobial-dose doxycycline (20 mg) has been investigated in a double-blind, placebo-controlled trial in the treatment of moderate facial acne. Positive outcomes were achieved with no development of resistant organisms or change in normal skin flora.^{82,83} Adverse effects include resistant bacteria, folliculitis, candidiasis, gastrointestinal upset, and phototoxic effects such as photoonycholysis.⁸⁴

Minocycline is another commonly prescribed oral antibiotic used in the treatment of moderate to severe acne vulgaris. It is more effective than tetracycline because of greater lipid solubility and enhanced penetration into tissue and sebaceous follicles.²⁶ It is dosed similarly to doxycycline (100 mg/day or 50 mg twice daily) and on an indefinite basis in selected patients.

Of the tetracyclines, minocycline has the most reported adverse effects.⁷⁹ Neither tetracycline nor doxycycline contains an amino acid side chain found in minocycline that has potential to form a reactive metabolite. Perhaps related to this, in addition to usual tetracycline adverse effects, minocycline can cause hypersensitivity syndromes, serum sickness-like illness discoloration of skin, nail, and bone; hepatitis, nephritis, vestibular toxicity, drug-induced lupus erythematosus, intracranial hypertension, pseudotumor cerebri,⁸⁵ systemic eosinophilia,⁷⁹ severe fever,⁸⁶ depersonalization symptoms,⁸⁷ and cutaneous hyperpigmentation of at least four distinct types.⁸⁸

1. Blue-black pigmentation confined to sites of scarring or inflammation on the face
2. Blue-gray circumscribed pigmentation of normal skin of the lower legs and forearms
3. Diffuse muddy brown pigmentation of normal skin accentuated in sun-exposed areas
4. Circumscribed blue-gray pigmentation within acne scars confined to the back

Systemic Agents: Second-Line Therapy Cotrimoxazole Cotrimoxazole (trimethoprim-sulfamethoxazole) or trimethoprim alone can be used for treating patients who do not tolerate tetracycline and erythromycin or in cases of resistance to these antibiotics.²⁶ The adult dosage is usually 800 mg sulfamethoxazole and 160 mg trimethoprim twice daily.

Hormonal Therapy Hormonal therapy is useful in treating acne in women with elevated or normal serum androgens. It can also be warranted for female patients with severe seborrhea, clinically apparent androgenic alopecia, seborrhea/acne/hirsutism/alopecia syndrome, late-onset acne, and with proven ovarian or adrenal hyperandrogenism.⁸⁹

Hormonal therapy is absolutely contraindicated in women who want to become pregnant because of the risk of sexual organ malformation in a developing fetus.²⁵

Antiandrogens, or androgen-receptor blockers, should be avoided during pregnancy.⁵ Both cyproterone (not available in the United States) and spironolactone should be used for acne only in women, because they lead to feminization in men.⁹⁰

Cyproterone Acetate Cyproterone acetate (CPA) (although not available in the United States) is the most widely used antiandrogen compound. It is a progestational agent that blocks the androgen receptors and also inhibits synthesis of adrenal androgens. In Europe and Canada, CPA is widely used in women for the treatment of acne, with or without signs of hyperandrogenism, and as an oral contraceptive formulation (CPA 2 mg with ethinyl estradiol 35 mcg or 50 mcg).⁹¹

Adverse effects include menstrual abnormalities, breast tenderness and enlargement, nausea and vomiting, fluid retention, leg edema, headache, and melasma.

Chlormadinone Acetate Chlormadinone acetate (2 mg), alone or in combination with 50 mcg ethinyl estradiol or 50 mcg mestranol in a contraceptive pill, is available in several European countries and is slightly less efficacious than CPA.⁹²

Spironolactone Spironolactone, an antiandrogen and inhibitor of 5 α -reductase, reduces sebum production and improves acne at dosages of 50 to 200 mg twice daily in patients with acne resistant to conventional therapy.⁸⁹ Most commonly, it is used in countries where other antiandrogen drugs are not available.

Adverse effects are dose dependent and can be lessened by initiating therapy with doses as low as 25 mg/day. They include potential hyperkalemia, irregular menses, breast tenderness, headache, and fatigue.²³

Drospirenone Drospirenone, a derivative of spironolactone, has been introduced in Europe as another antiandrogen agent that is a useful alternative in some patients.⁹¹

Flutamide Flutamide, a drug approved for treatment of prostate cancer, blocks the androgen receptor. It is used in combination with oral contraceptives in seborrhea and acne therapy for females.⁹⁰ The dose is usually 250 to 500 mg twice daily over 6 months.

Flutamide use is limited because of reports of fatal hepatitis requiring monitoring of liver function during therapy.⁹⁰ Pregnancy must be avoided because of the risk of feminization of a male fetus.⁵

Estrogens Estrogens are indicated in female patients with clinical evidence of hyperandrogenism. They suppress the ovarian produc-

tion of androgens. In addition, they can decrease acne by directly opposing the effects of androgens locally within the sebaceous gland and regulating genes that negatively influence sebaceous gland growth or lipid production.⁹³

Estrogens are of limited use because the dose of estrogen required for suppression of sebum production is greater than that required to suppress ovulation. Response to 0.035 to 0.050 mcg of ethinyl estradiol or its esters occurs in some women, but higher doses are often required.⁹³ Breast examinations and Pap smears can be recommended in women receiving long-term estrogen therapy; other serious adverse effects such as clotting and hypertension are possible but very rare in young healthy females.

The mechanism of action of estrogens in acne can include: a direct effect within the sebaceous gland opposing the effects of androgens, inhibition of androgen production by gonadal tissue via a negative feedback loop on pituitary gonadotrophin release, and regulation of genes that influence sebaceous gland growth or lipid production.

Oral Contraceptives Oral contraceptives containing two agents, an estrogen and a progestin, are used as an alternate treatment for moderate acne in women. Estrogen-containing contraceptive agents that are currently approved for the treatment of acne are norgestimate with ethinyl estradiol and norethindrone acetate with ethinyl estradiol.¹⁶

Oral contraceptives decrease free testosterone levels by increasing sex hormone-binding globulin, which binds circulating testosterone causing it to be biologically inactive. They also inhibit the ovarian production of androgens by suppressing ovulation. This overall antiandrogen effect leads to a decrease in sebum production.⁹⁴

Common adverse effects of oral contraceptives include nausea and vomiting, breast tenderness, headache, spotting and breakthrough bleeding, edema of the venous system of the lower extremities, decreased libido, increased appetite, and weight gain. A transient flare of inflammatory acne can also accompany the initiation of therapy. The most serious adverse effect of oral contraceptives, thromboembolism, has been greatly reduced by the use of lowered doses of estrogens.⁸⁹

Gonadotropin-Releasing Hormone Agonists Gonadotropin-releasing hormone agonists (buserelin, nafarelin, and leuprolide), available as injectable drugs or nasal spray, suppress the production of ovarian androgens and are reported to have some efficacy in acne. However, by reducing estrogen, they can produce menopausal symptoms (headache and bone loss). They have not been demonstrated to be safe and effective for treatment of acne.⁸⁹

Corticosteroids Low-dose corticosteroids (prednisone, prednisolone, or dexamethasone) are indicated in patients with adrenal hyperandrogenism or acne fulminans.

Dapsone Oral dapsone, a sulfone, has been used for treatment of acne conglobata (a rare condition that is highly inflammatory; onset usually occurs in adults) and acne inversa (chronic lesions in the axillary and groin areas).⁹⁵

Nicotinamide Topical 2% nicotinamide can be effective in reducing sebum excretion rate in some individuals.⁹⁶

Oral nicotinamide in combination with oral zinc, copper and folic acid is noted to have both antiinflammatory and antibacterial activity and has undergone clinical studies for the treatment of acne vulgaris. This combination tablet can be an effective therapy for the treatment of acne vulgaris when used alone or with topical therapies.⁹⁷

PHARMACOECONOMIC CONSIDERATIONS

Although costs of therapy with oral isotretinoin are greater than with other therapeutic choices in the first year, this option can be more cost-effective than long-term antibiotic treatment in severe acne.⁷⁴

EVALUATION OF THERAPEUTIC OUTCOMES

See Tables 100–6 through 100–10 for prototypical examples of pharmaceutical care plans in the evaluation of therapeutic outcomes for each grade of acne severity.

TABLE 100-6 Typical Pharmaceutical Care Plan for Mild Comedonal Acne

MARIA LETIZIA MUSUMECI, AND GIUSEPPE MICALI

KEY CONCEPTS

- 1 Exogenous trigger factors such as climate, stress, alcohol, smoking, infection, trauma, and drugs can aggravate psoriasis.
- 2 As a result of pathogenic T-cell production and activation, psoriatic epidermal cells proliferate at a rate sevenfold faster than normal epidermal cells.
- 3 In general, psoriatic lesions are characterized by sharply demarcated, erythematous papules and plaques often covered with silver-white scales.
- 4 Goals of treatment are usually directed at skin normalization: reduction or clearing of erythema, papules, and plaques, as well as scales.
- 5 A variety of topical (corticosteroids, anthralin, and vitamin D analogues) and systemic (acitretin, cyclosporine, tacrolimus, methotrexate, mycophenolate mofetil, sulfasalazine, 6-thioguanine, and hydroxyurea) pharmacotherapeutic agents can be used for treating psoriasis, with treatment determined by the severity of a patient's condition and the probability of controlling long-term symptoms with minimal adverse effects. Biologic agents (infliximab, etanercept, alefacept, adalimumab or efalizumab) and photochemotherapy with oral methoxypsoralen and ultraviolet A light (PUVA) or ultraviolet B light can provide additional options, especially for patients with severe or refractory cases.
- 6 Combination, rotational, and sequential therapy is commonly used in the treatment of psoriasis to achieve a response, increase effectiveness of treatment, or enable lowering of doses of individual agents.

Psoriasis is a common chronic inflammatory skin disorder characterized by recurrent exacerbations and remissions of thickened, erythematous, and scaling plaques. The clinical appearance of psoriasis can be cosmetically disfiguring, and the disease can be physically and emotionally debilitating, especially for patients with severe disease.

EPIDEMIOLOGY

Psoriasis is universal in occurrence and affects nearly 7 million Americans with approximately 14 million physician visits over the 12-year

period from 1990 to 2001.¹ The disorder occurs in all racial groups but is most prevalent in whites. It is equally common in males and females. Two peaks of age of onset have been described: The greatest incidence is between 20 and 30 years, and a smaller peak occurs between 50 and 60 years of age²; however, the age of onset is widely variable from infancy to old age. Although rarely life-threatening, psoriasis has an adverse physical and emotional impact on quality of life.^{3,4}

ETIOLOGY

Psoriasis is a complex and multifactorial disease that is apparently associated with interaction between environmental factors (exogenous or endogenous antigens) and a specific genetic background. Environmental factors involved in disease development are not completely known or understood.⁵

ENVIRONMENTAL FACTORS

Factors such as climate, stress, alcohol, smoking, infection, trauma, and drugs can aggravate psoriasis. Warm seasons and sunlight reportedly improve psoriasis in 80% of patients, whereas 90% report worsening in cold weather. In addition, stress worsens psoriasis in up to 40% of patients; however, the exact role stress plays in exacerbation of psoriasis is uncertain. Alcohol seems to have a greater influence on the progression of psoriasis in men, and the association between smoking and psoriasis seems to be stronger in women.⁶

Infection has been identified retrospectively as a common precipitating factor in psoriasis.⁷ Approximately 25% of patients have initial onset of the disease after clinically documented infections, and more than one-half have exacerbations within 3 weeks after an upper respiratory infection. A variant known as guttate (small drop-like plaques) psoriasis is often associated with infections of group A β -hemolytic streptococci.⁷

Psoriatic lesions can develop at the site of injury on normal-appearing skin (Koebner response). This response can be induced by a variety of trauma that includes rubbing, venipuncture, bites, surgery, and mechanical pressure. The mechanism for a Koebner response is unknown, is not unique to psoriasis, and yet occurs in a majority of psoriatic patients. Duration of time between injury and lesion development can vary from a day to several weeks.

Lithium carbonate, β -adrenergic blocking agents, some antimarial agents, nonsteroidal antiinflammatory drugs, and tetracyclines are among the most commonly reported drugs to exacerbate psoriasis or to trigger psoriasiform lesions.⁸

GENETIC FACTORS

There is a significant genetic component in psoriasis, but the exact mode of inheritance is uncertain.⁹ Most patients with psoriasis have at least one immediate relative with the disorder.¹⁰ Monozygotic

Learning objectives, review questions,
and other resources can be found at
www.pharmacotherapyonline.com.

twins have a higher concordance for psoriasis than dizygotic twins. Some studies have implied that the development and severity of psoriasis is influenced by gender of the contributing parent. However, recent linkage analysis indicates that the susceptibility genes likely play an important role in the pathogenesis of early onset psoriasis with no predilection for gender.¹¹

A number of genetic loci have been identified by genome-wide linkage scans and several loci have been replicated: *PSORS1* on chromosome 6p, within the major histocompatibility complex, *PSORS2* on chromosome 17q, *PSORS3* in the *SLC12A8* gene, and *PSORS4* on chromosome 1q. *PSORS4* is likely to be involved in terminal differentiation of keratinocytes. Several other loci have been identified; however they are not always replicated in other pedigrees. The most consistently identified loci *PSORS1* accounts for an estimated 30% to 50% of the genetic contribution to psoriasis.¹²

Studies of histocompatibility antigens in psoriatic patients indicate statistically significant associations on the B, C, and D loci, more specifically, human leukocyte antigen (HLA) B13, HLA-B17, and HLA-B37.²

A significant association also occurs with HLA-Cw6, where the relative likelihood for developing psoriasis is 9 to 15 times normal.² Moreover, evidence exists for an “early onset” psoriasis susceptibility locus at 9q33-9q34.¹¹ Identification of multiple loci for psoriasis susceptibility indicates that psoriasis is a genetically heterogeneous disease with different genetic causes, and a strong candidate gene for sequencing remains to be identified.

PATHOPHYSIOLOGY

IMMUNOLOGIC MECHANISMS

Recently, attention has been directed to cell-mediated immune mechanisms in psoriasis. A central role for activated T cells has been demonstrated by response to drugs that block T-cell activation, migration, or cytokine secretion in psoriasis.¹³

Cutaneous inflammatory T-cell-mediated immune activation requires two T-cell signals that are mediated via cell-cell interactions by surface proteins and by antigen-presenting cells (APCs) such as dendritic cells or macrophages.

The “first signal” is the interaction of the T-cell receptor with antigen presented by the APC.

The “second signal,” also called *costimulation*, is mediated through various surface interactions. Both signals are essential for initial activation of T cells in psoriasis.¹⁴

Once T cells are activated, they migrate from lymph nodes and the circulation into skin. In psoriatic lesions, T cells migrate into the epidermis, whereas T cells are not normally located in the epidermis of normal skin. Specific cell-surface proteins on T cells and vascular endothelium including selectins, integrins, and other adhesion molecules mediate this movement. For example, the mechanism of cellular interaction between lymphocyte function-associated antigen-1 (LFA-1) on T cells and intercellular adhesion molecule-1 on endothelial cells is the basis for development of one of the biologic agents, alefacept. Once in the skin, activated T cells secrete various cytokines that induce the pathologic changes of psoriasis.¹⁵ Cytokines are proteins secreted by immune cells that bind to very specific receptors on the cell surface, influencing keratinocytes and other cells to produce pathologic changes characteristic of psoriasis.

The cytokine profile in psoriasis is known as a T-helper cell type 1 (TH₁) response; this subset of T cells produces primarily interferon- γ (INF- γ), tumor necrosis factor- α (TNF- α), and interleukin (IL)-2.¹⁶ Other local cells, including keratinocytes, dendritic cells, and local neutrophils, are induced to produce other cytokines, including TNF- α , IL-23, IL-20,¹² transforming growth factor- α (TGF- α), TGF- β , amphiregulin, IL-1, IL-6, and IL-8,¹⁶ which are believed to be impor-

TABLE 101-1 Chemical Mediators of Inflammation in Psoriasis (CMI)

CMI	Cell Type	Outcome
GM-CSF	T cells	↑ mononuclear cells, ↑ neutrophils
INF- γ	T cells	↑ E selectin, ↑ ICAM, ↓ IL-4, ↑ keratinocytes, ↑ MHC I and II, ↑ VCAM, ↓ TH ₂
IL-2	T cells	↑ macrophages, ↑ TH ₁ cells
IL-3	T cells	↑ dendritic cells, ↑ macrophages
IL-8	Keratinocytes, neutrophils	↑ vascular response
IL-12	APC	↑ TH ₁ cells
IP-10	Keratinocytes	↑ leukocyte adhesion
MIG	Keratinocytes	↑ leukocyte adhesion
RANTES	Keratinocytes	↑ IL-12
TNF- α	Keratinocytes, macrophages, T cells	↑ E selectin, ↑ ICAM
VEGF	Keratinocytes, T cells	↑ TH ₁ cells, ↑ VCAM
		↑ angiogenesis

APC, antigen-presenting cell; GM-CSF, granulocyte-macrophage colony-stimulating factor; ICAM, intercellular adhesion molecule; INF, interferon; IL, interleukin; IP, inflammatory protein; MHC, major histocompatibility complex; MIG, monokine induced by interferon- γ ; RANTES, regulated on activation, normal T-cell expressed and secreted; TNF, tumor necrosis factor; TH₁, T-helper cell type 1; TH₂, T-helper cell type 2; VCAM, vascular cell adhesion molecule; VEGF, vascular endothelial growth factor. Data from Mehlig S, Gordon KB. From laboratory to clinic: Rationale for biologic therapy. *Dermatol Clin* 2004;22(4):371-377, vii-viii.

tant in the pathophysiology of psoriasis. All of these cytokines are important in the pathophysiologic development of psoriasis CSTL, and represent possible targets of biologic therapies.

Cytokines and chemokines with a currently recognized potential role in psoriasis include the following (Table 101-1): granulocyte-macrophage colony-stimulating factor; regulated on activation, normal T-cell expressed and secreted (RANTES; causes keratinocyte proliferation); epidermal growth factor and monokine induced by interferon- γ (MIG; increases neutrophil migration); IL-8 and inducible protein-10 (increases differentiation of TH₁ cells); IL-12 and macrophage inflammatory protein-3 α (MIP-3 α ; produces angiogenesis); IL-1 and thymus and activation-regulated chemokine (TARC; produces epidermal hyperplasia); IL-6 (increases other chemokine release); INF- γ (increases upregulation of adhesion molecules on endothelial cells); TNF- α ; and vascular endothelial growth factor (VEGF).

DEFECTS IN THE EPIDERMAL CELL CYCLE

As a result of pathogenic T-cell production and activation, psoriatic epidermal cells proliferate at a rate sevenfold faster than normal epidermal cells. The germinative cell population increases in psoriatic skin, and duration of the epidermal cell cycle is nearly eight times faster than normal skin.¹⁷ Lesion-free skin in psoriatic patients generally is considered to be involved because epidermal proliferation is elevated in apparently normal skin of psoriatic patients.

CLINICAL PRESENTATION OF PSORIASIS

General

- Although psoriasis is a nonmalignant, hyperproliferative epidermal cell disorder, it results in accumulated, immature, excessively thickened skin that is manifested as plaques.

Symptoms

- Psoriatic lesions are relatively asymptomatic; however, pruritus is a complaint in about 25% of patients. Severe, widespread psoriasis can involve symptomatology similar to that of exfoliative dermatitis, which can include fever and chills. Psoriatic arthritis is a distinct clinical entity in which both psoriatic lesions and inflammatory arthritis-like symptoms occur. Classically, distal interphalangeal joints and adjacent nails are involved, but knees, elbows, wrists and ankles also can be involved.

Signs

- In general, psoriatic lesions are characterized by sharply demarcated, erythematous papules and plaques often covered with silver-white scales. Initial lesions are usually small papules that enlarge over time and coalesce into plaques, sometimes as serpiginous or geographic forms. If the covering scale is removed, a salmon-pink to erythematous lesion is exposed, perhaps with punctate bleeding from prominent dermal capillaries (Auspitz sign).
- Psoriatic lesions vary in appearance depending on the anatomic site and the variant of psoriasis. The most common type of psoriasis is psoriasis vulgaris. Scalp involvement can vary from diffuse scaling on an erythematous scalp to thickened plaques with exudation, microabscesses and fissures. Trunk, back, arm, and leg lesions can appear as generalized, scattered, discrete, guttate (resembling drops or spots), or large plaques. Palms, soles, face, and genitalia can be commonly involved. Affected nails often are pitted with subungual keratotic material. Yellowing under the nail plate also can be seen.

Laboratory Tests

- Skin biopsy of lesional skin is useful in confirming the diagnosis.

Other Diagnostic Tests

- None

TREATMENT

Psoriasis

Goals of treatment of psoriasis are directed at skin normalization: reduction or clearing of erythema, papules, and plaques, as well as scales. Reduction or clearing of skin signs as a treatment objective leads to normalized cosmesis and improvement in quality of life. A goal of therapy is to achieve resolution of lesions, but partial clearing is sometimes acceptable when using regimens with decreased toxicity and increased patient acceptability.

The psoriasis area and severity index (PASI) serves as a uniform method to determine the extent of body surface area affected, along with the degree of erythema, induration, and scaling. Mild psoriasis is considered to have a PASI score of less than 12, moderate involvement is PASI 12 to 18, and severe psoriasis is PASI greater than 18.

Another method to determine disease activity is the Physician Global Assessment (PGA), which summarizes erythema, induration, scaling and extent of plaques relative to baseline assessment. Although the PASI and PGA are commonly used, they fail to measure quality of life and patient well-being. The National Psoriasis Foundation Psoriasis Score (NPF-PS) was developed in response to these limitations by incorporating quality of life and patient's perception of well-being as well as induration, extent of involvement, physician's static global assessment and pruritus.

The results of a comparison study of disease measurement systems showed that NPF-PS strongly correlated with PASI and PGA but better reflected patient perception.¹⁸

As a new class of agents, the biologic agents were required to demonstrate a PASI 75% decrease for approval by the Food and Drug Administration (FDA). No prior nonbiologic agents were required to meet such a high standard to be approved.

■ GENERAL APPROACH TO TREATMENT

Although the exact cause of psoriasis is unknown, in a majority of patients, pharmacotherapy is usually effective in establishing good

clinical control. Psoriasis can be a lifelong relapsing and remitting disease, so therapy should be selected with careful consideration of long-term adverse effects. Major points for consideration include the extent and site of disease involvement, the patient's age, and concurrent associated diseases.

Keratolytics

Keratolytic agents are used to remove scale, smooth the skin, and decrease hyperkeratosis. The mechanism of action of salicylic acid, one of the most commonly used keratolytics, is disruption in corneocyte-to-corneocyte cohesion in the abnormal horny layer of psoriatic skin. For this reason, salicylic acid is especially useful at anatomic sites where thick scales are present.

When applied to large, inflamed areas of skin, salicylic acid can induce salicylism, with symptoms of nausea, vomiting, tinnitus, and hyperventilation. Salicylate poisoning in small children is potentially more serious than in older people because they are at higher risk of developing metabolic acidosis. Fatal cases of percutaneous salicylate intoxication have been reported in children and adults.

The keratolytic effect of salicylic acid enhances penetration and efficacy of some other topical agents such as corticosteroids.⁵

Salicylic acid, as a gel or lotion, is usually applied two to three times a day in concentrations of 2% to 10%.

■ NONPHARMACOLOGIC THERAPY

Emollients

Emollients are frequently used during therapy-free periods to minimize skin dryness that can lead to early recurrence. These agents hydrate stratum corneum and minimize cutaneous transepidermal water loss (evaporation). Hydration causes the stratum corneum to swell and flattens the surface contour. Emollients effective as moisturizers decrease binding forces within the horny layer, enhance desquamation, and eliminate scaling. Emollients also can increase pliability of the skin, have antipruritic activity, and possess mild vasoconstrictor activity.

As lotions, creams, or ointments, emollients often need to be applied several times per day (about four times per day) to achieve a beneficial response. Adverse effects of emollients include folliculitis and allergic or irritant contact dermatitis.

Balneotherapy

Balneotherapy (and climatotherapy) is a therapeutic approach that consists of bathing in waters containing certain salts, often combined with natural exposure to the sun. Certain areas around the world have been targeted as excellent places to receive balneotherapy (or climatotherapy); the Dead Sea is salt filled, located below sea level, and capable of enhancing exposure to a natural ultraviolet A (UVA) light source. The Kangal hot spring in Turkey and the Blue Lagoon in Iceland are also notable salt-containing waters. The salts in these waters are a mixture of salts that reduce activated T cells in skin and are remittive for psoriasis. Reduction in serum manganese and lithium levels is significant after bathing with Dead Sea salt, an effect believed to be related to effectiveness of the salts.¹⁹

■ PHARMACOLOGIC THERAPY

Topical treatments for mild to moderate psoriasis include corticosteroids, vitamin D analogues, tazarotene, and others. The systemic treatments for moderate to severe psoriasis include biologic agents, cyclosporine, acitretin, and others. See Tables 101-2 and 101-3 for topical and systemic psoriasis treatment regimens and adverse effects.

Various pharmacotherapeutic approaches to psoriasis management include combinations of topical and systemic agents.

TABLE 101-2 Selected Topical Psoriasis Treatment Regimens and Adverse Effects

Therapy	Regimen	Selected Adverse Effects
Emollients	Approximately 4 times per day	Folliculitis, allergic or irritant contact dermatitis
Salicylic acid	2–3 times per day	Irritation, salicylism with symptoms of nausea, vomiting, tinnitus, or hyperventilation
Coal tar	Apply in the evening, allowing to remain through the night	Irritation, photoreactions, unpleasant odor, staining skin and clothing
Corticosteroids	2–4 times per day	Local tissue atrophy, degeneration, and striae; epidermal thinning; acneiform eruptions; bacterial or fungal skin infections; glucocorticoid systemic effects
Calcipotriene	1–2 times/day, no more than 100 g/wk	Burning and stinging (10% of patients), irritant contact dermatitis
Anthralin	Usually applied in the evening, allowed to remain overnight; short-contact regimens can also be used	Stains skin and clothing; irritation
Tazarotene	1 time per day, usually in the evening	Pruritus, burning, stinging, and erythema

Topical Therapy: First-Line Agents

Corticosteroids Topical corticosteroids are the most widely used agents for the treatment of psoriasis in the United States. They are often used to decrease erythema, scaling, and pruritus. Topical vasoconstricting potencies of corticosteroids are ranked by the Stoughton-Cornell classification in seven classes (Table 101–4). Class I corticosteroids, very high-potency, include products such as clobetasol propionate, halobetasol propionate, and betamethasone dipropionate (optimized vehicle).²⁰

High-potency agents are used primarily as alternatives to systemic adrenocorticoid therapy when local therapy is feasible. Examples of conditions for which very-high-potency products are used include thick, chronic psoriatic plaques. They should be used for

finite periods of time (as short as possible) and on relatively small body surface areas.

Class VII corticosteroids are agents with the lowest level of vasoconstricting potency (e.g., hydrocortisone 1%). They have a weak antiinflammatory effect and are safest for long-term application. These products are also the safest products for use on the face and intertriginous areas, in infants and young children, and with occlusion when necessary and appropriate.

Intermediate classes include products with a medium-potency ranking and are used in moderate inflammatory dermatoses. Medium-potency preparations can be used on the face and intertriginous areas for limited periods of time.²⁰

The mechanism of action of corticosteroids in psoriasis is not fully understood.²¹ Topical corticosteroids appear to inhibit phos-

TABLE 101-3 Selected Systemic Psoriasis Treatment Regimens and Adverse Effects

Therapy	Regimen	Selected Adverse Effects
Acitretin	25–50 mg/day until lesions have resolved	Hypervitaminosis A (dry lips/cheilitis, dry mouth, dry nose, dry eyes/conjunctivitis, dry skin, pruritus, scaling, and hair loss), hepatotoxicity, skeletal changes, hypercholesterolemia, hypertriglyceridemia
Adalimumab	40 mg subcutaneously once weekly or every other week	Rhinitis, injection site reactions, upper respiratory infections, flu-like symptoms, nausea, headache; can increase opportunistic infections, malignancy, neurologic demyelinating diseases
Alefacept	15 mg intramuscularly once weekly	Pharyngitis, influenza-like symptoms, chills, dizziness, nausea, headache, injection site pain and inflammation, and nonspecific infection; opportunistic infections and malignancy are rare
Cyclosporine	2.5–4 mg/kg per day in two divided doses; can increase to 5 mg/kg per day in 1 month if no response	Nephrotoxicity, malignancies, hypertension, hypomagnesemia, hyperkalemia, alterations in liver function tests, elevations of serum lipids, gastrointestinal intolerance, paresthesias, hypertrichosis, gingival hyperplasia
Etanercept	50 mg subcutaneously twice a week	Local reaction at the injection site (20% of patients); respiratory tract and gastrointestinal infections, abdominal pain, nausea and vomiting, headaches, rash; serious infections (including tuberculosis) and malignancies are rare
Efalizumab	1 mg/kg subcutaneously once weekly	Headache, nausea, chills, nonspecific infection, pain, fever, and asthenia; no evidence drug causes organ toxicity, serious infection, or malignancy
Infliximab	5 or 10 mg/kg for three intravenous infusions at weeks 0, 2, and 6	Headaches, fever, chills, fatigue, diarrhea, pharyngitis, upper respiratory and urinary tract infections; hypersensitivity reactions (urticaria, dyspnea, hypotension); lymphoproliferative disorders
Hydroxyurea	1 g/day; can increase to 2 g/day	Bone marrow toxicity with leukopenia or thrombocytopenia, cutaneous reactions, leg ulcers, megaloblastic anemia
Methotrexate	7.5–15 mg per week, increased incrementally by 2.5 mg every 2 to 4 weeks until response; maximal doses are approximately 25 mg/wk	Anemia, leukopenia, thrombocytopenia, hepatotoxicity, gastrointestinal upset, nausea, vomiting, mucosal ulceration, stomatitis, malaise, headaches, pulmonary toxicity
Mycophenolate mofetil	500 mg 4 times a day, up to maximum of 4 g/day	Gastrointestinal toxicity (diarrhea, nausea, vomiting), hematologic effects (anemia, neutropenia, thrombocytopenia), viral and bacterial infections; lymphoproliferative disease or lymphoma can occur
Sulfasalazine	3–4 g/day for 8 weeks	Gastrointestinal upset
Tacrolimus	0.05 mg/kg daily, with increases to 0.10 mg/kg daily at 3 weeks and to 0.15 mg/kg daily at 6 weeks, depending on results	Nephrotoxicity, immunosuppression, gastrointestinal upset, diarrhea, nausea, paresthesias, hypertension, tremor, insomnia
Tazarotene	4.5 mg daily	Cheilitis, dry skin, headache, arthralgia, myalgia, back pain; no evidence of drug causing hyperlipidemia, hypercholesterolemia, abnormal liver function tests, desquamation, eye dryness, or alopecia
6-Thioguanine	80 mg twice weekly, increased by 20 mg every 2–4 weeks; maximum dose 160 mg three times per week	Bone marrow suppression; gastrointestinal complications including nausea and diarrhea; elevation of liver function tests

^aVasoconstricting potency ranking is I (highest) to VII (lowest); denotes unreported vasoconstricting potency ranking.

pholipase A, and to thus reduce levels of arachidonic acid, prostaglandins, and leukotrienes in skin. Moreover, steroid receptors have been identified in skin, with synthesis and mitosis of DNA in epidermal cells being inhibited by topical corticosteroids as demonstrated by decreased epidermal proliferation.²²

Topical corticosteroid adverse reactions are not uncommon. Local tissue atrophy, epidermal and dermal degeneration, and striae are manifestations of corticosteroid effect on collagen synthesis and fibroblast growth. If detected early, atrophy and striae can be reversible on drug discontinuation, but in numerous cases of prolonged therapy with high-potency agents, these atrophic changes can be long lasting. Thinning of the epidermis can result in visibly distended capillaries (telangiectasias) and purpura. Acneiform eruptions and masking of symptoms of bacterial or fungal skin infections also have been reported with topical corticosteroid use.²³

Systemic consequences of topical corticosteroid use include risk of suppression of the hypothalamic-pituitary-adrenal axis, hyperglycemia, and development of cushingoid features. Avoidance of prolonged therapy with very-high-potency agents minimizes the risk of these adverse effects. Tachyphylaxis and rebound flare of psoriasis after abrupt cessation of topical corticosteroid therapy can also occur. With proper monitoring, topical corticosteroids are a safe and effective adjunctive approach to psoriasis treatment.²³

Topical corticosteroids are available in ointments, creams, lotions, gels, sprays, shampoos, and mousses. An ointment is considered the most clinically effective dosage form in psoriasis treatment because it consists of an oily phase that is occlusive and conveys a hydrating effect. Because of the lipophilicity of ointments, penetration of corticosteroid into dermis is enhanced, resulting in increased vasoconstriction.

Ointments are not suitable for use in areas such as the axilla, groin, or other intertriginous areas where maceration and folliculitis can develop secondary to the occlusive effect. Creams—typically emulsified products with an aqueous phase—are preferred by some patients as more cosmetically desirable. They can be used in intertriginous areas even though their lower oil content makes them more drying than ointments.

Topical corticosteroids are usually applied 2 to 4 times daily during long-term therapy.

Vitamin D Analogues Vitamin D, important in cellular and systemic calcium metabolism, also inhibits keratinocyte differentiation and proliferation, suggesting a role in the treatment of hyperkeratotic skin disease. Vitamin D and its analogues provide antiinflammatory benefits by inducing a shift toward TH₂ cytokine expression, with a decrease in IL-2, IL-6, IL-8, INF- γ , and granulocyte-macrophage colony-stimulating factor.²⁴ Moreover, it induces inhibition of nuclear factor kappa B (NF- κ B) protein in lymphocytes and nuclear factor of activated T cells leading to a reduced transcription of IL-2.²⁴

However, use of vitamin D has been limited by its propensity to cause hypercalcemia. This has driven the development of analogues of vitamin D with less effect on calcium homeostasis. Calcipotriene binds to vitamin D receptors as does vitamin D, but it is 100 times less active on systemic calcium metabolism because of its rapid local metabolism.²⁵ Its long-term effect on altered calcium homeostasis is unknown. On average, improvement is seen within 2 weeks of treatment with calcipotriene, with approximately 70% of patients demonstrating marked improvement after 8 weeks of therapy. Adverse effects of calcipotriene include lesional and perilesional irritation, occurring in approximately 10% of treated patients and consisting of mild burning and stinging. Irritant contact dermatitis is reported to occur more commonly on the face. Calcipotriene, available in a 0.005% concentration as a cream, ointment, and solution, is generally applied one to two times per day (no more than 100 g/wk).

Although calcitriol (1,25-dihydroxyvitamin D₃) is not yet available in the United States, it is used in the treatment of mild to moderate

plaque psoriasis. As demonstrated in several open-label or randomized, double-blind, controlled trials, calcitriol is effective in improving or clearing psoriatic plaques. A 0.03% formulation showed clearance or considerable improvement in 89% of patients.²⁶

Tacalcitol (1 α , 24-dihydroxyvitamin D₃) is a biologically active hormone derived from vitamin D. In a study of 157 patients with chronic plaque psoriasis, tacalcitol ointment applied once daily during a 6-month treatment period decreased mean PASI score by 67% and body area affected from 13.3% to 8.8%. Reported adverse effects of tacalcitol are limited to local, transient, mild irritation.²⁷

Tazarotene Tazarotene, a synthetic retinoid, is a prodrug that exerts its pharmacologic activity when hydrolyzed to its active metabolite, tazarotenic acid. Like other topical retinoids, it modulates keratinocyte proliferation and differentiation.²⁸

Based on the results of clinical trials, tazarotene is effective for the treatment of mild to moderate plaque psoriasis. These trials have demonstrated treatment success, defined as greater than 50% improvement of psoriasis from baseline including reduction of plaque elevation, scaling, and erythema, for both the gel and cream formulations.²⁸

Predominant treatment-related adverse effects are mild to moderate pruritus, burning, stinging, or erythema. These local reactions have been shown to be dose- and frequency-related.²⁸ Tazarotene is often used in combination with topical corticosteroids to decrease the incidence of local adverse events and to increase efficacy.¹⁰ Application of the gel to eczematous skin or to more than 20% of body surface area is not recommended because this can lead to extensive systemic absorption.

Tazarotene is available as a 0.05 or 0.1% gel and cream, and is applied once a day, usually in the evening.

Topical Therapy: Second-Line Agents

Coal Tar The use of tar as coal tar, shale tar, or wood tar has a long history in antipsoriatic therapy. In recent years, wood and shale tars have fallen out of use because they demonstrate relatively less efficacy than coal tar. Coal tar contains numerous hydrocarbon compounds formed from distillation of bituminous coal.

Although the mechanism of action is not fully understood, coal tar, when applied to normal skin, stimulates transient epidermal hyperplasia followed by a cytostatic effect with epidermal thinning. There is evidence that ultraviolet B (UVB) light-activated topical coal tar forms photo adducts with epidermal DNA, thereby inhibiting DNA synthesis. This downregulated epidermal proliferation rate approaches a normal rate of proliferation and leads to reduction in plaque elevation.²⁹

Coal tar treatment is a burdensome, time-consuming treatment with disadvantages that include local irritation, unpleasant odor, staining of skin and clothing, and increased sensitivity to ultraviolet (UV) light, including the sun. The risk of carcinogenicity is low; however, there are cases indicating a higher rate of nonmelanoma skin cancers in patients chronically exposed to tar and UV light.³⁰

Coal tar preparations of 2% to 5% tar are available in lotions, creams, shampoos, ointments, gels, and solutions. It also can be used in bath water. It is generally applied in the evening and allowed to remain in skin contact through the night.

Anthralin Anthralin, an anthrone derivative of chrysarobin, was introduced under the name dithranol in Great Britain decades ago. Chronic plaque-type and guttate psoriasis respond better than other variants to anthralin treatment. Topical anthralin, particularly with UV light, is long established as an effective approach to the treatment of psoriasis.³¹

Anthralin possesses antiproliferative activity on human keratinocytes, inhibiting DNA synthesis by intercalation between DNA strands.³² It induces NF- κ B in murine keratinocytes. Because NF-

κ B is involved in the transcription of proinflammatory cytokines such as IL-6, IL-8, and TNF- α , these findings can be helpful in explaining the irritant properties of anthralin. Other hypotheses support the role of anthralin-generated free radicals in producing both antipsoriatic effects and irritation.

The patient must apply anthralin products only to affected areas of skin because contact with uninvolved skin can result in excessive and unwanted irritation and staining. Skin staining usually disappears within 1 to 2 weeks of discontinuation. Staining of affected plaques is a positive response sign because cell turnover has been slowed enough to take up the stain.

Inflammation, irritation, and staining of skin and clothing (via oxidation and binding to keratins) are often therapy-limiting effects.

Fortunately, anthralin exerts its clinical effects at low cellular concentrations; classic anthralin therapy starts with low concentrations (0.1% to 0.25%) and gradually proceeds to higher concentrations (0.5% to 1%). Short-contact anthralin therapy regimens are alternative modes of application with decreased local adverse effects. Liposomal-based anthralin 0.5% gel can also be used for short contact therapy (10–20 minutes) and can noticeably reduce staining of skin and irritation.³¹

Anthralin traditionally was formulated in stiff paste bases to provide adherence to plaques. Subsequently, cream and ointment formulations have been developed that are more cosmetically appealing and appear to be equivalent in efficacy. Usually it is applied in the evening and allowed to remain overnight.

Topical Calcineurin Inhibitors (TCIs) Pimecrolimus and tacrolimus are calcineurin inhibitors capable of exerting a local immunomodulating effect that can serve to normalize hyperproliferation of epidermis. As topical agents, tacrolimus and pimecrolimus are approved for the treatment of atopic dermatitis; however, regulatory approval regarding the efficacy of these agents in psoriasis is yet to be completed. The benefit in using these agents, as opposed to topical corticosteroids, is that these immunomodulators do not cause skin atrophy. Although pivotal trials are not yet published regarding the efficacy of pimecrolimus and tacrolimus in the treatment of plaque-type psoriasis, clinical studies have shown efficacy on facial and intertriginous psoriasis.³³

Although not commercially available in the United States, sirolimus is an immunosuppressive drug similar in structure to tacrolimus, however it does not inhibit calcineurin. Sirolimus inhibits a central kinase that transduces signals from the IL-2 receptor. By blocking this receptor, sirolimus inhibits T-cell stimulation by IL-2.³⁴ Clinical studies have demonstrated that topical sirolimus sufficiently crosses the stratum corneum/epidermis and is therefore effective in psoriasis.³⁵

Systemic Therapy: First-Line Agents

Biologic Therapy The field of biologic therapy is expanding rapidly as a result of advances in recombinant DNA technology, microbiology, and immunology. In dermatology, biologic therapies—primarily immunomodulating agents designed to alter immune responses—are the basis for treatment of cutaneous diseases such as psoriasis and atopic dermatitis. These agents, produced in vitro through recombinant DNA technology, fall into three categories: (1) recombinant human cytokines, (2) humanized monoclonal antibodies, and (3) molecular receptors that can bind target molecules.

The biologic agents currently FDA approved for the treatment of moderate to severe psoriasis are infliximab, etanercept, alefacept, and efalizumab. One agent, adalimumab, is currently FDA approved for the treatment of psoriatic arthritis but not yet approved for psoriasis.

CLINICAL CONTROVERSY

Although some authors seem to successfully argue the advantages of remittive therapy in a potentially lifelong disorder,³⁶ others hypothesize the notion that biologic agents are excessively costly and that less expensive alternatives need development.³⁷ Although difficult to assess, and not established for all agents, given careful oversight, patient quality of life can be improved with an acceptable risk-to-benefit ratio, and improved cost effectiveness can be attained if remittive therapy is accomplished with some biologic agent.³⁸

In psoriasis, biologic agents typically act through one or more of the following mechanisms: (1) elimination of activated T cells, (2) inhibition of T-cell activation, (3) interference with T-cell trafficking to the skin, (4) neutralization of the effects of TH₁-type cytokines, and (5) induction of immune deviation by introducing TH₂-type cytokines.³⁹

Tumor Necrosis Factor Inhibitors

Infliximab Infliximab is a chimeric monoclonal antibody (immunoglobulin G₁; IgG₁) directed against TNF- α . It binds with high affinity to the soluble and transmembranous forms of TNF- α and inhibits binding of TNF- α with its receptors. TNF- α is believed to play an important role in the pathogenesis of psoriasis. Increased amounts of TNF- α have been found in psoriatic lesions. The proposed mechanism of action of TNF- α includes stimulation of synthesis of numerous cytokines and induction of the expression of intracellular adhesion molecules on endothelial cells and keratinocytes.⁴⁰

Infliximab has been used for treatment of rheumatoid arthritis and Crohn disease for years. Recently, the FDA expanded the indications for infliximab to include psoriatic arthritis, and now also adults with chronic severe plaque psoriasis.

One double-blind, randomized, placebo-controlled clinical trial studied the effectiveness and safety of infliximab in patients with moderate to severe psoriasis. A good response was seen in 82% and 91% of patients treated with infliximab 5 mg/kg or 10 mg/kg, respectively. Median time to response for all patients receiving infliximab was 4 weeks. The investigators concluded that patients treated with infliximab had a high degree of clinical improvement with rapid response rate, similar to that observed with cyclosporine therapy.⁴¹

The most common adverse effects of infliximab are headaches, fever, chills, fatigue, diarrhea, pharyngitis, upper respiratory and urinary tract infections, and hypersensitivity reactions (urticaria, dyspnea, and hypotension). Infliximab has been also associated with infections and lymphoproliferative disorders. It is not associated with end-organ toxicity, and blood counts, liver enzyme levels, kidney function, and complement values can be expected to remain normal during treatment. This gives it a major advantage over other systemic psoriasis treatments.

Infliximab is administered in three doses at weeks 0, 2, and 6, of 5 mg/kg or 10 mg/kg by slow intravenous infusion.⁴¹

Etanercept Etanercept, another TNF- α blocker, is a genetically engineered fusion protein that combines the extracellular domain of the TNF- α receptor with the crystallizable fragment (Fc) region of human IgG₁. Etanercept binds free and membrane-bound TNF- α , competitively interfering with the interaction of TNF- α with cell-bound receptors and inhibits the effects of this cytokine on target cells. Unlike the chimeric infliximab, etanercept is fully humanized, thereby minimizing the risk of immunogenicity.⁴²

Etanercept has been approved in several countries, including the United States, for subcutaneous treatment of rheumatoid arthritis, psoriatic arthritis, and more recently psoriasis. Safety and efficacy of

etanercept for psoriatic arthritis and psoriasis were demonstrated in a 12-week randomized, double-blind, placebo-controlled trial of twice-weekly subcutaneous injections of etanercept 25 mg. The median reduction in PASI in the treatment group was 46%, compared with 8.7% in the placebo group.⁴³ During phase III trials etanercept was evaluated at 3 different doses: low (25 mg per week), medium (25 mg twice weekly), and high (50 mg given twice weekly). After 12 weeks of treatment a 75% reduction in PASI score was achieved by 4% of subjects given placebo, 14% of subjects given low-dose, 34% of the subjects given medium-dose, and 49% of the subjects given the high-dose. These results were statistically significant for all three doses when compared to the placebo group. The subjects continued to improve with further treatment and at 24 weeks 25%, 44%, and 59% of the low, medium, and high-dose subjects, respectively, achieved a 75% reduction in PASI score.⁴⁴

Adverse effects of etanercept include a local reaction at the injection site (20% of patients), respiratory tract and gastrointestinal infections, abdominal pain, nausea and vomiting, headaches, and rash. Serious infections (including tuberculosis) and malignancies have rarely been observed.

Etanercept is usually given in doses up to 50 mg subcutaneously twice a week.

Adalimumab Adalimumab is a human IgG₁ monoclonal TNF- α antibody. The binding of adalimumab results in the inactivation of the proinflammatory cytokine TNF- α . It is currently approved for the treatment of rheumatoid arthritis and psoriatic arthritis and is undergoing trials for psoriasis.

In a series of nine patients adalimumab was found to be effective for psoriasis refractory to other treatments including infliximab and etanercept. Adalimumab was dosed at 40 mg every 14 days administered subcutaneously as monotherapy, and after 12 weeks 56% of patients showed a 75% reduction in PASI score. There was continued improvement after 20 weeks.⁴⁵

In a multicenter, randomized, placebo-controlled trial, the efficacy and safety of two dosages of adalimumab (40 mg every other week or weekly) versus placebo were assessed for 12 weeks in the treatment of moderate to severe plaque psoriasis with a 48-week extension trial. At 12 weeks 53% of the subjects that received 40 mg every other week and 80% of the subjects that received 40 mg per week had a reduction of 75% or more in the PASI score. Also, these responses were sustained for those who continued treatment for 60 weeks.⁴⁶

Adalimumab has a favorable safety profile. The most common adverse events were rhinitis, upper respiratory tract infections, nausea, flu-like syndrome, headache, and injection site reactions. In clinical trials for rheumatoid arthritis, anti-adalimumab antibodies were seen in 12% of subjects receiving adalimumab as monotherapy. Theoretically adalimumab should be less immunogenic than the chimeric antibody infliximab.⁴⁷

There is concern that adalimumab can be associated with malignancy, in particular lymphoma, infections, such as tuberculosis, histoplasmosis, pneumococcus, and listeria; adverse neurologic effects including the potential role in causing demyelinating disease.¹³

Adalimumab is given as a dose of 40 mg every other week or every week.

CLINICAL CONTROVERSY

It has been reported that treatment with adalimumab, infliximab and etanercept leads to non-neutralizing antibody production, the long-term significance of which is unknown. Some clinicians believe that antibody production can be related to a lack of efficacy, although others believe that antibody production and efficacy are unrelated. Further, adalimumab as a “fully humanized” product would be expected to produce less antibody production.

Although 12% of subjects in a trial of adalimumab tested positive for adalimumab antibodies, efficacy and pattern or frequency of adverse events did not correlate with production, or lack of production, of antibodies to adalimumab.⁴⁸

In an adalimumab cohort study, anti-adalimumab antibodies were detected in 17% of subjects. Significantly more nonresponders had anti-adalimumab antibodies than responders (34% vs. 5%), and subjects with anti-adalimumab antibodies had less clinical improvement of disease. On follow-up, subjects with anti-adalimumab antibodies also had lower serum adalimumab concentrations than those without anti-adalimumab antibodies.⁴⁹

In a further adalimumab study, 87% of subjects showed antibodies to adalimumab. Five of seven subjects with adverse drug reactions and all subjects with lack of efficacy were associated with antibody formation. Adalimumab, in spite of its “fully humanized” status, apparently also has immunogenic potential.⁵⁰

Thirteen percent of subjects were positive for anti-infliximab antibodies after the first 2 intravenous infusions. With subsequent infusions, more subjects became antibody positive (44% at 6 months), correlating with diminished trough levels of infliximab. These authors concluded that the development of anti-infliximab antibodies is associated with increased risk of infusion reaction and treatment failure.⁵¹

Immunogenicity of etanercept has also been studied with once-weekly dosing. Antibodies to etanercept are likely to be non-neutralizing and occur in approximately 5% of patients.⁵²

T-Cell Activation Inhibitors

Alefacept Alefacept is a dimeric fusion protein that combines the first extracellular domain of human LFA-3 with the Fc portion of human IgG₁. The LFA-3 segment of alefacept binds specifically to the cluster of differentiation 2 (CD2) on T cells to prevent costimulatory signals delivered by LFA-3 and thereby inhibits cutaneous T-cell activation and proliferation. Alefacept also induces selective apoptosis of memory-effector T cells and produces a dose-dependent decrease in circulating total lymphocytes.^{10,53}

Alefacept is approved for treatment of moderate to severe plaque psoriasis and is also effective for the treatment of psoriatic arthritis.⁵⁴ Significant clinical response is achieved after approximately 3 months of therapy, and improvements are relatively long lasting.

Alefacept is well tolerated, and its safety profile is equivalent to that of placebo. The most common adverse events are mild and include pharyngitis, influenza-like symptoms, chills, dizziness, nausea, headache, injection site pain and inflammation, and nonspecific infection; the frequency of these effects is low. Also, the drug produces no increase in the rate of opportunistic infections or malignancies.⁵⁵ Weekly visits to a physician's office for drug administration and CD4 T-cell monitoring are required, and not all patients respond to treatment.

Alefacept is administered by intramuscular injection in once-weekly doses of 15 mg for 12 weeks.

Efalizumab Efalizumab is a humanized monoclonal antibody (IgG₁) against CD11- α integrin. CD11- α /CD18 comprise subunits of LFA-1, a T-cell surface molecule important in T-cell activation, T-cell migration into skin, and cytotoxic T-cell function.⁵⁶

Clinical studies with efalizumab have shown efficacy with few adverse effects. In an open-label, multicenter, dose-escalating study of repeated intravenous infusions of efalizumab over 7 weeks in 39 subjects with moderate to severe psoriasis, the individuals who were exposed to the optimum dose (1 mg/kg weekly) showed a mean decrease in PASI of 47%.⁵⁷

In a phase III multicenter trial subjects received efalizumab subcutaneously at 1.0 or 2.0 mg/kg/week or placebo for 12 weeks. Twenty-two percent of the subjects that received 1 mg/kg/week and

28% of the subjects that received 2 mg/kg/week had an improvement of 75% or more in the PASI. Also, 77% of those subjects who improved 75% or more at the initial 12-week treatment period maintained improvement through week 24.⁵⁸

The most frequent adverse effects of efalizumab are mild to moderate influenza-like complaints such as headache, nausea, chills, nonspecific infection, pain, fever, and asthenia.⁵⁹ There have been cases of exacerbations of psoriasis on discontinuation of the drug, leading to the suggestion that patients might need to continue treatment with this drug to maintain suppression of their disease. However, there have been no significant increases in malignant disease, opportunistic infections, signs of immunosuppression, hepatotoxicity, or nephrotoxicity.¹³

The usual dose is 1 mg/kg subcutaneously once weekly.

Systemic Therapy: Second-Line Agents

Acitretin Acitretin, an oral retinoid, is the active metabolite of etretinate and has demonstrated clinical effects similar to etretinate but with fewer adverse effects.⁶⁰ Acitretin is indicated for the treatment of severe psoriasis, including erythrodermic and generalized pustular types but is more useful as an adjunct in the treatment of plaque psoriasis. In contrast to the fast-acting cyclosporine and methotrexate, acitretin resolves psoriatic lesions more slowly.

Acitretin has a shorter half-life than etretinate. Its mechanism of action is not completely understood; it might achieve benefits by acting on retinoid receptors in the keratinocyte nucleus to correct abnormal cell differentiation.

Acitretin has shown good results when combined with other psoriatic therapies, including PUVA and UVB and topical calcipotriol.²⁸ The combination of acitretin and PUVA is highly effective and provides faster and more complete clearance, as well as allowing a decrease in the doses of both agents, thereby limiting the risk of adverse effects.⁶⁰

Adverse effects are dose dependent. They include hypervitaminosis A (i.e., dry lips/cheilitis, dry mouth, dry nose, dry eyes/conjunctivitis, dry skin, pruritus, scaling, and hair loss), hepatotoxicity, skeletal changes, hypercholesterolemia, and hypertriglyceridemia. To counteract hyperlipidemic effects, gemfibrozil has been studied for concomitant use with acitretin. In addition, acitretin is a known teratogen and thus is contraindicated in females who are pregnant or who plan pregnancy within the 3 years following drug discontinuation.²⁸

Absorption is enhanced when taken with food. Concurrent ingestion of alcohol converts acitretin to etretinate, which has a longer half-life. Therefore, alcohol must not be ingested by female patients during treatment with acitretin and for 2 months following treatment.

An initial recommended dose of acitretin is 25 to 50 mg once daily, with therapy continued until lesions have resolved. A dosage of 50 mg/day is typically required for plaque psoriasis, and even at this relatively high dose, acitretin is only moderately effective. It is better tolerated when taken in conjunction with a meal.

Cyclosporine An effective immunosuppressive agent that inhibits the first phase of T-cell activation, cyclosporine is used in the treatment of both cutaneous and arthritic manifestations of severe psoriasis.⁶¹ It also inhibits the release of inflammatory mediators from mast cells, basophils, and polymorphonuclear cells.⁶²

A meta-analysis of 579 patients with severe psoriasis treated with either 2.5 or 5 mg/kg per day of cyclosporine for 10 to 12 weeks found that the PASI decreased by 70% and 72%, respectively.⁶³ An oral microemulsion formulation of cyclosporine has shown a better pharmacokinetic profile, resulting in a more consistent and predictable rate of absorption than the original formulation.⁵

The major concerns with the use of cyclosporine are nephrotoxicity, hypertension, and potential risk of malignancy. Published studies have demonstrated interstitial fibrosis and renal tubular

atrophy on kidney biopsy specimens in patients treated for more than 2 years with cyclosporine. To decrease the risk of nephrotoxicity, the dose of cyclosporine should be kept below 5 mg/kg per day, and if serum creatinine levels increase by more than 30% the dose of cyclosporine should be decreased or discontinued. In addition, use for more than 2 years of cumulative treatment can increase the risk of malignancy, including skin cancers (non-melanoma) and lymphoproliferative disorders. One study has suggested that cyclosporine renders malignancies more aggressive.⁶⁰ Other complications include hypomagnesemia, hyperkalemia, decreased liver function, elevation of serum lipids, gastrointestinal intolerance, paresthesias, hypertrichosis, and gingival hyperplasia.^{62,64}

Before initiating therapy with cyclosporine, patients should have the following laboratory tests done: electrolyte panel, renal panel (calcium, phosphate, magnesium, blood urea nitrogen, and two baseline measurements of serum creatinine), uric acid, liver function tests, triglycerides and complete blood count, as well as an accurate baseline blood pressure.

Serum creatinine should be monitored every 2 weeks for the first 3 months, then once a month for the duration of treatment.⁶⁴

See Chap. 92 on solid organ transplantation for a discussion of drug interactions involving cyclosporine.

The typical dose of cyclosporine is usually between 2.5 and 5 mg/kg per day.

Tacrolimus Tacrolimus is a macrolide immunosuppressive agent indicated for the prevention of organ transplant rejection and can be useful as an alternative treatment in severe recalcitrant psoriasis. Tacrolimus, like cyclosporine, inhibits T-cell activation.¹⁰

Adverse effects include diarrhea, nausea, paresthesias, hypertension, tremor, and insomnia. Other toxicities with topical tacrolimus—including renal insufficiency and immunosuppression—have been rarely reported.⁶⁵

See Chap. 92 on solid organ transplantation for a discussion of drug interactions involving tacrolimus.

Although not FDA approved in recalcitrant plaque-type psoriasis, patients have received tacrolimus at oral doses of 0.05 mg/kg per day (increased up to 0.15 mg/kg per day as needed).⁶⁶

Pimecrolimus Pimecrolimus is a macrolide immunosuppressive agent that inhibits both TH₁ and TH₂ cytokines as well as inhibits degranulation of mast cells. Although it is currently not commercially available in the United States, it is being studied for treatment of moderate to severe psoriasis. A multicenter 12-week clinical trial demonstrated a dose-dependent reduction in psoriasis severity when oral pimecrolimus was given at dosages of 10 mg, 20 mg, 30 mg, or placebo twice daily. Responses at 20 mg and 30 mg doses were statistically significant ($P < 0.001$). The drug is well tolerated, and it is not expected to produce major organ toxicities. The most common adverse event reported is a transient feeling of warmth.⁶⁷

Methotrexate Methotrexate, a common antimetabolite, was introduced several decades ago for the treatment of psoriasis and remains an effective therapeutic approach for psoriasis. It is a synthetic analogue of folic acid that acts as a competitive inhibitor of the enzyme dihydrofolate reductase and is responsible for the conversion of dihydrofolate to tetrahydrofolate. Tetrahydrofolate is an essential cofactor for the synthesis of thymidylate and purine nucleotides required for DNA and RNA synthesis.⁶⁵

Methotrexate inhibits replication and function of T and B cells and suppresses secretion of various cytokines such as IL-1, INF- γ , and TNF- α . It also suppresses epidermal cell division. Methotrexate is indicated in patients with moderate to severe psoriasis.⁶⁵

Methotrexate is particularly beneficial for patients with psoriatic arthritis. It is also indicated for patients that are refractory to topical or UV therapy.⁶⁰ Methotrexate should be avoided in patients with active infections because of its immunosuppressive activity.⁶⁸

Methotrexate is associated with nausea and vomiting as well as mucosal ulceration, stomatitis, malaise, headaches, macrocytic anemia, and pulmonary toxicity. Nausea and macrocytic anemia can be ameliorated by administering oral folic acid in doses of 1 to 5 mg/day.

Bone marrow toxicity that leads to leukopenia, anemia, and thrombocytopenia has been shown to be induced by methotrexate. A serious long-term adverse effect is hepatotoxicity. Consequently, methotrexate should typically be avoided in patients with liver disease. Risk factors for hepatotoxicity include a history of excessive alcohol consumption, hepatitis, persistent elevated liver function tests, and family history of inheritable liver disease.⁶⁵

Malignant lymphomas have been reported in several patients treated with methotrexate.

In some cases, lymphomas regressed when methotrexate was discontinued, suggesting a causal relationship. A large cohort study indicated that patients with psoriasis are at increased risk for developing lymphoma. However, the cause of this increased rate of lymphoma is unknown and could be attributed to psoriasis severity, the treatment, or an interaction between these risk factors.⁶⁹ Methotrexate is contraindicated in pregnant women because it is teratogenic.⁶⁵

The starting methotrexate dose is 7.5 to 15 mg per week, and this is increased incrementally by 2.5 mg every 2 to 4 weeks until a response is evident. Maximal doses are typically approximately 25 mg per week. It can be administered orally, subcutaneously, or intramuscularly. During treatment complete blood count, renal function, and liver panel should be checked monthly. Methotrexate is renally excreted and should therefore not be administered to patients with impairment of kidney function.⁶⁵

Drug interactions can potentiate methotrexate toxicity. For example nonsteroidal antiinflammatory drugs can reduce renal clearance of methotrexate, resulting in toxic levels.⁷⁰ Leucovorin (folinic acid) can be given (20 mg every 6 hours) when there is evidence of methotrexate toxicity. Table 101–5 lists selected drugs that interact with, and increase toxicity of, methotrexate.

Mycophenolate Mofetil Mycophenolate mofetil, a semisynthetic morpholinoester of mycophenolic acid, initially was used to

prevent acute rejection after renal and cardiac transplantation, but it is now used as part of combination therapy in moderate to severe psoriasis and other autoimmune dermatoses. It reversibly blocks de-novo synthesis of guanine nucleotides required for DNA and RNA synthesis. The drug has been shown to have a specific lymphocyte antiproliferative effect.⁷¹

Although not FDA approved for this indication, oral mycophenolate mofetil appears effective in the treatment of moderate to severe plaque-type psoriasis; however, additional clinical trials will be necessary to demonstrate efficacy and safety.⁶⁵ Future therapy can also include topical mycophenolic acid, which is not commercially available.⁷² Commonly reported adverse effects of mycophenolate mofetil include gastrointestinal toxicity (diarrhea, nausea, and vomiting), hematologic effects (anemia, neutropenia, and thrombocytopenia), and an increased incidence of viral and bacterial infections. Lymphoproliferative disease or lymphoma has developed in up to 1% of patients who received mycophenolic acid with other immunosuppressive agents increased up to 4 g/day.

See Chap. 92 on solid organ transplantation for a discussion of drug interactions involving mycophenolate mofetil.

Mycophenolate mofetil is usually given 500 mg 4 times a day, up to a maximum of 4 g/day.

Sulfasalazine Sulfasalazine, commonly used in the treatment of inflammatory bowel disease and rheumatoid arthritis, is selectively used as an alternative treatment, particularly in patients with concurrent psoriatic arthritis. Sulfasalazine is an antiinflammatory agent that inhibits 5-lipoxygenase. When used as a single agent in the treatment of psoriasis, it is not as effective as is therapy with methotrexate, PUVA, or acitretin. One possible advantage of sulfasalazine therapy compared with other systemic treatments is its relatively high margin of safety.

See Chap. 94 on rheumatoid arthritis for a discussion of drug interactions involving sulfasalazine. The usual dose of oral sulfasalazine is 3 to 4 g/day for 8 weeks.¹⁰

6-Thioguanine A purine analog that acts as an antimetabolite in the S-phase of cell division, 6-thioguanine is approved for treatment of leukemia but has been used as an alternative treatment for psoriasis for decades when conventional therapies have failed.⁷³ It appears to be less hepatotoxic than methotrexate and therefore may be more useful in treating hepatically compromised patients with severe psoriasis.

Adverse effects of 6-thioguanine include bone marrow suppression, gastrointestinal complications including nausea and diarrhea, and elevation of liver function tests.

The typical dose of 6-thioguanine is 80 mg twice weekly, increased by 20 mg every 2 to 4 weeks. Its maximum dose is considered to be 160 mg three times a week.

See Chap. 130 on cancer treatment and chemotherapy for a discussion of drug interactions involving 6-thioguanine.

Hydroxyurea Hydroxyurea inactivates the enzyme ribonucleotide reductase, inhibiting cell synthesis in the S-phase of the DNA cycle. An antimetabolite that is primarily used to treat hematologic malignancies, it has been used for the treatment of psoriasis for more than three decades.⁶⁰ It is selectively used, particularly in those with liver disease who would be at risk of adverse effects with other antipsoriatic agents. However, hydroxyurea is less effective than methotrexate.¹⁰

Adverse effects of hydroxyurea are bone marrow toxicity with leukopenia or thrombocytopenia, cutaneous reactions, leg ulcers, and megaloblastic anemia.

See Chap. 130 on cancer treatment and chemotherapy for a discussion of drug interactions involving hydroxyurea.

The typical dose of hydroxyurea is 1 g/day, with gradual increase to 2 g/day as needed as tolerated. Improvement is gradual, usually seen after 4 weeks of therapy.¹⁰

TABLE 101-5 Selected Drugs That Can Increase the Toxicity of Methotrexate	
Mechanism	Drug
Additive or synergistic toxicity	Ethanol
	Pyrimethamine
	Trimethoprim-sulfamethoxazole
Decreased renal elimination of methotrexate	Aminoglycosides
	Cephalothin
	Colchicines
	Cyclosporine
	Nonsteroidal antiinflammatory drugs (naproxen and ibuprofen)
	Penicillins
	Phenylbutazone
	Probenecid
	Salicylates
	Sulfonamides
Displacement of methotrexate from protein binding	Barbiturates
	Phenytoin
	Probenecid
	Retinoids
	Salicylates
	Sulfonamides
	Sulfonylureas
	Tetracycline
	Ethanol
	Retinoids
Hepatotoxicity	
Intracellular accumulation of methotrexate	Dipyridamole

Tazarotene Tazarotene is a receptor selective retinoid. The oral dosage form is not yet FDA approved. Oral retinoids have been successfully used in the treatment of psoriasis, however, their use is limited because of systemic adverse effects and teratogenicity.

Phase III trials demonstrate that oral tazarotene given 4.5 mg daily is effective for the treatment of moderate to severe psoriasis. Safety and tolerability data suggest that tazarotene may have an improved profile compared to established retinoids. Also, tazarotene does not significantly increase triglycerides, cholesterol, liver function tests, desquamation, eye dryness, or alopecia. However, there are no head-to-head trials with the currently approved oral retinoid, acitretin, therefore it remains unclear whether tazarotene is any safer or more effective. The major limitation with the use of oral tazarotene is embryotoxicity and teratogenicity.⁷⁴

■ COMBINATION, ROTATIONAL, AND SEQUENTIAL THERAPY

Frequently, monotherapy with a systemic agent does not provide optimal outcomes. Combination therapy of systemic agents with other modalities can enhance therapeutic benefit. In addition, the dose of each pharmacotherapeutic agent can be reduced if used in combination, and this can result in lower toxicity.⁶⁰

Combinations can include:

- Acitretin + UVB light
- Acitretin + PUVA (UVA combined with psoralen, usually methoxsalen)
- Methotrexate + UVB light
- PUVA + UVB light
- Methotrexate + cyclosporine

In addition to combination therapy, biologic agents can also be used in rotational therapy. Patients can receive a biologic regimen for a limited period of time and can be then switched to a nonbiologic regimen, continuing on a rotational basis. One objective of rotational therapy is to minimize cumulative drug toxicity.

Sequential therapy is another treatment strategy designed to optimize therapeutic outcome. It involves rapid clearing of psoriasis with aggressive therapy by an agent such as cyclosporine, followed by a transitional period in which a safer long-term drug such as acitretin

is introduced at maximal dosing. Subsequently, a maintenance period with acitretin in lower doses, or if necessary, acitretin in combination with UVB or PUVA, can be continued.⁷⁵ Topical sequential therapy can involve the use of a class I corticosteroid (very high potency) and calcipotriene in three different phases to attain rapid clearing of psoriatic lesions while minimizing side effects.⁷⁶

Combination or rotational therapies with biologic agents can also be clinically useful.²⁵

Possible pharmacotherapeutic approaches to the treatment of psoriasis are shown in the treatment algorithm (Fig. 101–1).

Phototherapy

Ultraviolet B Light Therapy and PUVA Therapy UVB light (290 to 320 nm) continues to be an important phototherapeutic intervention for psoriasis.

Exposure to UV light by natural sunlight has been used to treat psoriasis for centuries. At the beginning of the 20th-century patients were treated with topical, occlusive coal tar all day and night, removing the tar just before exposure to a hot quartz mercury vapor lamp (Goeckerman therapy).¹⁰ Subsequent development of various forms of UVB phototherapy has led to the use of more precise wavelengths within the UVB range to achieve an optimal therapeutic benefit for psoriasis.

The most effective wavelength of UVB for treatment of psoriasis is 310 to 315 nm, and this has led to the development of a UVB *narrowband* (NB) light source, in which 83% of the UVB emission is at 310 to 313 nm.⁷⁷ Numerous clinical trials have demonstrated efficacy of NB-UVB for the treatment of plaque-type psoriasis.⁷⁸

Numerous topical and systemic psoriatic therapies (discussed individually below) are used adjunctively to hasten and improve the response to UVB phototherapy. Emollients enhance efficacy of UVB and can be applied to the skin just before treatments for this purpose.²⁰ Several studies showed an advantage to combining short-contact anthralin with UVB.²⁰ The addition of calcipotriene or topical retinoids also improved results compared to UVB alone. However, topical application should be after or at least 2 hours before UVB therapy because phototherapy can inactivate the topical product.⁷⁹ UVB phototherapy has also produced more effective results when added to systemic psoriatic treatments, such as methotrexate and retinoids.⁷⁹

FIGURE 101-1. Psoriasis treatment spectrum. (PUVA, photochemotherapy with oral methoxypsoralen using ultraviolet A light; UVA, ultraviolet A light; UVB, ultraviolet B light.)

TABLE 101-6 Light-Reactive Skin Types

Fitzpatrick Phototypes	I		II	III	IV	V	VI	
	Lightest skin							Darkest skin
Cesarini phototypes	0	I	II	IIIa	IIIb	IV	V	VI

Data from Guinot C, Malvy DJ, Latreille J, et al. Sun-reactive Skin Type in 4912 French adults participating in the SU.VI.MAX study. *Photochem Photobiol* 2005;81(4):934-940.

PUVA is a photochemotherapeutic approach to treatment of psoriasis. Although burdensome, photochemotherapy is an important treatment consideration for patients with moderate to severe psoriasis, when time needed to treat and risk factors are balanced with potential benefit.

The mechanism of action of both UVB and PUVA in treating psoriasis is thought to be immunomodulatory. Although the mechanism of action is not fully understood, UVB and PUVA have antiproliferative, antiinflammatory, and immunosuppressive effects. Phototherapy with UVB also induces T-cell apoptosis.⁸⁰ Candidates for PUVA therapy usually have moderate to severe, incapacitating psoriasis unresponsive to conventional topical and systemic therapies.

A randomized double-blind study compared PUVA with NB-UVB for the treatment of chronic plaque psoriasis in 88 subjects. In those with skin phototypes I through IV, PUVA was significantly more effective than NB-UVB (84% vs. 65%; $P = 0.02$). The median number of treatments to clearance was significantly lower in the PUVA group (17.0 vs. 28.5; $P < 0.001$). Six months after the cessation of therapy, 68% of PUVA-treated subjects and 35% of NB-UVB-treated subjects were still in remission. This study indicates that PUVA achieves clearance in more subjects with fewer treatment sessions and results in longer remissions than NB-UVB.⁸¹

Adverse effects from oral methoxsalen include nausea, dizziness, and headache. Long-term adverse effects from combined psoralen (methoxsalen) and UV light include actinic skin damage, solar elastosis, dry and wrinkled skin, and hyperpigmentation or hypopigmentation. An increased risk of skin cancers, both squamous cell carcinoma and melanoma, exists after PUVA therapy, and is correlated with the cumulative UVA exposure.⁸² Although the proportion of patients with malignant melanoma has remained small, an increase in malignant melanoma has been observed in patients who received more than 250 PUVA sessions.

Oral methoxsalen is usually dosed with milk or food to minimize risk of nausea and gastrointestinal upset.

Systemic PUVA is approved for the treatment of psoriasis. It consists of oral ingestion of a potent photosensitizer such as methoxsalen (8-methoxypsoralen) at a constant dose (0.6 to 0.8 mg/kg) and variable doses of UVA, depending on patient skin phototype and history of previous response to UV radiation¹⁰ (skin phototype classifications⁸³ are listed in Table 101-6). Approximately 2 hours after ingesting methoxsalen, the patient is exposed to UVA light. Photochemotherapy is performed two or three times a week. In most patients, control and partial clearing occurs by the twenty-fifth treatment.

Another method, that can have less carcinogenic potential, is to topically deliver the photosensitizer (methoxsalen) to the skin by addition to bath water (bath PUVA),⁸⁴ or as a topical cream (PUVA cream)⁸⁵ instead of through systemic administration. The major advantages of this therapy are minimal risk of systemic effects and overall reduction of UVA dose to one-fourth that required with conventional PUVA. A relative risk reduction of nonmelanoma skin cancer has also been demonstrated.

with regard to melanoma and nonmelanoma skin cancers indicate an increased risk for melanoma,⁸² or at least the risk cannot be ruled out,⁸⁷ and also an increased incidence of nonmelanoma skin cancers in association with PUVA.⁸⁸ One study demonstrated a dose-dependent increased risk for genital tumors in men treated with PUVA, specifically, a 53-fold increased risk for invasive penile and scrotal squamous cell carcinoma.⁸⁹

Excimer Laser Phototherapy

Lasers have been used for the treatment of psoriasis with variable results. Most laser therapy has been ineffective, whereas the excimer laser, which generates a high-energy 308-nm UVB wavelength is effective at clearing psoriasis and inducing moderately prolonged remissions.^{90,91} Unfortunately, this approach to therapy is limited to treatment of individual, isolated plaques. The excimer laser has some advantages over traditional NB-UVB phototherapy, including

TABLE 101-7 Evidence Basis for Selected Pharmacotherapeutic Approaches to the Treatment of Psoriasis

Pharmacotherapy	Level of Evidence ^a
Topical	
Calcineurin inhibitors	4
Coal tar	4
Corticosteroids	1
Anthralin	1
Tazarotene	2
Vitamin D analogs	1
Systemic	
Acitretin	3
Cyclosporine	1
Methotrexate	3
Biologics	
Efalizumab	1
Etanercept	1
Infliximab	1
Adalimumab	1
Phototherapy	
UVB	2
PUVA	2

PUVA, photochemotherapy with oral methoxypsoralen; UVB, ultraviolet B.

^aLevel of evidence:

1. Intervention is supported by studies with grade A₁ evidence^b or studies with grade A₂ evidence whose results are predominantly consistent with one another.
2. Intervention is supported by studies with grade A₂ evidence or studies with grade B evidence whose results are predominantly consistent with one another.
3. Intervention is supported by studies with grade B evidence or studies with grade C evidence whose results are predominantly consistent with one another.
4. Little or no systematic empirical evidence.

^bGrade of evidence

A₁, Meta-analysis that includes at least one randomized study with grade A₂ evidence. In addition, the results of the different studies included in the meta-analysis must be consistent with one another.

A₂, A high-quality (e.g., sample-size calculation, flow chart, intention-to-treat (ITT) analysis, sufficient size) randomized, double-blind comparative clinical study.

B, Randomized clinical study of lesser quality or other comparative study (nonrandomized, cohort, or case-control study).

C, Noncomparative study.

D, Expert opinion.

Data from Nast A, Kopp I, Augustin M, et al. German evidence-based guidelines for the treatment of Psoriasis vulgaris (short version). *Arch Dermatol Res* 2007;299(3):111-138.

CLINICAL CONTROVERSY

Although PUVA is apparently not responsible for increased incidence of internal malignancy,⁸⁶ the risk-to-benefit considerations

the capability to successfully treat psoriatic plaques with fewer treatments and with a smaller UV radiation dose. Moreover, it may have a lower risk of carcinogenicity and photoaging.^{91,92}

PHARMACOECONOMIC CONSIDERATIONS

Outpatient costs for a patient with mild to moderate psoriasis can run as high as \$4,000 per patient per year. Psoriasis is a chronic disease with patients either requiring treatment or being in remission. Patients with severe psoriasis can be disabled. A patient with early onset of psoriasis can require treatment for more than 50 years.

By effectively controlling psoriasis, costs to patients, lost work days, and health plan costs can be reduced. However, relatively high treatment failure rates are reported for traditional therapies in place before the advent of biologic agent therapies.⁹³ This unmet need will be examined with further placement of biologic agents as established treatment options for moderate to severe psoriasis.

EVALUATION OF THERAPEUTIC OUTCOMES

See Tables 101–2 and 101–3 for pharmaceutical regimens and adverse effects and Fig. 101–1 for treatment algorithm based on severity of psoriasis. Table 101–7 provides evidence basis for selected pharmacotherapeutic approaches to the treatment of psoriasis.⁹⁴ An additional evidence-based review compared the equivalent percent reduction in PASI 75% score after 3 months treatment for most pharmacotherapeutic approaches to psoriasis. Of note, in descending order of efficacy: tar + light > cyclosporine > infliximab > PUVA > methotrexate > adalimumab > acitretin > etanercept > efalizumab > alefacept.⁹⁵ Although this evidence-based ranking is reported by the authors to be a rough (and not necessarily accurate) attempt to assess peer-reviewed publications, it presents an interesting perspective to consider when determining first-line versus second-line therapy.

ABBREVIATIONS

APC: antigen-presenting cell

CD2: cluster of differentiation 2

CD4: cluster of differentiation 4

CD28: cluster of differentiation 28

Fc: fragment, crystallizable (of immunoglobulin)

HLA: human leukocyte antigen

INF- γ : interferon- γ

IgG₁: immunoglobulin G₁

IL-2: interleukin-2

IL-4: interleukin-4

IL-8: interleukin-8

IL-10: interleukin-10

LFA-1: lymphocyte function-associated antigen-1

LFA-3: lymphocyte function-associated antigen-3

LFA-3/TIP: recombinantly engineered LFA-3/Ig G1 human fusion protein

MIG: monokine induced by interferon- γ

MIP-3 α : macrophage inflammatory protein-3 α

NBUVB: narrowband ultraviolet B

NF- κ B: nuclear factor kappa B

NPF-PS: National Psoriasis Foundation Psoriasis Score

PASI: psoriasis area and severity index

PGA: Physician Global Assessment

PUVA: photochemotherapy with oral methoxypsoralen and ultraviolet A light

RANTES: regulated on activation, normal T-cell expressed and secreted

TARC: thymus- and activation-regulated chemokine

TCI: topical calcineurin inhibitor

TH₁: T-helper cell type 1

TH₂: T-helper cells type 2

TNF- α : tumor necrosis factor- α

UVA: ultraviolet A

UVB: ultraviolet B

VEGF: vascular endothelial growth factor

NINA H. CHEIGH

KEY CONCEPTS

- 1 Atopic dermatitis is increasing in prevalence by a two- to three-fold increase, particularly in industrialized countries; with an association with other immunoglobulin E (IgE)-mediated diseases such as allergic rhinitis and asthma.
- 2 Typically starting in infancy, atopic dermatitis can present at any age, although the clinical presentation can differ at varying ages.
- 3 Infants typically have face, trunk, and neck involvement whereas older children and adults present in the antecubital and popliteal fossa, hands, and face.
- 4 Patients with atopic dermatitis are extremely susceptible to potential allergens causing irritations: aeroallergens (dander, grass, mold, pollen), food (eggs, peanuts, soy, milk), detergents and soaps, and chemicals, varying humidities, temperature, and emotional stress.
- 5 Most patients with atopic dermatitis have elevated serum IgE levels, as well as eosinophilia. But, pathogenesis involves this along with a complex process including lymphocytes, macrophages, and mast cells.
- 6 Control of flare-ups includes identification and elimination of trigger allergens, as well as maintaining skin patency.
- 7 Topical corticosteroids and emollients are the mainstay for treatment of atopic dermatitis.
- 8 Topical immunomodulators, tacrolimus and pimecrolimus applied topically, have demonstrated a new option for patients with mild to severe cases of atopic dermatitis.
- 9 In severe, refractory cases, atopic dermatitis can be treated with ultraviolet (UV) radiation, oral corticosteroids, cyclosporine, azathioprine, methotrexate, and interferon- γ .

Atopic dermatitis, a common pervasive inflammatory skin condition, is notorious for creating a vicious cycle of itching and scratching. Chronic, relapsing, itchy and inflamed skin is the trademark symptom of atopic dermatitis (or atopic eczema).¹ This highly itchy skin, described as an itch so unbearable that patients often find that they must scratch until it is replaced by pain, naturally results in scratching. Although the term *atopy* is widely

accepted throughout clinical medicine to describe a person's susceptibility to hay fever, asthma, and atopic dermatitis, there is no precise definition or marker of atopy.² Certainly there is an association among these chronic conditions, as some 80% of children with AD eventually develop allergic rhinitis or asthma, or have some family history of either.^{3,4}

The significant increase in prevalence of atopic dermatitis has been well documented over a wide variety of age groups and geographic locations. Levels of air pollution, industrialization and urbanization, dietary modifications, and higher socioeconomic class are some of the factors that have been attributed to the increase in prevalence. Although approximately one half of the cases are diagnosed by the first year of life, atopic dermatitis typically results in a longer-term condition, as one third of these patients have some form of atopic dermatitis into adulthood.⁵ Prevalence in school-aged children is approaching 17%.⁶ Those with severe symptoms and early onset have a greater likelihood for a more pervasive course of disease.

Many times, atopic dermatitis is not perceived as a major illness and is frequently dismissed as a minor skin condition. However, studies have demonstrated considerable financial, emotional, and social impact on families of those with moderate-severe atopic dermatitis.⁷ An Australian study reported results of significantly more stress in taking care of a child with moderate-severe atopic dermatitis than that of a child with insulin-dependent diabetes.⁸ Disturbed or lack of sleep has also been reported.⁹ In the United States, atopic dermatitis represents some 4% of emergency room visits. The health systems of all countries are burdened with the heavy economic load of direct and indirect costs of treatment and social morbidity.¹⁰

ETIOLOGY

Over the past few decades, there have been significant contributions to researching the cause of this condition. Even so, there is no absolute known cause, as this seems to be a disease of complicated genetic, environmental, and immunologic mechanisms. There is a notable strong hereditary component with atopic dermatitis, such as if one parent has an atopic condition, there is a 60% likelihood that the child will be atopic. If both parents are afflicted, it is possible that the child will have an 80% chance of developing an atopic condition.¹¹ It is also known that there is a stronger influence of paternal atopic dermatitis and asthma as opposed to maternal history. Most patients with atopic dermatitis are found to have elevated eosinophils and serum IgE levels, which supports that 80% of children with atopic dermatitis eventually develop some sort of allergic rhinitis or asthma.

It seems almost every immunocyte, including Langerhans cells, monocytes, macrophages, lymphocytes, mast cells, and keratinocytes, have demonstrated some abnormality in atopic dermatitis.¹²

www.pharmacotherapyonline.com.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Intense itching (pruritus) and skin reactivity are the hallmarks of atopic dermatitis, and it is characterized by episodic flares. Atopic flares are classified as mild, moderate, or severe depending on the degree and severity of those symptoms. Typically, there are three different types of skin lesions associated with atopic dermatitis: acute, subacute and chronic.¹³ The acute rash results in lesions that are intensely pruritic, erythematous papules and vesicles over erythematous skin. These itchy lesions are subsequently associated with scratching that results in excoriations and exudates. Subacute lesions are typically thicker, paler, scaly, erythematous, and excoriated plaques. Chronic lesions are characterized by thickened plaques, accentuated skin markings (lichenification), and fibrotic papules. Most patients exhibit all three lesion types. At all phases, the atopic skin usually has a dry luster to the skin.¹

Atopic dermatitis commonly involves the extensor surfaces of the extremities, trunk, face, scalp, and neck.¹⁴ Although infantile eczema commonly subsides in severity, it often causes the adult to develop a tendency for inflammatory, erythematous, pruritic reactions when exposed to irritants. When atopic dermatitis presents in older children or adults, the lesions are present in the flexural areas of the antecubital and popliteal fossa. Atopic skin is associated with xerosis, which is recognized as a fine scaling, noninflamed skin involving large areas of the body. Atopic skin has a genetic decreased ability for keratinocytes to bind water, thus giving patients with atopic dermatitis dry skin, despite the weather.¹⁵ The atopic epidermis not only triggers pruritus, but also results in an abnormal protective layer, predisposing irritation from allergens.

DIAGNOSIS

Hanifin and colleagues published the first major and minor diagnostic criteria for atopic dermatitis in 1980.¹³ These diagnostic criteria include the presence of pruritus, with three of more of the following:

1. History of flexural dermatitis of the face in children younger than 10 years of age
2. History of asthma or allergic rhinitis in the child or first-degree relative
3. History of generalized xerosis (dry skin) within past year
4. Visible flexural eczema
5. Onset of rash younger than 2 years of age

If diagnosis of atopic dermatitis cannot be made, the presenting symptoms can be indicative of a wide array of other conditions and differential diagnoses, and thus referral to a specialist is warranted.¹⁶ It should be noted that these are working criteria to aid the clinician in proper diagnoses. Although elevated IgE and peripheral eosinophilia are most likely found in atopic dermatitis, there is no one single laboratory test that is used to reliably diagnose atopic dermatitis, as some patients do not present with such abnormalities.¹⁶ Skin prick tests or enzyme-linked immunosorbent assay (ELISA) tests can be used to aid in identification and exclusion of allergic triggers but are not specific or sensitive enough to be diagnostic.

Not only is there a lack of absolute diagnoses or laboratory tests, there also remains a lack of standardization in objective severity scales for the disease. Of the systems available, the Severity Scoring of Atopic Dermatitis (SCORAD) index, adapted by the European Task Force on Atopic Dermatitis¹⁷ was the most often used but also

demonstrated interobserver variation. As such, it was concluded that there is no overall consensus of an objective severity scale, and that further research is warranted.¹⁸

ALLERGEN TRIGGERS

Immunological triggers that contribute to atopic dermatitis development include food allergens and aeroallergens. Serum IgE levels are elevated in most patients with atopic dermatitis. A variety of allergens cause approximately 85% of atopic dermatitis patients to demonstrate an immediately positive skin test of serum IgE antibody.¹ It is important to note, however, that atopic dermatitis is not a purely IgE-type of condition, as this would indicate an immediate hypersensitivity mast-cell mechanism. There is evidence that T-helper type 2 (TH₂) cells are found in atopic individuals, and play an important role in the condition.¹⁹ Studies have demonstrated flaring of atopic dermatitis on exposure to various aeroallergens such as horse dander, grass, and ragweed pollen.¹ Although it is difficult to avoid variation in the performance and evaluation of these types of tests, it is established that patch tests with allergens can result in eczematous reactions.³ The most common household aeroallergens include dust mites, cat dander, and molds. Dust mites, which are a particularly commonly encountered allergen, were reported in more than 45% of American homes in a concentration that exceeded levels needed for sensitization.¹⁹ Even so, there are many simple steps to aid in reducing the amount of dust mites in homes.

Food allergy is also a contributing factor to atopic dermatitis, and generally, the more severe the atopic dermatitis and younger the patient, the more likely food allergy is the culprit to the symptoms.²⁰ Egg, milk, peanut, soy, and wheat are noted to account for almost 90% of food allergy in children with atopic dermatitis.²¹ Even so, it seems that almost a third of the children with atopic dermatitis and food allergies will “outgrow” the allergy over 1 to 3 years.²² But given this, it is essential that patients (parents) are properly instructed on how to read labels for “hidden sources” of allergenic foods. It is recommended that patients be rechallenged at certain times to determine if the food allergy is truly outgrown.²²

Question remains as to whether breast-feeding helps prevent allergy, but for obvious reasons, this cannot be ethically studied. Human breast milk is the most hypoallergenic substance to nourish infants, but there lacks evidence that either prolonged breast-feeding or manipulations of a mother’s diet during lactation protects in the development of atopic dermatitis in infants with family history of atopy.²³ In infants with a strong family history, thus posing them as high risk, there may be a decrease in atopic dermatitis during the first 4 years of life by prolonged breast-feeding (4–6 months), and introduction of solid foods at a later development time (4 months of age).²⁴ Exclusive breast-feeding during the first 3 months of life has also been associated with a lower incidence of atopic dermatitis in childhood.²⁵

In stressful situations, where the patient is frustrated or embarrassed, there is an increased likelihood of itching, sweating, and scratching.¹ Although stress itself does not cause atopic dermatitis per se, it can exacerbate the condition.²⁶ Stress management, relaxation, and behavioral modification can be important.

Knowing that atopic patients are more susceptible to irritants, it is important to identify and eliminate common irritants. Soaps, detergents, abrasive clothing, smoke, and exposure to extremes in temperature and humidity can be aggravating factors. Although UV light can be beneficial to some patients, sunscreens should be used to avoid sunburns, but care should be used in selection as many chemical sunscreens can cause contact dermatitis. In addition, as modernization and “Westernization” occurs, people spend the majority of their time in modern buildings with reduced ventila-

tion. This has resulted in an increased load of chemical vapors and gasses, and indoor house dust mites and mold.²⁴

COMPLICATIONS

Atopic skin also has a predisposition for increased microbial organisms, namely *Staphylococcus aureus*, which is found in more than 90% of atopic dermatitis skin lesions.¹³ Bacteria can secrete toxins, which bind to a high number of T cells and can lead to erythroderma and acute inflammatory processes of the skin. Although short courses of antistaphylococcal antibiotics or topical therapy is appropriate, colonization with resistant organisms is possible.⁶ Patients with atopic dermatitis are also more prone to herpes simplex infections than in the general population.²⁷ Patients respond well to oral antiviral therapy with acyclovir or valacyclovir. But it is important for the clinician to maintain therapy of the atopic dermatitis lesions while treating the herpes infection.⁶ In addition, fungal pathogens, particularly *Malassezia furfur* or *Pityrosporum ovale*, have been identified. Antifungals such as ketoconazole and itraconazole seem to work well as there is additional antiinflammatory effect as well.⁶

Patients with atopic dermatitis can also present with eyelid dermatitis, nipple dermatitis, and cheilitis of the lips. Eyelid dermatitis and chronic blepharitis are commonly associated with atopic dermatitis and can result in visual impairment from corneal scarring. Other ocular complications include atopic keratoconjunctivitis, vernal conjunctivitis, and keratoconus.¹

TREATMENT

Atopic Dermatitis

Currently, there is no 100% cure for atopic dermatitis. As such, this condition requires a management plan, including identification and avoidance of external triggers, maintenance of skin patency, and various therapeutic options for symptomatic relief. Therapy should be individualized, and a multipronged approach should be initiated. Reduction of symptoms, prevention of recurrent flares, and attempting to modify the course of the disease, while minimizing exposure to potential toxicity of the drugs is the long-term management indicated for atopic dermatitis (Fig. 102–1).

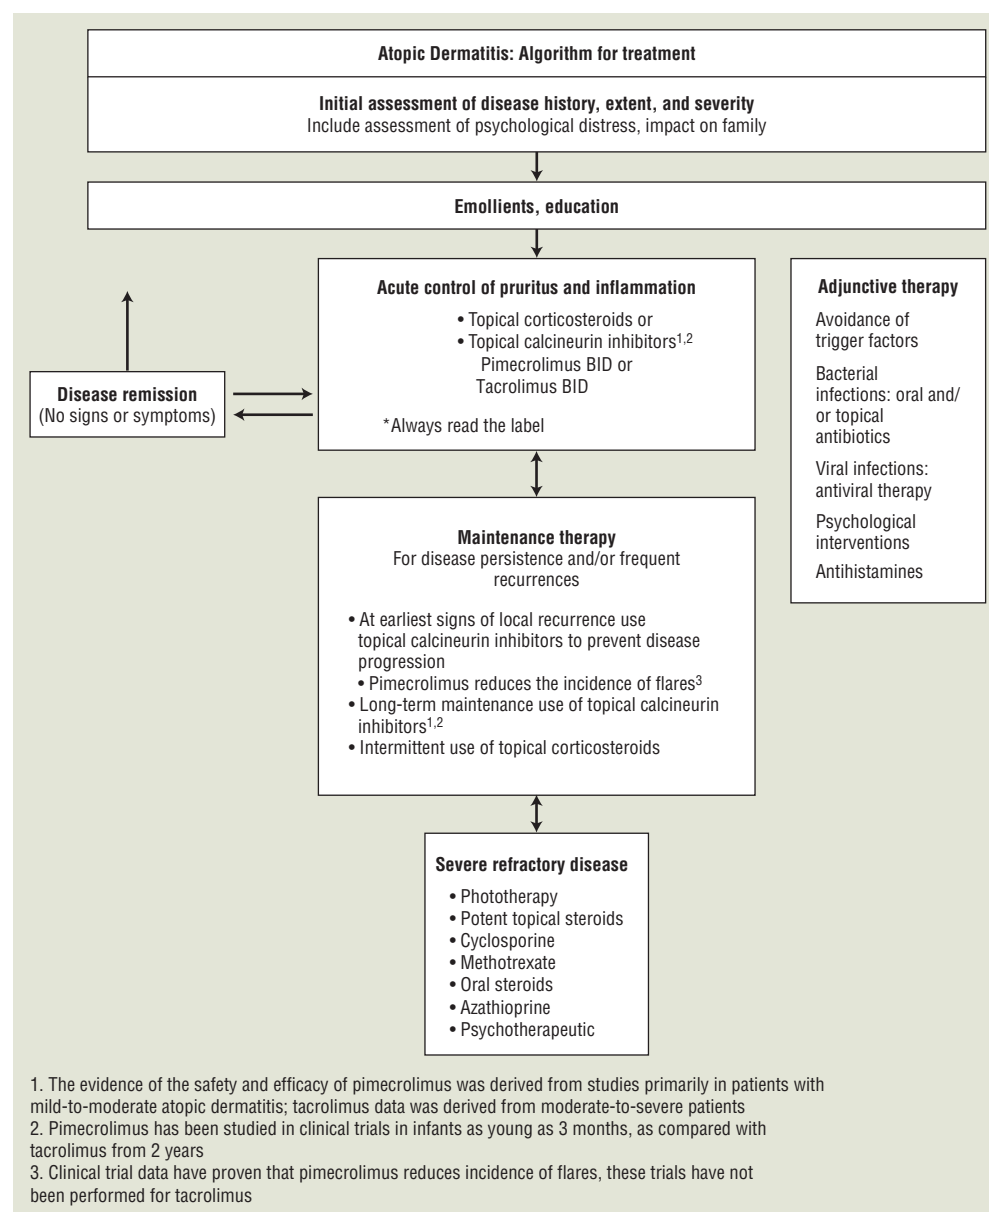

FIGURE 102-1. Treatment of atopic dermatitis. (bid, twice daily.)

■ NONPHARMACOLOGIC

Given that patients with atopic dermatitis are more susceptible to irritants than normal individuals, it is important to identify possible aggravating factors that can trigger a flare-up. Recommendations can include avoiding extraneous perfumed or dyed soaps and detergents, using a second rinse cycle for laundry, avoiding extremes of temperature fluctuations, and otherwise being cognizant of potential allergens. Sunscreens should be used in patients with atopic dermatitis, but judicious use of nonchemical agents (physical sunscreens such as titanium or zinc-oxide containing products) are probably less likely to cause further irritation or contact dermatitis.¹

The epidermis of atopic skin has been shown to have a reduced capability of holding moisture. This inherent dry skin is also exacerbated by external changes including weather changes and other allergen exposures. Thus, the importance of maintaining proper skin patency cannot be overstressed, as slight irritations to atopic skin can result in microfissures, which act as a portal of entry for various pathogens.¹⁶ Simple, nonpharmacologic and preventive measure should be recommended for all patients with atopic dermatitis. Skin hydration is a key component to atopic disease management. Lotions can worsen xerosis whereas thick creams (e.g., Cetaphil, Eucerin) or ointments (e.g., Aquaphor, petroleum jelly) are better at protecting against dryness. Although there is some controversy with showering versus bathing, the most important factor is immediate application of the emollient after cleansing. Avoidance of extraneous fragrances, dyes, and preservatives, as well as understanding a potential role of excipient contact allergy is also of importance in emollient selection (Table 102–1).

■ PHARMACOLOGIC
Topical Corticosteroids

Topical corticosteroids have been the standard in treating the inflammation and pruritus related to atopic dermatitis. Typically, they are used in short-term reactive treatment of acute flare-ups but must still be supplemented with emollient use. Clinicians unfamiliar with topical corticosteroids find them a challenge to use because of the numerous types, strengths, generic versus brand, formulations, and when and where to use the product. The corticosteroids are ranked according to potency dependent on vasoconstrictor assays. Various drug references will list these according to various classifications. Most commonly, the highest potency steroids are used for short periods of time (generally less than 3 weeks) for acute flare-ups of atopic dermatitis, or for lichenified (thickened) lesions. Because of their potential adverse effects, these steroids should not be used on the face, mucous membranes, eyelids, or skin-fold areas.¹⁶ The moderate-strength steroids can be used for more chronic atopic

TABLE 102-1 Nonpharmacologic Management of Atopic Dermatitis

- Identify and eliminate potential allergens
- Reduce frequency of bathing; bathe every other day
- Use tepid water in baths
- Avoid irritating soaps (dyes, fragrances, and preservatives can all contribute to further exacerbations)
- Avoid washcloths or irritating scrubs
- Air dry skin and gently pat dry
- Apply emollient (preferably an ointment or cream, again watching for dyes, fragrances, and preservatives) within 3 minutes after bathing
- Keep fingernails short and clean to prevent scratching
- Consider cotton gloves to prevent scratching at night
- Use cotton sheets and pajamas
- Avoid harsh laundry detergents (some contain allergens)
- Moisturize as often as necessary to keep skin soft and pliable (at least twice a day)

dermatitis, typically on the trunk or extremities. Low potency steroids are typically used in children.

The vehicle in which the steroid is based is also of importance. As in emollients, the ointments are far better at occluding the epidermis, and thus results in enhanced percutaneous absorption of the corticosteroid compared to the same strength cream. This can be a better choice for a lichenified lesion, or if an acute flare-up is being treated as the enhanced occlusion will result in better absorption.¹⁶ Other methods of occlusion, such as use of Saran wrap, tight-fitting clothes, or diapers can also increase the absorption significantly.²⁸ This may or may not give the desired effect that the clinician expects, and thus he or she should be aware of this potential. The vehicle can also be chosen based on the area of the body. For example, if application should occur in hairy areas such as scalp or beard, a solution or gel can be more aesthetically pleasing. These are important considerations when recommending a corticosteroid, or when counseling a patient on its appropriate use.

Typically, most corticosteroids are applied once to multiple times daily although there is no clear benefit with more than a once daily application.²⁹ Should the steroid be used in conjunction with other topical agents, including moisturizers, it is important that the corticosteroid be applied first, rubbed in well, followed by the other product. In dispensing a corticosteroid, a good rule of thumb would be that approximately 30 gm of cream or ointment can cover the average-sized adult once. Thus, if treatment needs to be twice daily to the entire body for 2 weeks, the average adult will go through nearly 1 kg (2 lb) of topical corticosteroid. Failure to respond to topical corticosteroid use is sometimes simply caused by inadequate supply.¹

Concerns of adverse effects from the steroids have resulted in restrictions of its use on certain anatomical areas and use in children. Both healthcare providers' and patients' lack of confidence in the safety of topical corticosteroid use has resulted in both nonadherence and undertreatment.¹⁶ Potential for adverse effects is dependent on a variety of factors. The concentration applied, the amount applied, how often applied, and for how long applied can be important factors to consider for the development of adverse effects. Long-term topical corticosteroid use primarily results in cutaneous abnormalities such as skin atrophy, striae, hypopigmentation, and steroid-induced acne. Systemic effects, namely, hypothalamic-pituitary-adrenal (HPA) axis suppression, growth retardation, and other adrenal abnormalities have been reported and thus have resulted in limiting topical steroid use in children (Table 102–2).^{5,16}

Antihistamines

As atopic dermatitis results in pruritus, antihistamines are used to attempt to break the “scratch–itch cycle.” Despite frequent use there are few clinical studies that support its efficacy, and this is likely because all pruritus is not histamine mediated.^{1,16} Mediators such as neuropeptides and cytokines have demonstrated importance in the itch related to atopic dermatitis.⁶ Because pruritus is worse at night,

TABLE 102-2 Topical Corticosteroid Use in Atopic Dermatitis

- Potency of the steroid depends on the vasoconstrictive properties*
- Typically, with high-potency steroids:
 - Use no longer than 3 weeks
 - Use on thickened lesions
 - Not for use on face, skinfolds, or mucous membranes
- The vehicle is as important as the steroid concentration*
- Occlusives can increase percutaneous absorption
 - Ointments are stronger than creams, which are stronger than lotions
 - Gels can be beneficial for hairy or oily areas
- Use with moisturizers*
- Apply corticosteroid first
 - The goal is to increase moisturizers while decreasing corticosteroid use

the sedating antihistamines (i.e., hydroxyzine or diphenhydramine), can offer an advantage by facilitating sleep, whereas the newer nonsedating antihistamines have shown variable results. A tricyclic antidepressant, doxepin, which inhibits both H_1 and H_2 receptors, has also been used in doses of 10 to 75 mg at night, and up to 75 mg twice daily in adults. This can be beneficial in those atopic patients who have some depression as well.^{1,16,30} Topical antihistamines, such as doxepin 5% cream or diphenhydramine cream, also have demonstrated neutral results but are generally not recommended because of high cutaneous sensitization from its excipient ingredients.^{6,16}

Topical Immunomodulators

Topical calcineurin inhibitors, such as tacrolimus and pimecrolimus, offer a more long-term option, as they can be used on all body locations for prolonged periods without fear of corticosteroid-induced adverse effects. As skin atrophy is a main concern for long-term use of topical corticosteroids, the atrophogenic potential of tacrolimus and pimecrolimus were evaluated in healthy volunteers. Data indicate the potential for longer term use without fear of skin atrophy.^{31,32} These agents form a complex that results in inhibition of calcineurin, which normally initiates T-cell activation. Through inhibition, the complex subdues the inflammatory component of atopic dermatitis.³³ Although both of the structures are similar, topical pimecrolimus has been shown to be more lipophilic than topical tacrolimus, thus resulting in reduced cutaneous penetration.^{33,34}

A number of studies have demonstrated the short-term and long-term effectiveness of topical tacrolimus 0.03% and 0.1% ointment in atopic dermatitis for children and adults.³³ When used twice daily, the patients reported a significant reduction in pruritus, clearance of lesions, and otherwise increased quality of life. Current FDA approvals indicate the 0.03% or 0.1% ointment for moderate to severe atopic dermatitis in adults, and 0.03% ointment for atopic dermatitis in children aged 2 to 15 years.³³ Topical tacrolimus is indicated for second-line therapy for short-term and noncontinuous therapy of moderate-severe atopic dermatitis who have failed other therapies. Several studies in children and adults have demonstrated reduction of frequency of atopic dermatitis flares and symptoms by tacrolimus ointment.³⁵⁻⁴⁰ A head to head comparison found comparable efficacy of tacrolimus 0.1% ointment to topical hydrocortisone butyrate 0.1%, a midpotency corticosteroid.⁴¹

The safety of topical tacrolimus has been evaluated with the most common complaints being transient itching or burning at the site of application. Although there are no data to support this, many clinicians recommend pretreatment with topical corticosteroids to wave off the tacrolimus induced burning and erythema. There are systemic adverse effects of tacrolimus that have been well documented but have not been observed in patients using the topical ointment for atopic dermatitis.⁴² Patients who receive long-term systemic immunosuppressants are prone to developing actinic keratoses, viral warts, and nonmelanoma skin cancers. The FDA issued a black box warning for long-term use of tacrolimus and pimecrolimus acknowledging that there is no direct causal evidence of skin cancers and the use of topical calcineurin inhibitors. Long-term studies are in progress.⁴³

Topical pimecrolimus 1% cream has also been demonstrated to be safe and effective in long-term atopic dermatitis.³³ Multicenter, randomized, double-blind trials in infants and children found that flare-ups were prevented, as well as a reduction in disease severity overall.⁴⁴ Even those who did require the steroids for flare-ups, it was found that the duration of steroid use was significantly shorter, which support using pimecrolimus as a first-line therapy.^{45,46} Pharmacokinetic studies have evaluated the systemic concentration of pimecrolimus absorbed in children. These studies conclude that pimecrolimus is well tolerated locally, and systemic effects were not seen.⁴⁷

Although no comparable data exist, it appears that tacrolimus can be more effective in clearing severe cases of atopic dermatitis than

TABLE 102-3 Topical Immunomodulator Use in Atopic Dermatitis

- Tacrolimus (Protopic) 0.1% ointment: for moderate to severe AD in adults not responding adequately to other therapies
- Tacrolimus 0.03% ointment: for moderate to severe AD in children older than 2 years of age
- Pimecrolimus (Elidel) 1% cream: for mild to moderate AD in children and adults (it has been studied in infants as young as 3 months of age)
 - Apply twice daily
 - Can be used for longer term
 - Can result in reduction in flare-ups

AD, atopic dermatitis.

pimecrolimus.³³ There are no direct comparative data as of yet, but there seems to be increased transient local burning with topical tacrolimus, possibly because of a higher immunosuppressant activity. A recent 2-year study of infants who were treated with pimecrolimus 1% cream at the first signs and symptoms of atopic dermatitis flares found progressive reduction in pimecrolimus use, supporting early intervention.⁴⁸ Corticosteroids and pimecrolimus cream were evaluated in infants and children 3 months to 11 years of age with mild to severe atopic dermatitis. Pimecrolimus was applied at the first signs of flare, and if the dermatitis was not controlled, a mid-potency steroid was applied in replacement of the evening cream. This was the first study to evaluate efficacy and safety of combined use, and it found that this was an effective steroid-sparing option to treating atopic dermatitis (Table 102-3).⁴⁹

Tar Preparations

Coal tar preparations demonstrated antipruritic and antiinflammatory properties on the skin.¹ Coal tar has been used in combination with topical corticosteroids, as an adjunct to reduce the strength of a corticosteroid, and in conjunction with UV light therapies. These preparations are available as crude coal tar (1%–3%), or liquor carbonis detergens (LCD) (5%–20%). At times, coal tar can be compounded by pharmacists into various concentrations, or even in conjunction with topical corticosteroids. Coal tar preparations should not be used on acute oozing lesions, as this would result in stinging and irritation.⁵⁰ The strong odor and staining of clothing is typically a limiting factor to its use. Thus, patients can be instructed to use the product at bedtime and rinse it off in the morning. In addition, folliculitis and photosensitivity have also been reported.

REFRACTORY THERAPIES

Wet Dressings and Occlusion

Cool wet dressings or total body wraps placed directly onto the skin can be effective in relieving itch, particularly at night. Wet wraps used in conjunction with topical corticosteroids can be used for acute flares, or those with chronic, lichenified lesions.⁵⁰ Skin maceration, fissures, and subsequent infections can occur, and thus these occlusive dressings should be limited to severe, chronic lesions. Tepid compresses applied to skin for 20 minutes four to six times daily can aid in drying out the oozing lesions.

Ultraviolet Light

Ultraviolet light can have phototherapeutic benefits to patients with severe atopic dermatitis. Although natural sunlight can be a source, ensuring that the sunlight is not associated with high heat or humidity (which can exacerbate the condition further) is difficult. Thus, short-wave ultraviolet B (UVB) therapies can be useful as adjunctive therapy in chronic, recalcitrant atopic dermatitis.⁵¹ At times, higher intensity ultraviolet A (UVA) therapy has been therapeutic in acute exacerbations, and the mechanism indicates that eosinophils and epidermal Langerhans cells may be targets for high-

intensity UVA.⁵² Photochemotherapy with oral methoxypsoralen therapy followed by UVA (PUVA) can be indicated in severe, widespread atopic dermatitis, particularly in corticosteroid failure.⁵³ Adverse effects, such as erythema and pigmentation, to premature photoaging and cutaneous malignancies are possible, and thus caution should be used in determining the risks versus benefit.

■ SYSTEMIC IMMUNOSUPPRESSANTS

If aggressive topical therapy, or phototherapy fail to control atopic dermatitis symptoms, the systemic immunosuppressant agents can play a role. Given that atopic dermatitis is a T-cell mediated disease with involvement from Langerhans cells, eosinophils, and mast cells, it is logical to consider the use of immunosuppressant agents. However, because of the possible adverse effects associated with these agents, judicious use of systemic immunosuppressants in severe, recalcitrant, or widespread disease is warranted.⁵⁴

Systemic Corticosteroids

Oral corticosteroids, such as prednisone, can be indicated in the treatment of severe chronic atopic dermatitis.^{1,6} Typically, a short course (e.g., prednisone 40–60 mg/day for 3–4 days, then 20–30 mg/day for 3–4 days) can be used to control a severe flare. Proper tapering is necessary, as its misuse has resulted in dramatic improvement of symptoms followed by a significant rebound flare on discontinuation of the medication.¹⁶ Long-term use can cause the known adverse effects of systemic corticosteroids, such as hypertension, growth and developmental issues, or cushingoid features. Thus, use of the agents, particularly in children, should be limited to rare, severe conditions.⁵⁴ Concomitant and proper use of intensified skin care, particularly of topical corticosteroid and emollient use during the therapy is also of utmost importance.

Cyclosporine

Although cyclosporine is currently approved by the FDA for use in psoriasis, it has been effective in treating many skin diseases.⁵⁴ Similar to systemic corticosteroids, rebound flare-ups of atopic dermatitis are possible with cyclosporine use. Oral cyclosporine can be used on a short-term basis for severe, recalcitrant disease in adults at a dose of 5 mg/kg/day.^{54,55} Children with recalcitrant disease can be started at a lower dose of 3 mg/kg/day, with caution. Tolerability in children is good, and most common adverse effects are limited to abdominal pain and headaches.⁵⁶ In one study of adults, 150 mg/day was effective compared to 300 mg/day in the short term with better renal tolerance.⁵⁷ Short courses of 5 mg/kg/day for 12 weeks also have been successful in treating atopic dermatitis.⁵⁸ Adverse effects, such as renal toxicity, have been shown to be mild and reversible in a long-term multicenter study evaluating safety for cyclosporine use in adults.⁵⁶ Even so, appropriate monitoring parameters, namely electrolytes, renal function, complete blood counts, fasting lipid profiles, and uric acid levels, should be measured at the baseline and reviewed. Cyclosporine also has a large propensity for drug–drug interactions, and careful monitoring is required.

Azathioprine

Azathioprine, a purine analog, is another systemic immunosuppressant that can be helpful in severe atopic dermatitis. The main disadvantage as compared to cyclosporine is its delayed onset of action of 4 to 6 weeks. Most of the reports of azathioprine use has been in uncontrolled, open, and retrospective trials. Thus, it is difficult to determine a dosing regimen, as no consistent regimen was evaluated. Despite the numerous adverse effects including myelosuppression, hepatotoxicity, gastrointestinal disturbances, among others, there is evidence that azathioprine can be helpful in reduction of atopic dermatitis disease activity.⁵⁴

Antimetabolites

Mycophenolate mofetil (MMF), an immunosuppressant used in organ transplant, has demonstrated clearing of atopic dermatitis resistant to other therapies in short-term, open-label studies.¹ As dose finding and well-controlled studies are not available for MMF use in atopic dermatitis, it should be used with caution, and discontinued if the patient does not respond within 4 to 8 weeks of therapy.^{1,54}

Methotrexate, an antimetabolite, is a folic acid antagonist primarily used as an antineoplastic agent and in the treatment of psoriasis. Although there are no controlled studies examining its use specifically for atopic dermatitis, there is anecdotal evidence on its effectiveness at a dosage of 2.5 mg per day given four times a week.^{1,54} Because of its myelosuppressive effects, patients' hematologic parameters should be closely monitored. Other adverse effects can include hepatotoxicity, pulmonary toxicity, and gastrointestinal toxicity. Folic acid supplementation should also be instituted.

Interferon- γ

Interferon- γ , which is a known inhibitor of TH₂ cells, was considered a logical choice in suppressing the IgE responses in atopic dermatitis. Several multicenter, double-blind, placebo-controlled trials have demonstrated clinical improvement with its use in atopic dermatitis.^{1,54} Interferon injections are expensive and can be associated with flulike symptoms such as fever, chills, headache, myalgia, arthralgia, nausea, vomiting, and diarrhea. Further controlled studies are warranted before its routine use for atopic dermatitis patients.

CLINICAL CONTROVERSY

Atopic dermatitis and contact dermatitis (both the irritant and allergic types) are eczematous diseases with similar pathologies. Although atopic dermatitis, unlike contact dermatitis, maintains an important genetic component, there is now evidence that these diseases may be more related to each other. Consensus currently is that atopic and acute contact dermatitis are both immune mediated, and atopic dermatitis increases one's susceptibility to irritant contact dermatitis. More investigations are needed, but understanding the possible links between atopic dermatitis and contact dermatitis can aid clinicians in understanding the pathophysiology, diagnosis, and treatment of patients who are ailing from these diseases.⁵⁹

EVALUATION OF THERAPEUTIC OUTCOMES

The overall goal for managing patients with atopic dermatitis is to control the condition by preventing flare-ups and overall produce a better quality of life without complications. It is important for a patient with atopic dermatitis to consult with a healthcare practitioner in helping to identify and eliminate trigger factors and allergens and to communicate regarding nonpharmacologic management of the disease. All patients with atopic dermatitis should be counseled on the importance of emollient use and other measures for proper skin care.

Depending on the severity of the disease, some patients might warrant a need for low strength topical corticosteroids for maintenance use.

CONCLUSIONS

Management should include controlling “flare-ups,” allergen avoidance, proper bathing and skin hydration, and control of humidity. Currently, topical corticosteroids remain as the mainstay for treat-

ment of flare-ups associated with atopic dermatitis. But, a recent study showed that 73% of patients worried about using topical corticosteroids for fear of adverse effects. Twenty-four percent were concerned enough that they were nonadherent with the corticosteroid use.⁶⁰

ABBREVIATIONS

ELISA: enzyme-linked immunoabsorbent assay

HLA: hypothalamic-pituitary-adrenal

IgE: immunoglobulin E

LCD: liquor carbonis detergens

SECTION 15

HEMATOLOGIC DISORDERS

CHAPTER

103

Hematopoiesis

WILLIAM P. PETROS AND MICHAEL CRAIG

KEY CONCEPTS

- 1 Leukocytes are subdivided into specific cell types that have important functional differences.
- 2 All hematopoietic cells are thought to be generated from one common type of cell (stem cell).
- 3 Blood concentrations of some hematopoietic cell types may not be reflective of total body content.
- 4 Cytokines such as colony-stimulating factors are important regulators of hematopoiesis.
- 5 The kinetics of hematopoietic cells vary with cell type, maturity, pathophysiology, and external stimuli.
- 6 Both the number of cells and other cofactors determine the clinical consequences of neutropenia or anemia.

Hematopoiesis is defined as the formation and maturation of blood cells and their derivatives. This process is important to a wide array of physiologic functions such as hemostasis, immunity, and oxygen delivery. There is a tremendous daily turnover rate of cells in this system, with more than 6 billion cells produced per kilogram of body weight every 24 hours.¹ These accelerated processes result in vastly exaggerated and rapid responses to the slightest perturbation.

In humans, hematopoiesis takes place primarily in the bone marrow. Hematopoietic cells were among the first to be evaluated for their biologic function and pattern of maturation, and identification of the protein molecules (cytokines) that regulate this system has yielded an extraordinary amount of information regarding its control. The process of continual hematopoietic cell production is complicated, involving interactions between immature cells, the surrounding microenvironment, and cytokines.

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

HEMATOPOIETIC SYSTEM

The hematopoietic system consists of three primary cell components: leukocytes, platelets, and erythrocytes. The first group encompasses a functionally diverse group of cells that includes neutrophils, eosinophils, basophils, monocytes/macrophages, lymphocytes, and plasma cells. Typical concentrations of mature hematopoietic cells found in the peripheral blood of adults are shown in Table 103–1.

LEUKOCYTES

Neutrophils (Segs and Bands)

1 The major functions of neutrophils (also known as polymorphonuclear leukocytes) are to prevent pathogenic microorganism invasion and to localize and kill these microorganisms if they do invade the body. These effects are mediated by a series of events, including migration to the site (chemotaxis), recognition/attachment to the invader, phagocytosis, lysosomal fusion, degranulation, and local generation of oxidants (respiratory burst) and degrading enzymes (Fig. 103–1).² A neutrophil is attracted to the site of infection by chemotactic factors. Once migration to the site has occurred, the neutrophil ingests the opsonized microorganism. Opsonization is the process whereby antibody and complement coat the microorganism, allowing for increased neutrophil recognition. Following ingestion or phagocytosis, the cytoplasmic granules within the neutrophil fuse with the phagosome or phagocytosed microorganism, thereby initiating degranulation and release of enzymes. These degrading enzymes kill the microorganism through oxygen reduction. Secretion of these enzymes can also result in localized host tissue injury. The actions of cytokines such as granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF) may intensify neutrophil activity.³

Eosinophils

Although eosinophils are less efficient than neutrophils, they elicit similar effector functions. Eosinophil activity is directed primarily against large invaders, such as helminths and other parasites that cannot be phagocytized. During an allergic reaction, activated mast cells secrete chemicals that attract and stimulate eosinophils, which in turn produce substances that neutralize or degrade the reaction

TABLE 103-1 Average (Normal Range) Adult Blood Cell Concentration			
White cell count (cells/mm ³)			
Red cell count (× 10 ⁶ /mm ³)	Male	5.21	(4.52–5.90)
	Female	4.60	(4.10–5.10)
Hemoglobin ^a (g/dL)	Male	15.7	(14.0–17.5)
	Female	13.8	(12.3–15.3)
Hematocrit	Male	0.46	(0.42–0.50)
	Female	0.40	(0.36–0.45)
Mean corpuscular volume (fL/red cell)			
Platelet count (cells/mm ³)			
		88.0	(80.0–96.1)
		311,000	(172,000–450,000)

^aCan be 0.5–1.0 g/dL lower in black patients.

products of mast cells. Unfortunately, the eosinophil constituents can also damage normal tissue and cause secondary histamine release. High concentrations of eosinophils for prolonged periods can result in damage to the cardiac and central nervous systems, with possible pulmonary and dermatologic involvement.⁴

Basophils and Mast Cells

Through a massive release of their granule contents on stimulation, basophils and mast cells function as mediators of inflammatory processes. The released chemicals include heparin, histamine, and other substances. The mediator can be vasoactive, bronchoconstrictive, and/or chemotactic (attractive) for eosinophils.^{5,6}

Monocytes/Macrophages

Derived from the granulocyte-monocyte colony-forming unit, monocytes are peripheral cells in transit from the bone marrow to

tissues. Once in the tissues, under the influence of local factors, monocytes become macrophages. Macrophages exist in the liver (Kupffer cells), spleen, lymph nodes, microglial (CNS) cells, skin (Langerhans cells), and bone (osteoclasts).

Monocytes and macrophages perform a variety of functions, including initiation of immune responses for recognition by lymphocytes, regulation of immune response intensity, phagocytosis of foreign invaders, tumor cytotoxicity, degradation of cellular debris, and secretion of peptide molecules called *monokines* (a subclassification of cytokines).⁷ Examples of monokines include interferons, tumor necrosis factor, and interleukin-1 (IL-1). Monokines and other cytokines regulate the activity of these cells.

Lymphocytes

The primary functions of lymphocytes are to control and be the effector cells for the immune system. Many of these cells also are important synthetic sites for various cytokines. Lymphocytes can be functionally divided into cells that display cell-mediated immunity (T cells) and those that are responsible for humoral immunity (B cells) (Table 103–2). Several different T-cell subtypes are found in peripheral blood. These include the cytotoxic suppressor T cells (CD8), which attack intracellular pathogens and regulate the size and duration of the immune response, as well as helper T-cells (CD4). The latter cells are responsible for delayed hypersensitivity, stimulation of B-cell differentiation (maturation), and antibody production, in addition to regulation of inflammatory reactions. B lymphocytes ultimately become plasma cells, which produce immunoglobulin specific for an antigen attached to the cell’s surface.

Null cells are a separate subset of lymphocytes that lack surface markers of B or T origin. These cells, also referred to as large granular

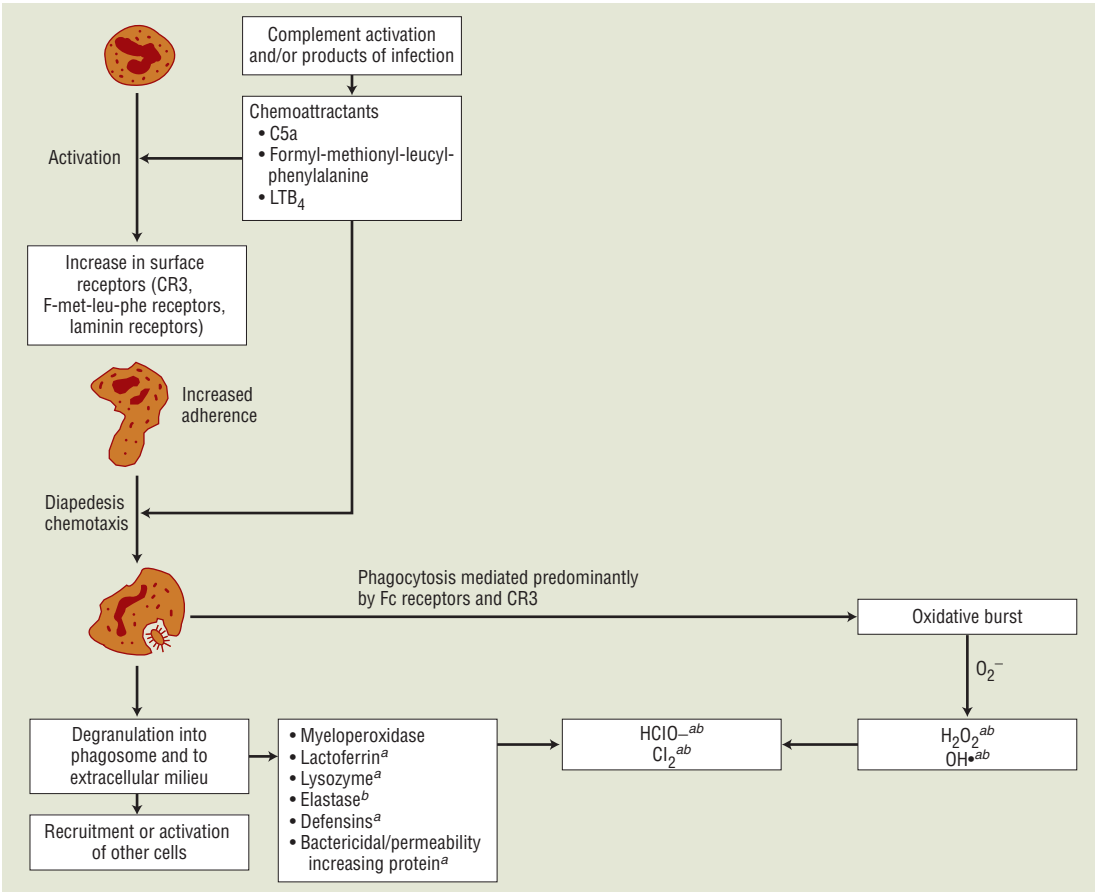

FIGURE 103-1. Neutrophil responses to infection or inflammation. ^aMicrobicidal. ^bDamage to host tissues. (CR3, complement receptor type 3; C5a, complement 5a; Fc, crystallizable fragment of immunoglobulin; H₂O₂, hydrogen peroxide; LTB₄, leukotriene B₄; O₂⁻, oxygen.)

TABLE 103-2 Lymphocyte-Mediated Immune Function**Cellular immunity (T cells)**

1. Provides resistance against intracellular pathogens such as viruses, protozoa, fungi, and bacteria
2. Mediates allogeneic transplant rejection and graft-versus-host disease
3. Responsible for contact dermatitis
4. Mediates adoptive immunotherapy

Humoral immunity (B cells)

1. Serves as major component of allergic reactions and other autoimmune diseases
2. Aids in eradication of encapsulated bacteria
3. Inactivates circulating toxins
4. Can play role in antitumor reactions

lymphocytes, are thought to perform functions such as direct cytotoxicity to foreign entities, and they act either alone (natural killer cells) or in concert with immunoglobulin (antibody-dependent cellular cytotoxicity).^{8,9} (Further details regarding lymphocytes are found in Chap. 89.)

PLATELETS

There are several mechanisms by which platelets (thrombocytes) interact to facilitate blood coagulation. These include localization of the thrombus and provision of a specific receptor site for clotting factors, as well as the necessary phospholipid surface for the conversion of prothrombin to thrombin, and protection of thrombin from antithrombin. The process begins with a vascular injury that causes platelets to adhere to the exposed collagen fibers of the damaged wall as blood flows out. These events require the presence of other plasma proteins, namely von Willebrand factor. Platelets then aggregate through a process that is calcium dependent. Following aggregation, various platelet mediators are released (thromboxane, serotonin, and platelet factor V), resulting in the formation of an irreversible platelet aggregate with subsequent formation of a stable fibrin cross-linked clot.^{10,11}

ERYTHROCYTES

The primary function of the erythrocyte is to carry oxygen from the lungs to the peripheral tissues. Its optimal design enables efficient oxygen transport via the hemoglobin molecule. The general metabolic state of the patient and local factors control oxygen release.

Some drugs selectively accumulate in erythrocytes, resulting in substantial differences when comparing blood to plasma drug concentrations. In a few instances, enzymes found in erythrocytes (e.g., aldehyde dehydrogenase) can impact on the systemic metabolism of drugs.

HEMATOPOIETIC STRUCTURE AND COMPARTMENTS

Embryonic development of hematopoietic tissue occurs in the yolk sac mesenchyme, with fetal transition occurring in the liver and spleen. Very immature hematopoietic cells can also appear in umbilical cord blood, but not many are evident in the peripheral blood of adults.¹² The ultimate location of immature hematopoietic cells is in the bone marrow. The average adult has approximately 1.7 L of bone marrow, which provides an optimal environment for the development and proliferation of hematopoietic cells.

The hematopoietic bone marrow is located primarily in the central portion of the pelvis, ribs, vertebrae, skull, and femoral and humeral epiphyses. The anatomic structure of the bone marrow is characterized by the central venous marrow sinus, which is linked by coarse vascular sinusoids that intertwine a reticulin mesh where the cells are suspended.

Thus hematopoiesis occurs in the extravascular marrow spaces, which also contain endothelial cells, fibroblasts, macrophages, and adipocytes, collectively termed *bone marrow stroma*.¹³ Stromal cells are thought to be important hematopoietic components, providing growth factors, collagen, and cell-adhesion proteins.¹⁴ When these cells are combined with accessory cells (lymphocytes/monocytes) and cytokines, the mixture is referred to as the *hematopoietic microenvironment*.

Egress of more mature cells from the bone marrow occurs through the endothelial cell barrier. Release of cells such as neutrophils can be stimulated by complement, steroids, or endotoxin. Immature (progenitor) cells that can ultimately become any one of the blood cellular components can be mobilized from the bone marrow into peripheral blood by the administration of a cytotoxic chemotherapy drug (e.g., cyclophosphamide)¹⁵ or a colony-stimulating factor (G-CSF or GM-CSF).¹⁶ This process is commonly referred to as *priming* the bone marrow for peripheral blood progenitor or stem cell transplantation (see Chap. 142).

② The least mature hematopoietic cell, accounting for only a small fraction of a percentage of bone marrow cells, is referred to as the *stem cell*. Because these cells have the unique potential to ultimately become any of the mature hematopoietic cells, they are termed *pluripotent*. Importantly, they have self-renewal capacity (Fig. 103-2).¹⁷ Extensive research has been conducted describing the morphologic and immunologic characteristics indicative of the earliest stem cell, but investigators have yet to arrive at a consensus model. Only a small percentage of these cells are likely to be dividing at any one time, and thus most are dormant in the cell cycle.

Stem cell renewal and differentiation occur within the bone marrow under the influence of the marrow microenvironment. The stromal compartment is divided into mesenchymal stem cells (producing osteoblasts, adipocytes and fibroblasts); hematopoietic monocytes-macrophages/osteoclasts; and endothelial-like cells. All of these stromal cells are necessary to support stem cell proliferation and division by providing anchorage for adhesion and secreting various hematopoietic growth factors necessary for differentiation. The characteristics of the local microenvironment (cellular matrix and growth factor concentrations) influence the differentiation of a particular hematopoietic lineage, favoring it over another.

The next step in hematopoietic cell differentiation is thought to be represented by committed pluripotent stem cells that can still differentiate into any cell line (red blood cells [RBCs], white blood cells [WBCs], and platelets); however, they have a limited capacity for self-renewal (see Fig. 103-2).

Cells that differentiate can proceed to either myeloid or lymphoid cell precursors (oligopotent progenitors). These cells can ultimately become B or T lymphocytes in the case of lymphoid cells. Myeloid progenitors can become granulocytes, erythrocytes, monocytes, or megakaryocytes, as displayed in Fig. 103-2. Nomenclature for immature hematopoietic cells often uses terms developed during in vitro experiments of cell proliferation. Thus the term *burst-forming unit* (BFU) or *colony-forming unit* (CFU) is added to the suffix of the cell lines ultimately produced by the specific cell.

Leukocytes found in the peripheral blood can generally be classified into neutrophils (the most frequently occurring blood leukocyte, subdivided into the more mature segs and less mature bands), lymphocytes, monocytes, eosinophils, basophils, and the tissue derivative of basophils, mast cells. Immature neutrophils such as metamyelocytes are rarely seen in peripheral blood. Strictly speaking, the group of cells referred to as granulocytes includes neutrophils, eosinophils, and basophils, although common use tends to include only the neutrophils. The terminally differentiated leukocytes, which are usually not seen in blood, include the macrophage or histiocyte (derived from monocytes) and plasma cells (derived from B lymphocytes).

③ Most of the body's neutrophils and neutrophilic precursors reside in the bone marrow (approximately 9 billion cells) in contrast

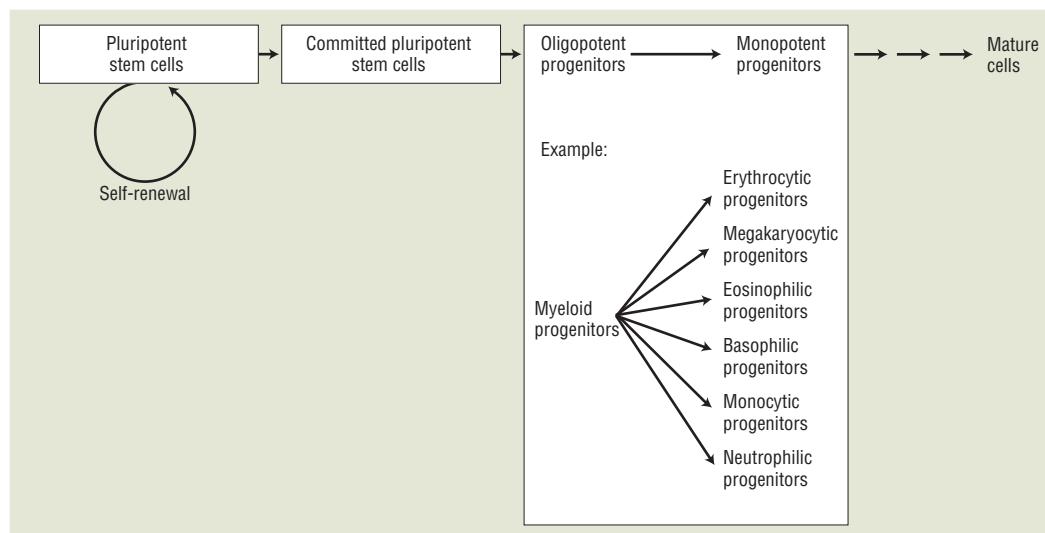

FIGURE 103-2. Rudimentary model of hematopoiesis, displaying the basic steps a cell may take from its inception as a stem cell in the bone marrow, through stages in which it can become multiple (oligopotent) or only one specific (monopotent) type of mature blood cell.

to the circulation (approximately 700 million). Similarly, only 1% of the eosinophils in the body are found in peripheral blood, whereas the skin, lungs, and gastrointestinal tract are the preferred sites of residence.⁴ There is no marrow reserve pool of monocytes. Neutrophil development in the bone marrow begins with the stem cell and proceeds through intermediate precursors, such as the myeloblast, promyelocyte, myelocyte, and metamyelocyte.

Only a small fraction of the total body pool of lymphocytes resides in the blood. Immature T cells are evident in the circulation on their way to full maturation in the thymus. Mature B lymphocytes express surface immunoglobulin, which functions as an antigen receptor. Most of these cells migrate from the bone marrow to areas such as the lymph nodes (dense collections of lymphocytes, plasma cells, and macrophages that are supplied by postcapillary venules and drained by a system of efferent lymphatics) and spleen, where antigenic stimulation results in specific immunoglobulin production.¹³ Approximately 75% of blood lymphocytes are T cells; 15% null cells, and 10% B cells. Various antigens expressed on the surface of leukocytes, depending on the degree of cell maturity and function, are termed clusters of differentiation (CD).

Progenitor cells that give rise to platelets are referred to as colony-forming unit megakaryocytes. Megakaryocytes account for only 0.05% to 0.02% of marrow cells. Morphologic changes in both the cytoplasm and nucleus accompany the maturation of megakaryocytes. Therefore, at differing stages of maturation, it is possible to see granules, organelles, and increasing segmentation of the nucleus. Cells in this lineage progress through three stages of development: commitment, proliferation, and differentiation, similar to that of leukocytes.^{18,19} Receptors for the cytokine thrombopoietin are expressed on both megakaryocytes and platelets, as well as hematopoietic stem cells.

The term *erythron* has been used to describe collectively the erythropoietic cellular pathway, composed of all cells involved in erythropoiesis, starting with the earliest committed erythroid progenitor and ending with the mature circulating RBC. The earliest cell committed to the erythroid lineage is known as a burst-forming unit erythroid (BFU-E). Through in-vitro culture systems, one BFU-E can proliferate into several hundred progeny. These cells are followed in differentiation by the colony-forming unit erythroid (CFU-E) cell, and subsequently by the nucleated normoblast and the immediate RBC precursor, the circulating anuclear reticulocyte as outlined in Fig. 103-3. The remaining RNA is typically lost from the

RBC within 2 days of its appearance in the peripheral blood; thus the mature cell does not synthesize new proteins such as enzymes.²⁰

The erythrocyte precursor cell types display a continuum of changes in shape, hemoglobin concentration, Rh antigen, and erythropoietin (EPO) receptor expression with maturity. However, mature erythrocytes express significantly lower EPO receptor density than do proerythroblasts.²¹

Neonatal RBCs contain primarily fetal hemoglobin. Adult hemoglobin, 85% of which is synthesized in the erythropoietic marrow,

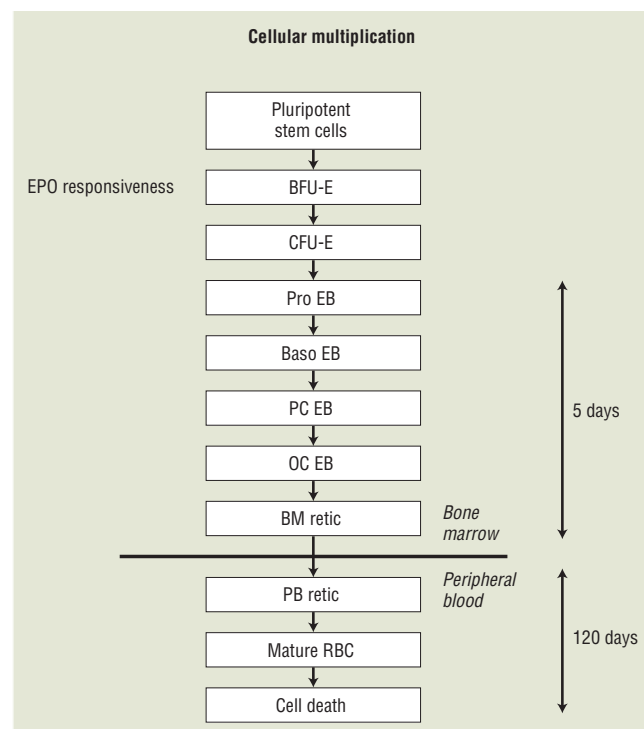

FIGURE 103-3. Proposed differentiation pattern of cells into mature erythrocytes with identification of various immature cell types. In addition, the cells that may be stimulated by the cytokine erythropoietin (EPO) are identified. (BM, bone marrow; BFU, burst-forming unit; CFU, colony-forming unit; E, erythroid; EB, erythroblast; OC, orthochromatophilic; PB, peripheral blood; PC, polychromatophilic; RBC, red blood cell; retic, reticulocyte.)

replaces the fetal hemoglobin within a few months. Heme-synthesizing cells must have mitochondria; therefore its synthesis cannot occur in the mature erythrocyte. Genetic alterations in hemoglobin structure can dramatically alter the stability or solubility of the hemoglobin and also cell conformation. The characteristic biconcave-disk shape of the normal RBC is approximately 8×2 micrometers. Pathologic alterations in plasma lipids can affect the outer phospholipid membrane of the RBC, thus changing the cell's shape and survival. Blood types are characterized by the antigenic structure of the external surface of the cell membrane. The interactions of antibodies with RBC surface antigens affect the membrane function, integrity, and phagocytosis of the cells.

REGULATION OF CELL PROLIFERATION AND DIFFERENTIATION

The generic model of cell maturation presented in Fig. 103-2 includes a population of stem cells, thought to be capable of self-renewal, which provides the initial cell (committed progenitor) for subsequent maturation, differentiation (i.e., commitment to a cell line), and expansion into all blood cell types. This is followed by an initial differentiation step when a cell is produced (oligopotent progenitor) that will ultimately become one of only several mature blood cell types. Finally, monopotent progenitors are noted in which differentiation is restricted to one cell type. The latter cells then undergo a series of maturation steps, ultimately resulting in a mature cell.

STEM CELLS

4 The action of a stem cell in self-renewing rather than differentiating, and the selection of lineage by a multipotential progenitor cell during the differentiation process is thought to be a chain of stochastic (random) events. Conversely, the survival and proliferation of the subsequent progenitor cells are thought to be regulated (positively and negatively) by the group of cytokines referred to as hematopoietic growth factors (colony-stimulating factors, hematopoietins, or hematopoietic cytokines).²² Receptors for a variety of hematopoietic growth factors are present on the surface of stem cells, which agrees with in vitro studies demonstrating stimulatory activity for cytokines such as stem cell factor (SCF), IL-1, IL-6, G-CSF, IL-10, IL-11, IL-12, IL-13, thrombopoietin, basic fibroblast growth factor, and leukemia inhibitory factor, when present in combinations. The function of hematopoietic growth factors ultimately results in regulating intracellular transcription factors, which are the driving force behind determination of the ultimate cell lineage. Whether or not the therapeutic use of a hematopoietic growth factor that is thought to act primarily on more mature cells will exhaust (deplete) the stem-cell pool over the course of multiple cycles of therapy is under active debate and study.²³ Proposed “cascades” of hematopoiesis are represented in Figs. 103-3 through 103-6. Inserted within some figures are the suspected sites in the process where hematopoietic growth factors are thought to interact by promoting the production, proliferation, and survival of hematopoietic cells. These schema are simple representations of a system of complex interactions between stimulatory and inhibitory cytokines that may not be adequately described by the in-vitro models used thus far to define them. (Details regarding the clinical pharmacology of individual hematopoietic growth factors are presented in Chap. 130.)

Immature bone marrow precursor cells such as the myeloblast (first recognizable cell of granulocytic differentiation), promyelocyte, myelocyte, and erythroblast are thought to be capable of replication. This is in contrast to most mature hematopoietic cells, which are incapable of division. Exceptions to the latter statement include monocytes, macrophages, and tissue mast cells. Evaluation

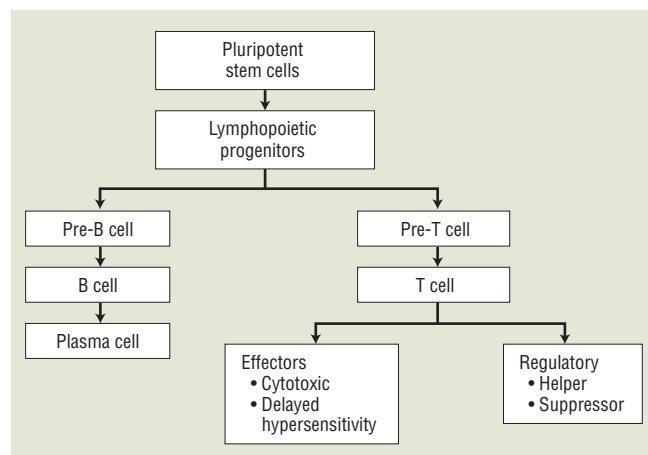

FIGURE 103-4. Pattern of lymphocyte maturation and differentiation into T and B cells. The plasma cell is a factory for antibodies, whereas the T cells have both effector and regulatory functions on the immune system.

of reasons for a change in hematopoietic cellular concentration over time must be conducted with a thorough knowledge of the mechanisms of both cellular production and destruction.

NEUTROPHILS

Blood neutrophils are in constant exchange with an equal number of *marginated* cells. The latter are adhered to the walls of vessels in the peripheral blood, liver, lungs, and spleen. Therefore, demargination or the opposite, increased adhesion, can dramatically change the peripheral neutrophil concentration, even though cell production remains constant. A variety of stimuli can result in demargination, including infection, exercise, epinephrine, corticosteroids, and sickle cell anemia.²⁴ Conversely, transient neutropenia can

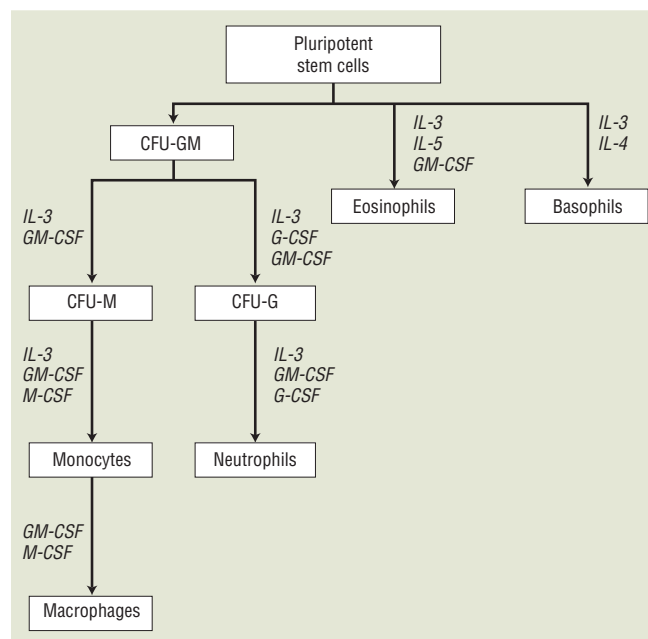

FIGURE 103-5. Maturation of precursor cells into granulocytes and macrophages, including some intermediate precursor cells (CFU-GM, -G, and -M). The hematopoietic growth factors that affect the more terminal (mature) pathways are also shown. (Hematopoietic growth factors that regulate immature cell types are not displayed.) (CFU, colony-forming unit; CSF, colony-stimulating factor; G, granulocyte; GM-CSF, granulocyte-macrophage colony-stimulating factor; IL, interleukin; M, monocyte.)

FIGURE 103-6. Maturation steps of megakaryocyte precursors prior to becoming mature platelets. (BFU, burst-forming unit; CFU, colony-forming unit; MK, megakaryocyte.)

occur through stimulation of margination by conditions such as malaria, some viral infections, and onset of hemodialysis.²⁵

Normally, it takes 14 days for neutrophil production and differentiation in the bone marrow. It is believed that G-CSF, GM-CSF, and IL-3 are important regulatory molecules of neutrophil production (see Fig. 103-5). A healthy adult will produce approximately 1.6 billion neutrophils per kilogram body weight per day.²⁶ As blood neutrophils are totally replaced at least twice in each 24-hour period, the average circulation time for any one cell is approximately 6 to 12 hours. Most of this removal is thought to be for effector functions in the tissues and not simply an elimination process.

5 The total number of noncirculating (i.e., storage) neutrophils is more than 15 times the number in blood. Absolute storage cell numbers are subject to alteration by prior exposure to chemotherapy or deficiency in cofactors required for their synthesis (e.g., folate). When conditions call for an acute increase in blood neutrophils, the pattern of cells thus changes to one more similar to that in the marrow (i.e., band concentration increases relative to segmented neutrophil (seg) concentration; normal ratio <0.1 to 0.3).²⁷ This phenomenon, often referred to as a *shift to the left*, denotes a circulating neutrophil population made of less mature cells. Infectious processes frequently provoke such a shift, as well as an increased outflow of cells from storage forms in the bone marrow, but extreme cases can require so many granulocytes at the infection site that marrow pools are depleted, resulting in neutropenia. Cytokine expression, and thus hematopoiesis, can be impaired in the elderly, resulting in a reduced ability to tolerate myelosuppressive chemotherapy.²⁸

EOSINOPHILS

The typical blood circulation time for an eosinophil is approximately 6 hours, but it can survive weeks within tissues. Cytokines thought to be important in eosinophil production or function include IL-1, IL-3, GM-CSF, G-CSF, and perhaps most important, IL-5. Corticosteroids cause a transient margination of eosinophils and inhibit release of mature cells from the bone marrow.⁴

MONOCYTES AND MACROPHAGES

Both macrophages and T lymphocytes secrete cytokines that stimulate monocytopoiesis.²⁹ Examples of cytokines that act on relatively mature monocytes include macrophage colony-stimulating factor (M-CSF) and GM-CSF. Blood monocytes have a shorter marrow transit time than neutrophils (6 vs. 13 days, respectively), and there is no monocyte reserve in the marrow.²⁷ The peripheral blood

turnover of these cells is much slower (circulation half-life, 3 days) than for neutrophils; similarly, tissue macrophages are thought to be very long-lived. Macrophages may be able to produce their own progeny as well as attract additional monocytes for differentiation in the local environment.

LYMPHOCYTES

Immature T cells produced in the bone marrow ultimately migrate to the thymus, where they both expand and mature into immunologically competent cells (see Fig. 103-4). A variety of cytokines, including IL-2, IL-4, and IL-7, facilitate lymphopoiesis, whereas others such as transforming growth factor- β may decelerate this process.³⁰ T lymphocytes are probably the longest lived hematopoietic cell, as there is experimental evidence that the life span of some is more than 10 years.

The term *lymphokine* is used to describe cytokines secreted by T cells. Lymphokines such as IL-2 are important in both activation and proliferation of the immune response, whereas monokines are also important regulators of lymphocyte development. T and B lymphocytes have important interactions with each other in both lymphocyte development and activation, which seem necessary for immunocompetence. There is some evidence for age-associated reductions in circulating helper and suppressor T cells and B cells.³¹

PLATELETS

Thrombopoiesis is the term used to describe the process of platelet production. The bone marrow manufactures 40,000 platelets/mL of blood each day. Proliferation and differentiation of platelet precursors are thought to be primarily influenced by cytokines such as IL-6, IL-11, leukemia inhibitory factor, and perhaps most specifically, by thrombopoietin (Fig. 103-6).^{32,33} Other hematopoietins that may act in concert, producing synergistic effects include IL-3, IL-1, GM-CSF, EPO, and SCF.³⁴ The platelet survival time is a clinical test that can estimate the rate of platelet turnover.³⁵ In healthy individuals, this time is 9.5 ± 0.6 days.³⁶

ERYTHROCYTES

The normal life span of a RBC is approximately 100 to 120 days, with a circulating cell turnover rate of 1% per day. Thus a typical adult produces approximately 200 billion reticulocytes every day. Conditions such as anemia or hypoxemia primarily stimulate the tubular interstitial cells of the renal cortex to produce EPO by interaction with the renal oxygen sensor. The degree of elevation in blood EPO concentrations is dependent on the severity of anemia or hypoxemia. This in turn recruits RBC precursors and shortens the normal time for differentiation if adequate cofactors such as iron, folate, and vitamin B₁₂ are present. Although the overall time for differentiation is shortened (as is the duration of time that a reticulocyte spends in the marrow), the RBC's blood maturation time is lengthened. The increase in EPO concentrations is relatively quick (within hours), but the effects on marrow transpire over several days. The ultimate increase in RBC mass occurs at an even slower pace, generally over weeks to months (see Fig. 103-3). Multiple other endogenous cytokines are also thought to play a role in either stimulating or inhibiting erythropoiesis by acting on the early progenitors. These include GM-CSF, G-CSF, IL-1, IL-3, IL-6, IL-9, SCF, and some stromal proteins.²¹

Adequate production of RBCs for a degree of anemia is best assessed by evaluation of the number of circulating reticulocytes. Although the normal range is approximately 0.4% to 1.7% of the RBCs, this percentage would obviously be higher in anemic patients with adequate productive capacity. The calculation of a corrected reticulocyte count involves multiplying the percentage of circulating

FIGURE 103-7. Correction of hematocrit with the marrow and blood reticulocyte maturation times. With a hematocrit of 45, the blood reticulocytes circulate for 1 day, whereas reduction in hematocrit to 15 results in a 2.5-day circulation time. The numbers found under the blood reticulocyte concentrations can be used as a correction factor in evaluation of reticulocyte concentrations. (From Hillman et al.³⁷)

reticulocytes by the hemoglobin concentration and dividing the result by the normal hemoglobin level expected for a healthy patient with similar characteristics. Additional correction accounts for the increased life span of reticulocytes in the peripheral blood, depending directly on the patient's degree of anemia. Figure 103-7 displays correction factors that can be used to accommodate these changes.³⁷

Direct assessment of erythropoiesis in the bone marrow can be performed by estimating the myeloid-to-erythroid cell ratio from a marrow aspirate. The range of the normal adult ratio is 3:1 to 5:1, but changes in erythroid or myeloid production can obviously influence the ratio. RBCs lose flexibility with age and eventually undergo lysis or are phagocytized and removed by the monocyte-macrophage system (primarily via the spleen). Accelerated red cell destruction can be grossly quantitated by determining increases in plasma concentrations of bilirubin and lactate dehydrogenase.³⁷

Although clinical laboratories measure RBC concentrations with excellent accuracy, the most useful tool for assessment of the blood's oxygen-carrying capacity is the hemoglobin concentration because of the variability in RBC size. The average RBC and hemoglobin concentrations in healthy adult male and female patients are approximately 5.21 and $4.60 \times 10^6/\text{mm}^3$, respectively; and 15.7 and 13.8 g/dL, respectively. Variations in normal concentrations will also be evident, depending on age, menstruation status, race, environmental factors, and pregnancy.³⁸

DISEASE-ASSOCIATED HEMATOPOIETIC CHANGES

NEUTROPHILS

6 The usual definition of neutropenia is an absolute neutrophil count below $1,800$ cells/ mm^3 in white patients, $1,400$ cells/ mm^3 in black patients, and $1,500$ cells/ mm^3 for children 1 month to 10 years old. Clinical manifestations of neutropenia (i.e., infection) are not typically evident without other cofactors until the concentration decreases below $1,000$ cells/ mm^3 .³⁹ Accompanying factors that can influence the risk of infection for a particular patient include skin and mucous membrane integrity; vascular tissue supply; nutritional status; and lymphopenia, monopenia, or hypogammaglobulinemia. Persistent agranulocytosis (<500 cells/ mm^3 or no measurable neutrophils) is almost uniformly fatal without the use of supportive antibiotics.

Disorders resulting in defective granulopoiesis can be subdivided into those that result in marrow aplasia or diseases that replace the normal neutrophilic component (see Chap. 107 for drug-induced neutropenia). Diseases associated with granulopoietic suppression include viral infection, tuberculosis, anorexia, autoimmune diseases (e.g., systemic lupus erythematosus), Felty syndrome (rheumatoid arthritis, splenomegaly, and leukopenia), aplastic anemia, myelodysplastic syndromes, and leukemias.^{39,40} A congenital form of severely defective neutrophil production (Kostmann syndrome) has been described that is possibly a result of defective regulation of the late-acting hemopoietin G-CSF.⁴¹ Patients with the rare disorder of cyclic neutropenia display periodic wide fluctuations in the WBCs at approximately 3-week intervals that last for 3 to 6 days. Other forms of chronic neutropenias can occur with adequate marrow stores and can be relatively benign in symptomatology.

Neutrophilia is typically defined as an absolute neutrophil count greater than $7,500$ cells/ mm^3 of blood and is sometimes referred to as a leukemoid reaction, if extreme.²⁴ Acute neutrophilia can be a result of emotional or physical stimuli (e.g., exercise, seizures, labor, pain, or temperature changes), infections, inflammation or tissue necrosis, or drugs or toxins (e.g., CSFs, epinephrine, corticosteroids, lithium, vaccines, or endotoxin). Chronic causes of increased neutrophilia include persistent infections, inflammation, malignancies, drugs, metabolic or endocrine disorders, cigarette smoking, hereditary or congenital abnormalities, and myeloproliferative diseases such as polycythemia vera.²⁴

EOSINOPHILS

Eosinophilia (absolute count greater than 700 cells/ mm^3) can result from neoplastic processes, parasitic or fungal infections, gastrointestinal disorders, malignancies, dermatitis, granulomatous disorders (e.g., sarcoidosis or Wegener granulomatosis), or collagen-vascular diseases in addition to the more typical cause, allergic reactions.⁴² One mechanism that may be common to several of these etiologic factors is antigenic stimulation of T cells, which produces a cytokine (IL-5) that mediates eosinophil proliferation.⁴³ Infections can cause eosinopenia; however, its significance is not thought to be of concern in that setting.

BASOPHILS

Basophilia occurs frequently in patients with myeloproliferative disorders and in association with inflammatory reactions and diseases. Viral infections, iron deficiency, or lung cancer can sometimes increase basophil counts. Mastocytosis is usually evident only on analysis of tissue or bone marrow mast cells. Causes include hypersensitivity reactions, malignancy, osteoporosis, and chronic liver or renal disease.

MONOCYTES

Monocytosis (>800 cells/ mm^3 of blood) occurs with some infections (e.g., tuberculosis, histoplasmosis, toxoplasmosis, bacterial endocarditis, and salmonellosis), collagen vascular diseases (rheumatoid arthritis and systemic lupus erythematosus), gastrointestinal disorders (ulcerative colitis and alcoholic liver disease), leukemias, and up to 60% of nonhematologic malignancies, whereas abnormally low monocyte concentrations occur in patients with hairy cell leukemia or aplastic anemia.⁴⁴

LYMPHOCYTES

Significant reductions in lymphocyte concentration ($<1,000$ cells/ mm^3 of blood) can be evident without apparent cause or in a variety of diseases, including acute inflammatory disorders, severe uremia,

immune deficiency diseases such as systemic lupus erythematosus, chronic infections such as tuberculosis or human immunodeficiency virus (HIV) infection, malignancies, and connective tissue diseases.⁴⁵ Lymphocytosis ($>4,000$ cells/mm³) can occur with mononucleosis, pertussis, measles, or chickenpox, and in lymphoid malignancies. A progressive increase in mature lymphocytes can be indicative of chronic lymphocytic leukemia. Increased levels of atypical lymphocytes can occur in patients with infections (e.g., mononucleosis, hepatitis, or cytomegalovirus), allergic reactions, or lymphomas.⁴⁶

PLATELETS

Both qualitative and quantitative platelet disorders have important pathophysiologic consequences. Thrombocytopenia, defined as a platelet count less than 150,000 cells/mm³, can result from a defect in production, increased sequestration, or accelerated destruction.⁴⁷

Certain stimuli can damage the marrow by reducing the number of megakaryocytes available. Drugs, chemicals, radiation, and infection are among the potential causes of marrow injury. Diseases that produce general bone marrow failure or those that invade the bone marrow can result in thrombocytopenia. Examples of the latter include cancers such as leukemia, lymphoma, myelofibrosis, myelodysplasia, and metastatic solid tumors (breast and prostate cancer), and infections such as those caused by mycobacteria. Suboptimal platelet production can also result from defects in maturation seen with vitamin B₁₂ and/or folate deficiency or in congenital syndromes.⁴⁸ Alteration in platelet distribution can also result in thrombocytopenia. Splenomegaly is the most frequent cause of increased platelet sequestration.

Idiopathic thrombocytopenic purpura (ITP) is associated with accelerated destruction of platelets and is a common cause of thrombocytopenia. Antiplatelet antibodies combine with platelets in ITP, thus sensitizing them to removal by the immune system. Accelerated platelet destruction can also occur in patients with connective tissue disorders. Approximately 14% of patients with systemic lupus erythematosus experience thrombocytopenia similar to ITP.

Most patients with essential thrombocythemia (450,000 to $>1,000,000$ cells/mm³) are initially asymptomatic and diagnosed by the laboratory finding. The high platelet concentration is thought secondary to enhanced destruction. Patients can experience thromboembolic episodes and hemorrhage. The mechanisms mediating these effects are not well understood, but they are observed more frequent in the elderly or in those with platelet concentrations $>1,000,000$ cells/mm³.

ERYTHROCYTES

Anemia has been typically defined by data reported from the World Health Organization as follows: men with hemoglobin <13 gm/dL or women with values of <12 gm/dL. The clinical accuracy of these values have been recently challenged.⁴⁹ Commonly encountered factors which can significantly impact on what one would consider a “normal” hemoglobin concentration include: race, age, home altitude, and smoking status.

Suboptimal erythropoiesis can be classified by changes in the size of RBCs noted on examination of the peripheral blood. Because the excretory and endocrine functions of the kidney usually mirror each other, renal dysfunction can lead to anemia by reduction in EPO production, resulting in a normochromic, normocytic pattern. Other causes of insufficient erythropoiesis include replacement of bone marrow by fibrosis, solid tumors, or leukemia, as well as defects in erythroid maturation. Relative deficiencies in the cofactors required for heme-RBC synthesis such as iron, folate, and vitamin B₁₂ can also be important contributors. Structurally, RBC macrocytosis denotes defects in the maturation of the nucleus,

whereas microcytosis is indicative of cytoplasmic defects (reduced hemoglobin synthesis). (A detailed description regarding the pathogenesis and treatment of anemic disorders is found in Chap. 104.)

Exaggerated erythropoiesis with increased RBC mass (polycythemia) can be mistaken for a reduction in plasma volume. Symptoms are not always immediately evident but can progress to reduced tissue oxygenation, thrombosis, and congestive heart failure. The most common cause is hypoxia; alternative causes can be grouped according to their ability to stimulate EPO production. EPO (or a similar cytokine) can be produced in response to genetic alterations or a variety of malignancies, including angioblastoma, hepatomas, and hypernephroma.⁵⁰ Polycythemia vera, a malignancy of the bone marrow stem cells, results in an increased sensitivity of RBC precursors to stimulation by EPO and is accompanied in many patients by thrombocytosis and leukocytosis.

CLINICAL USES OF HEMATOPOIETIC CELLS

HEMATOPOIETIC STEM CELL TRANSPLANTATION

High-dose chemotherapy with or without irradiation is beneficial in the treatment of a number of malignant diseases (see Chap. 142). The dose of chemotherapy that can be administered, however, is limited by hematopoietic toxicity that can result in prolonged periods of pancytopenia with the attendant risks of serious infection and bleeding. The infusion (transplantation) of hematopoietic stem cells following the high-dose therapy can overcome this hematopoietic toxicity, resulting in subsequent repopulation of the bone marrow and recovery of hematopoiesis. Hematopoietic stem cell transplantation (HSCT) involves the collection of hematopoietic stem cells from the donor, administration of intensive doses of chemotherapy (with or without irradiation) to the recipient, and infusion of the donor stem cells to the recipient. If the donor and recipient are the same individual (i.e., the patient serves as his or her own donor), the procedure is termed *autologous* HSCT. If the stem cells come from another individual, the procedure is termed *allogeneic* HSCT. Most allogeneic donors are human leukocyte antigen (HLA)-matched siblings, but the use of alternative donors such as HLA-matched unrelated donors or umbilical cord blood cells is increasing.

Allogeneic transplantation is complicated by the immune recognition of host tissues by donor T lymphocytes, resulting in a syndrome called graft-versus-host disease (GVHD). Because immune recognition of tumor cells also occurs (graft-versus-tumor effect), the relapse rates associated with allogeneic transplants are lower than those associated with autologous transplants for similar disease stages. Allogeneic transplantation is commonly used for diseases primarily involving the bone marrow, such as acute and chronic leukemias, aplastic anemia, thalassemia, and severe combined immunodeficiency syndrome.

Autologous transplantation is commonly used in non-Hodgkin lymphoma, Hodgkin lymphoma, multiple myeloma, and a relatively small subset of patients with solid tumors. A number of laboratory techniques are evolving to allow the bone marrow harvested for autologous transplantation to expand in the laboratory prior to infusion and to cleanse the marrow of potential malignant cell contamination.

Small numbers of hematopoietic progenitor (stem) cells capable of reconstituting hematopoiesis circulate in the blood under normal circumstances.⁵¹ Commonly referred to as peripheral blood progenitor cells (PBPCs), these circulating progenitor cells increase in number during recovery from myelosuppressive chemotherapy or after treatment with cytokines such as G-CSF or GM-CSF.^{16,52} These

cells can be collected by a process called leukapheresis and stored for intravenous reinfusion following high-dose chemotherapy. Intravenous reinfusion is feasible because cell “homing” is facilitated through cytokines, chemokines, adhesion molecules, and integrins. Hematopoietic recovery is generally more rapid following rescue with PBPCs as compared with rescue with bone marrow. Potential tumor cell contamination can also be less with PBPC transplants. The use of PBPCs has essentially replaced the use of autologous and allogeneic bone marrow.

Cytokine-mobilized PBPC transplants from allogeneic donors have been shown to result in more rapid white cell and platelet engraftment and shorter hospital stays than bone marrow transplants.⁵³ The incidence of acute GVHD is not increased, but there is a significant increase in the incidence of chronic GVHD with PBPC transplants. Relapse rates and overall survival rates are similar with the use of allogeneic PBPC or bone marrow.

Only approximately one-third of patients who would otherwise be eligible for allogeneic bone marrow transplantation (BMT) have HLA-matched related donors. One alternative is the use of closely HLA-matched, unrelated donor marrow. The National Marrow Donor Program (NMDP) is a registry of volunteer marrow donors. By coordinating the activities of a network of donor, collection, and transplant centers, the NMDP facilitates the identification of potential donors and the procurement of marrow. Unrelated donor marrow transplants are associated with an increased risk of GVHD as compared to related donor transplants, but recent advances in tissue typing and donor matching and GVHD prophylaxis have resulted in comparable overall survival rates for many diseases.

Grafts of PBPCs from unrelated donors are also increasingly used for transplantation. The cells are collected by leukapheresis after mobilization of PBPCs by giving the donor G-CSF. This spares the donor from potential complications related to general or spinal anesthesia and pain associated with bone marrow harvest. Unrelated PBPC transplants are associated with more rapid engraftment as compared to unrelated BMT, with no increase in GVHD or relapse rates.⁵⁴

Many patients do not have HLA-matched family members or unrelated donors in the marrow registries. An alternative for these patients is the use of human umbilical cord blood, which contains hematopoietic stem cells capable of reconstituting bone marrow function following high-dose chemotherapy.⁵⁵ An almost unlimited number of cord blood donors is potentially available, because the cord and its associated blood are commonly discarded following delivery. There are cord blood banks in which cord blood cells are HLA-typed, cryopreserved, and made available for transplantation for appropriate recipients. The majority of early cord blood progenitor cell transplantations were performed in children because of the relatively small number of cells available from a cord blood unit, although the number of cord blood transplantations performed in adults is increasing.⁵⁶ A major problem with cord blood transplants is a more prolonged period of neutropenia (often greater than 1 month.) This leads to additional infectious complications and associated morbidity. Laboratory methods to expand the number of progenitor cells in cord blood units are under investigation. Cord blood transplants are thought to lead to less GVHD than transplants from matched unrelated donors with similar degrees of matching, and they might prove to be an important source of progenitor cells for transplantation in the near future.

The application of allogeneic transplantation has been limited to younger patients without comorbid conditions secondary to the toxicity of the myeloablative preparative regimen and the allogeneic bone marrow or PBPC graft. Recently, a number of centers have reported successful allogeneic engraftment following nonmyeloablative, immunosuppressive conditioning regimens.^{57,58} The goal of this approach is to establish donor hematopoiesis and a graft-

versus-tumor effect while minimizing toxicity. These transplants can be offered to older patients and to patients with diminished end-organ function. This approach has also been used for patients with disorders that might be responsive to immune-based therapy, such as renal cell carcinoma.

ADOPTIVE IMMUNOTHERAPY

Experiments involving the administration of immune system cells for the purpose of cancer treatment (adoptive immunotherapy) have been conducted for well over a decade; however, the clinical benefit has only recently been substantiated. As described earlier, nonspecific, total depletion of donor T cells following high-dose chemotherapy and stem-cell reinfusion produces fewer graft-versus-host effects, but attenuated anticancer responses. However, it has been shown that careful attention to the T-cell dose and timing of infusion can maximize the potential for beneficial immunologic responses and minimize graft-versus-host effects. It has been found that the administration of allogeneic donor lymphocyte infusions to patients with leukemia relapse following myeloablative stem cell transplantation has anticancer efficacy in diseases such as chronic myelogenous leukemia (65% complete response), acute nonlymphocytic leukemia, or myelodysplastic syndrome (25% complete response).⁵⁹ Some of these remissions have prolonged durability. Similar strategies have been used in nonmyeloablative stem cell transplantation. The complications of donor lymphocyte infusions include the obvious risk of GVHD, but the condition does not develop in all patients who have clinical benefit. This mode of therapy can also result in marrow aplasia for approximately 20% of patients, but it is self-limiting or treatable with G-CSF in most cases.

TRANSFUSION AND BLOOD PRODUCT SUPPORT

Advances in blood banking and transfusion support have been critical to the improved outcome of therapy for patients with hematologic and malignant diseases. Platelet transfusions are indicated for the prevention and treatment of bleeding. In general, prophylactic platelet transfusions are not indicated for platelet counts above 10,000 cells/mm³ unless the patient is febrile or actively bleeding. Platelets are available as pooled random donor concentrates obtained from RBC donations (six to eight donors per transfusion) or single-donor platelets collected by apheresis.

Administration of multiple platelet transfusions increases the risk of developing a platelet-refractory state termed *alloimmunization*. This effect is thought to be an immune-mediated reaction to HLA antigens on donor platelets or WBC contaminants. A common method of identifying such patients is evaluation of platelet counts within an hour of transfusion. For example, a 1-m² person should obtain an increase in platelet concentration between 7,000 and 11,000 cells/mm³ for each unit of platelet concentrate administered (in the absence of other risk factors such as infection, splenomegaly, etc.). The diagnosis can be confirmed by in-vitro demonstration of platelet antibodies. The use of leukocyte filters prior to storage of donated platelets or ultraviolet (UV) irradiation of the product has been shown to decrease the development of alloimmunization and refractoriness to platelet transfusions. Leukocyte filters also decrease the risk of transmission of cytomegalovirus and febrile transfusion reactions. Treatment of alloimmunized patients often entails use of platelets obtained from single donors (to lessen exposure to HLA), or use of HLA-compatible or platelet cross-match-compatible donors. Unfortunately, such approaches are not always effective and additional therapies (plasma exchange or intravenous immunoglobulin) have been added with some limited success.

Packed RBC transfusions are indicated to keep hemoglobin levels above 7 to 8 g/dL to maintain adequate oxygen-carrying capacity. Each unit of packed RBCs should increase the hemoglobin level by approximately 1 g/dL unless active blood loss is evident. RBCs should also be filtered to reduce the risk of nonhemolytic, febrile transfusion reactions. Patients who are candidates for HSCT should receive blood products that have been irradiated with 2,500 cGy to prevent transfusion-associated GVHD.

Fresh frozen plasma (within 6 hours of collection) contains the components of the coagulation system and is indicated for the replacement of deficient coagulation factors II, V, VII, X, XI, and XIII. A unit of fresh frozen plasma has a volume of about 250 mL. Factor VIII and IX deficiencies are treated with specific factor concentrates. Fresh frozen plasma is also used for the rapid reversal of warfarin anticoagulation and in the treatment of disseminated intravascular coagulation. Thrombotic thrombocytopenic purpura is treated by means of therapeutic plasma exchange with fresh frozen plasma as the replacement fluid. Frequent, but inappropriate indications for fresh frozen plasma include: immunodeficiency, burns, wound healing, and volume expansion. Cryoprecipitate, which contains factor VIII, von Willebrand factor, and fibrinogen, is indicated for the treatment of von Willebrand disease that does not respond to desmopressin acetate and for fibrinogen replacement (see Chap. 105).

INTRAVENOUS IMMUNOGLOBULIN

Pharmaceutical products containing immunoglobulin for intravenous use in humans are pooled from blood collection in more than 1,000 donors for each lot of drug. The high number of donors provides a wide diversity in the capability of the antibodies to react with antigenic targets. Products are similar in content of each immunoglobulin G (IgG) subclass, but the titers against specific antigens vary between manufacturers (as do other pharmaceutical characteristics, such as osmolality).

CLINICAL CONTROVERSIES

Intravenous immunoglobulin products vary by the number of donors used to produce the product, titers for specific antigens, and methods used for purification. Products are often marketed and selected based on these criteria; however, the clinical relevance of each is unclear.

The IV administration of immunoglobulin has been used in a variety of hematologic disorders, but for most of these situations, it is still considered experimental or indicated only when other therapeutic options have been exhausted. Patients with deficient immunoglobulin production (e.g., agammaglobulinemia or hypogammaglobulinemia) or function (e.g., chronic lymphocytic leukemia, multiple myeloma, and children with HIV) can benefit from this therapy, with the goal of increasing the IgG level such that there is less chance for bacterial infection (>500 mg/dL). This approach has other pharmacologic properties as well, including blockade of crystallizable fragment (Fc) of immunoglobulin receptors, modification of complement activation, and modulation of the immune response by anti-idiotypic antibodies.⁶⁰ It is also beneficial for patients with ITP who are at high bleeding risk or need higher platelet counts prior to surgery.^{61,62} Posttransplant prophylaxis (approximately 3 months) with Ig given IV is also sometimes used in patients receiving allogeneic HSCT for prevention of bacterial sepsis and acute GVHD. The IV treatment with Ig can benefit patients whose platelet counts do not increase substantially despite transfusions, owing to the formation of alloantibodies.

A number of immunoglobulin products are available that provide more specific immunity toward selected antigens. These pharmaceuticals are generated from individuals who have been exposed to the antigen and thus developed antibody “titers” more specific to the infectious agent. Products include antithymocyte globulin, botulism immunoglobulin, cytomegalovirus immunoglobulin, hepatitis B immunoglobulin, rabies immunoglobulin, respiratory syncytial virus immunoglobulin, tetanus immunoglobulin, Rh(D) immunoglobulin, and varicella-zoster immunoglobulin.

KEY CONCEPTS

- 1 Anemias are a group of diseases characterized by a decrease in either the hemoglobin (Hb) or the volume of red blood cells (RBCs), which results in decreased oxygen-carrying capacity of the blood.
- 2 Anemias are generally a sign of underlying pathology; therefore, determining the cause of the anemia is important. Possible consequences of chronic anemia include reduced quality-of-life, decreased survival, and increased risk of cardiac complications, neurologic dysfunction, and surgical complications. Awareness of anemia, its detection, investigation, and management must be raised.
- 3 Patients with acute-onset anemias are most likely to present with tachycardia, lightheadedness, and dyspnea. Patients with chronic anemia often present with weakness, fatigue, headache, vertigo, faintness, and pallor.
- 4 Iron-deficiency anemia (IDA) is characterized by decreased levels of ferritin (most sensitive marker) and serum iron, as well as decreased transferrin saturation; Hb and hematocrit (Hct) decline later. Total iron-binding capacity (TIBC) is increased. RBC morphology includes hypochromia and microcytosis. Most patients with IDA are adequately treated with oral ferrous (Fe^{2+}) sulfate therapy, although parenteral iron therapy is necessary in selected patient populations.
- 5 Vitamin B_{12} deficiency, a macrocytic anemia, can be due to inadequate intake, decreased absorption, or inadequate utilization. Anemia caused by a lack of intrinsic factor, resulting in decreased vitamin B_{12} absorption, is called *pernicious anemia*. Vitamin B_{12} levels and the reticulocyte count usually are low. Neurologic symptoms are often present and can become irreversible if the vitamin B_{12} deficiency is not treated promptly. Oral or parenteral therapy can be used for replacement therapy.
- 6 Folic acid deficiency, a macrocytic anemia, results from inadequate intake, decreased absorption, hyperutilization, or inadequate utilization. Treatment consists of oral administration of folic acid, even in patients with absorption problems. Adequate folic acid intake is essential in women of childbearing age to decrease the risk of neural tube defects in their children.
- 7 Anemia of chronic disease is a diagnosis of exclusion. It results from chronic inflammation, infection, or malignancy and can occur as early as 1 to 2 months after the onset of these processes. The serum iron level usually is decreased, but in contrast to IDA, the serum ferritin concentration is normal or increased and TIBC is normal or decreased. Treatment is aimed at correcting the underlying pathology.
- 8 Anemia is a common complication in critically ill patients and is almost universally found in this patient population. Contributing factors include sepsis, frequent blood samples, surgical blood loss, immune-mediated functional iron deficiency, decreased erythropoietin (EPO) production, reduced RBC life span, and active bleeding. Low serum iron, TIBC, and low iron/TIBC ratio result. Serum ferritin is normal to high. Whether exogenous EPO improves clinical outcomes in critically ill patients is not clear.
- 9 Anemia is one of the most prevalent clinical problems observed in the elderly, although it is not an inevitable outcome of aging. Anemia is associated with an increased risk of hospitalization and mortality, reduced quality of life, and decreased physical functioning. Patients with iron deficiency may have concurrent folic acid or vitamin B_{12} deficiency.
- 10 IDA is a leading cause of infant morbidity and mortality. The age of the child can yield some clues to the etiology of the anemia. Age- and sex-adjusted norms must be used in the interpretation of laboratory results in pediatric patients. Primary prevention of IDA is the goal. A therapeutic trial of oral iron is the standard of care. EPO can be used for treatment of anemia of prematurity.
- 11 Hemolytic anemia results in decreased survival time of RBCs secondary to destruction in the spleen or circulation. Hemolytic anemias usually are normocytic and normochromic, with increased levels of reticulocytes, lactate dehydrogenase, and indirect bilirubin. Treatment is directed toward correcting or controlling the underlying pathology.

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

According to the World Health Organization, as many as four to five billion people (66%–80% of the world's population) may be iron deficient, and two billion people (30% of the world's population) are anemic. Anemia defined as hemoglobin (Hb) <13 g/dL in men or <12 g/dL in women (as recommended by the World Health Organization) occurs in approximately 3.5 million Americans based on self-reported data from the National Center for Health Statistics. It is estimated that millions of people are unaware they have anemia, making it one of the most underdiagnosed conditions in the United States. The prevalence of iron-deficiency anemia has been stable in the last decade since the mid-1990s in the United States, with the

highest rate in minority and poor children.¹ The highest prevalence is seen in women, African Americans, the elderly, and low-income persons. Laboratory data from the third National Health and Nutrition Examination Survey (NHANES) reports anemia prevalence is 5.7% in infants, 5.9% in teenage girls, 5.8% in young women, and 4.4% in elderly men.² The estimated prevalence of anemia in the surgical population is as high as 75%.³ Obesity surgery is increasingly common. Depending on the type of bariatric procedure, nutritional deficiency may be an issue. Gastric bypass may result in calcium, folate, vitamin B₁₂, and iron deficiencies. Prevalence data are confounded by the lack of a standardized definition of anemia. Because no screening guidelines for anemia in the elderly exist, the prevalence may be even higher than suspected. The United States Preventive Services Task Force (USPSTF) guidelines for asymptomatic pregnant women recommend routine screening for iron-deficiency anemia (IDA).

The importance of anemia often is overlooked and undertreated. Evidence suggests that anemia is not an innocent bystander; it can affect both length and quality of life. Retrospective observational studies in hemodialysis patients and heart failure patients suggest that anemia is an independent risk factor for mortality.⁴ In addition, anemia significantly influences morbidity, as shown in patients with end-stage renal disease, chronic kidney disease, and heart failure.⁵ Quality-of-life data in anemic patients are primarily based on studies in cancer patients.⁶ Anemia is associated with psychomotor and

cognitive abnormalities in children. Similarly, among adults, anemia is associated with cognitive dysfunction in patients with renal failure, those with cancer, and among community-dwelling elders.⁷ During pregnancy, anemia has been associated with increased risk for low birth weights, preterm delivery, and perinatal mortality.^{8,9} Maternal IDA may be associated with postpartum depression and poor performance by offspring on mental and psychomotor tests. The effect of treatment on patient outcomes must be the focus of research on each specific type of anemia. Global goals of treatment in anemic patients are to alleviate signs and symptoms, correct the underlying etiology, and prevent recurrence of anemia.

1 Anemias are a group of diseases characterized by a decrease in either Hb or red blood cells (RBCs), resulting in reduced oxygen-carrying capacity of the blood. Anemias can result from inadequate RBC production, increased RBC destruction, or blood loss. They can be a manifestation of a host of systemic disorders, such as infection, chronic renal disease, or malignancy. Because anemias are often a sign of underlying pathology, rapid diagnosis of the cause is essential.

2 Anemias can be classified on the basis of the morphology of the RBCs, etiology, or pathophysiology (see Table 104-1 for examples). This chapter focuses on IDA, anemia of chronic disease (ACD), and anemias associated with vitamin B₁₂ and folic acid deficiency. Characteristic changes in the size of RBCs seen in erythrocyte indices can be the first step in the morphologic classification and understanding of the anemia.

TABLE 104-1 Classification Systems for Anemias

I. Morphology	Gastritis
Macrocytic anemias	Hemorrhoids
Megaloblastic anemias	Chronic hemorrhage
Vitamin B ₁₂ deficiency	Vaginal bleeding
Folic acid deficiency anemia	Peptic ulcer
Microcytic hypochromic anemias	Intestinal parasites
Iron-deficiency anemia	Aspirin and other nonsteroidal anti-inflammatory agents
Genetic anomaly	Excessive RBC destruction
Sickle cell anemia	Extracorporeal (outside the cell) factors
Thalassemia	RBC antibodies
Other hemoglobinopathies (abnormal hemoglobins)	Drugs
Normocytic anemias	Physical trauma to RBC (artificial valves)
Recent blood loss	Excessive sequestration in the spleen
Hemolysis	Intracorporeal factors
Bone marrow failure	Heredity
Anemia of chronic disease	Disorders of hemoglobin synthesis
Renal failure	Inadequate production of mature RBCs
Endocrine disorders	Deficiency of nutrients (B ₁₂ , folic acid, iron, protein)
Myelodysplastic anemias	Deficiency of erythroblasts
II. Etiology	Aplastic anemia
Deficiency	Isolated (often transient) erythroblastopenia
Iron	Folic acid antagonists
Vitamin B ₁₂	Antibodies
Folic acid	Conditions with infiltration of bone marrow
Pyridoxine	Lymphoma
Central, caused by impaired bone marrow function	Leukemia
Anemia of chronic disease	Myelofibrosis
Anemia of the elderly	Carcinoma
Malignant bone marrow disorders	Endocrine abnormalities
Peripheral	Hypothyroidism
Bleeding (hemorrhage)	Adrenal insufficiency
Hemolysis (hemolytic anemias)	Pituitary insufficiency
III. Pathophysiology	Chronic renal disease
Excessive blood loss	Chronic inflammatory disease
Recent hemorrhage	Granulomatous diseases
Trauma	Collagen vascular diseases
Peptic ulcer	Hepatic disease

RBC, red blood cell.

Anemias are classified by RBC size as macrocytic, normocytic, or microcytic. Vitamin B₁₂ deficiency and folic acid deficiency both are macrocytic anemias. An example of a microcytic anemia is iron deficiency, whereas a normocytic anemia may be associated with recent blood loss or chronic disease. More than one anemia and etiology can occur concurrently. Inclusion of the underlying cause of the anemia makes diagnostic terminology easier to understand (e.g., microcytic anemia secondary to iron deficiency).

Microcytic anemias are pathogenically a result of a quantitative deficiency in Hb synthesis, usually due to iron deficiency or impaired iron utilization. As a result, erythrocytes containing insufficient Hb are formed. Microcytosis and hypochromia are the morphologic abnormalities that provide evidence of impaired Hb synthesis. Macrocytic anemias can be divided into megaloblastic and nonmegaloblastic anemias. The type of macrocytic anemia can be distinguished microscopically by peripheral blood smear examination. Megaloblasts are distinctive cells that express a biochemical abnormality of retarded DNA synthesis, resulting in unbalanced cell growth. Megaloblastic anemias affect all hematopoietic cell lines. The most common cause of megaloblastic anemia is vitamin B₁₂ and/or folate deficiency. Nonmegaloblastic anemias do not have a common pathogenic mechanism and may be macrocytic or normocytic. This type of macrocytic anemia may be due to etiologies such as liver disease, hypothyroidism, hemolytic anemia, and alcoholism. Hemolytic anemias often are macrocytic, resulting in increased reticulocyte counts, and reticulocytes are larger on average than more mature red cells.

MATURATION AND DEVELOPMENT OF RED BLOOD CELLS

In adults, RBCs are formed in the marrow of the vertebrae, ribs, sternum, clavicle, pelvic (iliac) crest, and proximal epiphyses of the long bones. In children, most bone marrow space is hematopoietically active to meet increased RBC requirements.

In normal RBC formation, a pluripotent stem cell yields an erythroid burst-forming unit. Erythropoietin (EPO) and cytokines such as interleukin-3 and granulocyte-macrophage colony-stimulating factor stimulate this cell to form an erythroid colony-forming unit in the marrow. The erythroid colony-forming unit is very sensitive to EPO and produces proerythroblasts. Subsequent divisions yield basophilic erythroblasts, polychromatic erythroblasts, pyknotic erythroblasts, reticulocytes, and finally erythrocytes. During this process, the nucleus becomes smaller with each division, finally disappearing in the normal erythrocyte (Fig. 104-1). Hb and iron are incorporated into the gradually maturing RBC, which eventually is released from the marrow into the circulating blood as a reticulocyte. The maturation process usually takes approximately 1 week. The reticulocyte loses its nucleus and becomes an erythrocyte within several days. The circulating erythrocyte is a nonnucleated, nondividing cell. More than 90% of the protein content of the erythrocyte consists of the oxygen-carrying molecule Hb. Erythrocytes compose 40% to 50% of the total blood volume and have a normal survival time of 120 days.

STIMULATION OF ERYTHROPOIESIS

The hormone EPO, 90% of which is produced by the kidneys, initiates and stimulates the production of RBCs. Erythropoiesis is regulated by a feedback loop. The main mechanism of action of EPO is preventing apoptosis, or programmed cell death, of erythroid precursor cells and allowing their proliferation and subsequent maturation. A decrease in tissue oxygen concentration signals the kidneys to increase the production and release of EPO into the plasma, which (a) stimulates stem cells to differentiate into pro-

FIGURE 104-1. Erythrocyte maturation sequence. (EPO, erythropoietin; GM-CSF, granulocyte-macrophage colony-stimulating factor; IL-3, interleukin-3.)

erythroblasts, (b) increases the rate of mitosis, (c) increases the release of reticulocytes from the marrow, and (d) induces Hb formation. Under normal circumstances, the RBC mass is kept at an almost constant level by EPO matching new erythrocyte production to the natural rate of loss of RBCs. Accelerated Hb synthesis makes possible achievement of the critical Hb concentration necessary for RBCs to mature more rapidly. A feedback mechanism stops further RBC nucleic acid synthesis, causing an earlier release of reticulocytes. Early appearance of large quantities of reticulocytes in the peripheral circulation (reticulocytosis) is an indication of increased RBC production.

SYNTHESIS OF HEMOGLOBIN

Hb consists of a protein component with two α - and two β -chains. Each chain is linked to a heme group consisting of a porphyrin ring structure with an iron atom chelated at its center, which is capable of binding oxygen. The initial step in the synthesis of heme from the substrate succinyl CoA and glycine requires the presence of pyridoxine phosphate (vitamin B₆) as a catalyst. Following its synthesis in the cytoplasmic mitochondria of the RBC, heme diffuses into the extramitochondrial space, combines with the completed α - and β -chains, and forms Hb.

Under normal conditions, the body produces approximately 6.25 g of Hb daily. If the bone marrow functions at maximal capacity, the normal RBC survival time of 120 days can decrease to 18 to 20 days before an anemia develops. When hemolytic destruction of RBCs exceeds marrow production capacity and anemia develops, the Hb value decreases to a steady-state level at which production is equal to destruction. Hb values in these hemolytic anemias, such as sickle cell anemia (see Chap. 106), will remain stable unless other factors further shorten the RBC life span.

The affinity of Hb for oxygen is influenced by three intracellular components and by temperature. Increasing hydrogen ion concen-

tration (decreasing pH), carbon dioxide, and 2,3-bisphosphoglycerate, together with increased temperature, all enhance the ability of Hb to release oxygen into tissue by decreasing oxygen affinity. This physiologic compensation also increases plasma volume, which can increase tissue perfusion.

BODY IRON

The normal iron content of the body is approximately 3 to 4 g. Iron is a component of Hb, myoglobin, and cytochromes. Approximately 2.5 g of the iron exists in the form of Hb, and approximately 400 mg exists as iron-containing proteins such as myoglobin and cytochromes. Another 3 to 7 mg of iron is bound to transferrin in plasma, and the remaining iron exists as storage iron in the form of ferritin or hemosiderin. Due to the toxicity of inorganic iron, the body has an intricate system for iron absorption, transport, storage, assimilation, and elimination. Hepcidin is a regulator of intestinal iron absorption, iron recycling and iron mobilization from hepatic stores. It is a peptide made in the liver, distributed in plasma and excreted in urine. Hepcidin inhibits efflux of iron through ferroportin. Hepcidin synthesis is increased by iron loading and decreased by anemia and hypoxia. Hepcidin is induced during infections and inflammation, which allows iron to sequester in macrophages, hepatocytes, and enterocytes.¹⁰ As a result, hepcidin likely is an important mediator of ACD.

ABSORPTION OF IRON

Iron is best absorbed in its ferrous (Fe²⁺) form. The normal daily western diet contains approximately 12 to 15 mg of iron, mainly in the ferric (Fe³⁺) nonabsorbed form. After iron is ionized by stomach acid and then reduced to the Fe²⁺ state, it is absorbed primarily in the duodenum, and to a smaller extent in the jejunum, via intestinal mucosal cell uptake. Subsequently, it is transferred across the cell into the plasma. Iron absorption is not directly correlated to iron intake. As physiologic iron levels decrease, gastrointestinal absorption of iron increases.

The daily recommended dietary allowance for iron is 8 mg in adult males and postmenopausal females, and 18 mg in menstruating females. Children require more iron because of growth-related increases in blood volume, and pregnant women have an increased iron demand brought about by fetal development. Iron overload does not occur, however, because only the amount of iron lost per day is absorbed. The amount of iron absorbed from food depends on the body stores, the rate of RBC production, the type of iron provided in the diet, and the presence of any substances that may enhance or inhibit iron absorption.

Heme iron, which is found in meat, fish, and poultry, is approximately three times more absorbable than the nonheme iron found in vegetables, fruits, dried beans, nuts, grain products, and dietary supplements. Forty percent of iron from animal sources is in the heme form. Heme and nonheme iron are absorbed by different receptors on the intestinal mucosa. The iron contents of some foods high in iron are listed in Table 104–2. Gastric acid and other dietary components such as ascorbic acid increase the absorption of nonheme iron. Dietary components that form insoluble complexes with iron (phytates, tannates, and phosphates) decrease absorption. Phytates, a natural component of grains, brans, and some vegetables, can form poorly absorbed complexes and partially explain the increased prevalence of IDA in poorer countries, where grains and vegetables compose a disproportionate amount of the normal diet, with the more readily absorbable heme iron lacking in the diet. Polyphenols bind the iron and decrease nonheme iron absorption when large amounts of tea or coffee are consumed with a meal. Although the mechanism is unknown, calcium inhibits absorption

TABLE 104-2 Good Sources of Iron

Food	Serving Size	Amount (mg)
Total cereal	1 cup	18
Grape-Nuts cereal	1 cup	18
Instant Cream of Wheat	1 cup	8.2
Instant plain oatmeal	1 cup	6.7
Wheat germ	1 oz.	2.6
Broccoli	1 medium stalk	2.1
Baked potato	1 medium	2.7
Raw tofu	1/2 cup	4
Lentils	1/2 cup	3.3
Beef chuck	3 ounces	3.2

of both heme and nonheme iron. Epidemiologic studies show a correlation between milk intake and prevalence of iron deficiency. Finally, because gastric acid improves iron absorption, patients who have undergone a gastrectomy or have achlorhydria have decreased iron absorption.¹¹

INCORPORATION OF IRON INTO HEME

The specific plasma transport protein transferrin delivers iron to the bone marrow for incorporation into the Hb molecule. Transferrin enters cells by binding to transferrin receptors, which circulate and then attach to cells needing iron. Conversely, there are fewer transferrin receptors on the surface of cells that do not need iron, thus preventing iron-replete cells from receiving excess iron.¹²

Circulating transferrin normally is approximately 30% saturated with iron. Transferrin delivers extra iron to other body storage sites, such as the liver, marrow, and spleen, for later use. This iron is stored within macrophages as ferritin or hemosiderin. Ferritin consists of a Fe³⁺ hydroxyphosphate core surrounded by a protein shell called *apoferritin*. Hemosiderin can be described as compacted ferritin molecules with an even greater iron/protein shell ratio. Physiologically it is a more stable, but less available, form of storage iron.

NORMAL DESTRUCTION OF RED BLOOD CELLS

Phagocytic breakdown destroys older blood cells, primarily in the spleen, but also in the marrow (Fig. 104–2). Amino acids from the globin chains return to an amino acid pool; heme oxygenase acts on the porphyrin heme structure to form biliverdin and to release its iron. Iron returns to the iron pool to be reused, although biliverdin is further catabolized to bilirubin. The bilirubin is released into the plasma, where it binds to albumin and is transported to the liver for glucuronide conjugation and excretion via bile. If the liver is unable to perform the conjugation, as occurs with intrinsic liver disease or oversaturation of conjugation enzymes by excessive cell hemolysis, the result is an elevated indirect (unconjugated) bilirubin. If the biliary excretion pathway for the already conjugated bilirubin is obstructed, an elevated direct bilirubin results. Comparison of direct and indirect bilirubin values helps to determine if the defect in bilirubin clearance occurs before or after bilirubin enters the liver. The Hb in RBCs, which is destroyed by intravascular hemolysis, becomes attached to haptoglobin and is carried back to the marrow for processing in the normal manner.

DIAGNOSIS OF ANEMIA

GENERAL PRESENTATION

History, physical examination and laboratory testing are used in the evaluation of anemia. The workup determines if the patient is

FIGURE 104-2. Destruction of red blood cells (RBCs).

bleeding and investigates potential causes of the anemia, such as increased RBC destruction, bone marrow suppression, or iron deficiency. Occupation, social habits, travel history, and diet all can be important in identifying causes of anemia. Additionally, information about concurrent nonhematologic disease states and a drug ingestion history are essential when evaluating the cause of the anemia (see Chap. 107). History of blood transfusions, liver disease, peptic ulcers, gastrointestinal tract malignancies, and exposure to toxic chemicals also should be obtained.

Because anemias are a sign of disease, clinical presentation may relate to the underlying pathology. Presenting signs and symptoms of anemias depend on the rate of development and the age of the patient, as well as the cardiovascular status of the patient. Severity of symptoms does not always correlate with the degree of anemia. If the myocardium is healthy and the anemia evolves slowly, the combined effects of the shift in the oxygen dissociation curve and increased cardiac output may allow acclimatization at very low Hb concentrations. Mild anemia often is associated with no clinical symptoms and often is found incidentally upon obtaining a complete blood count (CBC) for other reasons. The signs and symptoms in elderly patients with anemia may be attributed to their age or concomitant disease states. Levels of Hb tolerated by younger persons may not be tolerated by the elderly. Patients with cardiac or pulmonary disease may be less tolerant of mild anemia. Premature infants with anemia may be asymptomatic or have tachycardia, poor weight gain, increased supplemental oxygen needs, or increased episodes of apnea or bradycardia.

CLINICAL PRESENTATION OF ANEMIA

General

- Patients may be asymptomatic or have vague complaints
- Patients with vitamin B₁₂ deficiency may develop neurologic consequences
- In ACD, signs and symptoms of the underlying disorder often overshadow those of the anemia

Symptoms

- Decreased exercise tolerance
- Fatigue
- Dizziness
- Irritability
- Weakness
- Palpitations
- Vertigo
- Shortness of breath
- Chest pain
- Neurologic symptoms in vitamin B₁₂ deficiency

Signs

- Tachycardia
- Pale appearance (most prominent in conjunctivae)
- Decreased mental acuity
- Increased intensity of some cardiac valvular murmurs
- Diminished vibratory sense or gait abnormality in vitamin B₁₂ deficiency

Laboratory Tests

- Hb, hematocrit (Hct), and RBC indices may remain normal early in the disease and then decrease as the anemia progresses
- Serum iron is low in IDA and ACD
- Ferritin levels are low in IDA and normal to increased in ACD
- TIBC is high in IDA and is low or normal in ACD
- Mean corpuscular volume is elevated in vitamin B₁₂ deficiency and folate deficiency
- Vitamin B₁₂ and folate levels are low in their respective types of anemia
- Homocysteine is elevated in vitamin B₁₂ deficiency and folate deficiency
- Methylmalonic acid is elevated in vitamin B₁₂ deficiency

Other Diagnostic Tests

- Schilling test may help uncover intrinsic factor deficiency
- Bone marrow testing with iron staining can indicate low iron levels in IDA and adequate stores in ACD

3 Anemia of rapid onset is most likely to present with cardiorespiratory symptoms such as tachycardia, palpitations, angina, hypotension, lightheadedness, and breathlessness due to decreased oxygen delivery to tissues or hypovolemia in those with acute bleeding. With severe intravascular blood volume loss, peripheral vasoconstriction and central vasodilation preserve blood flow to vital organs. Systemic small-vessel dilation eventually increases tissue oxygenation. Vascular compensation results in decreased systemic vascular resistance, increased cardiac output, and tachycardia. With acute hemolysis and reduced RBC mass, some decrease in blood volume, but not in plasma volume, is seen.

If onset is more chronic, presenting symptoms may include fatigue, weakness, headache, symptoms of heart failure, vertigo,

faintness, sensitivity to cold, pallor, and loss of skin tone. Traditional signs of anemia, such as pallor, have limited sensitivity and specificity and may be misinterpreted. With chronic bleeding, there is time for equilibration with extravascular space, and total blood volume remains normal.

Possible manifestations of IDA include glossal pain, smooth tongue, reduced salivary flow, pica (compulsive eating of nonfood items), and pagophagia (compulsive eating of ice). These symptoms are not likely to appear until the Hb concentration falls to a level of 9 g/dL or below.

Clinically, patients with vitamin B₁₂ deficiency may be pale and mildly icteric, and they may develop gastric mucosal atrophy. Neurologic findings in vitamin B₁₂ deficiency, which often precede hematologic findings, may be partly due to impairment of conversion of homocysteine to methionine, as methionine is necessary for production of choline and choline-containing phospholipids. Neurologic effects of vitamin B₁₂ deficiency may occur even in the absence of anemia. Early neurologic findings include numbness and paresthesias, then peripheral neuropathy, ataxia, diminished vibratory sense, decreased proprioception, and imbalance, as demyelination of the dorsal columns and corticospinal tract develop. Vision changes may result from optic nerve involvement. Psychiatric findings include irritability, personality changes, memory impairment, dementia, depression, and, infrequently, psychosis. Other reported symptoms include glossitis, muscle weakness, dysphagia, and anorexia. Pernicious anemia is associated with increased risk of gastric cancer.

Symptoms associated with folate deficiency are similar to those seen in patients with vitamin B₁₂ deficiency, with the absence of neurologic symptoms. Although the symptoms of anemia will improve with folate replacement and a partial hematologic response will occur, the neurologic manifestations of vitamin B₁₂ deficiency will not be reversed with folic acid replacement therapy and consequently may progress or become irreversible if not treated.

LABORATORY EVALUATION

The initial evaluation of anemia involves a CBC (including RBC indices), reticulocyte index, and examination of a stool sample for occult blood. The results of the preliminary evaluation determine the need for other studies, such as examination of a peripheral blood smear. Based on laboratory test results, anemia can be categorized into three functional defects:

1. RBC production failure (hypoproliferative)
2. Cell maturation ineffectiveness
3. Increase in RBC destruction

Table 104-3 lists normal hematologic values, although these values may differ in certain populations, such as individuals living at high altitudes and endurance athletes.

Fig. 104-3 shows a broad, general algorithm for the diagnosis of anemias based on laboratory data. There are many exceptions and additions to this algorithm, but it can serve as a guide to the typical presentation of common types and causes of anemia. The algorithm is less useful in the presence of more than one cause of anemia.

Hemoglobin

Values given for Hb represent the amount of Hb per volume of whole blood. The higher values seen in males are due to stimulation of RBC production by androgenic steroids, whereas the lower values in females are due to decrease in Hb as a result of blood loss during menstruation. The Hb level can be used as a very rough estimate of the oxygen-carrying capacity of blood. Hb levels may be diminished because of a decreased quantity of Hb per RBC or because of a decrease in the actual number of RBCs. In pregnancy, Hb may not reflect red cell mass changes.

TABLE 104-3 Normal Hematologic Values

Test	Reference Range			
	2-6	6-12	12-18	18-49
Hemoglobin (g/dL)	11.5-15.5	11.5-15.5	M 13.0-16.0 F 12.0-16.0	M 13.5-17.5 F 12.0-16.0
Hematocrit (%)	34-40	35-45	M 37-49 F 36-46	M 41-53 F 36-46
MCV (fL)	75-87	77-95	M 78-98 F 78-102	80-100
MCHC (%)	—	31-37	31-37	31-37
MCH (pg)	24-30	25-33	25-35	26-34
RBC (million/mm ³)	3.9-5.3	4.0-5.2	M 4.5-5.3	M 4.5-5.9
Reticulocyte count, absolute (%)				0.5-1.5
Serum iron (mcg/dL)		50-120	50-120	M 50-160 F 40-150
TIBC (mcg/dL)	250-400	250-400	250-400	250-400
RDW (%)				11-16
Ferritin (ng/mL)	7-140	7-140	7-140	M 15-200 F 12-150
Folate (ng/mL)				1.8-16.0 ^a
Vitamin B ₁₂ (pg/mL)				100-900 ^a
Erythropoietin (mU/mL)				0-19

F, female; M, male; MCH, mean corpuscular hemoglobin; MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume; RBC, red blood cell; RDW, red blood cell distribution; TIBC, total iron-binding capacity.

^aVaries by assay method.

Hematocrit

Expressed as a percentage, hematocrit (Hct) is the actual volume of RBCs in a unit volume of whole blood. In general, it is approximately three times the Hb value. An alteration in this ratio may occur with abnormal cell size or shape and often indicates the pathology. A low Hct indicates a reduction in either the number or the size of RBCs or an increase in plasma volume.

Red Blood Cell Count

The RBC count is an indirect estimate of the Hb content of the blood; it is an actual count of RBCs per unit of blood.

Red Blood Cell Indices

Wintrobe indices describe the size and Hb content of the RBCs and are calculated from the Hb, Hct, and RBC count. RBC indices, such as mean corpuscular volume (MCV) and mean corpuscular Hb (MCH), are single mean values that do not express the variation that can occur in cells.

Mean Corpuscular Volume (Hct/RBC Count) MCV represents the average volume of RBCs. It may reflect changes in MCH, but it can be confounded. Cells are considered *macrocytic* if they are larger than normal, *microcytic* if they are smaller than normal, and *normocytic* if their size falls within normal limits. Folic acid and vitamin B₁₂ deficiency anemias yield macrocytic morphology, whereas iron deficiency and thalassemia are examples of microcytic anemias. MCV is falsely elevated in the presence of cold agglutinins and hyperglycemia. When IDA (decreased MCV) is accompanied by folate deficiency (increased MCV), failure to understand that the MCV represents an average RBC size creates the potential for overlooking the real cause of the anemia.

Mean Corpuscular Hemoglobin (Hb/RBC Count) MCH is defined as the percent volume of Hb in an RBC. It reflects the adequacy of iron supply to developing erythron. Two morphologic changes, microcytosis and hypochromia, can reduce MCH. A

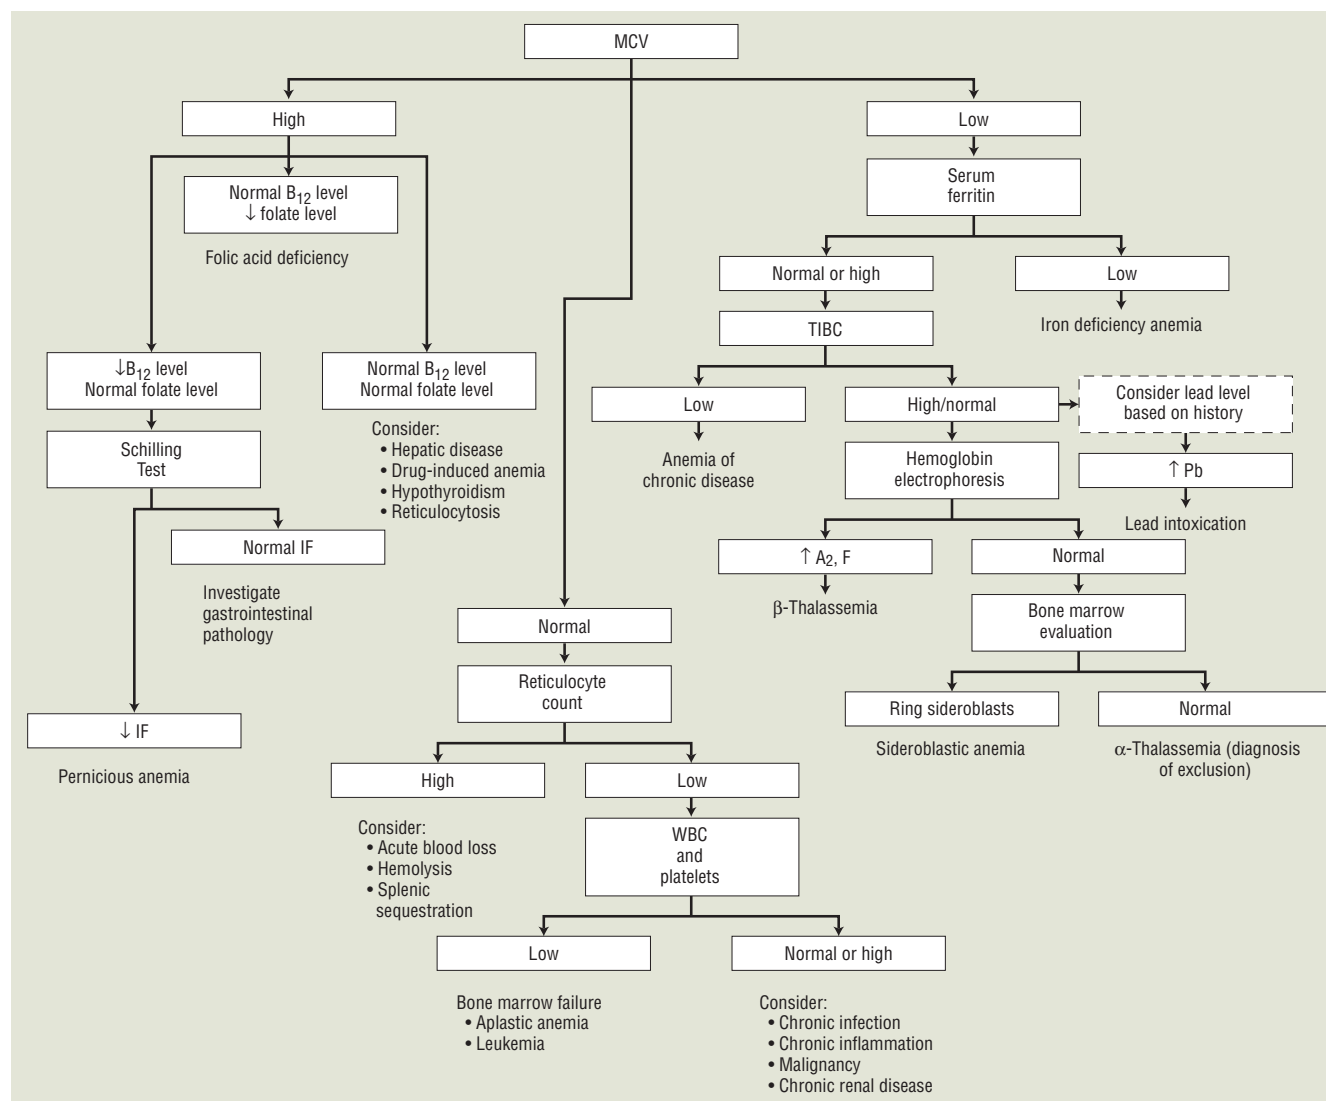

FIGURE 104-3. General algorithm for diagnosis of anemias. (↑, increased; ↓, decreased; A₂, hemoglobin A₂; F, hemoglobin F; IF, intrinsic factor; MCV, mean corpuscular volume; Pb, lead; TIBC, total iron-binding capacity; WBC, white blood cells.)

microcytic cell contains less Hb because it is a smaller cell, whereas a hypochromic cell has a low MCH because of the decreased amount of Hb present in a normocytic cell. Cells can be both microcytic and hypochromic, as seen with IDA, and the MCH alone cannot distinguish between microcytosis and hypochromia. The most common cause of an elevated MCH is macrocytosis (e.g., vitamin B₁₂ or folate deficiency).

Mean Corpuscular Hemoglobin Concentration (Hb/Hct)

The weight of Hb per volume of cells is the mean corpuscular Hb concentration (MCHC). Because MCHC is independent of cell size, it is more useful than MCH in distinguishing between microcytosis and hypochromia. A low MCHC always indicates hypochromia; a microcyte with a normal Hb concentration will have a low MCH but a normal MCHC. A decreased MCHC is seen most often in association with IDA.

Total Reticulocyte Count

Although an indirect assessment, the total reticulocyte count is an indication of new RBC production. It measures how quickly immature RBCs (reticulocytes) are produced by bone marrow and released into the blood. Reticulocytes circulate in the blood approximately 2 days before maturing into RBCs. In a normal situation, 1% of RBCs are replaced daily, representing a reticulocyte count of

1%. The reticulocyte count in normocytic anemia can differentiate hypoproliferative marrow from a compensatory marrow response to an anemia. A lack of reticulocytosis in anemia indicates impaired RBC production. Examples include iron deficiency, B₁₂ deficiency, ACD, malnutrition, renal insufficiency, and malignancy. A high reticulocyte count may be seen in acute blood loss or hemolysis. Occasionally, a patient's Hct decreases while the absolute number of reticulocytes remains the same, resulting in a falsely elevated reticulocyte percentage. Multiplying the reticulocyte percentage by the patient's Hct and then dividing the product by an average normal Hct (for men or women) produces a corrected percentage of reticulocytes (see Chap. 103). When the reticulocyte count is >2.5%, hemolysis may be present.

Red Blood Cell Distribution Width

The higher the red blood cell distribution width (RDW), the more variable the size of the RBCs. The RDW increases in early IDA because of the release of large, immature, nucleated RBCs to compensate for the anemia, but this change is not specific for IDA. The RDW also can be helpful in the diagnosis of a mixed anemia. A patient can have a normal MCV yet have a wide RDW. This finding indicates the presence of microcytes and macrocytes, which would yield a "normal" average RBC size. Use of RDW to distinguish IDA from ACD is not recommended.

Peripheral Blood Smear

The peripheral blood smear is an inexpensive tool that can supplement other clinical data or, in some cases, provide sufficient data alone to establish a diagnosis. It is used to exclude other causes of anemia and to detect evidence of marrow replacement. Peripheral blood smears provide information on the functional status of the bone marrow and defects in RBC production. Additionally, it provides information on variations in cell size (anisocytosis) and shape (poikilocytosis). Automated blood counters, used for the CBC, can flag specific RBC changes that can be confirmed by a peripheral blood smear. Blood smears are placed on a microscope slide and stained as appropriate. Morphologic examination includes assessment of size, shape, and color. The extent of anisocytosis correlates with increased range of cell sizes. Poikilocytosis suggests a defect in the maturation of RBC precursors in the bone marrow. The detected abnormalities can suggest pathology.

Serum Iron

The level of serum iron is the concentration of iron bound to transferrin. Normally, transferrin is approximately one-third bound (saturated) to iron. Unfortunately, the serum iron level of many patients with IDA remains within the lower limits of normal because a considerable amount of time is required to deplete iron stores, giving a false-negative test result. Serum iron levels show 20% to 30% diurnal variation (higher in the morning, lower in the afternoon) and 20% to 25% day-to-day variation.¹³ Variability results from technical and physiologic influences. Serum iron levels are decreased by infection and inflammation. Consequently, as a diagnostic tool, serum iron levels are best interpreted in conjunction with the TIBC. The serum iron level decreases with IDA and ACD and increases with hemolytic anemias and iron overload.

Total Iron-Binding Capacity

An indirect measurement of the iron-binding capacity of serum transferrin, TIBC evaluation is performed by adding an excess of iron to plasma to saturate all transferrin with iron. *Transferrin saturation* is another name for TIBC. Each transferrin molecule can carry two iron atoms. Normally, approximately 30% of available iron binding sites are filled. With this laboratory test, all binding sites are filled to measure TIBC. The excess (unbound) iron is then removed and the serum iron concentration determined. Unlike the serum iron level, the TIBC does not fluctuate over hours or days. TIBC usually is higher than normal when body iron stores are low. The finding of a low serum iron level and a high TIBC indicates IDA. The TIBC is actually a measurement of protein serum transferrin, which can be affected by a variety of factors. Patients with infection, malignancy, inflammation, liver disease, and uremia may have a decreased TIBC and a decreased serum iron level, which are consistent with the diagnosis of ACD. Oral contraceptive use and pregnancy can increase TIBC because serum transferrin production is increased with a variety of other proteins.

Percentage Transferrin Saturation

The ratio of serum iron level to TIBC indicates transferrin saturation. It reflects the extent to which iron-binding sites are vacant on transferrin and indicates the amount of iron readily available for erythropoiesis. It is expressed as a percentage, as described in the following formula: $\text{Transferrin saturation} = (\text{Serum iron} / \text{TIBC}) \times 100$.

Transferrin normally is 20% to 50% saturated with iron. In IDA, transferrin saturation of 15% or lower is commonly seen. Transferrin saturation is a less sensitive and specific marker of iron deficiency than are ferritin levels.

Serum Ferritin

The concentration of ferritin (storage iron) is proportional to total iron stores and therefore is the best indicator of iron deficiency or

iron overload. Ferritin levels indicate the amount of iron stored in the liver, spleen, and bone marrow cells. Low serum ferritin levels are virtually diagnostic of IDA because they decrease only in association with IDA. In contrast, serum iron levels may decrease in both IDA and ACD. Serum ferritin is an acute phase reactant, so chronic infection or inflammation can increase its concentration independent of iron status, masking depleted tissue stores. This limits the specificity and utility of the serum ferritin if the level is normal or high in a chronically ill patient. In these patients, iron, even if present in these tissue stores, may not be available for erythropoiesis.

Soluble Transferrin Receptor

The soluble transferrin receptor (sTfR) assay is a laboratory test considered to be a sensitive, early, highly quantitative marker of iron depletion. The sTfR concentration is inversely correlated with tissue iron stores, and elevated levels are predictive of iron deficiency. Unlike conventional laboratory tests, the sTfR is not an acute phase reactant, so its level remains normal in patients with chronic disease. It is a useful test for distinguishing ACD from IDA.¹⁴ The major limitation of this test is that it is not widely available in many laboratories and therefore is not commonly used in clinical practice.

Folic Acid

The results of folic acid measurements vary depending on the assay method used. Decreased serum folic acid levels indicate a folate deficiency megaloblastic anemia that may coexist with a vitamin B₁₂ deficiency anemia. Erythrocyte folic acid levels are less volatile than serum levels, because they are slow to decrease in an acute process such as drug-induced folic acid deficiency and slow to increase with oral folic acid replacement. Also, erythrocyte folic acid levels have the theoretical advantage of less susceptibility to rapid changes in diet and alcohol intake. Limitations with sensitivity and specificity do exist with measurements of RBC folate. It has been proposed that serum folate assay levels be drawn in patients with MCV >110 fL or in patients with a lower MCV and clinical features suggesting a macrocytic anemia. If the serum folate concentration is normal in a patient with suspected folate deficiency, then the red cell folate level should be measured.¹⁵

Vitamin B₁₂

Low levels of vitamin B₁₂ (cyanocobalamin) indicate vitamin B₁₂ deficiency. However, a deficiency may exist prior to the recognition of low serum levels, as serum values are maintained at the expense of vitamin B₁₂ tissue stores. Because vitamin B₁₂ deficiency and folate deficiency may overlap, serum levels of both vitamins should be determined. Vitamin B₁₂ levels may be falsely low with folate deficiency, pregnancy, and use of oral contraceptives.¹⁶

Schilling Test

The purpose of the rarely used Schilling urinary excretion test is to diagnose vitamin B₁₂ deficiency anemia caused by a B₁₂ absorption defect resulting from a lack of intrinsic factor (pernicious anemia). The patient initially receives an oral dose of radiolabeled vitamin B₁₂. Two hours later, the patient receives a large intramuscular dose of nonlabeled vitamin B₁₂ to saturate plasma transport proteins. Any excess vitamin B₁₂ that is not taken up by the transport proteins or stored in the liver is excreted in the urine. A 24-hour urine collection then is measured for radioactivity. If production of gastrointestinal intrinsic factor is sufficient, the radiolabeled B₁₂ will be absorbed initially, displaced by the injected B₁₂, and excreted in the urine.

If oral absorption is impaired, stage 2 of the test is conducted 5 to 7 days later. The second stage of the Schilling test differentiates

inadequate secretion of intrinsic factor by the stomach from an abnormality in absorption by the ileum. Generally, the finding of abnormal results for stage 1 followed by a normal result in stage 2 is consistent with pernicious anemia. If the results in part 2 still are low, then the third stage of the test is conducted to determine whether the cause of the deficiency is bacterial overgrowth or ileal disease.

Homocysteine

Vitamin B₁₂ and folate both are required for conversion of homocysteine to methionine. Increased serum homocysteine may suggest vitamin B₁₂ or folate deficiency. Homocysteine levels also can be elevated in patients with vitamin B₆ deficiency, renal failure, hypothyroidism, or a genetic defect in cystathionine β -synthase.¹⁷ Additionally, elevated levels have been caused by medications, including nicotinic acid, theophylline, methotrexate, and L-dopa.

Methylmalonic Acid

A vitamin B₁₂ coenzyme is needed to convert methylmalonyl coenzyme A to succinyl coenzyme A. Patients with vitamin B₁₂ deficiency may have increased concentrations of serum methylmalonic acid (MMA), which is a more specific marker for vitamin B₁₂ deficiency compared to homocysteine. MMA levels are not elevated in folate deficiency because folate does not participate in MMA metabolism. Levels of both MMA and homocysteine usually are elevated prior to the development of hematologic abnormalities and reductions in serum vitamin B₁₂ levels.¹⁶ MMA levels must be interpreted cautiously in patients with renal disease and hypovolemia because the levels may be elevated due to decreased urinary excretion.

Coombs Test

Antiglobulin tests, also called *Coombs tests*, indicate hemolytic anemia caused by an immune response. A direct Coombs test detects antibodies bound to erythrocytes, whereas an indirect Coombs test measures antibodies present in the serum. A positive finding on a direct Coombs test usually is indicative of antibody-mediated hemolysis.

Erythropoietin Levels

Healthy individuals require 10 to 30 milliunits/mL of EPO to maintain normal Hb and Hct concentrations. Endogenous EPO levels can increase 100- to 1,000-fold during hypoxia or anemia, but this marked increase does not occur in patients with significant renal disease, patients receiving chemotherapy, and patients with acquired immunodeficiency syndrome (AIDS), especially those taking zidovudine. These patients will have an EPO response that is insufficient to correct their anemia.

SPECIFIC ANEMIAS

IRON-DEFICIENCY ANEMIA

Epidemiology

Iron deficiency is the most common nutritional deficiency in developing and developed countries. More than 500 million people worldwide are estimated to have IDA.² Data from NHANES III indicates 1% to 2% of adult in the United States have IDA.¹⁸ Prevalence data vary because screening uses a simple Hb test, arbitrary normals are used, and selection of samples in population surveys tends to lead to errors. The normal ranges for Hb and Hct are so wide that a patient may lose up to 15% of RBC mass and still have a Hct within the normal range.

Etiology

Iron deficiency results from prolonged negative iron balance or failure to meet increased physiologic iron need. The onset of iron deficiency depends on an individual's initial iron stores and balance between iron absorption and loss. Multiple etiologic factors usually are involved. Certain groups at higher risk for iron deficiency include children younger than 2 years, adolescent girls, pregnant females, and elderly older than 65 years.

In less industrialized nations, the risks for developing IDA are largely related to dietary factors. Diets limited in meat or fresh fruits and vegetables or diets high in substances that form complexes with iron may result in IDA. Malabsorptive syndromes also may cause IDA. Situations that increase the demand for iron are frequent blood donations, participation in endurance sports, menstruation, pregnancy and lactation, infancy, and adolescence. Iron deficiency in pregnant women is so common that the Centers for Disease Control and Prevention (CDC) guidelines recommend initiation of low-dose iron supplements (30 mg/day) at the woman's first prenatal visit for primary prevention of IDA. At diagnosis, the cause of IDA must be considered a consequence of blood loss until proven otherwise. More than 50% of adults with IDA have some form of gastrointestinal bleeding. Blood loss may occur as a result of many disorders, including trauma, hemorrhoids, peptic ulcers, gastritis, gastrointestinal malignancies, arteriovenous malformations, diverticular disease, copious menstrual flow, nosebleeds, and postpartum bleeding. Occult blood loss from a single gastrointestinal lesion has been shown to be a frequent cause of "idiopathic" IDA.¹⁹

The possibility of multifactorial causes must always be considered. Medication history, specifically regarding recent or past use of iron or hematinics, alcohol, corticosteroids, aspirin, and nonsteroidal antiinflammatory drugs, is a vital part of the history. Other possible causes of hypochromic microcytic anemia include ACD, thalassemia, sideroblastic anemia, and heavy metal (mostly lead) poisoning (Fig. 104-3). Patients with IDA commonly undergo upper and/or lower endoscopy in an attempt to identify a bleeding gastrointestinal lesion. Patients with a medical history significant for IDA should be periodically reevaluated for iron deficiency.

Pathophysiology

Iron is vital to the function of all cells. It is a critical element in iron-containing enzymes such as the mitochondrial cytochrome system. Without iron, cells lose their capacity for electron transport and energy metabolism. Because iron is a cofactor for oxidative metabolism, dopamine and DNA synthesis, and free radical function in neutrophils, IDA can be associated with abnormal neurotransmitter function and altered immunologic and inflammatory defenses. The balance of iron metabolism is designed to conserve iron for reutilization. The margin between the amount of iron available for absorption and the body's iron requirement is narrow for growing infants and female adults, which explains why IDA prevalence is highest in these populations. Risk of iron deficiency is related to levels of iron loss, iron intake, iron absorption, and physiologic demands. Iron deficiency usually is the result of a long period of negative iron balance. Manifestations of iron deficiency occur in three stages: prelatent, latent, and IDA. *Prelatent* iron deficiency refers to a reduction in iron stores without reduced serum iron levels and can be assessed with serum ferritin measurement. In this first stage, iron stores can be depleted without causing anemia. The stores allow iron to be utilized when there is an increased need for Hb synthesis. Once stores are depleted, there still is adequate iron from daily RBC turnover for Hb synthesis. Further iron losses would make the patient vulnerable to anemia development. *Latent* iron deficiency occurs when iron stores are depleted, but Hb is above the lower limit of normal for the population but may be

reduced for a given patient. This can be determined by serial CBC measurements. Findings include reduced transferrin saturation and increased TIBC. IDA occurs when the Hb falls to less than normal values. Deficiency progresses to the classic hypochromia and microcytosis of iron-deficient erythropoiesis.

Another classification of iron deficiency is in accordance with clinical state: iron-store depletion, iron-deficient erythropoiesis, or IDA. The mildest form, iron-store depletion, occurs when there is an increase in formal physiologic demands, which occurs in rapid growth in infancy or adolescence, menstruation, or with an inadequate diet. Limited RBC production and iron-deficient erythropoiesis can occur with blood loss or malabsorption, which can progress to IDA. Iron-store depletion and iron-deficient erythropoiesis may not be associated with any distinctive clinical findings.

Laboratory Findings

④ Abnormal laboratory findings in patients with IDA generally include low serum iron and ferritin levels and high TIBC. The first apparent sign of iron deficiency is the increased RDW, although the finding is not specific to IDA. In the early stages of IDA, RBC size is not changed. Low ferritin concentration is the earliest and most sensitive indicator of iron deficiency. However, ferritin may not correlate with iron stores in the bone marrow because renal or hepatic disease, malignancies, infection, or inflammatory processes may increase ferritin values.²⁰ Hb, Hct, and RBC indices usually remain normal.

In the later stages of IDA, Hb and Hct fall below normal values, and a microcytic hypochromic anemia develops. Microcytosis may precede hypochromia, as erythropoiesis is programmed to maintain normal Hb concentration in deference to cell size. As a result, even slightly abnormal Hb and Hct levels may indicate significant depletion of iron stores and should not be ignored. In terms of RBC indices, MCV reduction occurs earlier in iron-deficient hematopoiesis than does reduction in Hb concentration.

Transferrin saturation (i.e., serum iron level divided by the TIBC) is useful for assessing IDA. Low values likely indicate IDA, although low serum transferrin saturation values also may be present in inflammatory disorders. Fortunately, the TIBC usually helps to differentiate the diagnosis in these patients: TIBC >400 mcg/dL suggests IDA, whereas values <200 mcg/dL usually represent inflammatory disease. With continued progression of IDA, anisocytosis occurs and poikilocytosis develops, as seen on peripheral blood smear and indicated by increased RDW. In rare cases, a bone marrow examination is indicated to assess bone marrow iron stores. Bone marrow examination reveals absent iron stores in IDA. Documentation of decreased hemosiderin can confirm the diagnosis of IDA. In microcytic anemias due to all other causes, iron stores are detectable. Serum transferrin receptor can be used to diagnose iron-store depletion and defects in iron delivery to the marrow. Commercial assays are available but are not well standardized. An elevated serum transferrin receptor level would be expected in IDA and a normal level in ACD.

TREATMENT

Iron-Deficiency Anemia

The severity and cause of IDA determines the approach to treatment.²¹ Treatment is focused on replenishing iron stores. Because iron deficiency can be an early sign of other illnesses, treatment of the underlying disease may aid in the correction of iron deficiency. The USPSTF has concluded that evidence is insufficient to recommend for or against routine iron supplementation for nonanemic pregnant women.

DIETARY SUPPLEMENTATION AND THERAPEUTIC IRON PREPARATIONS

Treatment of IDA usually consists of dietary supplementation and administration of therapeutic iron preparations. Iron is poorly absorbed from vegetables, grain products, dairy products, and eggs; it is best absorbed from meat, fish, and poultry. Beverages have been shown to affect iron absorption. Meat, orange juice, and other ascorbic acid-rich foods should be included with meals, whereas milk and tea should be consumed in moderation between meals. In most cases of IDA, oral administration of iron therapy with soluble Fe^{2+} iron salts is appropriate.

CLINICAL CONTROVERSY

Daily Fe^{2+} sulfate is not tolerated by all patients and can be difficult to administer in populations of developing nations. Weekly rather than daily supplements have been used, with conflicting efficacy results. The weekly approach follows the natural pattern of mucosal cell iron turnover.

Fe^{2+} sulfate, succinate, lactate, fumarate, glycine sulfate, glutamate, and gluconate are absorbed similarly. The addition of copper, cobalt, molybdenum, or other minerals or hematinics provides no advantage but adds expense. The carbonyl iron may be advantageous because of lower risk for death in cases of accidental overdose. Iron is best absorbed in the reduced Fe^{2+} form, with maximal absorption occurring in the duodenum, primarily due to the acidic medium of the stomach. The presence of mucopolysaccharide chelator substances prevents the iron from precipitating and maintains the iron in a soluble form. In the alkaline environment of the small intestines, iron tends to form insoluble complexes that are unavailable for absorption. Slow-release or sustained-release iron preparations do not undergo sufficient dissolution until they reach the small intestines, which significantly reduces iron absorption and can attenuate the hematinic effects. This is especially true when enteric-coated preparations are used in achlorhydric patients. The dose of iron replacement therapy depends on the patient's ability to tolerate the administered iron. Tolerance of iron salts improves with a small initial dose and gradual escalation to the full dose. In patients with IDA, the general recommendation is administration of approximately 200 mg of elemental iron daily, usually in two or three divided doses to maximize tolerability. However, if patients cannot tolerate this daily dose of elemental iron, smaller amounts of elemental iron (e.g., single 325-mg tablet of Fe^{2+} sulfate) usually is sufficient to replace iron stores, albeit at a slower rate. Table 104-4 lists the percentage of elemental iron of commonly available iron salts. The percentage of iron absorbed decreases progressively as the dose increases, although the absolute amount absorbed increases. Iron preferably is administered at least 1 hour before meals because food interferes with iron absorption. Many patients must take iron with food because they experience nausea and diarrhea when iron is administered on an empty stomach.

Adverse reactions to therapeutic doses of iron are primarily gastrointestinal in nature and consist of a dark discoloration of feces, constipation or diarrhea, nausea, and vomiting. Gastrointestinal side effects usually are dose-related and are similar among iron salts when equivalent amounts of elemental iron are administered. Administration of smaller amounts of iron with each dose may minimize these adverse effects. Histamine₂ blockers or proton pump inhibitors that reduce gastric acidity may impair iron absorption. Table 104-5 lists drug interactions with iron. Failure to develop at least some mild gastrointestinal symptoms may suggest nonadherence. If these side effects become intolerable, the total daily dose can be decreased to 110 to 120 mg of elemental iron, or

TABLE 104-4 Oral Iron Products

Salt	Elemental Iron Percentage	Elemental Iron Provided
Ferrous sulfate	20%	60–65 mg/324–325 mg tablet 18 mg iron/5 mL syrup 44 mg iron/5 mL elixir 15 mg iron/0.6 mL drop
Ferrous sulfate (exsiccated)	30%	65 mg/200 mg tablet 60 mg/187 mg tablet 50 mg/160 mg tablet
Ferrous gluconate	12%	36 mg/325 mg tablet 27 mg/240 mg tablet
Ferrous fumarate	33%	33 mg/100 mg tablet 63–66 mg/200 mg tablet 106 mg/324–325 mg tablet 15 mg/0.6 mL drop 33 mg/5 mL suspension
Polysaccharide iron complex	100%	150 mg capsule 50 mg tablet 100 mg/5 mL elixir
Carbonyl iron	100%	50 mg caplet

the dose can be taken with meals. It should be noted, however, that administration of iron with meals reduces the amount of iron absorbed by more than half.

Failure to respond to appropriate treatment regimens necessitates reevaluation of the patient's condition. Occasionally a “therapeutic trial of iron” approach will be used to confirm a presumptive diagnosis of IDA. Common causes of treatment failure include poor patient adherence, inability to absorb iron, incorrect diagnosis, continued bleeding, or a concurrent condition that impairs full reticulocyte response. Even when iron deficiency is present, response may be impaired when a coexisting cause for anemia exists. Rarely a patient is not able to absorb iron, most often due to previous gastrectomy or celiac disease. Malabsorption can be ruled out by the iron test, in which plasma iron levels are determined at half-hour intervals for 2 hours following the administration of 50 mg of elemental iron as liquid Fe^{2+} sulfate. If plasma iron levels increase by >50 mcg/dL during this time, absorption is satisfactory. Regardless of the form of oral therapy used, treatment should continue for 3 to 6 months after the anemia is resolved to allow for repletion of iron stores and to prevent relapse.

TABLE 104-5 Iron Salt–Drug Interactions

Drugs That Decrease Iron Absorption	Object Drugs Affected by Iron
Al-, Mg-, and Ca^{+2} -containing antacids	Levodopa ↓ (chelates with iron)
Tetracycline and doxycycline	Methyldopa ↓ (decreases efficacy of methyldopa)
Histamine ₂ antagonists	Levothyroxine ↓ (decreased efficacy of levothyroxine)
Proton pump inhibitors	Penicillamine ↓ (chelates with iron)
Cholestyramine	Fluoroquinolones ↓ (forms ferric ion–quinolone complex)
	Tetracycline and doxycycline ↓ (when administered within 2 hours of iron salt)
	Mycophenolate ↓ (decreases absorption)

■ PARENTERAL IRON THERAPY

When evidence of iron malabsorption or intolerance to orally administered iron is seen or long-term nonadherence is suspected, parenteral iron therapy may be warranted. Patients with significant blood loss who refuse transfusions and cannot take oral iron therapy also may require parenteral iron therapy. Parenteral iron does not lead to a quicker hematologic response than that of oral iron. The ideal parenteral iron supplement would be safe, efficacious, and convenient and would maintain consistent patient outcomes. Three different parenteral iron preparations currently available in the United States are iron dextran, sodium ferric gluconate, and iron sucrose (Table 104-6). They differ in their molecular size, degradation kinetics, bioavailability, and side-effect profiles. Although toxicity profiles of these agents differ, clinical studies indicate that each is efficacious. Most of the recent research on intravenous iron has been performed in hemodialysis patients. Dextran parenteral preparations have been associated with death due to anaphylactic reactions. These reactions may be related to immune reactions to the iron–carbohydrate or iron–dextran complex. Another theory for the anaphylaxis is the high-molecular-weight dextran component, which may be antigenic even when not complexed to iron. The safety profile of iron is largely assessed by spontaneous reports to the Food and Drug Administration (FDA) and retrospective and open-label prospective studies. Results of these studies suggest that Fe^{3+} gluconate and iron sucrose are safer than iron dextran.²² The concern with parenteral iron is that iron may be released too quickly and overload the ability

TABLE 104-6 Comparison of Parenteral Iron Preparations

	Sodium Ferric Gluconate	Iron Dextran	Iron Sucrose
Amount of elemental iron	62.5 mg iron/5 mL	50 mg iron/mL	20 mg iron/mL
Molecular weight	Ferlecit: 289,000–444,000 daltons	Infed: 165,000 daltons DexFerrum: 267,000 daltons	Venofer: 34,000–60,000 daltons
Composition	Ferric oxide hydrate bonded to sucrose chelates with gluconate in a molar rate of 2 iron molecules to 1 gluconate molecule	Complex of ferric hydroxide and dextran	Complex of polynuclear iron hydroxide in sucrose
Preservative	Benzyl alcohol 9 mg/5 mL 20% (975 mg in 62.5 mg iron)	None	None
Indication	Treatment of iron-deficiency anemia in patients undergoing chronic hemodialysis who are receiving supplemental erythropoietin therapy	Treatment of patients with documented iron deficiency in whom oral therapy is unsatisfactory or impossible	Treatment of iron-deficiency anemia in patients undergoing chronic hemodialysis who are receiving supplemental epoetin alfa therapy
Warning	No black box warning; hypersensitivity reactions	Black box warning: anaphylactic-type reactions	Black box warning: anaphylactic-type reactions
IM injection	No	Yes	No
Usual dose	125 mg (10 mL) diluted in 100 mL normal saline, infused over 60 minutes; also can be administered as a slow IV injection (rate of 12.5 mg/min).	100 mg undiluted at a rate not to exceed 50 mg (1 mL) per min	100 mg into the dialysis line at a rate of 1 mL (20 mg of iron) undiluted solution per minute
Treatment	8 doses \times 125 mg = 1,000 mg	10 doses \times 100 mg = 1,000 mg	Up to 10 doses \times 100 mg = 1,000 mg
Common adverse effects	Cramps, nausea and vomiting, flushing, hypotension, rash, pruritus	Pain and brown staining at injection site, flushing, hypotension, fever, chills, myalgia, anaphylaxis	Leg cramps, hypotension

of transferrin to bind it, leading to free iron reactions that can interfere with neutrophil function.

Iron dextran, a complex of Fe³⁺ hydroxide and the carbohydrate dextran, contains 50 mg of iron per milliliter and can be given via the intramuscular or intravenous route. Different brands of iron dextran are available and differ in their molecular weight. They are not interchangeable.

Iron dextran must be processed by macrophages for the iron to be biologically available. The absorption and metabolism vary with the route and amount of drug given. Absorption of an intramuscular dose of iron dextran occurs in two phases. During the first 72 hours, iron dextran is absorbed primarily through the lymphatics into the left superior vena cava. A smaller amount is absorbed directly through the intramuscular capillary network into the blood. A second, slower phase involves uptake of the iron–dextran complex by macrophages, with subsequent transport through the lymphatics into the blood. The macrophages phagocytize the iron–dextran complex and cleave the dextran moiety, which makes free iron available to the body as circulating iron, transferrin-bound iron, or storage iron (ferritin and hemosiderin). Iron dextran can remain within these cells for many months. Approximately 60% of an intramuscular dose of iron dextran is absorbed after 3 days, and up to 90% is absorbed within 3 weeks. The remainder is absorbed slowly over several months or longer.

When intravenous iron dextran is given, the iron is taken up immediately by the mononuclear phagocytic system. Small-to-intermediate intravenous doses can be cleared from the plasma within 3 days of administration. In contrast, larger intravenous doses of iron dextran are processed by the mononuclear phagocytic system at a constant rate of 10 to 20 mg/h and result in high plasma concentrations of iron dextran for as long as 3 weeks.

The iron dextran package insert carries a black box warning regarding the risk of anaphylaxis and a test dose is required before administration of the repletion dose. Methods of intravenous administration include multiple slow injections of undiluted iron dextran solution or an infusion of a diluted preparation. This latter method often is referred to as *total dose infusion*. The intramuscular administration of iron dextran should take place via Z-tract injection technique (a technique for handling intramuscular injections of irritating substances with minimal tracking of the medication through surrounding tissues) to minimize staining of the skin. Because each intramuscular dose is limited to 2 mL (100 mg of iron), multiple injections often are required. Daily intramuscular doses should not exceed 25 mg in patients weighing less than 5 kg, 50 mg in patients weighing less than 10 kg, and 100 mg in all other patients. Problems with intramuscular administration include patient discomfort, unpredictable delivery, sterile abscesses, tissue necrosis, and atrophy. In addition, up to 30% of an administered dose remains physiologically unavailable. For these reasons, the intravenous route is the preferred parenteral route of administration.

Equations for calculating the appropriate dose of parenteral iron in patients with IDA or anemia secondary to blood loss are listed in Table 104–7. Doses given by intravenous administration should not exceed 50 mg of iron per minute (1 mL/min). It is suggested that all patients considered for an iron dextran injection receive a test dose of 25 mg intramuscularly or intravenously, or a 5- to 10-minute infusion of the diluted solution. Patients then should be observed for more than 1 hour for untoward reactions. An anaphylaxis-like reaction generally responds to intravenous epinephrine, diphenhydramine, and corticosteroids. If the test dose is tolerated, patients receiving total dose infusions can undergo infusion of the remaining solution during the next 2 to 6 hours.

Total replacement doses of intravenous iron dextran have been given as a single dose, diluted in 250 to 1,000 mL normal saline or 5% dextrose in water and infused over 4 to 6 hours. A test dose still is

TABLE 104-7 Equations for Calculating Doses of Parenteral Iron

In patients with iron deficiency anemia:

Adults + children >15 kg

$$\text{Dose (mL)} = 0.0442 (\text{Desired Hb} - \text{Observed Hb}) \times \text{LBW} + (0.26 \times \text{LBW})$$

$$\text{LBW males} = 50 \text{ kg} + (2.3 \times \text{inches over 5 ft})$$

$$\text{LBW females} = 45.5 \text{ kg} + (2.3 \times \text{inches over 5 ft})$$

Children 5–15 kg

$$\text{Dose (mL)} = 0.0442 (\text{Desired Hb} - \text{Observed Hb}) \times W + (0.26 \times W)$$

In patients with anemia secondary to blood loss (hemorrhagic diathesis or long-term dialysis):

$$\text{mg of iron} = \text{blood loss} \times \text{hematocrit},$$

where blood loss is in milliliters and hematocrit is expressed as a decimal fraction.

Hb, hemoglobin; LBW, lean body weight; mL, milliliter; W, weight.

required. The ability to give a total dose infusion is a benefit of iron dextran over the other parenteral iron products. Iron dextran is best utilized when smaller frequent doses of sodium ferric gluconate or iron sucrose are impractical, as with peritoneal dialysis.

Patients who receive total dose infusions are at higher risk for adverse reactions, such as arthralgias, myalgias, flushing, malaise, and fever. Other adverse reactions of iron dextran include staining of the skin, pain at the injection site, allergic reactions, and rarely anaphylaxis. Patients most likely to experience adverse effects with iron dextran include individuals with a history of allergies, asthma, or inflammatory diseases. Patients with preexisting immune-mediated diseases, such as active rheumatoid arthritis or systemic lupus erythematosus, are considered at high risk for adverse reactions because of their hyperreactive immune response capabilities.

Sodium ferric gluconate is a complex of iron bound to one gluconate and four sucrose molecules in a repeating pattern. Its molecular weight is 289,000 to 440,000 daltons. Sodium ferric gluconate is available in an aqueous solution. No direct transfer of iron from the Fe³⁺ gluconate to the transferrin occurs. The complex is taken up quickly by the mononuclear phagocytic system and has a half-life of approximately 1 hour in the bloodstream. It is supplied in 5-mL ampules containing 62.5 mg of elemental iron. It has been available in Europe since 1959 and was introduced for use in the United States in 1999. It is FDA-indicated for iron supplementation in hemodialysis patients. The difference in the time of availability between Europe and the United States makes difficult the comparison of allergy and anaphylaxis reports for sodium ferric gluconate complex and iron dextran. Sodium ferric gluconate appears to produce fewer anaphylactic reactions than does iron dextran. According to the package insert, a test dose of sodium ferric gluconate is not required. If given, a test dose is administered as 2 mL (25 mg of elemental iron) in 50 mL normal saline intravenously over 60 minutes. Although sodium ferric gluconate can be administered undiluted as a slow intravenous injection (up to 12.5 mg/min), it is most commonly administered as 10 mL (125 mg of elemental iron) in 100 mL normal saline intravenously over 1 hour. Most hemodialysis patients require a minimum total of 1 g of elemental iron over eight dialysis sessions to replete their stores. Side effects of sodium ferric gluconate include cramps, nausea, vomiting, flushing, hypotension, intense upper gastric pain, rash, and pruritus.

Iron sucrose is a polynuclear iron (III) hydroxide in sucrose complex with a molecular weight of approximately 34,000 to 60,000 daltons. It is available in 5-mL single-dose vials. Each vial contains 100 mg (20 mg/mL) of iron sucrose. Following intravenous administration of iron sucrose, the iron is released directly from the circulating iron sucrose to the transferrin and is taken up by the mononuclear phagocytic system and metabolized. The half-life is approximately 6 hours, with a volume of distribution similar to that of iron dextran. For adults undergoing hemodialysis, iron sucrose is administered as an intravenous dose of 100 mg one to three times per week to a total dose of 1,000 mg in 10 doses. It can be given directly into the dialysis

line by slow intravenous injection (20 mg iron [1 mL] per minute) or via infusion without the requirement for a test dose. For infusion, it must be diluted in normal saline (maximum 100 mL) immediately prior to use and infused over a minimum of 15 minutes. Iron sucrose injection should not be administered concomitantly with oral iron preparations because it will reduce the absorption of oral iron. Adverse effects include leg cramps and hypotension. Iron sucrose has been shown to be well tolerated but has less-than-expected efficacy at maintaining Hb >11 g/dL and transferrin saturation >25%.²³ Approximately 50% of patients studied had serum ferritin levels >1,100 ng/mL, which suggests iron overload. The reduced hematologic response and development of high serum ferritin levels may be due to oversaturation of transferrin and release of free iron. Varying doses of iron sucrose may not produce these results. Overall, iron sucrose has been shown to be safe and efficacious.

■ TRANSFUSIONS

Another form of treatment involves blood transfusions. The decision to manage anemia with blood transfusions is based on the evaluation of risks and benefits. Transfusion of allogeneic blood is indicated in acute situations of blood loss when hemodynamic support is needed. Blood transfusion in chronic anemia can elevate Hb concentration in the short term but does not address the underlying disorder. In critically ill patients, the risk of infection, length of stay, and economic cost increase with each unit of transfused packed RBCs.²⁴ Once Hct decreases to <30%, the oxygen-carrying capacity in patients with coronary disease is dangerously compromised, and ischemia can occur. Tachycardia, angina, ischemic patterns on electrocardiogram, cerebrovascular insufficiency, postural hypotension, and prerenal azotemia may suggest that transfusions should be provided to maintain the Hct >30%. An exception to this treatment option is patients who have developed low Hct values over extended time periods. These patients often demonstrate cardiac compromise after transfusion despite Hct levels in the 20% range. These patients should receive iron therapy, followed by transfusion only if necessary. Guidelines for transfusion in perisurgical anemias suggest 6 to 8 g/dL of Hb as a threshold for treatment, with no benefit at levels >10 g/dL.²⁵

Evaluation of Therapeutic Outcomes

A positive response to a trial of oral iron therapy results in a modest reticulocytosis in 5 to 7 days, with an increase in Hb at a rate of approximately 2 to 4 g/dL every 3 weeks until Hb is normalized. As the Hb level approaches normal, the rate of increase slows progressively. A Hb response of <2 g/dL over a 3-week period warrants further evaluation. If the patient does not develop reticulocytosis, reevaluation of the diagnosis or iron replacement therapy is necessary.

Iron therapy should continue for a period sufficient for complete restoration of iron stores. Serum ferritin concentrations should return to the normal range prior to discontinuation of iron. The time interval required to accomplish this goal varies, although at least 3 to 6 months of therapy usually is warranted. Patients with negative iron balances caused by bleeding may require iron replacement therapy for only 1 month after correction of the underlying lesion, whereas patients with recurrent negative balances may require long-term treatment with as little as 30 to 60 mg of elemental iron daily.

When large amounts of parenteral iron are administered, by either total dose infusion or multiple intramuscular or intravenous doses, the patient's iron status should be closely monitored. For patients intolerant of iron dextran, ferric gluconate and iron sucrose are alternatives. Cost, number of infusions, impact on need to transfuse, and concurrent EPO supplementation affect the choice of parenteral iron products. Patients receiving regular intravenous iron should be monitored for clinical or laboratory evidence of iron toxicity or overload. Iron overload may be indicated by abnormal

hepatic function tests, serum ferritin >800 ng/mL, or transferrin saturation >50%. Serum ferritin and transferrin saturation should be measured in the first week after doses of 100 to 200 mg and 2 weeks after larger intravenous iron doses. Hb and Hct should be measured weekly, and serum iron and ferritin levels should be measured at least monthly. Serum iron values can be obtained reliably 48 hours after intravenous dosing.

MEGALOBlastic ANEMIAS

Macrocytic anemias are divided into megaloblastic and nonmegaloblastic anemias. Macrocytosis, as seen in megaloblastic anemias, is caused by abnormal DNA metabolism resulting from vitamin B₁₂ or folate deficiency. It also can be caused by administration of various drugs, such as hydroxyurea, zidovudine, cytosine arabinoside, methotrexate, azathioprine, 6-mercaptopurine, and cladribine.

In vitamin B₁₂ or folate deficiency anemia, megaloblastosis results from interference with folic acid- and vitamin B₁₂-interdependent nucleic acid synthesis in the immature erythrocyte. The rate of RNA and cytoplasm production exceeds the rate of DNA production. The maturation process is retarded, resulting in immature large RBCs (macrocytosis). RNA and DNA synthesis depend on a series of reactions catalyzed by vitamin B₁₂ and folic acid because of their role in the conversion of uridine to thymidine. As shown in Fig. 104-4, dietary folates are absorbed in this process and converted to 5-methyl-tetrahydrofolate (A), which then is converted via a B₁₂-dependent reaction (B) to tetrahydrofolate (C). After gaining a carbon, tetrahydrofolate is converted to 5,10-methyl-tetrahydrofolate (D), a folate cofactor used by thymidylate synthetase (E) in the biosynthesis of nucleic acids. The 5,10-methyl-tetrahydrofolate cofactor is converted to dihydrofolate (F) during biosynthesis. Dihydrofolate reductase normally reduces dihydrofolate back to tetrahydrofolate (C), which can again pick up a carbon and be recycled to produce more 5,10-methyl-tetrahydrofolate (D).

Although vitamin B₁₂ deficiency and folate deficiency are common causes of macrocytosis, other possible causes must be considered if these deficiencies are not found. Other causes of macrocytosis include (a) a shift to immature or stressed RBCs as seen in reticulocytosis, aplastic anemia, and pure RBC aplasia; (b) a primary bone marrow disorder such as myelodysplastic syndromes, congenital dyserythropoietic anemias, and large granular lymphocyte leukemia; (c) lipid abnormalities as seen with liver disease,

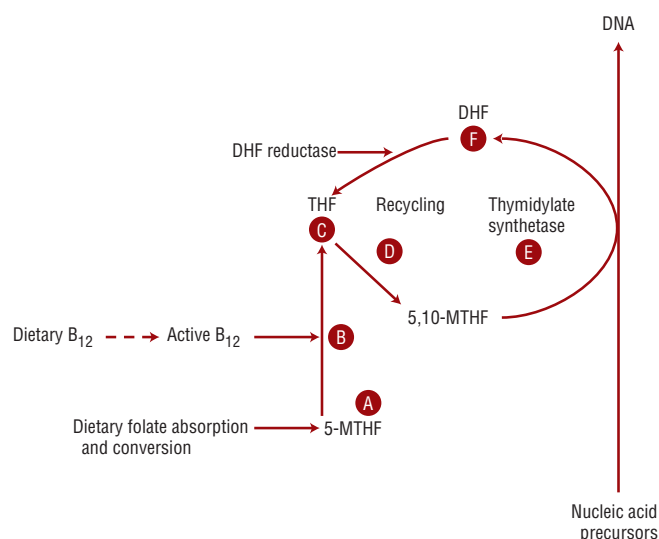

FIGURE 104-4. Drug-induced megaloblastosis. (DHF, dihydrofolate; 5-MTHF, 5-methyl-tetrahydrofolate; 5,10-MTHF, 5,10-methyl-tetrahydrofolate THF; THF, tetrahydrofolate.)

hypothyroidism, or hyperlipidemia; and (d) unknown mechanisms resulting from alcohol abuse and multiple myeloma. Macrocytosis is the most typical morphologic abnormality associated with excessive alcohol consumption. Even with adequate folate and vitamin B₁₂ levels and the absence of liver disease, patients may present with an alcohol-induced macrocytosis. Cessation of alcohol ingestion results in resolution of the macrocytosis within a couple of months.

VITAMIN B₁₂ DEFICIENCY ANEMIA

Epidemiology

The prevalence of pernicious anemia in the United States has been estimated at 151 per 100,000 and is slightly more common in women.²⁶ However, this figure may be underestimated because of the aging population and universal use of gastric acid-suppressing agents, which may inhibit the release of cobalamin from food. Older adults in the United States have a high prevalence (up to 15%) of elevated MMA levels and associated low or low-normal vitamin B₁₂ levels, likely due to atrophic gastritis and malabsorption of food-bound vitamin B₁₂.²⁶

Etiology

5 The three major causes of vitamin B₁₂ deficiency are inadequate intake, malabsorption syndromes, and inadequate utilization. Inadequate dietary consumption of vitamin B₁₂ is rare. It usually occurs only in patients who are strict vegans and their breast-fed infants, chronic alcoholics, and elderly patients who consume a “tea and toast” diet because of financial limitations or poor dentition. Decreased vitamin B₁₂ absorption is seen in patients with pernicious anemia, which is caused by the absence of intrinsic factor due to autoimmune destruction of the gastric parietal cells, atrophy of the gastric mucosa, or stomach surgery. It is most commonly seen in Europeans of northern descent and in African Americans; it is rarely diagnosed in patients younger than 35 years. Patients with pernicious anemia are prone to gastric polyps and have an increased incidence of stomach cancer. The most frequent cause of low serum B₁₂ levels is cobalamin malabsorption, which results in the inability of vitamin B₁₂ to be cleaved and released from proteins in food because of inadequate gastric acid production.²⁷ Conditions leading to this phenomenon include subtotal gastrectomy, atrophic gastritis resulting in decreased acid pepsin production, and prolonged use of acid suppression therapy. In these individuals, supplemental cobalamin is well absorbed because it is not protein bound. Some experts suggest that adults older than 50 years consume vitamin B₁₂ in the crystalline form to meet the recommended dietary allowance as this form does not require gastric acid or enzymes for digestion.²⁸ Additionally, treatment of *Helicobacter pylori* may improve vitamin B₁₂ status because this bacterial infection is a cause of chronic gastritis.²⁹ Vitamin B₁₂ deficiency may result from overgrowth of bacteria in the bowel that use vitamin B₁₂ or from injury or removal of ileal receptor sites where vitamin B₁₂ and the intrinsic factor complex are absorbed. Blind loop syndrome, Whipple disease, Zollinger-Ellison syndrome, tapeworm infestations, intestinal resections, tropical sprue, surgical resection of the ileus, pancreatic insufficiency, inflammatory bowel disease, advanced liver disease, tuberculosis, and Crohn disease all may contribute to the development of vitamin B₁₂ deficiency.³⁰

Pathophysiology

Vitamin B₁₂ works closely with folate in the synthesis of building blocks for DNA and RNA, is essential in maintaining the integrity of the neurologic system, and plays a role in fatty acid biosynthesis and energy production. It is a water-soluble vitamin obtained exogenously by ingestion of meat, fish, poultry, dairy products, and fortified cereals. Body stores range from 2 to 5 mg, of which

approximately half is in the liver. The recommended daily allowance is 2 mcg in adults and 2.6 mcg in pregnant or breast-feeding women. The average western diet provides 5 to 7 mcg of vitamin B₁₂ daily, of which 1 to 5 mcg is absorbed. Vitamin B₁₂ deficiency takes several years to develop following vitamin deprivation because of efficient enterohepatic circulation of the vitamin.

Once dietary cobalamin enters the stomach, pepsin and hydrochloric acid release the cobalamin from animal proteins. The free cobalamin then binds to R-protein, which is released from parietal and salivary cells. In the duodenum, the cobalamin bound to R-protein is joined by cobalamin-R-protein complexes that have been secreted in the bile. Pancreatic enzymes degrade both biliary and dietary cobalamin-R-protein complexes, releasing free cobalamin. The cobalamin then binds with intrinsic factor that serves as a cell-directed carrier protein similar to transferrin for iron. This complex attaches to mucosal cell receptors (cubilin) in the distal ileum, the intrinsic factor is discarded, and the cobalamin is bound to transport proteins (transcobalamin I, II, and III). The cobalamin bound to transcobalamin II is secreted into the circulation and is taken up by the liver, bone marrow, and other cells via endocytosis. The cobalamin then is converted into its two coenzyme forms (methylcobalamin and adenosylcobalamin). Consequently, most circulating cobalamin is bound to transcobalamin I and transcobalamin III. However, an alternate pathway for vitamin B₁₂ absorption independent of intrinsic factor or an intact terminal ileum accounts for a small amount of vitamin B₁₂ absorption.³⁰ This alternate pathway involves passive diffusion and accounts for approximately 1% absorption of the ingested vitamin B₁₂.

Laboratory Findings

In macrocytic anemias, MCV usually is elevated to 110 to 140 fL, but some patients deficient in vitamin B₁₂ may have a normal MCV. Mild leukopenia and thrombocytopenia are often present because abnormal DNA synthesis can affect all blood cells. Advanced cases of vitamin B₁₂ deficiency may result in pancytopenia. A peripheral blood smear demonstrates macrocytosis accompanied by hypersegmented polymorphonuclear leukocytes (one of the earliest and most specific indications of this disease), oval macrocytes, anisocytosis, and poikilocytosis. Serum lactate dehydrogenase and indirect bilirubin levels may be elevated as a result of hemolysis or ineffective erythropoiesis. Other laboratory findings include a low reticulocyte count, low serum vitamin B₁₂ level (<150 pg/mL), and low Hct. Bone marrow biopsy will reveal marked erythroid hyperplasia and megaloblastic changes in the cells of erythroid lineage.

In the early stages of vitamin B₁₂ deficiency, classic signs and symptoms of megaloblastic anemia may not be evident, and serum levels of vitamin B₁₂ may be within normal limits. Therefore, measurement of MMA and homocysteine is useful because these parameters are often the first to change. Because MMA and homocysteine are involved in enzymatic reactions that depend on vitamin B₁₂, a deficiency in vitamin B₁₂ leads to accumulation of serum MMA and homocysteine. Elevations in MMA are more specific for vitamin B₁₂ deficiency, whereas elevated homocysteine can be indicative of either vitamin B₁₂ or folic acid deficiency but offers greater specificity for folate plasma levels. Low levels of vitamin B₁₂ result in hyperhomocysteinemia, which some studies have reported to be an independent risk factor for cerebrovascular, peripheral vascular, coronary, and venous thromboembolic disease.³¹

CLINICAL CONTROVERSY

Hyperhomocysteinemia may be linked to dementia and Alzheimer's disease. Controversy exists whether supplementation with vitamin B₁₂ or folate for reducing homocysteine levels would have a beneficial effect on cognition.

Blood levels should be drawn in all patients with suspected vitamin B₁₂ deficiency. Vitamin B₁₂ values <150 pg/mL in patients with macrocytosis, hypersegmented polymorphonuclear leukocytes, peripheral neuropathy, or dementia are suggestive of B₁₂ deficiency. Approximately one third of patients with pernicious anemia do not demonstrate macrocytosis if their condition is complicated by iron deficiency, thalassemia, or a predominant neurologic involvement.

Vitamin B₁₂ values of 200 to 300 pg/mL are suggestive of depletion, and patients should undergo repeated testing in 1 to 3 months. A Schilling test may be performed to diagnose pernicious anemia, but the usefulness of this test is questionable and rarely alters the clinical management of the vitamin B₁₂ deficiency. The Schilling test was once performed to determine whether replacement of vitamin B₁₂ should occur via an oral or parenteral route, but evidence now shows that oral replacement is as efficacious as parenteral supplementation because of the vitamin B₁₂ absorption pathway independent of intrinsic factor. Other limitations to the Schilling test include its complicated protocol, the need for a 24-hour urine collection, certification issues, difficulty in obtaining radiolabeled vitamin B₁₂, and difficulty in interpreting results in patients with renal insufficiency.³⁰

Other potentially useful tests include antibody testing and serum gastrin levels. Positive anti-intrinsic factor antibodies may be present in approximately half of patients with pernicious anemia but is highly specific for the disease.¹⁶ In addition, an estimated 85% of patients have anti-parietal cell antibodies, but this test is not specific because 3% to 10% of healthy patients have these antibodies.¹⁶ When evaluating low serum vitamin B₁₂ levels, other causes besides dietary deprivation and malabsorption should be ruled out. For example, levels may be falsely low in patients receiving antibiotics, anticonvulsants, cytotoxic agents, oral contraceptives, and high-dose vitamin C.

TREATMENT

Vitamin B₁₂ Deficiency Anemia

The goals of treatment for vitamin B₁₂ deficiency include reversal of hematologic manifestations, replacement of body stores, and prevention or resolution of neurologic manifestations. Early treatment is of paramount importance because neurologic damage may be irreversible if the deficiency is not detected and corrected within months. Permanent disabilities may range from mild paresthesias and numbness to memory loss and outright psychosis. In addition to replacement therapy, any underlying etiology that is treatable, such as bacterial overgrowth, should be remedied. In the rare cases of nutritional deficiency, oral or parenteral administration of vitamin B₁₂ is beneficial. Patients should be counseled on the types of foods high in vitamin B₁₂ content (Table 104-8). Oral administration of vitamin B₁₂ also can be used effectively to treat pernicious anemia or cobalamin deficiency due to ileal resection but in much larger doses than those used to treat other causes of vitamin B₁₂ deficiency. Oral replacement therapy can be used because of the aforementioned alternate pathway of absorption, independent of intrinsic factor. Daily oral doses (1–2 mg) of vitamin B₁₂ is as effective as intramuscular administration in achieving hematologic and neurologic responses.³² If vitamin B₁₂ levels are marginally low and either MMA or both MMA and homocysteine levels are elevated, administration of 1 mg of oral vitamin B₁₂ daily should be strongly considered.³³ Timed-release preparations of oral cobalamin should be avoided.³⁴ Nonprescription 1-mg cobalamin tablets are available. The only contraindications to oral replacement therapy are the inability to take medications orally, diarrhea, and vomiting. A commonly used initial parenteral vitamin B₁₂ regimen consists of daily injections of 1,000 mcg of cyanocobalamin for 1 week to saturate vitamin B₁₂ stores in the body and resolve clinical manifestations of the deficiency. Thereafter, it can be given weekly for 1 month and monthly

TABLE 104-8 Good Sources of Vitamin B₁₂

Food	Serving Size	Amount (mcg)

thereafter for maintenance. Vitamin B₁₂ also can be effectively administered parenterally in 2- to 3-month increments.³⁵ Hydroxocobalamin is a less popular formulation of parenteral vitamin B₁₂. Its low utilization rate may be due to the occasional development of antibodies to the hydroxocobalamin–transcobalamin II complex. Parenteral therapy is preferred for patients exhibiting neurologic symptoms until resolution of symptoms and hematologic indices because the most rapid-acting therapy is necessary.³⁶ When patients are converted from the parenteral to the oral form of cobalamin, 1 mg of oral cobalamin daily can be initiated on the due date of the next injection.

In addition to the oral and parenteral forms, vitamin B₁₂ is available as a nasal spray for patients in remission following intramuscular vitamin B₁₂ therapy who have no nervous system involvement. The nasal spray is administered once weekly. Intranasal administration should be avoided in patients with nasal diseases or those receiving medications intranasally in the same nostril. Patients should not administer the spray 1 hour before or after ingestion of hot foods or beverages, which can impair cobalamin absorption. The efficacy of the nasal spray formulation has not been well studied, and it should be used for maintenance therapy only after hematologic parameters have normalized.

Potential adverse effects with vitamin B₁₂ replacement therapy are rare. Uncommon side effects include hyperuricemia and hypokalemia due to marked increase in potassium utilization during production of new hematopoietic cells. Rebound thrombocytosis may precipitate thrombotic events. Another side effect of vitamin B₁₂ therapy is fluid retention, which is more likely to occur in patients with compromised cardiovascular status because of an expansion in intravascular volume secondary to the sudden increase in production of RBCs. Rare cases of anaphylaxis with parenteral administration of cobalamin have been reported.

Evaluation of Therapeutic Outcomes

Most patients respond rapidly to vitamin B₁₂ therapy. The patient will experience an improvement in strength and well-being within a few days. If glossitis is present, improvement is seen within 24 hours. Bone marrow becomes normoblastic after 24 hours but is not evident in the plasma for another 7 days. Reticulocytosis is evident in 2 to 5 days and peaks around day 7. Hb begins to rise after the first week, and leukocyte and platelet counts normalize after approximately 7 days. Hypersegmented neutrophils persist for approximately 2 weeks. A CBC count and serum cobalamin level usually are drawn 1 to 2 months after initiation of therapy and 3 to 6 months thereafter for surveillance monitoring. Homocysteine and MMA levels should be repeated 2 to 3 months after initiation of replacement therapy to evaluate for normalization of levels, although levels begin to decrease in 1 to 2 weeks. Neuropsychiatric signs and symptoms can be reversible if treated early. If permanent

neurologic damage has resulted, progression should cease with replacement therapy. Slow response to therapy or failure to observe normalization of laboratory results may suggest the presence of an additional abnormality such as iron deficiency, thalassemia trait, infection, malignancy, or misdiagnosis.

FOLIC ACID DEFICIENCY ANEMIA

Epidemiology

Folic acid deficiency is one of the most common vitamin deficiencies occurring in the United States, largely as a result of its association with excessive alcohol intake and pregnancy.

Etiology

6 Major causes of folic acid deficiency include inadequate intake, decreased absorption, hyperutilization, and inadequate utilization. Because folic acid deficiency is associated with poor eating habits, it is common in elderly patients, teenagers whose diets consist of “junk food,” alcoholics, food faddists, the poverty stricken, and those who are chronically ill or in demented states. Folic acid absorption may decrease in patients who have malabsorption syndromes or those who have received certain drugs. In alcoholics with poor dietary habits, alcohol interferes with folic acid absorption, interferes with folic acid utilization at the cellular level, and decreases hepatic stores of folic acid.

Hyperutilization of folic acid may occur when the rate of cellular division is increased, as seen in pregnant women; patients with hemolytic anemia, myelofibrosis, malignancy, chronic inflammatory disorders such as Crohn disease, rheumatoid arthritis, or psoriasis; patients undergoing long-term dialysis; burn patients; and in adolescents and infants during their growth spurts. This hyperutilization eventually can lead to anemia, particularly when the daily intake of folate is borderline, resulting in inadequate replacement of folate stores.

Several drugs have been reported to cause a folic acid deficiency megaloblastic anemia. Some drugs (e.g., azathioprine, 6-mercaptopurine, 5-fluorouracil, hydroxyurea, and zidovudine) directly inhibit DNA synthesis. Other drugs are folate antagonists; the most toxic is methotrexate (other examples include pentamidine, trimethoprim, and triamterene). A number of drugs (e.g., phenytoin, phenobarbital and primidone) antagonize folate via poorly understood mechanisms but are thought to reduce vitamin absorption by the intestine (see Chap. 107). Because folic acid doses as low as 1 mg/day may affect serum phenytoin levels, routine folic acid supplementation is not generally recommended. The decline in phenytoin concentration usually is evidenced within the first 10 days and may decrease phenytoin levels by 15% to 50%.³⁷

Pathophysiology

Folic acid is a water-soluble vitamin readily destroyed by cooking or processing. It is necessary for the production of nucleic acids, proteins, amino acids, purines, and thymine, and hence DNA and RNA. It acts as a methyl donor to form methylcobalamin, which is used in the remethylation of homocysteine to methionine. Because humans are unable to synthesize sufficient folate to meet total daily requirements, they depend on dietary sources. Major dietary sources of folate include fresh, green, leafy vegetables, citrus fruits, yeast, mushrooms, dairy products, and animal organs such as liver and kidney. Most folate in food is present in the polyglutamate form, which must be broken down into the monoglutamate form prior to absorption in the small intestine. Once absorbed, dietary folate must be converted to the active form tetrahydrofolate through a cobalamin-dependent reaction. In 1997 the U.S. government mandated the fortification of grain products with folic acid in an attempt to

increase the dietary intake of folate by 100 mcg of folate daily per person. This amount of supplementation was chosen to decrease the incidence of neural tube defects without masking occult vitamin B₁₂ deficiency. As a result of grain product fortification, neural tube defect frequency has decreased by 25% to 30%.³⁸ Even though body demands for folate are high because of high rates of RBC synthesis and turnover, the minimum daily requirement is 50 to 100 mcg. In the general population, the recommended daily allowance for folate is 400 mcg in nonpregnant females, 600 mcg for pregnant females, and 500 mcg for lactating females.³⁹ Because the body stores approximately 5 to 10 mg of folate, primarily in the liver, cessation of dietary folate intake can result in megaloblastosis within 4 to 5 months. Folate is distributed to the other tissues primarily via enterohepatic recirculation. The methylated form of folate is reabsorbed from the bile into the serum. As folate enters the tissues, including erythrocytes, it endures for the remaining life span of the cell.

Laboratory Findings

It is of paramount importance to rule out vitamin B₁₂ deficiency when folate deficiency is suspected. Laboratory changes associated with folate deficiency are similar to those seen in vitamin B₁₂ deficiency, except vitamin B₁₂ levels are normal. Serum folate levels decrease to less than 3 ng/mL within a few days of reduced dietary folate intake. The RBC folate level (<150 ng/mL) also declines, and levels remain constant throughout the life span of the erythrocyte. An estimated 60% of patients with pernicious anemia have falsely low RBC folate levels, probably because of the cobalamin requirement for normal transfer of methyl-tetrahydrofolate from plasma to cells.¹⁶ Additionally, if serum or erythrocyte folate levels are borderline, serum homocysteine usually is increased with a folic acid deficiency. If serum MMA levels also are elevated, vitamin B₁₂ deficiency must be ruled out given that folate does not participate in MMA metabolism.

TREATMENT

Folic Acid Deficiency Anemia

Therapy for folic acid deficiency consists of administration of exogenous folic acid to induce hematologic remission, replace body stores, and resolve signs and symptoms. In most cases, 1 mg daily is sufficient to replace stores, except in cases of deficiency due to malabsorption, in which case doses of 1 to 5 mg daily may be necessary. Parenteral folic acid is available but rarely necessary. Synthetic folic acid is almost completely absorbed by the gastrointestinal tract and is converted to tetrahydrofolate without cobalamin. Therapy should continue for approximately 4 months if the underlying cause of the deficiency can be identified and corrected to allow for clearance of all folate-deficient RBCs from the circulation. Long-term folate administration may be necessary in chronic conditions associated with increased folate requirements. Patients with a folic acid deficiency should be placed on diets containing foods high in folate (Table 104-9). Low-dose folate therapy (500 mcg daily) can be administered when anticonvulsant drugs produce a megaloblastic anemia so that discontinuation of anticonvulsant therapy may not be necessary. Adverse effects have not been reported with folic acid doses used for replacement therapy. It is considered nontoxic at high doses and is rapidly excreted in the urine.

Although megaloblastic anemia during pregnancy is rare, the most common cause is folate deficiency. The condition usually manifests as an underweight premature infant and suboptimal health of the mother. Periconceptional folic acid supplementation is recommended to decrease the occurrence and recurrence of neural tube defects, specifically anencephaly and spina bifida. Folic acid

TABLE 104-9 Good Sources of Folate

Food	Serving	Amount (mcg)
Chicken liver	3.5 oz	770
Cereal	1/2 to 1 1/2 cups	100–400
Lentils, cooked	1/2 cup	180
Chickpeas	1/2 cup	141
Asparagus	1/2 cup	132
Spinach, cooked	1/2 cup	131
Black beans	1/2 cup	128
Pasta	2 oz	100–120
Kidney beans	1/2 cup	115
Lima beans	1/2 cup	78
White rice, cooked	3/4 cup	60
Tomato juice	1 cup	48
Brussels sprouts	1/2 cup	47
Orange	1 medium	47

supplementation at a dose of 400 mcg daily is recommended in low-risk women. Women who have previously given birth to offspring with neural tube defects or those with a family history of neural tube defects should ingest 4 mg daily of folic acid.^{37,38,40} Periconceptual use of a multivitamin containing folic acid is associated with a decreased incidence of congenital heart defects and possibly of orofacial clefts.⁴¹ Higher levels of folic acid supplementation should not be attained via ingestion of excess multivitamins because of the risk for vitamin A toxicity.⁴⁰ It is essential that women in their childbearing years maintain adequate folic acid intake.

Evaluation of Therapeutic Outcomes

Symptomatic improvement, as evidenced by increased alertness, appetite, and cooperation, often occurs early during the course of treatment. Reticulocytosis occurs within 2 to 3 days and peaks within 5 to 8 days after beginning therapy. Hct begins to rise within 2 weeks and should reach normal levels within 2 months. MCV initially increases because of an increase in reticulocytes but gradually decreases to normal.

ANEMIA OF CHRONIC DISEASE

Epidemiology

7 ACD is one of the most common forms of anemia seen clinically, particularly among the elderly. It is especially important in the differential diagnosis of iron deficiency. Because ACD, as the name implies, is associated with other prominent disease states, the usual signs and symptoms are often overlooked. The diagnosis of ACD usually is one of exclusion, with particular emphasis on the possibility of IDA as the primary anemia or as a coexistent anemia with ACD because of chronic disease–associated conditions (e.g., gastrointestinal blood loss from aspirin, other nonsteroidal antiinflammatory drugs, or steroids) or malignancy-associated bleeding. ACD is often observed in patients with diseases that last longer than 1 to 2 months, although it can occur in conditions with a fairly rapid onset of several weeks, such as pneumonia. It can coexist with anemia of chronic kidney disease, chemotherapy-induced anemia, and AIDS-related anemia. Anemia is the most common hematologic abnormality associated with human immunodeficiency virus (HIV), and the yearly incidence of developing anemia increases with disease progression.⁴² Anemia occurs commonly in patients with heart failure. A 1-g/dL decrease in Hb was independently associated with significantly increased mortality risk in several studies of the heart failure population.⁴³ The degree of anemia in ACD is generally associated with the severity of underlying disease. Table 104–10 lists common diseases associated with ACD.

TABLE 104-10 Diseases Causing Anemia of Chronic Disease

Common causes
Chronic infections
Tuberculosis
Other chronic lung infections (e.g., lung abscess, bronchiectasis)
Human immunodeficiency virus
Subacute bacterial endocarditis
Osteomyelitis
Chronic urinary tract infections
Chronic inflammation
Rheumatoid arthritis
Systemic lupus erythematosus
Inflammatory bowel disease
Inflammatory osteoarthritis
Gout
Other (collagen vascular) diseases
Chronic inflammatory liver diseases
Malignancies
Carcinoma
Lymphoma
Leukemia
Multiple myeloma
Less common causes
Alcoholic liver disease
Congestive heart failure
Thrombophlebitis
Chronic obstructive pulmonary disease
Ischemic heart disease

Etiology

ACD is a response to stimulation of the cellular immune system by various underlying disease processes. ACD commonly develops in AIDS patients, especially those with opportunistic infections or malnutrition, and is associated with increased morbidity and mortality. In patients with HIV, anemia is a predictor of progression to AIDS and is independently associated with an increased risk of death.⁴⁴ The etiology of anemia in patients with HIV is complex. HIV infects hematopoietic cells, which can lead to abnormal hematopoiesis and bone marrow suppression. In addition, the drugs used to treat AIDS and associated illness can cause bone marrow suppression.

Pathophysiology

ACD is a hypoproliferative anemia that traditionally has been associated with infectious or inflammatory processes, tissue injury, and conditions associated with release of proinflammatory cytokines. Alternative names include anemia of inflammation and cytokine-mediated anemia. The pathogenesis of ACD is multifactorial and is characterized by a blunted EPO response to anemia, impaired proliferation of erythroid progenitor cells, and disturbance of iron homeostasis. Increased iron uptake and retention occur within cells of the mononuclear phagocytic system. The RBCs have a shortened life span, and the bone marrow's capacity to respond to EPO is inadequate to maintain normal Hb concentration. The cause of this defect is uncertain but appears to involve blocked release of iron from cells in the bone marrow. Iron availability to erythroid progenitor cells then is limited. Various cytokines, such as interleukin-1, interferon- γ , and tumor necrosis factor released during these illnesses may inhibit the production or action of EPO or the production of RBCs.⁴⁵ Hepcidin may decrease duodenal absorption of iron and block release of iron from macrophages.⁴⁶

Laboratory Findings

No definitive test can confirm the diagnosis of ACD, and the diagnosis is often overlooked. The practitioner should maintain a

TABLE 104-11 Laboratory Value Differences Between Anemia of Chronic Disease and Iron-Deficiency Anemia

	Anemia of Chronic Disease	Iron-Deficiency Anemia	Both
Iron	↓	↓	↓
Transferrin	↓ or nl	↓	↓
Transferrin saturation	↓	↓	↓
Ferritin	↑ or nl	↓	↓ or nl
Soluble transferrin receptor	nl	↑	↑ or nl

nl, normal limits.

high index of suspicion in any patient with a chronic inflammatory or neoplastic disease. ACD may coexist with IDA and folic acid deficiency because many patients with these conditions have poor dietary intake or gastrointestinal blood loss. Examination of the bone marrow reveals an abundance of iron, suggesting that the release mechanism for iron is the central defect. Patients with ACD usually have a decreased serum iron level, but unlike patients with IDA, their serum ferritin level is normal or increased and their TIBC decreased. Transferrin saturation is decreased. ACD usually is normocytic and normochromic with mildly depressed Hb. With ACD, hypochromia usually precedes microcytosis, with the opposite finding in IDA. Patients with concurrent ACD and IDA usually have microcytes and a more severe anemia. Erythrocyte survival may be reduced in patients with ACD, but a compensatory erythropoietic response usually does not occur. A low reticulocyte count indicates underproduction of red cells (Table 104-11).

TREATMENT

Anemia of Chronic Disease

Treatment of ACD is somewhat less specific than treatment of other anemias. Guidelines exist for management of anemia in patients with cancer or chronic kidney disease (see Chaps. 130 and 47). Although the goals of therapy should include treating the underlying disorder and correcting reversible causes of anemia, accomplishment of these goals may not totally reverse hematologic and physiologic abnormalities. Iron is effective only if iron deficiency is present. During inflammation, oral or parenteral iron therapy is ineffective. Absorption is poor because of downregulation of ferroportin and iron diversion mediated by cytokines.⁴⁵ Because iron is a required nutrient for proliferating microorganisms, supplementation may increase the risk of infections. Parenteral iron may have a role for patients unresponsive to erythropoietic agents.

RBC transfusions are effective but should be limited to situations in which oxygen transport is inadequate due to concomitant medical problems. The transfusion threshold varies from 8 to 10 g/dL based on factors such as cost, convenience, and risk of complications. Risks may include transmission of bloodborne infections, development of autoantibodies, transfusion reactions, and iron overload. Assessment of the symptomatic state should always be considered before blood products are administered.

Erythropoietic agents have been used to stimulate erythropoiesis in patients with ACD as a relative EPO deficiency exists for the degree of anemia. Two agents are available: recombinant epoetin alfa and recombinant darbepoetin alfa. Although both agents share the same mechanism of action, darbepoetin alfa has a longer half-life and can be administered less frequently. FDA-approved uses for these agents include patients with cancer receiving chemotherapy, patients with chronic kidney disease, and patients with HIV receiving myelosuppressive therapy. These agents are sometimes used to treat ACD, currently not an FDA-approved indication. Patients with chronic disease may have a relatively impaired response to epoetin

alfa. The dosage of epoetin alfa is 50 to 100 units per kilogram three times per week. The dosage can be increased to 150 units per kilogram per dose if no increase in Hb concentration occurs after 6 to 8 weeks. Response to EPO varies depending on dose and cause of the anemia. EPO treatment is effective when the marrow has an adequate supply of iron, cobalamin, and folic acid. Whether EPO levels are a useful predictor of response is controversial.

EPO therapy usually is well tolerated. Iron deficiency can occur in patients treated with EPO, so close monitoring of iron levels is necessary. Oral iron supplementation should be given if transferrin saturation drops below 20% or the serum ferritin level drops below 100 ng/mL. Some patients develop “functional” iron deficiency, in which the iron stores are normal but the supply of iron to the erythroid marrow is less than necessary to support the demand for RBC production. Therefore, many practitioners routinely supplement EPO therapy with oral iron therapy. The hypertension commonly seen in patients with end-stage renal disease treated with EPO is far less common in AIDS patients. Potential toxicities of exogenous EPO administration include increases in blood pressure, nausea, headache, fever, bone pain, and fatigue. Other adverse effects include seizures, thrombotic events, and allergic reactions such as rashes and local reactions at the injection site.

Evaluation of Therapeutic Outcomes

One of the earliest responses to increased endogenous or exogenous EPO is an increase in blood reticulocyte count, which usually occurs in the first few days. Baseline iron status should be checked before and during treatment, as many patients receiving EPO require supplemental iron therapy. The optimal form and schedule of iron supplementation are not known. Hb levels should be checked 4 weeks after therapy initiation and then every 2 to 4 weeks thereafter. A fall in Hb during EPO therapy generally indicates a need for iron supplementation. Baseline and periodic monitoring of iron, TIBC, transferrin saturation, or ferritin levels may be useful in maximizing iron repletion and limiting the need for epoetin. Patients who do not respond to 8 weeks of optimal dosage should not continue taking EPO. Target Hb levels should be 11 to 12 g/dL. Cost is an issue with EPO therapy, so drug expense must be weighed against the effects on transfusions and hospitalizations.

ANEMIA OF CRITICAL ILLNESS

Epidemiology

8 Anemia is a common complication in critically ill patients and is found almost universally in this patient population.⁴⁷ Approximately 95% of patients have less than normal Hb levels by their third day in the intensive care unit (ICU).⁴⁸

Etiology

Factors that may contribute to anemia in critically ill patients include sepsis, taking of frequent blood samples, hemodilution, surgical blood loss, immune-mediated functional iron deficiency, decreased production of endogenous EPO, reduced RBC life span, and active bleeding, especially in the gastrointestinal tract. More commonly, a combination of these factors exists. Additional comorbid factors include coagulopathies and nutritional deficits such as malnourishment and altered absorption of vitamins and minerals, including iron, vitamin B₁₂, and folate.⁴⁹ Deleterious effects of anemia includes increased risk of cardiac-related morbidity and mortality, especially in patients with known cardiovascular disease. Continued tissue hypoxia can result in cerebral ischemia, myocardial ischemia, multiple organ deterioration, lactic acidosis, and death. Consequences of anemia in critically ill patients may be enhanced because of the increased metabolic demands of critical

illness. Weaning anemic patients from mechanical ventilation may be more difficult.⁵⁰

Pathophysiology

In anemia of critical illness, the mechanism for RBC replenishment and homeostasis is altered. The effect of various inflammatory cytokines on EPO may partly explain anemia of critical illness because inflammatory cytokines are associated with a blunted erythropoietic response.⁵¹ Inflammatory cytokines appear to directly inhibit RBC production and stimulate iron-binding proteins that sequester iron and limit RBC production.⁵¹ Increased nitric oxide production may alter iron metabolism; it inhibits erythroid amino-levulinic acid, decreases iron consumption, and decreases ferrochelatase activity, resulting in diminished oxygen transport by Hb and myoglobin.

Laboratory Findings

Anemia of critical illness is similar to ACD. Diminished Hb concentration is the most telling sign of anemia in the critically ill patient if hydration status is considered. MCV will assist in determining the cause of the anemia. Laboratory findings frequently seen in anemia of critical illness are low serum iron, TIBC, and iron/TIBC ratio. Transferrin saturation usually is less than 20% in anemia of critical illness due to functional iron deficiency. Serum ferritin is normal to high, as seen with ACD, and EPO levels usually are slightly decreased despite the presence of anemia, with minimal reticulocyte response.^{47,51} These findings differ from those in patients with IDA, who generally have elevated EPO concentrations in response to a low Hct.

TREATMENT

Anemia of Critical Illness

Patients with anemia of critical illness require the necessary substrates of iron, folic acid, and vitamin B₁₂ for RBC production. Because iron stores usually are insufficient to meet physiologic demands, administration of supplemental iron is necessary to support erythropoiesis. Parenteral iron is generally preferred in this population because patients often are undergoing enteral therapy or because of concerns regarding inadequate iron absorption. The disadvantage of parenteral therapy is the theoretical risk of infection.⁵²

CLINICAL CONTROVERSY

The low iron concentrations in critically ill patients may be a defense mechanism, as microbes require iron for sustenance. Therefore, diminished iron levels may inhibit bacterial growth. Further investigation of supplementation with iron is warranted.

Pharmacologic doses of EPO have been used to treat the anemia of critical illness. Few randomized controlled trials have evaluated the role of EPO in critically ill patients, and the results of these trials have not consistently shown a decrease in transfusion requirements in EPO-treated patients.⁵¹ The EPO dose is not firmly established, but a recommended dose is 40,000 units given subcutaneously once weekly for up to four total doses. Patients with a length of stay in the ICU longer than 1 week are most likely to benefit.⁵³ Further investigation is necessary to determine the effectiveness and the cost effectiveness of EPO in critically ill patients.⁴⁸ Use of darbepoetin for treatment of anemia of critical illness has not been examined.

Many critically ill patients receive RBC transfusions despite the inherent risks associated with transfusions. Stored RBCs may not function as well as endogenous blood. Although RBC transfusions may increase oxygen delivery to tissues, cellular oxygen may not

increase.⁵⁴ Transfusion practices in ICUs vary, and clinicians use different Hb concentrations as thresholds for administering transfusions. Study results suggest that RBC transfusions may decrease the likelihood of survival in some subgroups of critically ill patients.⁵⁵ Decisions to use transfusions must consider the risks, including transmission of infections; volume overload, especially in patients with renal or heart failure; iron overload; and immune-mediated reactions such as febrile reactions, hemolysis, and anaphylaxis. The clinician also must consider administrative, logistic, and economic factors, including the shortage of blood supplies.

Evaluation of Therapeutic Outcomes

Goals of therapy include maintenance of adequate tissue oxygenation and perfusion, immediate correction of severe anemia, and prevention and minimization of blood loss. The role of monitoring RBCs, Hb, Hct, EPO levels, and reticulocyte counts remains to be determined. Outcomes used in EPO studies are transfusion requirements and transfusion independence. Morbidity, mortality, and length of stay also are assessed. Clinicians should monitor predose hematocrit values and withhold therapy in patients with Hct exceeding 38% to decrease unnecessary doses of EPO and cost. Iron levels should be monitored to ensure that adequate amounts of iron are present to support an optimal erythropoietic response to epoetin alfa.

ANEMIA IN THE ELDERLY

Epidemiology

9 One of the most common clinical problems observed in the elderly is anemia. Anemia is a prevalent and increasing problem in the elderly, with approximately 20% of people 85 years and older affected.⁵⁶ Elderly patients with the highest incidence of anemia are those who are hospitalized, followed by residents of nursing homes and institutions, with an estimated rate of 31% to 40%.⁵⁷ The lowest incidence is seen in elderly patients who are community dwellers. Although the incidence of anemia is high in the elderly, anemia should not be regarded as an inevitable outcome of aging because an underlying cause can be identified in approximately two thirds of patients. Undiagnosed and untreated anemia can have severe ramifications. Anemia has been significantly associated with adverse outcomes, including all-cause hospitalization, hospitalization secondary to cardiovascular disease, and all-cause mortality.⁵⁸ Anemia is an independent predictor of death and major clinical adverse events in elderly patients with stable symptomatic coronary artery disease.⁵⁹ Anemia can cause neurologic and cognitive complications and can adversely influence quality-of-life and physical performance in the elderly.⁶⁰ Anemia may be an indication of serious diseases such as gastrointestinal cancer.

Pathophysiology

Aging is associated with a progressive reduction in hematopoietic reserve, which makes individuals more susceptible to developing anemia in times of hematopoietic stress.⁶¹ Dysregulation of proinflammatory cytokines, most notably interleukin-6, may inhibit EPO production or interact with EPO receptors.⁶² Although Hb levels may remain normal, the diminished marrow reserve leaves the elderly patient more susceptible to other causes of anemia. Renal insufficiency, which also is common in elderly patients, may reduce the ability of the kidneys to produce EPO. Patients often have a normal creatinine level but a diminished glomerular filtration rate. It has been suggested that a deficiency in endogenous EPO develops when the glomerular filtration rate falls below 50% of the normal range. Myelodysplasia is the cause of unexplained anemia in 20% of elderly individuals, whereas 30–50% are presumed to have multiple causes for their anemia.

Etiology

In the acute care setting, the top three causes of anemia in the elderly are chronic disease (35%), unexplained cause (17%), and iron deficiency (15%), whereas in community-based outpatient clinics, the most common causes are unexplained (36%), infection (23%), and chronic disease (17%).⁶³ Risk factors for the development of anemia in the elderly include race and ethnicity. The highest prevalence is seen in elderly blacks, those with serum albumin and serum creatinine abnormalities, and in patients with recent hospitalization or placement in an institution.⁵⁷

Anemia in the elderly usually is hyporegenerative and represents an inability of the aging hematopoietic system to replace the peripheral blood loss or respond to marrow insults. Unexplained causes may be due to inadequate diagnostic evaluation or absolute or relative EPO deficiency. Absolute deficiency may be associated with renal insufficiency, whereas relative deficiency may be due to the body's inability to provide adequate response to declining Hb levels.⁶³

Another common problem in the elderly is vitamin B₁₂ deficiency. The most common causes of clinically overt vitamin B₁₂ deficiency are food/cobalamin malabsorption (more than 60% of cases), pernicious anemia (15%–20% of cases), insufficient dietary intake, and malabsorption.⁶⁴ Patients, especially the elderly, with elevated serum MMA in the presence of borderline or even normal cobalamin levels may develop neuropsychiatric abnormalities. Treatment with cyanocobalamin may prevent further deterioration and result in improvement.

One often overlooked major factor that may contribute to anemia in the older population is nutritional status. Cross-sectional studies demonstrate a high prevalence of anemia and other nutritional deficiencies in low socioeconomic populations. Therefore, nutritional deficiencies that are not severe enough to affect the hematopoietic system in the younger population may contribute to anemia in the elderly. Edentulous or infirm elderly who may be too ill to prepare their meals are at risk for nutritional folate deficiency. Risk factors for inadequate folate intake in the elderly include low energy intake, inadequate consumption of fortified cereals, and failure to take a vitamin/mineral supplement.⁶⁵ However, unlike cobalamin levels, folate levels often increase rather than decline with age. High folate intake can occur if the elderly patient regularly uses a supplement and consumes fortified cereals.^{65,66}

Other common anemias in the elderly include IDA and ACD. Iron malabsorption may occur after total gastrectomy. Bleeding with resultant iron deficiency in the elderly may be due to carcinoma, ulcer, atrophic gastritis, drug-induced gastritis, postmenopausal vaginal bleeding, or bleeding hemorrhoids. Elderly women have a much lower incidence of IDA compared to younger, menstruating women. Until proven otherwise, iron deficiency in the elderly should be considered a sign of chronic blood loss. ACD is more common in the elderly, as diseases that contribute to ACD such as cancer, infection, and rheumatoid arthritis are more prevalent in this population.

Laboratory Findings

Elderly males may have lower Hb levels, but whether this condition is secondary to physiologic reasons or increased prevalence of anemia is not known. Low levels may be due to decreased androgen secretion in men or age-related changes in stem cells. For practical purposes, it is best to use usual adult reference values for laboratory tests in the elderly and realize that some mild anemias may go unexplained.

Anemia in elderly persons usually is normocytic and mild, with Hb values ranging between 10 and 12 g/dL in most anemic patients.⁵⁶ A CBC, including a peripheral blood smear and reticulocyte count, should be performed in any elderly patient with symptoms that may

be related to anemia. Patients also should be evaluated for signs of renal or hepatic failure and gastrointestinal or genitourinary blood loss. If the reticulocyte count is adequate, blood loss or RBC destruction should be suspected. A low count indicates decreased RBC production, so RBC indices should be evaluated. If MCV is >100 fL, further testing should be performed to evaluate for possible vitamin B₁₂ or folate deficiency. A vitamin B₁₂ deficiency may be present even when plasma levels of vitamin B₁₂ are within the normal range, but elevated MMA levels will detect the deficiency. A refractory macrocytic anemia in the elderly should raise suspicion of a myelodysplastic or leukemic syndrome. If MCV is <100 fL, further studies should be performed to determine if IDA or ACD is a possible cause.

With IDA, abnormal laboratory values are similar to those found in patients with microcytic anemia. However, serum iron and TIBC decrease with age, so the transferrin saturation ratio is less useful in the elderly. MCVs and mean cell Hb concentrations may appear normal even in the presence of IDA, as patients may have concurrent vitamin B₁₂ or folate deficiency anemias.

TREATMENT

Anemia in the Elderly

Depending on the cause of the anemia, treatment in the elderly is the same as that described for each type of anemia discussed in this chapter. With IDA it is essential to treat the underlying cause, if known (i.e., bleeding), and administer iron supplementation. Lower doses of iron supplementation are often recommended in the elderly (e.g., 325 mg of ferrous sulfate once daily) to decrease the incidence of gastrointestinal adverse effects, which can lead to considerable morbidity and poor adherence. Vitamin B₁₂ deficiency is treated with parenteral or oral vitamin B₁₂ supplementation; folic acid deficiency is treated with folic acid, generally at a dose of 1 mg daily. A meta-analysis showed that folic acid supplementation did not reduce the risk of cardiovascular disease or all-cause mortality in patients with a history of vascular disease.⁶⁷ The goal of treatment of ACD is resolution of the underlying cause, although treating the underlying chronic illness in elderly patients can be difficult. Results of several uncontrolled studies suggest that weekly EPO doses ranging from 9,000 to 20,000 units may be beneficial in elderly patients with ACD.⁶⁰ The medical and economic implications of anemia correction remain to be defined for ACD or undefined anemia.

Evaluation of Therapeutic Outcomes

Reticulocytosis usually starts within 1 week of oral supplementation with iron. If the reticulocyte count rises but the anemia does not improve, inadequate absorption of iron or continued blood loss should be suspected. Iron malabsorption due to atrophic or *Helicobacter pylori*-associated gastritis or celiac disease is not uncommon.⁶⁸ As with any form of anemia, symptomatic improvement should be evident shortly after starting therapy, and Hb/Hct should begin to rise within a few weeks of initiating therapy.

ANEMIA IN PEDIATRIC POPULATIONS

Epidemiology

⑩ IDA is a leading cause of infant morbidity and mortality around the world.⁶⁹ In the United States, the prevalence of IDA among children is declining as a result of improved iron supplementation.² Data from NHANES III indicated that 9% of children ages 12 to 36 months in the United States had iron deficiency and 3% had IDA.^{70,71} Lack of a normal Hb at birth directly affects nonstorage iron

and increases the risk of IDA in the first 3 to 6 months of life. Another study reports that as many as 20% of children in the United States and 80% of children in developing countries will have anemia before age 18 years.⁹ Children who are African American or Hispanic have a higher incidence of anemia.⁷² Requirements for iron absorption peak during puberty. In infants and children, 30% of daily iron needs must be met by dietary sources, compared to 5% in adults. An anemia of prematurity can occur 3 to 12 weeks after birth in infants younger than 32 weeks' gestation and spontaneously resolves by 3 to 6 months. The prevalence of vitamin B₁₂ deficiency has been identified as 1 in 1,255 for levels <100 pg/mL and 1 in 200 for levels of <200 pg/mL, with the lowest levels in non-Hispanic whites.⁷³

Pathophysiology

In contrast to anemias in adults, which tend to be manifestations of a broader underlying pathology, anemias in the pediatric population are more often due to a primary hematologic abnormality. The amount of iron present at birth depends on gestational length and weight. Erythropoiesis normally decreases after birth. A concurrent decrease in EPO production results in a physiologic anemia at 2 to 9 weeks of age. Iron stores are mostly depleted by age 6 months, although the blood volume doubles from 4 to 12 months.

Etiology

The age of the child can yield some clues regarding the etiology of the anemia. The optimal amount of nutritional iron and folate required varies among individuals based on life cycle stages. Two peak periods place children at risk of developing IDA. The first peak period occurs during late infancy and early childhood, when children undergo rapid body growth, have low levels of dietary iron, and exhaust stores accumulated during gestation. The second peak period occurs during adolescence, which is associated with rapid growth, poor diets, and onset of menses in girls. Some studies suggest that overweight children are at significantly higher risk for IDA. Proposed factors include genetic influences; physical inactivity, leading to decreased myoglobin breakdown and lower amounts of released iron into the blood; and inadequate diet with limited intake of iron-rich foods.⁷⁴

Conditions in the newborn period that can lead to IDA include prematurity, administration of EPO for anemia of prematurity, and insufficient dietary intake. Premature infants are at increased risk for IDA because of their smaller total blood volume, increased blood loss through phlebotomy, and poor gastrointestinal absorption. Blood loss and hemolysis are other common causes of anemia in neonates. However, iron deficiency can occur only after the birth weight has doubled in premature infants.⁹ Factors leading to unbalanced iron metabolism in infants include insufficient iron intake, decreased absorption, early introduction of cow's milk, intolerance of cow's milk, medications, and malabsorption. Dietary deficiency of iron in the first 6 to 12 months of life is less common today because of the increased use of iron supplementation during breastfeeding and use of iron-fortified formulas. Iron deficiency becomes more common when children change to regular diets.

Anorexia associated with infection can lead to decreased ingestion of iron-containing foods. Infection also can decrease erythropoiesis. When screening for iron deficiency in young children, a careful dietary history can help identify children at risk. Dietary deficiency has been defined as one or more of the following: fewer than five servings each of meat, grains, vegetables, and fruit per week; more than 16 oz of milk per day; or daily intake of fatty snacks, sweets, or more than 16 oz of soft drinks. High iron needs and the tendency to eat fewer iron-containing foods contribute to the etiology of iron deficiency during adolescence.

Other causes of microcytic anemia include thalassemia, lead poisoning, and sideroblastic anemia. Use of homeopathic or herbal

medications and exposure to paint or certain cooking materials may place children at risk for lead exposure. Normocytic anemias in children include infection with human parvovirus B19 and glucose-6-phosphate dehydrogenase (G6PD) deficiency. Macrocytic anemias are caused by deficiencies in vitamin B₁₂ and folate, chronic liver disease, hypothyroidism, and myelodysplastic disorders. Folic acid deficiency usually is due to inadequate dietary intake, but human milk and cow's milk provide adequate sources. Folic acid deficiency may be seen in infants and children who primarily consume goat's milk or health food milk alternatives, or in children with insufficient intake of green leafy vegetables. Vitamin B₁₂ deficiency due to nutritional reasons is rare but may occur due to a congenital pernicious anemia.

Laboratory Findings

When evaluating laboratory values in pediatric patients, the clinician must use age- and sex-adjusted norms. It is important to know that many blood samples are capillary samples, such as heel or fingersticks, which may have slightly different results than venous samples.

The USPSTF has concluded that evidence is insufficient to recommend for or against routine screening for IDA in asymptomatic children aged 6 to 12 months. The Hb is a sensitive test for iron deficiency, but it has a low specificity in childhood anemias. If an abnormality is found, a CBC should be ordered to evaluate MCV and determine whether the anemia is microcytic, normocytic, or macrocytic. A peripheral blood smear and reticulocyte count also may be helpful. The peripheral blood smear can indicate the etiology based on RBC morphology, and the reticulocyte count helps differentiate between decreased RBC production and increased RBC destruction. Other laboratory tests include serum iron, ferritin, TIBC, and transferrin saturation. Mild hereditary anemias may produce a mild hypochromic microcytic anemia that can be confused with IDAs. The RDW may be high with iron deficiency and is more likely to be normal with thalassemia. Laboratory features of anemia of prematurity include normocytic normochromic cells, low reticulocyte count, low serum EPO concentrations, and decreased RBC precursors in bone marrow. Laboratory diagnosis of vitamin B₁₂ deficiency in children is similar to that of adults and includes a CBC, measurement of vitamin B₁₂, and MMA and homocysteine levels. Serum or erythrocyte folate levels also should be measured if a folic acid deficiency anemia is suspected.

TREATMENT

Anemia in Pediatric Populations

Primary prevention of IDA in infants, children, and adolescents is the most appropriate goal because delays in mental and motor development are potentially irreversible. In 2006, the USPSTF published revised recommendations to screen and supplement iron deficiency in the United States, focusing on children and pregnant women.⁷⁵ The USPSTF recommends routine iron supplementation for asymptomatic children aged 6 to 12 months who are at increased risk for IDA. Fair evidence was found that iron supplementation (e.g., iron-fortified formula or iron supplements) may improve neurodevelopmental outcomes in children at risk for IDA and poor evidence for children 6 to 12 months of age not at risk for IDA.

Interventions likely to prevent anemia include diverse foods with bioavailable forms of iron, food fortification for infants and children, and individual supplementation. Routine screening for iron deficiency in nonpregnant adolescents is recommended only for those with risk factors, which include significant physical activity (especially in adolescent female athletes), vegetarian diets, malnutri-

tion, low body weight, chronic illness, or history of heavy menstrual blood loss.

Anemia of prematurity is frequently treated with RBC transfusions, with wide variations in transfusion practices among neonatal ICUs. Reasons for use include improved oxygen delivery, intravascular volume, reduced fatigue during feeding, and improved growth. EPO may be used to treat anemia of prematurity, but it is important to note that EPO pharmacokinetics differ depending on the developmental age of the infant. Use of EPO is controversial because it has not been shown to clearly reduce transfusion requirements. Other questions regarding use of EPO in anemia of prematurity remain unanswered. Which infants respond best to EPO, and what is the long-term benefit (if any) of decreasing transfusions? What is the role of supplemental parenteral iron and nutritional supplementation? Premature infants fed human milk need 2 mg/kg of iron supplementation daily. Infants on full enteral feedings treated with EPO need iron supplements in doses of 6 mg/kg/day.

For infants aged 9 to 12 months with a mild microcytic anemia, the most cost-effective treatment is a therapeutic trial of iron. Fe²⁺ sulfate at a dose of 3 mg/kg of elemental iron once or twice daily between meals for 4 weeks is recommended. In children who respond, iron should be continued for 2 to 3 months to replace storage iron pools, along with dietary intervention and patient education. If the anemia recurs, the workup should include determination of sources of occult blood loss. Higher doses of oral iron (6 mg/kg/day of elemental iron divided into two or three daily doses) are administered to older children. Parenteral iron therapy has a limited role and is rarely necessary. For nonresponders, a serum ferritin level can be drawn.

For the macrocytic anemias in children, folate can be administered in a dose of 1 to 3 mg daily. However, vitamin B₁₂ deficiency due to congenital pernicious anemia requires lifelong vitamin B₁₂ supplementation. Dose and frequency should be titrated according to clinical response and laboratory values. No data regarding the use of oral vitamin B₁₂ supplementation in children are available.

Evaluation of Therapeutic Outcomes

Therapeutic outcomes are assessed in children by monitoring Hb, Hct, and RBC indices 6 to 8 weeks after initiation of iron therapy. In premature infants, Hb or Hct should be monitored weekly. Reticulocyte counts should be checked 4 to 6 weeks after birth. Reticulocyte count, Hct, and absolute neutrophil counts are measured before and 1 to 2 weeks after starting EPO treatment. EPO should be held for an absolute neutrophil count of less than 1,000 cells/mm³. Serum ferritin levels may be helpful in infants who do not respond to therapy. EPO use in premature infants is not associated with the side effects frequently seen in adults.

HEMOLYTIC ANEMIA

Pathophysiology

11 Hemolytic anemia results from decreased survival time of RBCs secondary to destruction in the spleen or circulation. The severity of hemolytic anemia varies with the mechanism. Hemolysis may be mild, chronic, and compensated, or acute, severe, and life-threatening.

The normal 120-day life span of a RBC comes from its inherent flexibility in passing through the microvasculature and spleen without disruption of the cell membrane or sequestration and phagocytosis by the mononuclear phagocytic system. Hemolysis, as defined by an RBC life span of less than 120 days, results from one of three primary defects that are intrinsic or extrinsic in origin: (a) membrane defects, (b) alterations in Hb solubility or stability, and (c) changes in intracellular metabolic processes. Intrinsic defects are intracorporeal changes and often are genetically determined. Extrinsic defects, or extracorporeal changes, usually are the cause of acquired hemolytic

TABLE 104-12 Common Classes of Hemolytic Anemias

Intrinsic (intracorporeal; usually genetically inherited)	
Membrane defect	Spherocytosis and elliptocytosis
Hemoglobin defect	Sickle cell anemia Thalassemia syndrome
Metabolic defect	Glucose-6-phosphate dehydrogenase (G6PD) deficiency Many other enzyme deficiencies
Extrinsic	
Membrane defect	Autoimmune hemolytic anemias Oxidants, may cause unstable hemoglobin to clump

anemia. Acquired disorders result mainly from a direct effect on the membrane and less often from alterations in Hb or metabolism. Table 104-12 lists examples of the different classes of hemolytic anemias.

Causes of hemolytic anemia in younger patients differ from causes in elderly patients. Most younger patients exhibit congenital disease, whereas older patients most often experience autoimmune hemolytic anemia. A positive Coombs test is diagnostic in the latter group.

Alterations in Hb solubility or stability, as seen with sickle cell anemia and the thalassemias, cause cell deformations leading to hemolysis (see Chap. 106).

Finally, alterations in cell metabolism (enzymopathies) lead to hemolytic disease by changing cell dimensions and Hb solubility.

The two major metabolic pathways necessary for normal RBC metabolism are the hexose monophosphate shunt pathway, with its associated enzyme systems, and the Embden-Myerhof pathway of anaerobic glycolysis. The former is responsible primarily for maintaining Hb in the reduced state and thus preventing the formation of methemoglobin, whereas the latter metabolizes glucose to lactic acid, which leads to adenosine triphosphate formation.

The most common metabolic abnormality resulting in a hemolytic syndrome is G6PD deficiency in the hexose monophosphate shunt pathway (see Chap. 107). Hb is oxidized to methemoglobin and then to sulhemoglobin. Heinz bodies of denatured Hb form, resulting in damage to the RBC membrane. Hemolysis results from the action of the spleen and the mononuclear phagocytic system, which normally removes damaged cells. The disease more typically occurs in whites of Mediterranean descent upon exposure to oxidant drugs (e.g., sulfamethoxazole and dapsone) and chemicals or with infection.

Some drugs and ingested toxins (e.g., nitrofurantoin, cancer chemotherapy agents, phenazopyridine, sulfones, amyl nitrate, mothballs, paraquat, and hydrogen peroxide) can cause direct oxidative damage to erythrocytes (see Chap. 107).

Laboratory Findings

Hemolytic anemias tend to be normocytic and normochromic. An increased reticulocyte count is evidence of an attempt to maintain RBC mass. A peripheral blood smear may reveal sickle cells, target cells, spherocytes, elliptocytes, and fragmented RBCs. Decreased haptoglobin is seen, caused by increased Hb-haptoglobin complex formation. Lactate dehydrogenase level often is elevated secondary to release from RBCs, but this enzyme is very nonspecific. Hemoglobinuria may result, and an increase in indirect bilirubin often occurs.

TREATMENT

Hemolytic Anemia

Therapy for hemolytic anemia consists of managing the underlying cause of the anemia. Patients with G6PD deficiency should avoid

use of precipitating oxidant medications and chemicals. No specific therapy compensates for this enzyme deficiency. Steroids and other immunosuppressive agents have been used for management of autoimmune hemolytic anemias. A splenectomy is sometimes indicated in an attempt to reduce RBC destruction.

ANEMIAS CAUSED BY ABNORMAL HEMOGLOBIN SYNTHESIS

A defect in Hb synthesis or acquired defects in erythroid precursor cell metabolism may cause changes in iron incorporation, producing a cell with an excess of nonheme iron within the cytoplasm. These cells, called *sideroblasts*, cause sideroblastic anemia, which usually is microcytic. Sideroblastic anemia can be congenital (hereditary, sex-linked in males) or acquired. The acquired forms can be either primary or secondary to drugs, toxins (e.g., lead or alcohol), or other disease states. Reduced copper content of the blood, known as *hypocupremia*, has long been associated with sideroblastosis. Excess zinc intake causes sideroblastic anemia by binding preferentially to copper, impairing copper absorption, and leading to hypocupremia. Primary acquired sideroblastic anemia usually is classified as myelodysplastic syndrome and may eventually transform into acute myeloblastic leukemia.

Other hereditary defects in heme synthesis can lead to overproduction of heme precursors resulting in porphyria. The most common form, acute intermittent porphyria (AIP), results from a hereditary (autosomal dominant) partial deficiency in the enzyme uroporphyrinogen I synthetase, which is responsible for converting porphobilinogen to uroporphyrinogen. This deficiency inhibits the normal feedback mechanism of porphyrin synthesis, leading to excess production of the heme intermediate pigments uroporphyrin I and coproporphyrin I. The diagnosis of AIP is confirmed by detection of abnormal amounts of these products in urine and feces.

AIP is characterized by neuropsychiatric, neuromuscular, and autonomic dysfunction and intense abdominal pain. In the liver, this enzyme deficiency results in the increased inducibility of abnormal heme intermediates by certain drugs. Drugs and agents known to induce hepatic cytochrome P450 enzymes or to increase hepatic heme turnover are theoretically capable of precipitating porphyria. Barbiturates, estrogens, alcohol, and heavy metals (e.g., lead) have been documented to induce porphyria in genetically susceptible people.^{76–78}

Genetic expression of an abnormal amino acid substitution in either the α - or β -globin chains can lead to a variety of hemoglobinopathies causing hemolytic diseases, such as sickle cell anemia and thalassemia (see Chap. 106).⁷⁹ Four genes control α -chain production, and two genes regulate β -chain production. Thalassemias result when these genes are defective. If three or four α -genes or both β -genes are not functioning properly, a major thalassemia, which is often incompatible with life, develops. Fortunately, thalassemia minor (trait) is more common. The trait results from deficiencies in one or two α -genes or one β -gene. For example, if α -genes are affected, normal β -chains accumulate in the cell and damage the membrane. This cell is prematurely cleared from the circulation, exacerbating the anemia. Surviving cells have inadequate Hb and are microcytic and hypochromic. Hemolysis and ineffective erythropoiesis cause the anemia.

The thalassemias are widely disseminated throughout parts of Africa, the Mediterranean region, the Middle East, the Indian subcontinent, and southeast Asia, but occur sporadically in all racial groups. Specifically, β -thalassemia is well recognized in persons of Greek and Italian descent; whereas the α -thalassemic syndromes have an increased prevalence in African American, American Indian, and Asian groups. It frequently is asymptomatic. Transfusion therapy allows for normal growth and suppresses ineffective erythropoiesis. Iron supplementation is not needed unless the

patient has excessive blood loss and confirmed iron deficiency. It is important to distinguish thalassemia from IDA to avoid inappropriate iron therapy, as the excess iron may be deleterious and lead to possible organ damage. Iron overload causes most of the mortality and morbidity associated with thalassemia. Chelation therapy with deferoxamine is used but has limitations such as painful parenteral administration and cost. New oral iron chelators such as deferasirox are under development. Although both are microcytic, MCV tends to be much lower with thalassemia than with IDA. Target cells may be seen on the peripheral blood smear in patients with thalassemia. Finally, in contrast to patients with IDA, patients with thalassemia have normal or increased ferritin levels. Hundreds of these abnormal Hb diseases exist and are best diagnosed by Hb electrophoresis.

PHARMACOECONOMIC CONSIDERATIONS

Anemia has an independent impact on many clinical, functional, and economic indicators, and evidence suggests that treatment can improve patient outcomes. The implications of treating anemia are becoming increasingly recognized, especially in the elderly. The cost of the complications associated with anemia in the elderly is considerable because anemia has been associated with an increased risk of falls, dementia, depression, and general functional disability that increases the demand for long-term care services.⁸⁰ However, the causal link between anemia and the costs of these diseases is not known. Studies show that treatment of anemia in elderly patients with renal failure and heart failure is beneficial.⁸⁰ More research is needed to assess the costs and benefits of therapies in individuals and in groups, especially when treatment of mild anemia is considered.⁸¹

Although the direct medical costs of anemia are unknown, the direct costs of drug treatment must be weighed against the indirect costs associated with anemia.⁸² The costs of laboratory tests used to diagnose anemia, the role of screening for anemia, and the prevention of anemia are components that must be considered in the pharmacoeconomic analysis. Anemia practice guidelines within medical specialties must consider cost as they are developed. Additionally, the frequency of blood transfusions must be considered because it impacts cost and therapeutic decision making in patients.

For IDA, intravenous iron is costly but has superior bioavailability compared with oral preparations. In some individuals, the bioavailability advantage of parenteral iron over oral iron can be the difference in achieving a successful outcome. The benefits of using combination oral iron products designed to enhance absorption probably are not warranted.

With regard to vitamin B₁₂ deficiency, the cost of oral cyanocobalamin tablets and intramuscular injections is inexpensive. However, the parenteral route has significant additional costs, including the cost of a physician or nurse's visit for the injection or the cost of a home health visit. Additionally, many elderly patients may have difficulties attending extra clinic appointments because of transportation difficulties. A 90-day supply of nonprescription 1-mg oral tablets can be purchased for approximately \$5. The disadvantage of the nasal spray is its cost compared to the oral or parenteral route, with a 2-month supply costing approximately \$75.

For ACD, EPO is generally effective and safe, but it is expensive. The cost of intravenous iron is low compared with the cost of EPO. Because most patients with ACD are not symptomatic, they may feel no improvement with therapy. Symptom severity should be considered in the decision to use EPO. Transfusion use for treatment of ACD as an alternative to EPO must consider cost, convenience, and risk of complications.

Formal economic evaluation of treatment approaches for anemia of critical illness are generally lacking. Doses used for anemia of critical illness have been 40,000 units weekly, with a cost of approximately \$570. The cost of one unit of packed RBCs is \$191 to \$391

per dose based on factors such as donor recruitment and qualification; blood collection, processing, and screening; blood destruction, donor notification, and tracking; blood inventory, storage, and transport; and transfusion-related costs. Two or three doses of EPO are needed to avoid one RBC transfusion. Future studies may need to assess the cost per unit of RBC saved, which differs among institutions. Other pharmacoeconomic factors for consideration include morbidity and mortality of transfusion reactions, related infections, potential for medical errors, and availability of RBCs as a resource. Length of ICU stay, total hospital stay, and length of time on mechanical ventilation are other key factors.

ABBREVIATIONS

ACD: anemia of chronic disease
 AIDS: acquired immunodeficiency syndrome
 AIP: acute intermittent porphyria
 CBC: complete blood count
 CDC: Centers for Disease Control and Prevention
 EPO: erythropoietin
 Fe²⁺: ferrous iron
 Fe³⁺: ferric iron
 G6PD: glucose-6-phosphate dehydrogenase
 Hb: hemoglobin
 Hct: hematocrit
 HIV: human immunodeficiency virus
 IDA: iron-deficiency anemia
 MCH: mean corpuscular hemoglobin
 MCHC: mean corpuscular hemoglobin concentration
 MCV: mean corpuscular volume
 MMA: methylmalonic acid
 NHANES: National Health and Nutrition Examination Survey
 RBC: red blood cell
 RDW: red blood cell distribution width
 TIBC: total iron-binding capacity
 USPSTF: U.S. Preventive Services Task Force

BETSY BICKERT AND CHAR WITMER

KEY CONCEPTS

- 1 Hemophilia is an inherited bleeding disorder resulting from a congenital deficiency in factor VIII or IX.
- 2 The goal of therapy for hemophilia is to prevent bleeding episodes and their long-term complications and to arrest bleeding when it occurs.
- 3 Recombinant factor concentrates usually are first-line treatment of hemophilia because they have the lowest risk of infection.
- 4 The goal of therapy for von Willebrand disease is to increase von Willebrand factor and factor VIII levels to prevent bleeding during surgery or arrest bleeding when it occurs.
- 5 Factor VIII concentrates that contain von Willebrand factor are the agents of choice for treatment of type 3 von Willebrand disease and some type 2 von Willebrand disease, and for serious bleeding in type 1 von Willebrand disease.
- 6 Desmopressin acetate often is effective for treatment of type 1 von Willebrand disease. It also may be effective for treatment of some forms of type 2 von Willebrand disease.
- 7 The optimal approach for patients with disseminated intravascular coagulation remains to be determined. The goal of treatment is to diagnose and treat the underlying cause.
- 8 Prophylactic use of phytonadione can effectively prevent vitamin K-dependent bleeding in newborns.

Coagulation disorders result from a decreased number of platelets, decreased function of platelets, coagulation factor deficiency, or enhanced fibrinolytic activity. A series of complex actions and reactions of procoagulant and anticoagulant events regulate blood flow. Maintenance of blood flow involves the interplay of four major components: (a) the vessel wall, (b) platelets, (c) the coagulation system, and (d) the fibrinolytic system.

The traditional view of the coagulation cascade consisted of intrinsic, extrinsic, and common pathways where coagulation proteins directed and controlled coagulation. Coagulation could be initiated via either the intrinsic or the extrinsic pathway (Fig. 105–1). The extrinsic pathway is initiated by exposure of tissue during trauma. The intrinsic pathway is initiated when circulating factor XII comes in contact with the subendothelial membrane. These two

pathways converge at the activation of factor X, forming the common pathway. Although the historical model in Fig. 105–1 shows the basic dependency of the various coagulation factors, it does not reflect the interactions with platelets and the endothelium. Thus, it has been replaced by the cell-based model that more accurately describes these interactions (Fig. 105–2). This is known as the *tissue factor pathway* because it recognizes the central role of tissue factor in coagulation.

REGULATION OF HEMOSTASIS

COAGULATION FACTORS

Twelve plasma proteins are considered coagulation factors (Table 105–1). The coagulation factors can be divided into three groups on the basis of biochemical properties. These groups include vitamin K-dependent factors (II, VII, IX, and X), contact activation factors (XI and XII, prekallikrein, high-molecular-weight kininogen), and thrombin-sensitive factors (V, VIII, XIII, and fibrinogen).

Coagulation factors circulate as inactive precursors (zymogens). Coagulation of blood entails a cascading series of proteolytic reactions. At each step, a clotting factor undergoes limited proteolysis and becomes an active protease (designated by a lowercase “a,” as in Xa). These coagulation factors play key roles in the coagulation pathway.

VESSEL WALL AND PLATELETS

Blood vessel walls and activated platelets play central roles in primary hemostasis. Damage to a vessel wall initiates vasoconstriction and the exposure of collagen and tissue factor to blood. This exposure initiates coagulation via the tissue factor pathway.

Platelet function in response to vascular injury includes four phases: (a) adhesion, (b) secretion, (c) aggregation, and (d) elaboration of procoagulant activity. Release of von Willebrand factor from activated platelets and fibrinogen from the endothelium causes adhesion of platelets at the site. Platelets release granular contents, such as adenosine diphosphate and thromboxane A_2 , which lead to platelet aggregation. A platelet plug is formed that occludes the blood vessel lesion. Activated coagulation factors are generated at the site of bleeding on the activated platelets to form fibrin and stabilize the platelet plug. Factor XIIIa cross-links the fibrin and stabilizes the fibrin clot.¹

Unbound factors IIa, IXa, Xa, XIa, and XIIa are inactivated by antithrombin when they migrate to the endothelial cell surface. Heparin and heparin-like substances present on the surface of endothelial cells enhance the inhibitory capacity of antithrombin.¹ Thrombomodulin binds thrombin and activates protein C. Activated protein C and its cofactor, protein S, are vitamin K-dependent proteins that inactivate factor Va and VIIIa on the endothelial cell surface. These interactions localize the clotting to the site of injury and prevent clotting in the intact vascular system.

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

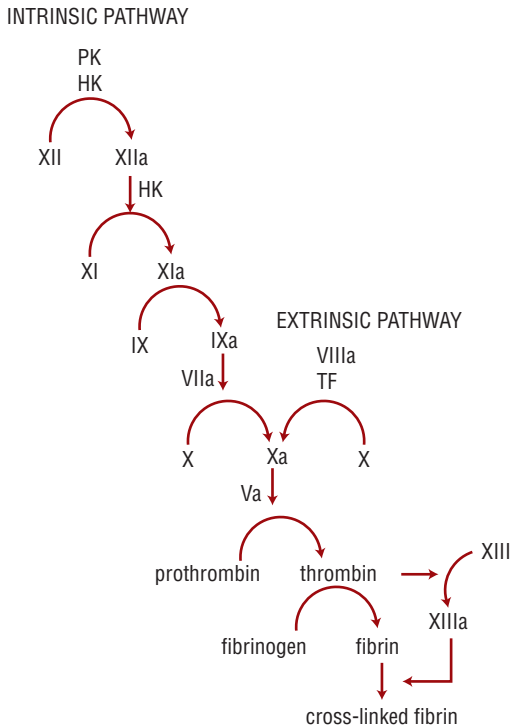

FIGURE 105-1. Cascade model of coagulation demonstrates activation via the intrinsic or extrinsic pathway. This model shows successive activation of coagulation factors proceeding from the top to the bottom where thrombin and fibrin are generated. TABLE 105-1 Blood Coagulation Factors

Factor ^a	Synonym	Biologic Half-life (h)	Blood Product Source
I	Fibrinogen	100–150	Cryoprecipitate (200–300 mg/bag)
II	Prothrombin	50–80	FFP, PCC
V	Proaccelerin	12–36	FFP
VII	Proconvertin	4–6	Recombinant VIIa, FFP, PCC
VIII	Antihemophilic factor	12–15	FFP, factor concentrates, cryoprecipitate
IX	Christmas factor	18–30	FFP, PCC, factor concentrates
X	Stuart-Power factor	25–60	FFP, PCC
XI	Plasma thromboplastin antecedent	40–80	FFP
XII	Hageman factor	50–70	Not associated with bleeding diathesis
XIII	Fibrin-stabilizing factor	150	FFP, cryoprecipitate, factor concentrate
VWF	von Willebrand factor	8–12	FFP, cryoprecipitate, factor concentrate

^aCoagulation factors are numbered with roman numerals in order of their discovery. The most common synonyms are listed. Factor III (tissue factor) and factor IV (calcium ions) have been omitted. There is no factor VI.
FFP, fresh-frozen plasma; PCC, prothrombin complex concentrate.

VIIa binds to exposed or expressed tissue factor (Fig. 105–2). The factor VIIa–tissue factor complex activates factors IX and X.² Activated platelets form complexes with factor IXa–factor VIIIa (tenase) and factor Xa–factor Va (prothrombinase). Tenase activates factor X, and prothrombinase converts prothrombin to thrombin. Thrombin activates platelets and catalyzes the conversion of fibrinogen to fibrin. Thrombin also amplifies coagulation by activating factors V, VIII, and XI.

FIBRINOLYSIS

The coagulation system regulates fibrin clot formation, whereas the fibrinolytic system dissolves the polymerized clot and restores blood flow. As a regulatory mechanism for maintaining blood flow, the fibrinolytic system removes fibrin deposits and prevents formation of unnecessary fibrin clots. It also contributes to localized repair of damaged endothelium.

Plasminogen is the primary compound of the fibrinolytic enzyme system. Plasminogen activators (tissue plasminogen activator and urokinase plasminogen activator) are released in response to thrombin, venous stasis, physical exercise, and ischemia.³ Activators convert plasminogen to plasmin in the presence of fibrin. Plasmin enzymatically digests fibrin, dissolves the clot, and releases a number of fibrin degradation products (FDPs). The interaction among plasminogen activators, plasminogen, and fibrin restricts the fibrinolytic activity to the site of the clot. Plasminogen activator inhibitor type 1 (PAI-1) blocks the plasminogen activators, whereas antiplasmin directly inhibits circulating plasmin to prevent systemic fibrinolysis.³

SIMPLE LABORATORY TESTS

The diagnosis of coagulation disorders can be established from a detailed clinical history, physical examination, and laboratory test results. The most common screening tests include prothrombin time (PT), activated partial thromboplastin time (aPTT), thrombin time, platelet count, and bleeding time.¹ The results of these standard laboratory procedures can distinguish bleeding disorders caused by defects in the intrinsic, extrinsic, and common coagulation pathways (Fig. 105–1) or alterations in the number of functioning platelets. Specific assays of individual coagulation factors and

TABLE 105-2 Laboratory Procedures

Procedure	Identifies	Cause of Prolonged Value	Clinical Manifestations
Bleeding time	Platelet number and function	Acquired platelet disorders (uremia) Vasculitis Connective tissue disorder Thrombocytopenia Inherited qualitative platelet defects Antiplatelet drugs von Willebrand disease	Bleeding from the gums Easy bruising Bleeding following surgery or tooth extraction Epistaxis Menorrhagia

HMWK, high-molecular-weight kininogen.

platelet function tests can be performed after abnormalities are identified by initial screening tests. The following is a brief review of widely available tests (summarized in Table 105–2).

Bleeding Time and Platelet Function Analyzer

Bleeding time assesses platelet and capillary function. Bleeding time reflects the time to cessation of bleeding following a standardized skin cut. This technique is patient and operator dependent. In the past 15 years has come increased recognition that the bleeding time has a number of disadvantages when applied as a screening test, resulting in the decreased popularity of this test.⁴ The bleeding time is insensitive to mild platelet defects and does not consistently predict a bleeding tendency.⁴ The platelet function analyzer (PFA-100) is an in vitro screen for platelet function and has been found to be superior to the in vivo bleeding time.⁴ The PFA-100 also has limitations; it is not diagnostic, and abnormal values require further evaluation. Patients with an abnormal bleeding time but a normal platelet count are arbitrarily designated as having qualitative abnormalities of platelet function. A prolonged bleeding time can be caused by incorrect performance of the test, thrombocytopenia, platelet dysfunction, von Willebrand disease, use of antiplatelet drugs (i.e., aspirin), renal failure (uremia), fibrinogen disorders, abnormal blood vessels, or collagen disorders.

Prothrombin Time

PT assesses the activity of the vitamin K–dependent proteins (factors II, VII, IX, and X, and proteins C and S) and the common pathway proteins (factors V and X).⁵ PT reflects the time required for fibrin strands to appear after the addition of tissue thromboplastin to the patient's plasma. Thus, PT provides evidence about the current synthetic capacity of the liver, the adequacy of vitamin K absorption, and the inhibition of clotting factor synthesis by warfarin. PT is expressed as an international normalized ratio that normalizes values, which is needed because of the variability of test reagents.⁶

Activated Partial Thromboplastin Time

aPTT measures the activity of the intrinsic system and common pathway (factors II, V, VIII, IX, X, XI, and XII, high-molecular-weight kininogen, prekallikrein, and fibrinogen). aPTT reflects the time required for a fibrin clot to form after a partial thromboplastin, calcium, and an activating agent are added to the patient's plasma. aPTT is widely used for monitoring heparin therapy.

Thrombin Time

The thrombin time measures the conversion of fibrinogen to fibrin and is affected by quantitative or qualitative abnormalities of fibrinogen, the presence of thrombin inhibitors, and fibrinogen degradation products. The thrombin time measures the time required for the formation and appearance of the fibrin clot after thrombin is added to plasma. It can be used to monitor the effect of systemic fibrinolytic therapy and can be modified for monitoring heparin therapy.

CONGENITAL COAGULATION DISORDERS

HEMOPHILIA

1 Hemophilia is a bleeding disorder that results from a congenital deficiency in a plasma coagulation protein. Hemophilia A (classic hemophilia) is caused by a deficiency of factor VIII, whereas hemophilia B (Christmas disease) is caused by a deficiency of factor IX. The incidence of hemophilia A is approximately 1 in 5,000 male births.^{7–9} Hemophilia B occurs less commonly, with only one fourth the incidence of hemophilia A.^{7–9} There are no significant racial differences in the incidence of hemophilia.

Approximately one-third of patients with severe hemophilia have a negative family history, presumably representing a spontaneous muta-

tion. Both hemophilia A and hemophilia B are recessive X-linked diseases, that is, the defective gene is located on the X chromosome. The disease usually affects only males; females are carriers. Affected males have the abnormal allele on their X chromosome and no matching allele on their Y chromosome, but their sons would be normal (assuming the mother is not a carrier) and their daughters would be obligatory carriers. Female carriers have one normal allele and therefore do not usually have a bleeding tendency. Sons of a female carrier and a normal male have a 50% chance of having hemophilia, whereas daughters have a 50% chance of being carriers. Thus, there is a “skipped generation” mode of inheritance in which the female carriers, who are the children of patients with hemophilia, do not express the disease but can pass it on to the next male generation.

Hemophilia has been observed in a small number of females. It can occur if both factor VIII and IX genes are defective,^{10,11} if a female patient has only one X chromosome, as in Turner syndrome,¹² or if the normal X chromosome is excessively inactivated through a process called *lyonization*.¹²

In 1984, researchers isolated and cloned the human factor VIII gene.^{13,14} It is a large gene, consisting of 186 kilobases (kb).^{14,15} More than 900 unique mutations in the factor VIII gene, including point mutations, deletions, and insertions, have been reported (<http://europium.csc.mrc.ac.uk>). Deletions and nonsense mutations are often associated with the more severe forms of factor VIII deficiency because no functional factor VIII is produced. In 1993, researchers identified an inversion in the factor VIII gene at intron 22 that accounts for approximately 45% of severe hemophilia A gene abnormalities.¹⁶ That discovery has greatly simplified carrier detection and prenatal diagnosis in families with this gene mutation. A more recently discovered inversion mutation involving intron 1 of the factor VIII gene accounts for an additional 5% of severe hemophilia mutations.¹⁷

The factor IX gene, cloned and sequenced in 1982,¹⁸ consists of only 34 kb and thus is significantly smaller than the factor VIII gene.^{13,15} Unlike the factor VIII gene in patients with severe hemophilia A, the factor IX gene in patients with hemophilia B has no predominant mutation. Direct gene mutation analysis is simpler in hemophilia B because of the smaller gene size, and to date more than 900 different mutations have been reported (<http://kcl.ac.uk/ip/petergreen/haemBdatabase.html>). Most of these mutations are single base pair substitutions. Approximately 3% of factor IX gene mutations are deletions or complex rearrangements, and the presence of these mutations is associated with a severe phenotype.¹⁴

Hemophilia B Leiden is a rare variant in which factor IX levels initially are low but rise at puberty. This phenotype results from a mutation in the promoter region of the gene that apparently is ameliorated by the action of testosterone.^{14,19,20} Identification of this genotype is clinically important because it confers a better prognosis.

Clinical Presentation

The characteristic bleeding manifestations of hemophilia include palpable ecchymoses, bleeding into joint spaces (hemarthroses), muscle hemorrhages, and excessive bleeding after surgery or trauma. The severity of clinical bleeding generally correlates with the degree of deficiency of factor VIII or factor IX. Factor VIII and factor IX activity levels usually are measured in units per milliliter, with 1 unit/mL representing 100% of the factor found in 1 mL of normal plasma. Normal plasma levels range from 0.5 to 1.5 units/mL.⁵ Patients with less than 0.01 units/mL (1%) of either factor are classified as having severe hemophilia, those with 0.01 to 0.05 units/mL (1%–5%) are moderate, and those with greater than 0.05 units/mL (5%) have mild hemophilia (Table 105-3). Patients with severe disease experience frequent spontaneous hemorrhages and joint space bleeding, whereas those with moderate disease have excessive bleeding following mild trauma and rarely experience spontaneous hemarthroses. Patients with mild hemophilia may have so few symptoms that their condition

TABLE 105-3 Laboratory and Clinical Manifestations of Hemophilia

	Severe (<0.01 units/mL)	Moderate (0.01–0.05 units/mL)	Mild (>0.05 units/mL)
Age at diagnosis	≤1 year	1–2 years	2 years–adult
Neonatal symptoms			
PCB	Usually	Usually	Rarely
ICH	Occasionally	Uncommonly	Rarely
Muscle/joint hemorrhage	Spontaneous	Minor trauma	Minor trauma
CNS hemorrhage	High risk	Moderate risk	Rare
Postsurgical hemorrhage (without prophylaxis)	Frank bleeding, severe	Wound bleed- ing, common	Wound bleeding
Oral hemorrhage follow- ing trauma, tooth extraction	Usually	Common	Common

Normal range of factor VIII/IX activity level is 0.5–1.5 units/mL (50%–150%). 1 unit/mL corresponds to 100% of the factor found in 1 mL of normal plasma.

CNS, central nervous system; ICH, intracranial hemorrhage; PCB, postcircumcisional bleeding.

is undiagnosed for many years, and they usually have excessive bleeding only after significant trauma or surgery. Occasionally those with severe disease (less than 1% factor activity) may not display a severe phenotype; conversely, some with milder forms of the disease may have more severe bleeding symptomatology. Patients with hemophilia usually present with clinical manifestations after age 1 year, when they begin to walk and increase their risk of bleeding.

CLINICAL PRESENTATION OF HEMOPHILIA

Signs and Symptoms

- Ecchymoses (palpable)
- Hemarthrosis (especially knee, ankle, and elbow)
- Joint pain
- Joint swelling and erythema
- Decreased range of motion
- Muscle hemorrhage
- Swelling
- Pain with motion of affected muscle
- Signs of nerve compression
- Potential life-threatening blood loss, especially with thigh bleeding
- Oral bleeding with dental extractions or trauma
- Hematuria
- Intracranial hemorrhage (spontaneous or following trauma)
- Excessive bleeding with surgery

Laboratory Testing

- Prolonged aPTT
- Decreased factor VIII or factor IX level
- Normal PT
- Normal platelet count
- Normal von Willebrand factor antigen and activity
- Normal bleeding time

Diagnosis

The diagnosis of hemophilia should be considered in any male with unusual bleeding. A family history of bleeding is helpful in the diagnosis but is absent in up to one third of patients.²¹ Brothers of patients with hemophilia should be screened; sisters should undergo carrier testing.

Advances in molecular genetic analysis have greatly improved the accuracy of carrier status evaluation. Thus, female relatives of patients with hemophilia who are at risk of being carriers for the disorder should be tested. Additionally, the appropriate factor level should be measured in female carriers to identify those with levels less than 0.3 units/mL (30%) who themselves might be at risk for bleeding.

Patients with severe hemophilia A should be tested for the common factor VIII gene inversions. If the patient has this mutation, family members should undergo testing to determine if they also have the mutation and thus are carriers. In patients with hemophilia A who lack the inversion mutation, other methods for determining the carrier status of their family members are available.^{22,23} Techniques for determining carrier status in families with hemophilia B are similar, although no predominant mutation like the factor VIII inversion has been found. The smaller size of the factor IX gene facilitates direct DNA mutational analysis.²³

Hemophilia can be diagnosed prenatally by chorionic villus sampling in gestational weeks 10 to 11 or by amniocentesis after 15 weeks' gestation.^{15,22} Fetal blood can be sampled and assayed directly for factor VIII levels by 18 to 20 weeks' gestation.^{15,22} This procedure is less useful for diagnosing factor IX deficiency because factor IX levels are physiologically low in fetuses and infants.

TREATMENT

Hemophilia

The comprehensive care of hemophilia requires a multidisciplinary approach. The patient is best managed in specialized centers with trained personnel and appropriate laboratory, radiologic, and pharmaceutical services. The healthcare team includes hematologists, orthopedic surgeons, nurses, physical therapists, dentists, genetic counselors, psychologists, pharmacists, case managers, and social workers.

Patients with hemophilia should receive routine immunizations, including immunization against hepatitis B. Hepatitis A vaccine is also recommended for patients with hemophilia because of the risk (albeit small) of transmitting the causative agent through factor concentrates.²⁴ Use of a small-gauge needle can prevent excessive bleeding. Some healthcare providers advocate subcutaneous rather than intramuscular immunizations to decrease the risk of hematoma formation.

A few special considerations apply to the perinatal care of male infants of hemophilia carriers. Intracranial or extracranial hemorrhage has been estimated to occur in 1% to 4% of newborns with hemophilia.²⁵ Vacuum extraction and forceps delivery increase the risk of cranial bleeding. Elective cesarean section has not prevented intracranial bleeding. There is no clear consensus on the optimal mode of delivery or the use of prophylactic factor replacement in male infants of hemophilia carriers.²⁵ Circumcision should be postponed until a diagnosis of hemophilia is excluded. Factor levels can be assayed from cord blood samples or from peripheral venipuncture. Arterial puncture should be avoided because of the risk of hematoma formation. If an infant has hemophilia, many clinicians recommend a screening head ultrasound to rule out an intracranial hemorrhage prior to discharge from the nursery.

② Intravenous factor replacement therapy for treatment or prevention of bleeding is the mainstay of treatment of hemophilia. Families usually learn how to treat patients receiving factor concentrate at home. Parents may learn to infuse factor for younger children, and older children and adult patients may learn self-administration. Home healthcare nursing support may be helpful, particularly for the youngest patients in whom venous access may be difficult. Administration of factor at home is more convenient for families and allows

for earlier treatment of acute bleeding episodes. However, serious bleeding episodes always require medical evaluation.

HISTORY OF HEMOPHILIA TREATMENT

Therapy for hemophilia has undergone dramatic advances over the past few decades. Fifty years ago, administration of fresh-frozen plasma was the only available treatment. The introduction of cryoprecipitate in the early 1960s allowed more specific therapy for hemophilia A.¹⁴ Intermediate-purity factor VIII and IX concentrates became available in the 1970s.¹⁴ Plasma-derived factor concentrates are made from the donations of thousands of people. Contamination of plasma pools with hepatitis B, hepatitis C, and the human immunodeficiency virus (HIV) during the late 1970s and early 1980s resulted in transmission to most patients with severe hemophilia. Since the mid-1980s, plasma-derived concentrates have been manufactured with a variety of virus-inactivating techniques, including dry heat, pasteurization, and treatment with chemicals (e.g., solvent detergent mixtures).¹⁴ Since 1986, no transmission of HIV through factor concentrates to patients with hemophilia in the United States has been reported.¹⁴ Protein purification, introduced in the 1990s, produced high-purity concentrates with increased amounts of factor VIII or factor IX relative to the product's total protein content. Recombinant factor VIII and then factor IX also became available.¹⁴ The first-generation recombinant factor VIII products utilize human and animal proteins in culture and add human albumin as a protein stabilizer.¹⁴ Second-generation recombinant factor VIII concentrates removed albumin as a protein stabilizer, and third-generation products lack human and animal proteins in the culture media.²⁶ Gene therapy for treatment of hemophilia is now in the early stages of clinical trials.

HEMOPHILIA A

Table 105–4 summarizes the factor VIII products currently available in the United States. Most patients are treated with high-purity products. In general, products that have the lowest risk of transmitting infectious disease should be used. Thus, recombinant products, when available, are generally used rather than plasma-derived products.

Recombinant Factor VIII

③ Derived from cultured Chinese hamster ovary cells or baby hamster kidney cells transfected with the human factor VIII gene,¹⁴ recombinant factor VIII is produced with recombinant DNA technology. Because it is not derived from blood donations, the risk of transmitting infections through administration of recombinant factor VIII is low. For this reason, recombinant products are generally favored over plasma-derived products. There still is a small risk of viral infection of the cell lines used to produce the clotting factor.²⁷ Furthermore, human and/or animal proteins are utilized in the production process of some recombinant products.²⁶ Therefore, these products have a theoretical risk of transmitting infection, although hepatitis and HIV infection have never been reported with their use.¹⁴ The presence of parvovirus B19 DNA has been reported in recombinant factor VIII products.²⁸ First-generation recombinant factor VIII products contain human albumin as a stabilizing protein.¹⁴ Second-generation recombinant factor VIII products add sucrose instead of human albumin as a stabilizer, but human albumin is utilized in the culture process. One second-generation product (ReFacto) has deletion of the B domain of the factor VIII gene, yielding a smaller protein product.²⁹ This B domain does not appear to be necessary for coagulation function. Third-generation recombinant factor VIII products contain no human protein in either the culture or in the stabilization processes.²⁶

Clinical trials have demonstrated that recombinant factor VIII products are comparable in effectiveness to plasma-derived products.²⁹ The risk of patients with severe hemophilia A developing an

inhibitory antibody to factor VIII with use of recombinant factor VIII is 28% to 33%.²⁹ This risk is higher than reported with plasma-derived products. The difference may be partly attributable to more frequent screening for inhibitors in the recombinant product trials, with detection of transient inhibitors that might have been missed in the trials with plasma-derived products.³⁰ However, the incidence of high-responding inhibitors, which are clinically significant, was higher in trials using recombinant factor VIII compared with those using a single plasma-derived product.³⁰

Plasma-Derived Factor VIII Products

Several different plasma-derived factor VIII products are available (Table 105-4). These products are derived from the plasma of thousands of donors and therefore potentially can transmit infection. Donor screening, testing plasma pools for evidence of infection, viral reduction through purification steps, and viral inactivation procedures (e.g., dry heat, pasteurization, and solvent detergent treatment) all have resulted in a safer product.²⁶ No cases of HIV transmission from factor concentrates have been reported since 1986.¹⁴ However, isolated cases of hepatitis C infection with use of plasma-derived products have been reported.¹⁴ Additionally, outbreaks of hepatitis A viral infections associated with plasma-derived products, likely because solvent detergent treatment does not inactivate this nonenveloped virus, have been reported.²⁴ Parvovirus has been reported to be present in both plasma-derived and recombinant factor VIII products.²⁸ Finally, there remains concern about the possibility of infection with as yet unidentified viruses that currently used methods would not inactivate.

Factor VIII concentrates can be classified according to their level of purity, which refers to the specific activity of factor VIII in the product. Cryoprecipitate is a low-purity product. Cryoprecipitate also contains von Willebrand factor, fibrinogen, and factor XIII. Current American Association of Blood Banks standards call for a minimum of 80 international units of factor VIII per pack.¹⁴ This

product is no longer considered a primary treatment of factor VIII deficiency in countries where factor VIII concentrates are available because cryoprecipitate does not undergo a viral inactivation process. Intermediate-purity products have a specific activity of factor VIII of 5 units/mg of protein, whereas high-purity products have up to 2,000 units/mg of protein.¹⁴ Ultrahigh-purity plasma-derived products are prepared with monoclonal antibody purification steps and have a specific activity of 3,000 units/mg of protein prior to addition of albumin as a stabilizer.

Factor VIII Concentrate Replacement

Appropriate dosing of factor VIII concentrate depends on the half-life of the infused factor, the patient's body weight, and the volume of distribution. The presence or absence of an inhibitory antibody to factor VIII and the titer of this antibody also influence treatment. Recovery studies, which measure the immediate postinfusion factor level, and survival studies, which assess the half-life of the factor, can establish patient-specific pharmacokinetics. The location and magnitude of the bleeding episode determine the percent correction to target as well as the duration of treatment. Serious or life-threatening bleeding requires peak factor levels of greater than 0.75 to 1 units/mL (75%–100%); less severe bleeding may be treated with a goal of 0.3 to 0.5 units/mL (30%–50%) peak plasma levels. Table 105-5 provides general guidelines for the management of bleeding in different locations.

Factor VIII is a large molecule that remains in the intravascular space. Therefore, the plasma volume (approximately 50 mL/kg) can be used to estimate the volume of distribution.³¹ In general, each unit of factor VIII concentrate infused per kilogram of body weight yields a 2% rise in plasma factor VIII levels. The following equation can be used to calculate an initial dose of factor VIII:

$$\text{Factor VIII (units)} = (\text{Desired level} - \text{Baseline level}) \times 0.5 \times (\text{Weight [in kilograms]})$$

TABLE 105-5 Guidelines for Factor Replacement Therapy for Hemorrhage in Hemophilia A and B

Site of Hemorrhage	Desired Hemostatic Factor Level (% of normal)	Comments
Joint	50%–70%	Rest/immobilization/physical therapy rehabilitation following bleed; several doses may be necessary to prevent or treat target joint
Muscle	30%–50% for most sites 70%–100% for thigh, iliopsoas, or nerve compression	Risk of significant blood loss with femoral/retroperitoneal bleed; bed rest for iliopsoas or other retroperitoneal bleeding
Oral mucosa	30%–50%	May try antifibrinolytic or topical thrombin prior to factor replacement for minor bleeding; higher factor levels may be needed for tongue swelling or risk of airway compromise; antifibrinolytic therapy should be used following factor replacement; do not use with aPCCs or PCCs
Gastrointestinal Hematuria	Initially 100%, then 30% until healing occurs 30% if no trauma 70%–100% if traumatic	Endoscopy is highly recommended; antifibrinolytic therapy may be useful
Central nervous system Trauma or surgery	Initially 100%, then 50%–100% for 10–14 days Initially 100%, then 50% until wound healing complete	If no pain or trauma, consider bed rest and fluids for 24 hours; factor should be given if hematuria persists; evaluate if hematuria persists; if trauma to abdomen or back, perform imaging and give aggressive factor replacement Lumbar puncture requires prophylactic factor coverage Perioperative and postoperative management plan must be in place preoperatively; evaluation for inhibitors is crucial prior to elective surgery

aPCC, activated prothrombin complex concentrate; PCC, prothrombin complex concentrate.

The baseline level usually is omitted from the equation because it is negligible compared to the desired level. The half-life of factor VIII ranges from 8 to 15 hours.³¹ It is generally necessary to administer half of the initial dose approximately every 12 hours to sustain the desired level of factor VIII. A single treatment may be adequate for minor bleeding, such as oral bleeding or slight muscle hemorrhages. However, because of the potential for long-term joint damage with hemarthroses, 2 or 3 days of treatment is often recommended for these bleeds. Serious bleeding episodes may require maintenance of 70% to 100% factor activity for 1 week or longer. As previously mentioned, factor VIII dosing depends on several variables, and each case must be considered individually. Individual pharmacokinetics may help guide treatment, particularly for serious bleeding episodes.

Alternatively, factor VIII can be administered as a continuous infusion when prolonged treatment is required (e.g., in the perioperative period or for serious bleeding episodes). Infusion rates ranging from 2 to 4 units/kg per hour usually are given in fixed-dose continuous infusion protocols, with the aim of maintaining a steady-state level of 60% to 100%.^{32,33} Administration of factor concentrate via continuous infusion may reduce factor requirements by 20% to 50% because unnecessarily high peaks of factor VIII that occur with bolus injections are avoided.³³ A gradual decrease in factor VIII clearance during the first 5 to 6 days of treatment contributes to the lower factor concentrate requirements.³² Daily monitoring of factor level can help determine the appropriate rate of infusion.

Administration of factor VIII concentrate via continuous infusion has been shown to be safe and effective,^{32,33} and it may be more convenient than bolus therapy for hospitalized patients. The advantages of continuous infusion include maintenance of a steady-state plasma level with avoidance of potentially subtherapeutic trough levels and a reduction in cost associated with decreased factor requirements. A potential side effect with continuous infusion is thrombophlebitis at the delivery site. Concomitant infusion of saline or the addition of heparin (2–5 units/mL) to the infusion bag can minimize this risk.^{32,33} Bacterial contamination of the concentrate is another theoretical concern. However, studies have shown that the products can remain sterile for more than 1 week if prepared and kept under appropriate conditions.^{32,33} Finally, concerns about the stability of the formulations appear to be unwarranted, as most high-purity factor VIII concentrates have been shown to remain stable for at least 7 days after reconstitution.³³ Exposure of factor VIII to light for 10 hours post reconstitution can cause a 30% decrease in the activity.³³ It would be prudent to shield the container with foil wrap or an appropriate bag.

Other Pharmacologic Therapy

Treatment with desmopressin acetate often is adequate for minor bleeding episodes in patients with mild hemophilia A. A synthetic analog of the antidiuretic hormone vasopressin, desmopressin causes release of von Willebrand factor and factor VIII from endogenous storage sites. It appears to be most effective in patients with higher baseline factor VIII levels (0.1–0.15 units/mL).³⁴ The recommended dose of desmopressin is 0.3 mcg/kg diluted in 50 mL of normal saline and infused IV over 15 to 30 minutes.^{15,34} Patients with mild or moderate hemophilia A should undergo a desmopressin trial to determine their response to this medication. At least a twofold rise in factor VIII to a minimal level of 0.3 units/mL within 60 minutes is considered an adequate response.³⁵ In adults with mild hemophilia A, the response rate to desmopressin has been reported to be 80% to 90%.³⁵ One study reported a lower response rate of 57% in pediatric patients with mild hemophilia A.³⁵ Furthermore, the response rate was related to age; the mean age of patients who responded to desmopressin was 5.2 years compared with 3 years for those who failed to respond. Seven of the 11 children who failed to respond to desmopressin initially demonstrated an adequate response when the desmopressin challenge was repeated at an older age.

Infusion of desmopressin can be repeated daily for up to 2 to 3 days. Tachyphylaxis, an attenuated response with repeated dosing, may develop after that time. The factor increase after the second dose of desmopressin is approximately 30% lower than after the initial dose.³⁴ Factor concentrate therapy may be necessary if the patient requires additional treatment. Factor levels should be measured to ensure that an adequate response has been achieved. Treatment with desmopressin will not result in hemostasis in patients who have severe hemophilia and those who are only marginally responsive. Desmopressin should not be used as primary therapy for life-threatening bleeding episodes such as intracranial hemorrhage or for major surgical procedures when a minimum factor VIII concentration of 0.7 to 1 units/mL is required.³⁴

Desmopressin can be administered intranasally via a concentrated nasal spray.^{34,36} It elicits a slower and less marked response, with a peak effect in 60 to 90 minutes after administration, somewhat longer than with desmopressin administered intravenously.^{34,36} The dosage is one spray (150 mcg) for children who weigh less than 50 kg and two sprays (300 mcg) for those who weigh more than 50 kg.¹⁵ The nasal spray may serve as an alternative to the intravenous formulation, especially in patients with mild bleeding episodes.

Few adverse effects are associated with desmopressin. The most commonly observed side effect is facial flushing.³⁴ Less frequently

reported side effects include mild headaches, increased heart rate, and decreased blood pressure. Thrombosis is a rare complication associated with desmopressin.³⁶ Because of its antidiuretic effects, desmopressin has the potential to cause water retention, which may lead to severe hyponatremia. This may be a particular problem in children younger than 2 years, in whom hyponatremic seizures have been reported.³⁶ Therefore, desmopressin should be used with caution in this age group.^{34,35} Patients with congestive heart failure may be at increased risk for developing hyponatremia with use of desmopressin.³⁴ Mild fluid restriction and monitoring of urine output are recommended with desmopressin administration.³⁶

Antifibrinolytic therapy inhibits clot lysis and therefore is a useful adjunctive therapy for treatment of hemophilia. These antifibrinolytic agents are particularly beneficial for treatment of oral bleeding because of the high concentration of fibrinolytic enzymes present in saliva. Two antifibrinolytics are aminocaproic acid and tranexamic acid. Aminocaproic acid is given at a dosage of 100 mg/kg (maximum 6 g) every 6 hours and can be administered orally or intravenously.¹⁵ The dosage of tranexamic acid is 25 mg/kg (maximum 1.5 g) orally every 8 hours or 10 mg/kg (maximum 1 g) intravenously every 8 hours.¹⁵

■ HEMOPHILIA B

Therapeutic options for hemophilia B have improved greatly over the past several years, first with the development of monoclonal antibody-purified plasma-derived products and then with the licensure of recombinant factor IX. Products currently available in the United States for treatment of hemophilia B are listed in Table 105–4.

Recombinant Factor IX

First marketed in the United States in 1999,¹⁴ recombinant factor IX is produced in Chinese hamster ovary cells transfected with the factor IX gene. Blood and plasma products are not used to produce recombinant factor IX or to stabilize the final product; thus, recombinant factor IX has an excellent viral safety profile.¹⁴ Clinical trials have shown the product to be safe and efficacious in the treatment of acute bleeding episodes and in the management of bleeding associated with surgical procedures.^{14,37,38} Although the half-life of recombinant factor IX is similar to that of the plasma-derived products, recovery is approximately 30% lower.^{37,39} As a result, doses of recombinant factor IX concentrate must be higher than those of plasma-derived products to achieve equivalent plasma levels. Because individual pharmacokinetics may vary, recovery and survival studies should be performed to determine optimal treatment.^{37–39} Recombinant factor IX is often considered the treatment of choice for hemophilia B.

Plasma-Derived Factor IX Products

High-purity factor IX plasma concentrates have been available in the United States since the early 1990s.¹⁴ These products are derived from plasma through biochemical purification and monoclonal immunoaffinity techniques. Other viral inactivation measures, such as solvent detergent or chemical treatment, are also used.

Before the high-purity products were approved for use, hemophilia B patients were treated with factor IX concentrates that also contained other vitamin K-dependent proteins (factors II, VII, and X), known as prothrombin complex concentrates (PCCs). These products contain small amounts of activated factors generated during processing, and their use has been associated with thrombotic complications, including deep-vein thrombosis, pulmonary embolism, myocardial infarction, and disseminated intravascular coagulation (DIC).^{14,40} The risk of such complications is highest in patients who are receiving high or repeated doses of PCCs, in those who have hepatic disease (the liver removes the activated factors from circulation), in neonates, and in patients who have experienced crush injuries or who are undergoing major surgery.^{14,40}

Concomitant use of PCCs and antifibrinolytics should be avoided because of the risk for thrombosis.

Because of the lower purity of PCCs and their thrombogenic potential, these products are not first-line treatment of hemophilia B, although they still are used for treatment of patients with hemophilia A or B who have developed inhibitory antibodies against factor VIII or factor IX, respectively. High-purity factor IX concentrates have excellent efficacy in the treatment of bleeding episodes and in the control of bleeding associated with surgical procedures.⁴¹ Their viral safety profile has been reported to be excellent,⁴¹ and the risk of thromboembolic complications is low.

Factor IX Concentrate Replacement

Factor IX is a relatively small protein. Unlike factor VIII, it is not limited to the intravascular space; it also passes into the extravascular compartment.³¹ This results in a volume of distribution that is about twice that of factor VIII. In general, for plasma-derived factor IX concentrates, each unit of factor IX infused per kilogram of body weight yields a 1% rise in the plasma level of factor IX (range 0.67%–1.28%).³¹ The following equation can be used to calculate the initial dose:

$$\text{Plasma-derived factor IX (units)} = (\text{Desired level} - \text{Baseline level}) \times (\text{Weight [in kilograms]})$$

As with the similar calculation for factor VIII dosing, the baseline level term can be omitted from the formula. Because recovery of recombinant factor IX is lower than that of the plasma-derived products, the following adjustment is made:

Pediatric dosing:

$$\text{Recombinant factor IX (units)} = (\text{Desired level} - \text{Baseline level}) \times 1.4 \times (\text{Weight [in kilograms]})$$

Adult dosing:

$$\text{Recombinant factor IX (units)} = (\text{Desired level} - \text{Baseline level}) \times 1.2 \times (\text{Weight [in kilograms]})$$

A recovery study to determine optimal dosing is recommended for patients who receive recombinant factor IX because of the wide interpatient variability in pharmacokinetics.

Because the half-life of factor IX is approximately 24 hours, dosing can be less frequent than with factor VIII. Table 105–5 provides general guidelines for dosing factor IX, based on the site and severity of the bleeding episode. As with factor VIII replacement therapy, individual pharmacokinetics may vary, and monitoring the patient's factor IX levels helps optimize therapy.

Prophylactic Replacement Therapy

Traditionally, factor concentrates for hemophilia patients have been given on demand, as the bleeding episode occurs. However, recurrent joint bleeding can damage the joint and lead to development of severe physical disability. Thus, it would be preferable to prevent bleeding episodes and avoid the resultant damage. Known as *prophylactic factor replacement therapy*, this approach entails regular infusion of concentrate to maintain the deficient factor at a minimum of 0.01 units/mL (1%).

In effect, prophylactic replacement therapy converts severe hemophilia into a milder form of the disease. The rationale for this approach is that patients with moderate hemophilia rarely experience spontaneous hemarthroses, and they have a much lower incidence of chronic arthropathy. Patients with hemophilia A usually require 25 to 40 units of factor VIII per kilogram of body weight, given every other day or three times per week.¹⁵ For hemophilia B, the usual dosage is 40 to 100 units/kg of factor IX

given twice weekly instead of three times weekly because of the longer half-life of factor IX.⁴²

Primary prophylaxis is regular replacement therapy started at a young age (usually before age 2 years), prior to the onset of joint bleeding.^{43,44} The results of primary prophylaxis have been very promising. In the Swedish experience, children who began prophylaxis at age 1 to 2 years experienced almost no bleeding episodes and had normal joint examinations and radiographs over a 5-year period.^{14,45} Secondary prophylaxis begins after significant joint bleeding has already occurred. It is associated with a significant reduction in the number of joint bleeding episodes and a better clinical and orthopedic outcome.^{46,47} However, radiographic evidence of joint disease rarely improves and often progresses despite the institution of secondary prophylaxis.^{14,45} Therefore, it may not be possible to avoid chronic arthropathy when prophylaxis is initiated after significant joint bleeding has already occurred; this supports a need for earlier intervention.

CLINICAL CONTROVERSY

Hemophilia patients may receive prophylactic factor concentrate therapy to prevent or decrease bleeding episodes, or they may receive on-demand factor concentrate therapy in response to a bleeding episode. In addition, prophylaxis may be primary or secondary. Controversy exists over whether the benefits of prophylaxis justify the cost, appropriate time to initiate prophylaxis, and appropriate dosing for prophylaxis.

Prophylactic replacement therapy now is in widespread use in Europe. In 2001 the Medical and Scientific Advisory Council of the National Hemophilia Foundation of the United States recommended primary prophylaxis (prior to onset of frequent bleeding) beginning at age 1 to 2 years for children with severe hemophilia. This therapeutic approach has many challenges and has not been widely accepted in the United States. Many institutions continue to use secondary prophylaxis, in which prophylaxis is started after a pattern of bleeding has been established. Several disadvantages are associated with a primary prophylactic regimen. Perhaps most important is the high cost of prophylactic replacement therapy. Factor requirements are estimated to be twofold to threefold higher with prophylactic regimens than with treatment on demand.^{45,48} Use of individual pharmacokinetics to titrate dosage may help to lessen costs.⁴⁸ Other issues to consider are the inconvenience to families and possible difficulties with compliance. Central venous lines may be necessary for frequent administration of factor concentrates, particularly in children younger than 5 years, who are at the age targeted for initiation of primary prophylaxis regimens. Potential complications of central venous access include surgical risks, infection, and catheter-related deep-vein thrombosis.^{49,50} Catheter-related sepsis has been reported to occur in up to 50% of patients with hemophilia who have central lines.⁴⁹ Catheter-related infectious complications appear to be more common in hemophilia patients who have developed inhibitory antibodies.⁵⁰ Finally, there are concerns that routine use of primary prophylaxis may overtreat some patients with severe hemophilia who do not have a severe clinical phenotype. Prospective randomized studies and more formal cost-effectiveness analyses are needed to determine the relative benefits and optimal timing of prophylactic factor replacement therapy.

■ TREATMENT OF INHIBITORS IN HEMOPHILIA

Neutralizing antibodies to factor VIII and IX, known as *inhibitors*, develop in a subset of patients with hemophilia, challenging the management of these patients. The development of inhibitors is the

most serious complication of factor replacement therapy. The reported incidence of inhibitor development varies considerably, depending on the population studied, the study design, the method of detection, and the frequency and duration of testing. In one systematic review, the overall prevalence of inhibitors in unselected patients with hemophilia was 5% to 7%.³⁰ The prevalence among patients with severe hemophilia was approximately 12% to 13%, which is higher than for unselected patients.³⁰ The reported cumulative incidence of inhibitors in hemophilia B is much lower, occurring in only 1% to 4% of patients.⁵¹

Most inhibitors develop in childhood, often after relatively few exposure days (median 9–12 days).⁵¹ Patients with severe hemophilia are much more likely to develop inhibitors than those with milder forms of the disease.³⁰ It is possible that the low levels of factor produced in patients with mild and moderate hemophilia induce immune tolerance in these individuals. In contrast, factor levels are undetectable in patients with severe hemophilia, and infused factor VIII, regarded as a foreign protein, may provoke an antibody response. The rate of inhibitor formation varies even among patients with identical mutations, which suggests that host factors modify the risk. One possibility is that human leukocyte antigen (HLA) genotype may influence the risk of inhibitor formation, but studies have been inconclusive.⁵²

Inhibitors usually are immunoglobulins of the immunoglobulin G subclass that are directed against the factor coagulant portion of the complex. The presence of an inhibitor is suspected when a decreased clinical response to factor replacement is observed. It may be discovered incidentally on routine laboratory screening. Inhibitors are measured with the Bethesda assay, and titers are reported in Bethesda units (BU). One BU is the amount of inhibitor needed to inactivate half of the factor VIII or factor IX in a mixture of inhibitor-containing plasma and pooled normal plasma.¹⁴ Patients with inhibitors to factor VIII or factor IX are divided into two groups: low responders, who have low levels of inhibitors (<5 BU/mL) and generally have little or no rise in antibody titers after exposure to the factor; and high responders (>5 BU/mL), who have higher inhibitor levels and develop an increase in antibody titer after exposure (anamnesic response).⁵³

Therapy for patients with inhibitors involves treatment of acute bleeding episodes and treatment directed at eradicating the inhibitor. The inhibitor titer, the site and magnitude of bleeding, and the patient's past response to therapy determine the approach to treatment. For patients with a low inhibitor titer, administration of high doses of the specific factor often can control bleeding episodes. Two to three times the usual replacement dose and more frequent dosing intervals often are necessary to overcome the antibody. Factor level monitoring and clinical assessments help to evaluate the adequacy of treatment. Additional supportive measures, such as immobilization and administration of antifibrinolytic agents, should be used, where appropriate.

In the presence of a high-titer inhibitor, it may be impossible to administer enough factor VIII or factor IX to neutralize the antibody and achieve a hemostatic plasma level. Therefore, in these patients treatment of bleeding episodes consists of use of agents that bypass the factor to which the antibody is directed. These include PCCs, activated PCCs, and recombinant activated factor VII.

PCCs contain the vitamin K–dependent factors II, VII, IX, and X. Small quantities of activated factors VII and IX are present in these products. Activated PCCs (aPCCs) contain greater quantities of the activated factors.⁵⁴ The usual dosage is 50 to 100 units/kg administered every 12 to 24 hours, depending on the severity of the bleeding episode.³⁰ The maximum dose should not exceed 200 units/kg/day. Use of PCCs and aPCCs, when not restricted to one or two doses, is effective in obtaining hemostasis in approximately 80% of bleeding episodes in patients with inhibitors, and aPCCs appear to be more effective than PCCs. As previously mentioned, there is a risk of

serious thrombotic complications, including pulmonary emboli, deep-vein thrombosis, and myocardial infarction associated with use of PCCs and aPCCs.⁵⁴ Additionally, because these products contain trace amounts of factor VIII and larger amounts of factor IX, they can stimulate an anamnestic response in patients with hemophilia A and, more commonly, in those with hemophilia B.⁵⁴ Other minor side effects include dizziness, nausea, hives, flushing, and headaches.⁵⁴ Patients with factor IX inhibitors occasionally develop severe allergic reactions in response to infusion of factor IX-containing products, so these patients should be monitored closely.⁵⁵

Recombinant factor VIIa, a newer bypassing agent, is thought to be hemostatically active only at the site of tissue injury where tissue factor is present; thus, the risk of systemic thrombotic events associated with this agent is minimal.⁵⁶ Additionally, because recombinant VIIa is not a plasma-derived product, both viral transmission and anamnestic responses to factor VIII or factor IX are unlikely.⁵⁴ The initial dose for bleeding episodes ranges from 35 to 120 mcg/kg.⁵⁴ Doses of 70 mcg/kg or higher are more effective, and often a dose of 90 to 120 mcg/kg is used for treatment of patients with hemophilia and inhibitors.^{54,57} A drawback is the product's short half-life, which necessitates dosing every 2 hours. Continuous infusion of recombinant factor VIIa, which may be more convenient and cost effective, has been successful, although studies are limited. Recombinant factor VIIa appears to be efficacious in controlling bleeding episodes and managing hemophilia during surgical procedures.⁵⁴ Patients treated with bypassing agents must be monitored clinically because no laboratory test directly measures the effectiveness of treatment.

Porcine factor VIII is an alternative therapeutic option for patients who have hemophilia A and inhibitors. In general, porcine factor VIII is most useful when the inhibitor titer is less than 50 BU.³¹ The recommended initial dose is 50 to 100 units/kg for those with inhibitor titers less than 50 BU.³¹ The rationale is that porcine factor VIII is enough like human factor VIII to participate in the coagulation cascade, yet most factor VIII inhibitors have absent or only weak neutralizing activity against nonhuman factor VIII. However, cross-reactivity with porcine factor VIII does occur, and a high titer of antibody against porcine factor VIII can develop. Although the rise in antibody titer with porcine factor VIII is generally lower than that seen with administration of human factor VIII, anamnestic rises in inhibitor titers to both porcine and human factor VIII may occur and can limit future use.⁵⁴ Other potential side effects include severe allergic reactions and thrombocytopenia.⁵⁴ Porcine factor VIII is no longer commercially available in the United States, but can be obtained for use in specific patients. Because of these limitations, porcine factor VIII usually is indicated only after the patient has not responded to recombinant factor VIIa and PCC or when the patient has severe hemorrhages.⁵⁴ An advantage to porcine factor VIII is that treatment response can be monitored with factor VIII levels.

The ideal therapy for patients with hemophilia and inhibitors is eradication of the inhibitor so that future treatment with factor VIII or factor IX concentrates is possible. Immune tolerance therapy, which involves the regular infusion of high doses of the factor to which the antibody is directed, may accomplish this eradication. A variety of different dosing regimens, ranging from 25 units/kg every other day to more than 200 units/kg every day, have been used. Some treatment protocols include adjunctive immunomodulatory therapy, such as administration of cyclophosphamide, prednisone, and intravenous immune globulin.⁵⁸ The overall success rate is 50% to 70% and is higher in patients with low inhibitor titers and in those with recent development of inhibitor.⁵² Weeks to years of therapy may be required to eradicate the antibody. Unfortunately, immune tolerance therapy is costly, time-consuming, and often requires placement of a central venous catheter.^{59,60} Once achieved, however, immune tolerance facilitates the management of bleeding episodes with specific factor replacement therapy. Rituximab, an anti-CD20 monoclonal

antibody has been used with some success in a few patients with acquired factor VIII inhibitors.⁶¹ The mechanism of action involves the rapid depletion of circulating B cells, which produce antibodies, including the anti-factor VIII antibody. Use of rituximab in patients with hemophilia and inhibitors has yet to be tested in large numbers of patients.

Figure 105–3 summarizes the therapeutic options in the management of hemophilia A patients with inhibitors. The same algorithm can be applied to the management of hemophilia B patients, except that factor IX should be substituted for factor VIII. Use of porcine factor VIII is not indicated for inhibitors in hemophilia B.

■ GENE THERAPY IN HEMOPHILIA

Use of gene therapy for hemophilia A and B is currently under investigation. A number of different viral and nonviral vectors have been used to transfer the recombinant factor gene to human cells, such as liver and muscle cells.^{62,63} Even low levels of factor expression through gene therapy should reduce bleeding episodes in patients with severe hemophilia, a rationale for gene therapy similar to that for prophylactic factor replacement. Furthermore, given the broad range of physiologically normal factor levels, very tight regulation of gene expression is not necessary. The safety and efficacy of this approach to treatment remain to be determined. Potential benefits to gene therapy include patient convenience, viral safety, and decreased cost. Possible drawbacks to gene therapy include a risk of inhibitor formation, tumorigenesis related to integration of the viral vector, possible germ-line transmission, and concerns about long-term gene expression.^{62,63}

■ PAIN MANAGEMENT IN HEMOPHILIA

Pain, both acute and chronic, can be a common occurrence in patients with hemophilia. The likely cause of acute pain is bleeding, and control of the bleeding episode should ease the pain. Chronic pain may be the result of permanent joint changes. Surgical intervention may help to alleviate the pain, as may an intensive physical therapy program.⁶⁴ Intraarticular administration of dexamethasone also may be useful.⁶⁵ Acetaminophen can be used, although narcotic analgesia may be required for more severe pain. Nonsteroidal antiinflammatory drugs impair platelet function and may increase the risk of bleeding in patients with hemophilia, although these drugs have been used for the management of chronic arthropathy. Cyclooxygenase-2 inhibitors have less antiplatelet activity and may be an option for pain management.

■ SURGERY IN HEMOPHILIA

In the patient with hemophilia undergoing a surgical procedure, the goal of treatment is maintaining factor levels of at least 0.5 to 0.7 units/mL (50%–70%) during surgery and in the postoperative period in order to prevent excessive bleeding. Intermittent dosing or continuous infusion factor replacement may accomplish this goal. Before surgery, factor concentrate usually is infused to obtain a plasma level of 1 unit/mL (100%).⁶⁶ Replacement therapy is continued to maintain plasma levels greater than 0.5 units/mL (50%) for 5 to 7 days or longer, depending on the type of surgery. Preoperative evaluation for elective procedures should include measurement of an inhibitor titer and assessment of the recovery and half-life of infused factor in the patient. Elective surgery should not proceed unless therapeutic plasma levels can be obtained.

Evaluation of Therapeutic Outcomes

The main goal in the treatment of hemophilia is controlling and preventing bleeding episodes and their long-term sequelae, such as chronic arthropathies. Pharmacologic and nonpharmacologic inter-

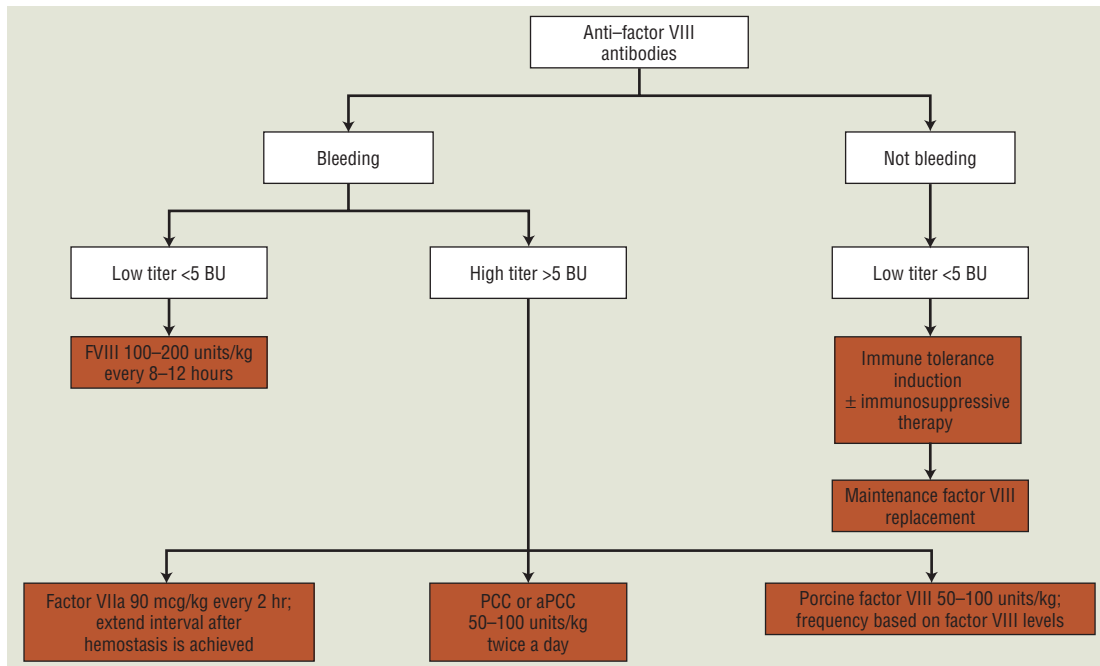

FIGURE 105-3. Treatment algorithm for the management of patients with hemophilia A and factor VIII antibodies. (aPCC, activated prothrombin complex concentrate; BU, Bethesda unit; PCC, prothrombin complex concentrate.)

ventions should be aimed at achieving this goal. Treatment response can be monitored through clinical parameters, such as cessation of bleeding and resolution of symptoms. Determination of plasma factor levels also may be helpful, particularly for severe bleeding episodes. Home therapy for administration of factor concentrates is common among these patients because this approach can lead to earlier treatment and more independence for the patient. Diaries in which the patient documents symptoms, the dose of factor replacement, adjuvant therapies used, and treatment response can help the caregiver evaluate the success of home therapy. Monitoring the number and type of bleeding episodes and measuring trough plasma factor levels makes it possible to evaluate the adequacy of prophylactic regimens. Physical examination with evaluation of joint range of motion and radiographs of target joints indicates the long-term success of preventing and treating arthropathies.

Clinicians should check for the development of inhibitors, especially in patients with severe disease and exposure to factor concentrates, at least yearly and with any suspicion of poor treatment response. The development of inhibitors challenges the management and control of bleeding episodes. A full understanding of the clinical situation and the titer of the inhibitor are mandatory to address all treatment options for each patient. Because no laboratory test measures the effectiveness of therapy in this scenario, close clinical monitoring for worsening or resolution of symptoms is essential for optimizing the outcome.

VON WILLEBRAND DISEASE

The most common congenital bleeding disorder, von Willebrand disease, has a prevalence of 1% to 2%.⁶⁷ von Willebrand disease refers to a family of disorders caused by a quantitative and/or qualitative defect of von Willebrand factor, a glycoprotein that plays a role in both platelet aggregation and coagulation. Unlike hemophilia, von Willebrand disease has an autosomal inheritance pattern, resulting in an equal frequency of disease in males and females.

The gene for von Willebrand factor is located on chromosome 12 and is 178 kb in length.⁶⁷ Transcription and translation produce a large primary product that subsequently undergoes complex modifications, resulting in von Willebrand factor multimers of various sizes with molecular weights ranging from 500 to 20,000 kDa.⁶⁷ Von

Willebrand factor is synthesized in endothelial cells, where it is either stored in Weibel-Palade bodies or secreted constitutively. It also is synthesized in megakaryocytes and stored in α -granules, from which it is released following platelet activation.⁶⁷

Von Willebrand factor is important for both primary and secondary hemostasis. In response to vascular injury, it promotes platelet adhesion by interacting with the glycoprotein Ib receptor on platelets.^{67,68} It can facilitate platelet aggregation by binding to the platelet glycoprotein IIb/IIIa receptor, although fibrinogen is the main ligand for this receptor.^{67,68} The highest-molecular-weight von Willebrand factor multimers appear to be the most important in platelet adhesion because their large surface area contains numerous binding sites for various ligands and receptors. An additional function of von Willebrand factor is that it is the carrier molecule for circulating factor VIII, protecting it from premature degradation and removal.⁶⁷ A deficiency of von Willebrand factor reduces the half-life of factor VIII and decreases plasma factor VIII levels. Therefore, von Willebrand factor plays a dual role in hemostasis, affecting both platelet function and coagulation.

Classification of von Willebrand Disease

von Willebrand disease consists of a heterogeneous group of disorders that can be classified into three major subtypes (Table 105-6). Types 1 and 3 are associated with quantitative defects in von Willebrand factor; type 2 mutations refer to functional abnormalities in von Willebrand factor. Determination of the disease subtype is important because it influences treatment.

TABLE 105-6 von Willebrand Disease

<i>von Willebrand factor (vWF)</i>
Large multimeric glycoprotein that is necessary for normal platelet adhesion, normal bleeding time, and stabilizing factor VIII.
<i>von Willebrand factor antigen (vWF:Ag)</i>
Antigenic determinant(s) on vWF measured by immunoassays; usually low in types 1 and 2; virtually absent in type 3.
<i>Ristocetin cofactor activity</i>
Functional assay of vWF activity based on platelet aggregation with ristocetin. Reduced by the same degree as vWF:Ag in types 1 and 3, but to a greater extent in type 2 disease (except 2B).

Type 1 von Willebrand disease is the most common type, accounting for 59% to 76% of cases.⁶⁷ It is characterized by a mild-to-moderate reduction in the level of von Willebrand factor (although its multimeric structure is normal) and a similar reduction in the level of factor VIII. It usually is inherited in an autosomal dominant fashion with variable penetrance and expression.⁶⁹ Bleeding symptoms often are very mild to moderate.⁶⁷

Type 2 von Willebrand disease, diagnosed in 9% to 30% of affected patients, is characterized by a qualitative abnormality of von Willebrand factor.⁶⁷ Bleeding manifestations may be more severe than with type 1 disease. Inheritance most often is autosomal dominant but may be recessive.⁶⁹ Type 2 von Willebrand disease can be subdivided into four variants. Type 2A is the most frequent subtype and is characterized by a reduced von Willebrand factor–platelet interaction and an absence of high- and intermediate-molecular-weight factor multimers. Type 2B is a less common variant characterized by an abnormal von Willebrand factor that has an increased affinity for the platelet glycoprotein Ib receptor. This is associated with thrombocytopenia, which usually is mild. In addition, there usually is an absence of high-molecular-weight forms of von Willebrand factor.⁶⁹ Type 2M arises from a qualitative defect in von Willebrand factor that impairs its binding to platelets; it is similar to type 2A, except that there is no measurable reduction in the high-molecular-weight multimers.⁶⁹ Finally, type 2N von Willebrand disease (Normandy) is a rare form of the disease in which von Willebrand factor has a markedly reduced affinity for factor VIII. This leads to a moderate-to-severe reduction of factor VIII plasma levels with normal von Willebrand factor levels.⁶⁹

Type 3 von Willebrand disease refers to a severe quantitative variant of the disease in which von Willebrand factor is nearly undetectable and factor VIII levels are very low. It often is inherited in an autosomal recessive fashion.⁶⁷ The clinical phenotype is severe, reflecting major deficits in primary hemostasis and coagulation. There also is a platelet-type pseudo–von Willebrand disease in which von Willebrand factor is normal but a defect in the platelet glycoprotein Ib receptor causes an increased affinity for normal von Willebrand factor.⁶⁷ As a result, platelet-type pseudo–von Willebrand disease is phenotypically similar to type 2B disease but should be distinguished from it because the treatment is different.

Acquired von Willebrand disease is a rare bleeding disorder that is similar to the congenital form of the disease. It has been reported primarily in association with autoimmune disorders, such as systemic lupus erythematosus, lymphoproliferative disorders, myeloproliferative disorders, hypothyroidism, and certain neoplastic diseases such as Wilms tumor and lymphoma.^{67,70} It has been reported in situations of high shear stress, such as aortic stenosis. Certain medications have been associated with acquired von Willebrand disease, including valproic acid, griseofulvin, hydroxyethyl starch, and ciprofloxacin.⁷⁰ Bleeding manifestations vary from mild to severe, and the condition often resolves with treatment of the underlying disease. Various mechanisms have been proposed, including autoantibodies to von Willebrand factor resulting in rapid removal from the plasma, adsorption to tumor cells or activated platelets, increased proteolysis, or mechanical destruction.⁷⁰

CLINICAL PRESENTATION OF VON WILLEBRAND DISEASE

- Clinical manifestations are variable; some patients are asymptomatic
- Mucocutaneous bleeding: epistaxis, gingival bleeding with minor manipulation, menorrhagia
- Easy bruising
- Postoperative bleeding

Diagnosis

When a patient has a lifelong history of mucocutaneous bleeding and a family history of abnormal bleeding, the clinician should suspect von Willebrand disease. Several different laboratory tests are helpful in the diagnosis of this hemostatic abnormality. Initial screening tests include determinations of PT, aPTT, and platelet count. PT is normal, whereas aPTT may be prolonged in relation to the reduction in plasma factor VIII levels. A normal aPTT does not rule out von Willebrand disease; specific laboratory assessment of the von Willebrand factor is required. The platelet count usually is normal, although thrombocytopenia is common in type 2B and platelet-type pseudo–von Willebrand disease. The bleeding time, which measures platelet function, often is prolonged but may be normal in patients with milder forms of the disease.

Specific laboratory tests for determining the presence of von Willebrand disease include measurement of von Willebrand factor antigen (vWF:Ag) level, factor VIII assay, determination of von Willebrand factor (ristocetin cofactor) activity, and von Willebrand factor multimer analysis. Plasma concentrations of von Willebrand factor increase with age, cigarette smoking, exercise, pregnancy starting in the second trimester, and infection, as well as with use of certain medications, such as corticosteroids, high-dose estrogen birth control pills, and desmopressin.^{71,72} Repeated test measurements may be necessary to make the diagnosis because of physiologic variations in plasma levels.

Electroimmunoassay, immunoradiometric assay, or enzyme-linked immunosorbent assay can be used to quantify vWF:Ag.⁶⁷ Because vWF:Ag levels are known to vary with different ABO blood types,⁷³ interpretation requires reference to values specific for the patient's blood type. The vWF:Ag level usually is low in types 1 and 2 von Willebrand disease and virtually absent in type 3 disease. Factor VIII levels are normal or mildly decreased in patients with type 1 or 2 disease and very low (<10%) in those with type 3 disease.⁶⁷ Ristocetin, an antibiotic that causes platelet aggregation in the presence of functional von Willebrand factor, is used to measure von Willebrand factor activity. The assay is performed by mixing platelet-free patient plasma, normal formalin-fixed platelets, and ristocetin and then quantitating the extent of platelet agglutination. Ristocetin cofactor activity usually is reduced in parallel to vWF:Ag levels in types 1 and 3 disease and decreased to a greater extent than vWF:Ag in type 2 disease (except type 2B).⁶⁹ Ristocetin-induced platelet agglutination is useful for further distinguishing type 2B disease, as a low concentration of ristocetin induces excessive aggregation in type 2B disease.

Von Willebrand factor multimers can be analyzed by separating them by size on an agarose gel. All multimer sizes are present in type 1 disease, whereas reduced levels of intermediate- and high-molecular-weight multimers are characteristic of type 2 disease. Type 3 patients lack all types of von Willebrand factor multimers. A summary of the laboratory findings in the various types of von Willebrand disease is provided in Table 105–6.

TREATMENT

von Willebrand Disease

4 The specific type of von Willebrand disease, as well as the location and severity of bleeding, determines the approach to treatment. Local measures, including pressure, ice, and topical thrombin, often can control superficial bleeding. Systemic treatment is used for bleeding that cannot be controlled in this manner and for prevention of bleeding with surgery. The goal of systemic therapy is correction of platelet adhesion and coagulation defects by stimulating the release of endogenous von Willebrand factor or by

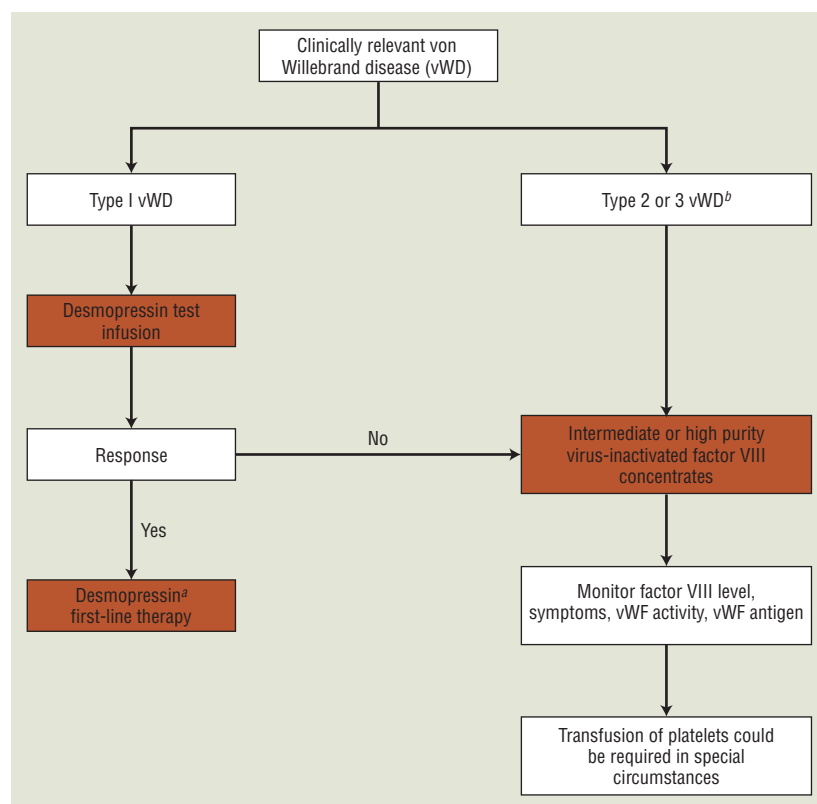

FIGURE 105-4. Guidelines for treatment of von Willebrand disease. ^aUse factor VIII concentrate for life-threatening bleeding. ^bSome patients with type 2 or 3 von Willebrand disease may respond to desmopressin.

administering products that contain von Willebrand factor and factor VIII. General guidelines for treatment of von Willebrand disease are shown in Fig. 105-4.

REPLACEMENT THERAPY

5 The treatment of choice for patients with types 2B, 2M, and 3 von Willebrand disease and for patients with type 1 or 2A von Willebrand disease who are unresponsive to desmopressin is replacement therapy with plasma-derived von Willebrand factor-containing products.⁶⁶ Several virus-inactivated, intermediate- or high-purity factor VIII concentrates contain sufficient amounts of functional von Willebrand factor.⁶⁶ Ultrahigh-purity (monoclonal antibody-derived) plasma-derived products and recombinant factor VIII products contain only negligible amounts of von Willebrand factor and are inadequate for treatment of von Willebrand disease. A very high-purity plasma-derived von Willebrand factor concentrate and a recombinant von Willebrand factor product are currently in clinical trials.⁶⁸ Because these von Willebrand factor concentrates do not contain appreciable factor VIII, concomitant administration of a factor VIII-containing product may be necessary for patients with severe disease and low levels of factor VIII.⁶⁸ Cryoprecipitate contains approximately 80 to 100 units of von Willebrand factor per unit (5–10 times more von Willebrand factor and factor VIII than fresh-frozen plasma), and in the past it was the mainstay of therapy for von Willebrand disease.⁶⁷ However, because cryoprecipitate is not virally inactivated, it is seldom used as first-line treatment. General guidelines for the dosing of replacement therapy in patients with von Willebrand disease unresponsive to desmopressin are provided in Table 105-7.

OTHER PHARMACOLOGIC THERAPY

6 Desmopressin stimulates the endothelial cell release of von Willebrand factor and factor VIII.⁶⁶ It is effective for patients with von Willebrand disease who have adequate endogenous stores of functional von Willebrand factor. This group includes most patients

with type 1 disease and some patients with type 2A disease. Conversely, desmopressin is not appropriate for patients with type 3 disease, who lack stores of von Willebrand factor.

CLINICAL CONTROVERSY

Some hematologists find desmopressin beneficial in treating patients with type 2B von Willebrand disease, whereas others believe it may exacerbate thrombocytopenia.

Desmopressin usually is not recommended for treatment of type 2B disease because the release of additional abnormal von Willebrand factor may exacerbate thrombocytopenia.⁶⁷ However, desmopressin has been reported to be beneficial in some patients with type 2B disease.⁶⁷ If desmopressin is used for treatment of type 2B disease, close monitoring is necessary.

The dose of desmopressin used for treatment of von Willebrand disease is identical to that used for treatment of mild factor VIII deficiency, 0.3 mcg/kg diluted in 30 to 50 mL of normal saline and given intravenously over 15 to 30 minutes.⁶⁶ In general, patients with von Willebrand disease have a better response to desmopressin than

TABLE 105-7 Replacement Therapy in von Willebrand Disease^a

Condition	Therapy
Major surgery	Maintain factor VIII level $\geq 50\%$ for 1 week Prolonged treatment in type 3 patients (>7 days)
Minor surgery	Maintain factor VIII level $\geq 50\%$ for 1–3 days Maintain factor VIII level $>20\%$ – 30% for an additional 4–7 days
Dental extraction	Single infusion to achieve factor VIII level $>50\%$ Desmopressin prior to procedure for type 1
Spontaneous or post-traumatic bleeding	Usually single infusion of 20–40 units/kg

^aThe yield of factor VIII after first infusion is similar to that observed in hemophilia A (about 2% increment over baseline amount for every 1 unit/kg of factor VIII infused).

those with hemophilia, with an average threefold to fivefold rise in von Willebrand factor and factor VIII levels.⁶⁷ These levels remain elevated for approximately 6 to 8 hours. The response to desmopressin in a given patient usually is consistent, and a trial of desmopressin should establish if the medication likely will be effective for the individual. Desmopressin is preferable to use of plasma-derived products for patients who have an adequate response because desmopressin does not carry a risk of viral transmission. An added benefit is the substantially lower cost of desmopressin compared to the plasma-derived products. (For a discussion of the side effects of desmopressin, see Treatment of Hemophilia A above.)

Desmopressin can be administered every 12 to 24 hours, but the response diminishes with repeated treatment.⁶⁸ After three to four doses, desmopressin often is no longer effective, and alternative replacement therapy may be necessary if prolonged treatment is required. Laboratory monitoring, including vWF:Ag measurements, factor VIII assays, ristocetin cofactor activity assessments, and clinical examinations, will determine the adequacy of treatment.

Intranasal administration of desmopressin, at the same dosage as that used for mild factor VIII deficiency, can be useful for treatment of mild bleeding episodes. One or two doses administered at the start of menses may be helpful in controlling menorrhagia.^{68,74} Oral contraceptives may also be very effective in controlling this symptom.⁶⁸ Inhibitors of the fibrinolytic system may be of special value in tissues rich in plasminogen activators, such as the mouth, especially with tooth extractions.⁶⁷ Antifibrinolytic agents can be used in the management of epistaxis, gastrointestinal bleeding, and menorrhagia. However, these agents should be avoided in urinary tract bleeding because of the risk of thrombosis and obstruction.⁶⁶

OTHER CONGENITAL FACTOR DEFICIENCIES

In addition to deficiencies in factors VIII and IX, congenital deficiencies in fibrinogen, in factors II, V, VII, X, XI, and XIII, and in combinations of factor deficiencies have been reported.⁷⁵ Contact factor abnormalities, including deficiencies in factor XII, high-molecular-weight kininogen, and prekallikrein, prolong the aPTT but do not lead to any bleeding diathesis. Identification of these disorders is important so that inappropriate treatment is not given. The only contact factor deficiency associated with bleeding symptoms is factor XI deficiency. Also known as hemophilia C, this deficiency is particularly common in people of Ashkenazi Jewish descent.^{75,76} Bleeding manifestations are variable. Bleeding usually does not occur spontaneously, but excessive bleeding may occur after trauma or surgery. Most other deficiencies are inherited as autosomal recessive disorders and are rare. Some patients with abnormal molecules, such as fibrinogen, may have an increased tendency to develop thromboembolic disease. Most of these deficiencies are treated with fresh-frozen plasma. Newer specific concentrates are becoming available. For example, a factor XIII plasma-derived concentrate is available, and recombinant VIIA is approved for use in patients with congenital VII deficiency. Cryoprecipitate, which is rich in fibrinogen, can be used to treat patients with fibrinogen deficiency or dysfunctional fibrinogen (dysfibrinogenemias).

COMPLICATIONS OF REPLACEMENT THERAPY

Transmission of blood-borne viruses is always a concern when blood and blood-derived products are used. The infection of a large number of hemophiliac patients with hepatitis viruses and HIV during the 1980s prompted the development of virucidal methods to inactivate infectious agents.^{8,15} All currently available plasma-derived factor concentrates come from screened donors and undergo viral inactivation procedures in an effort to reduce the risk of viral transmission. Heat treatment, which includes dry and wet heat, is one method of viral inactivation. Wet heat is applied while the concentrate is in

suspension or in solution (pasteurization) and appears to be more effective than dry heat.⁷⁷ Other methods of viral inactivation include chemical (solvent detergent) and affinity chromatography with monoclonal antibodies. Solvent detergent treatment inactivates lipid-coated viruses such as HIV and hepatitis B and C, but it is not effective against nonenveloped viruses, including hepatitis A.⁷⁷ Outbreaks of hepatitis A associated with factor concentrates have occurred.¹⁵ Another nonenveloped virus that has been identified in plasma-derived products, parvovirus B19,^{21,77} may be particularly important for patients with hemophilia and HIV infection because it can cause chronic anemia in patients with immune deficiency. Although concern has arisen, no evidence of transmission of variant Creutzfeldt-Jakob disease from plasma-derived products has been reported.²¹

Other complications associated with factor administration include allergic reactions, fever, chills, urticaria, and nausea. PCCs and aPCCs also have the potential to cause thromboembolic complications, including deep-vein thrombosis, pulmonary embolism, myocardial infarction, and DIC, likely related to the presence of activated factors.¹⁴ Antifibrinolytic agents should not be given to patients receiving PCCs or aPCCs to avoid thrombotic complications.

Porcine factor VIII, used in the treatment of patients with inhibitors to factor VIII, is not known to transmit human viruses. However, allergic-type reactions (e.g., fever, chills, skin rashes, nausea, and headaches) have been reported.⁵⁴ Patients who experience these reactions can be treated with steroids and/or diphenhydramine. Thrombocytopenia is another potential complication of porcine factor VIII use.⁵⁴

Recombinant factor VIII has a low risk of viral transmission. Adverse effects of these products include metallic taste, mild dizziness, mild rash, burning at the infusion site, and a small drop in blood pressure.⁷⁸

PHARMACOECONOMIC CONSIDERATIONS

Treatment of severe hemophilia often is expensive, with a substantial portion of the cost related to the expense of factor concentrates.⁵⁹ The highly purified plasma-derived products and recombinant factor concentrates are considerably more expensive than the low- and intermediate-purity products. However, the viral safety of recombinant products must be weighed against the added cost. Recombinant products are often used, particularly for children with hemophilia. With the more widespread use of prophylactic factor replacement regimens to prevent chronic arthropathy, factor usage and cost of treatment have greatly increased over that for on-demand therapy.¹⁴ The positive impact on patient lifestyle must be weighed against the drawbacks of cost, the potential need for permanent venous access, and patient compliance. Finally, the use of immune tolerance therapy is associated with extremely high factor usage and cost, but with the potential benefit of eradicating an inhibitor a life-threatening complication of hemophilia. A formal economic analysis has suggested that this therapy may be cost-effective over the patient's lifetime.⁵⁹

Optimal management of von Willebrand disease starts with adequate identification of the patient's disease type. Desmopressin is considerably less expensive than plasma-derived factor VIII concentrates.⁶⁷ It should be the treatment of choice for all patients responsive to the test dose because of its viral safety, reduced cost, and ease of administration.

ACQUIRED COAGULATION DISORDERS

DISSEMINATED INTRAVASCULAR COAGULATION

Systemic activation of coagulation that results from DIC leads to clot formation in the microvasculature, often with compensatory bleeding

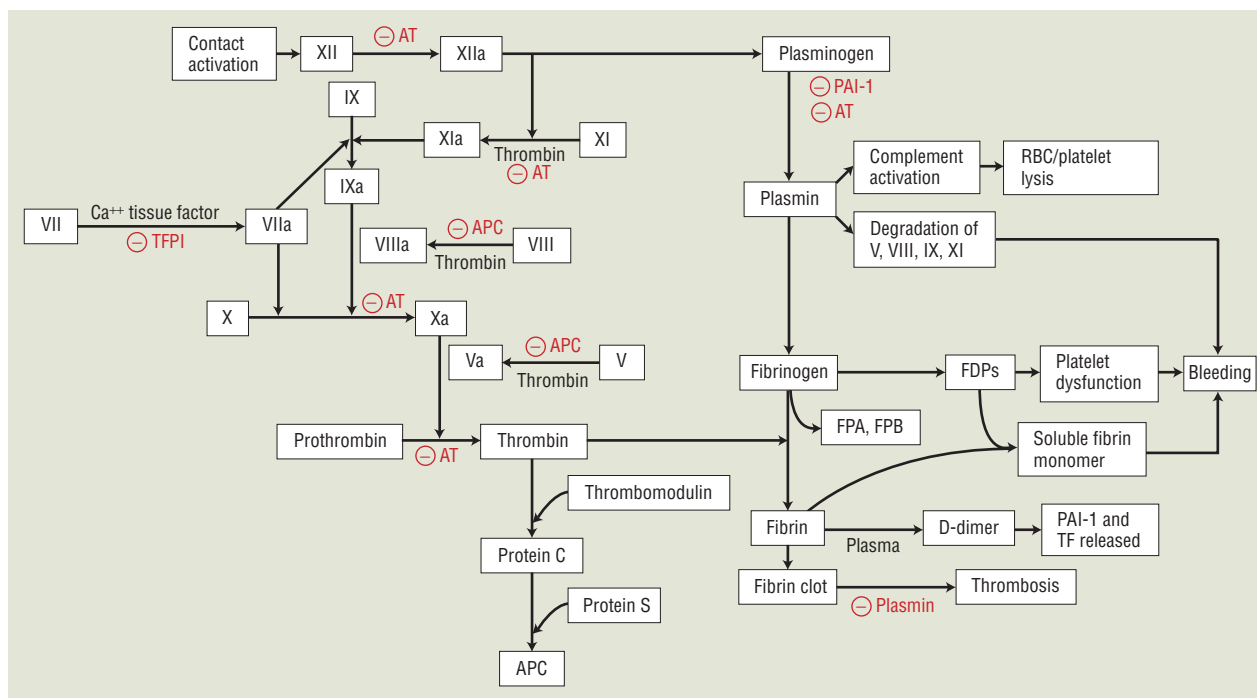

FIGURE 105-5. Pathophysiology of disseminated intravascular coagulation. (APC, activated protein C; AT, antithrombin; FDP, fibrin degradation product; FPA, fibrinopeptide A; FPB, fibrinopeptide B; PAI-1, plasminogen activator inhibitor type 1; RBC, red blood cell; TFPI, tissue factor pathway inhibitor.)

owing to biodegradation of coagulation factors and platelets. Although the causes for DIC can be diverse, the pathophysiology leading to DIC is the same once the triggering event occurs (Fig. 105–5). An overwhelming insult leads to the formation of thrombin and plasmin beyond the control of the regulatory systems. Once formed, thrombin leads to the cleavage of fibrinopeptide A and B from fibrinogen, leaving a fibrin monomer. The monomer polymerizes into a clot, leading to microvascular and macrovascular thrombosis while consuming platelets by trapping them in the clots. Thrombosis ultimately decreases blood flow to multiple organs, leading to organ damage. Plasmin cleaves fibrinogen into fibrin(ogen) degradation products, which can combine with the fibrin monomer before polymerization. This forms a soluble fibrin monomer that impairs hemostasis and leads to hemorrhage. Some of the FDPs may adhere to platelets, causing platelet dysfunction that may contribute to clinically significant hemorrhage. In addition, plasmin is a proteolytic enzyme that can degrade factors V, VIII, IX, and XI and other plasma proteins. Circulation of plasmin can activate the complement system, leading to red blood cell and platelet lysis. The activated complement system also increases vascular permeability that can cause hypotension and shock.⁷⁹

Complicating this process is an intricate web of feedback systems. Thrombin induces activation of factors V and XI, while it also activates protein C that inhibits the activation of the same. Antithrombin is a serine protease that mediates the antithrombotic effect of heparin. It also inhibits the activation of thrombin, plasmin, and factors IXa, Xa, XIa, and XIIa.⁸⁰ Acute DIC is characterized by rapid and extensive depletion of coagulation factors and inhibitors and excessive fibrinolysis in an attempt to compensate for microvascular clotting. Normally, a balanced dynamic process of clotting and fibrinolysis operates to prevent organ dysfunction, bleeding, or clotting. In acute DIC, excessive intravascular coagulation overcomes the normal inhibitory processes. In subacute or chronic DIC, the balance between depletion and synthesis of coagulation factors in the circulation may make the diagnosis difficult, because patients may be asymptomatic, bleeding, and/or forming thromboses.

In summary, bleeding problems observed during DIC can be the result of consumption of coagulation factors during clotting, depletion or dysfunction of platelets, interference in fibrin formation by FDPs, and lysis of clots by plasmin. Thrombosis occurs in parallel with the bleeding process, and the extent of microvascular obstruction will determine the degree of organ damage.

CLINICAL PRESENTATION OF DISSEMINATED INTRAVASCULAR COAGULATION

General

- Underlying illness (Table 105–8)

Signs and Symptoms

- Bleeding, thrombosis, or both
- Petechiae and purpura
- Peripheral cyanosis
- Hemorrhagic bullae

Laboratory Tests

- Elevated D-dimer
- Decreased antithrombin
- Decreased fibrinogen
- Thrombocytopenia
- Decreased proteins C and S
- Increased fibrinopeptides A and B
- Elevated prothrombin fragments 1 and 2
- Evidence of end-organ dysfunction or failure

Laboratory Diagnosis

The basis for a diagnosis of DIC is a combination of laboratory test results in the setting of a known causative clinical disorder.^{79,81–82} The relative importance of any particular laboratory test is controversial. Routine tests of blood coagulation, including PT and aPTT,

TABLE 105-8 Conditions Associated with Disseminated Intravascular Coagulation

Cardiovascular	Intravascular hemolysis	Miscellaneous
Acute myocardial infarction	Hemolytic transfusion reaction	Acid-base imbalance
Angiopathy	Hemolytic uremic syndrome	Acute liver failure
Aortic aneurysm	Minor hemolysis	Amphetamines
Aortic balloon assist devices	Massive transfusion	Anaphylaxis
Giant hemangiomas	Newborn	Autoimmune diseases
Peripheral vascular disease	Birth asphyxia	Cholestasis
Postcardiac arrest	Hypothermia	Chronic inflammatory diseases
Prosthetic devices	Meconium or amniotic fluid aspiration	Collagen vascular disease
Raynaud syndrome	Necrotizing enterocolitis	Craniotomy
Infectious	Respiratory distress syndrome	Extracorporeal circulation
Arbovirus	Shock	Extracorporeal membrane oxygenation
<i>Aspergillus</i>	Obstetrics	Fat embolism
<i>Candida albicans</i>	Abortion	Heat stroke
Cytomegalovirus	Amniotic fluid embolism	Hemorrhagic telangiectasia
Ebola virus	Fatty liver of pregnancy	Hepatitis
Gram-negative bacteria	Placental abruption	Leukemia
Gram-positive bacteria	Preeclampsia/eclampsia	Lightning strikes
Herpesvirus	Retained fetus syndrome	Near drowning
Histoplasma	Pulmonary	Organic solvent poisoning
Human immunodeficiency virus	Acute respiratory distress syndrome	Paroxysmal nocturnal hemoglobinuria
Influenza	Empyema	Peritoneovenous or pleurovenous shunts
Kala-azar	Hyaline membrane disease	Polycythemia rubra vera
Malaria	Pulmonary embolism	Renal vascular disorders
<i>Mycobacteria</i>	Pulmonary infarction	Severe anoxia
<i>Mycoplasma</i>	Tissue injury	Snake bite
Paramyxoviruses	Burns	Solid tumors
Rocky Mountain spotted fever	Crush injuries	Transplant rejection
Rubella	Extensive surgery	
Typhoid	Head trauma	
Varicella	Multiple trauma	
Variola		

are unreliable and of minimal use. PT and aPTT are prolonged in 50% to 60% of cases, but they may be decreased or normal.^{79,82} The thrombin time usually is prolonged because of the absolute decrease in fibrinogen as well as the presence of FDPs, which inhibit the conversion of fibrinogen to fibrin.⁷⁹

Liver disease may cause decreased synthesis of coagulation factors, and the subsequent abnormal laboratory results can be difficult to differentiate from DIC. Increased levels of FDPs are not specific to DIC, but elevated levels occur in 85% to 100% of patients with DIC.⁷⁹ Because FDPs are metabolized in the liver and excreted by the kidney, organ damage may increase the level of FDPs. However, an increased FDP level may help to identify compensated DIC, as it may be the only abnormal laboratory result. D-Dimer is formed when plasmin digests cross-linked fibrin; thus, the level of D-dimer is a more specific measure of FDPs.

Fibrinogen levels are an acute phase reactant, and a low level indicates DIC with only 28% sensitivity.⁸¹ Platelet counts usually are decreased in patients with DIC. Fifty percent of patients have schistocytes (red blood cell fragments) in fulminant DIC.⁷⁹ Unfortunately, these findings also may be evident in patients with severe liver disease with hypersplenism. Depressed levels of antithrombin, protein C, and protein S are seen in most patients. Severe initial decreases in antithrombin levels occur in septic DIC. Activity levels below 50% to 60% correlate with poor outcome.⁸⁰

Thrombin cleaves fibrinopeptides A and B from fibrinogen, so the levels of fibrinopeptides A and B should be elevated in patients with DIC. Initial studies have shown a good correlation between an elevated level of fibrinopeptide A and DIC, but other inflammatory conditions such as systemic lupus erythematosus, infections, and thrombosis also may result in elevated levels, thus decreasing the specificity of this test. Elevated prothrombin 1 and 2 levels indicate factor Xa generation and are a reliable DIC marker, indicating procoagulant activation.⁷⁹

Factor VIII and V levels should be decreased in DIC, but results of these tests may be quite variable because of systemic activation of the coagulation system. In clinical practice, serial results yielding a declining platelet count associated with an elevated D-dimer level along with depressed antithrombin and fibrinogen levels indicate a diagnosis of DIC.^{81,82} In lieu of molecular markers, measurements of prolonged PT or aPTT in conjunction with platelet count and fibrinogen are commonly used.

TREATMENT

Disseminated Intravascular Coagulation

7 If unrecognized and left untreated, DIC may lead to death as a result of hemorrhage or thrombosis. However, there is some controversy regarding optimal treatment because of the different mechanisms and clinical manifestations that can occur with DIC. Even so, there is a consensus that the most important step in therapy for DIC is treatment of the underlying disease.^{79,81} In a pregnant woman with placental abruption or retained placenta in whom the disease is self-limited, delivery of the fetus with the products of conception usually returns hemostasis to normal. In patients who have overwhelming sepsis or shock, antibiotics and treatment of hypotension are the mainstays of therapy. In patients who are receiving maximum treatment for the underlying condition but in whom the process is worsening or in whom bleeding develops, additional treatments may be used.

The efficacy of fresh-frozen plasma or platelet transfusions has not been proven in randomized clinical trials but is rational for patients who are bleeding or require invasive procedures.⁸¹ Fresh-frozen plasma replaces clotting factors, fibrinogen, protein S, protein C, and

antithrombin. If hypofibrinogenemia is severe, cryoprecipitate may be useful as a concentrated source of fibrinogen. Although it has been argued that replacement of coagulation factors may worsen the situation, in practice this does not appear to make the situation worse, and it frequently improves hemostasis.

Trials of antithrombin concentrate in the treatment of DIC from various causes show some beneficial effect on improving DIC score, decreasing duration of DIC, or improving end-organ function.^{80,81} A large multicenter, randomized controlled trial showed no significant decrease in mortality when used in septic patients. A subset analysis suggests antithrombin may be useful in the absence of heparin.⁸³ In addition to variable efficacy, antithrombin is an expensive product with only intermittent availability. Therefore, restricting its use to patients at high risk for morbidity and mortality should be considered.

CLINICAL CONTROVERSY

Heparin use in patients with disseminated intravascular coagulation may prevent the formation of new blood clots. The most common complication of heparin therapy is bleeding, so some clinicians find the risk too high to justify heparin use.

Anticoagulation in patients with DIC is controversial. The main pathogenic factor of DIC is considered to be the generation of intravascular thrombin. Interference of thrombin activity by an agent such as heparin appears to be a logical therapeutic step. The main advantage of heparin is that it can prevent further thrombosis and consumption of hemostatic factors, but it has no effect on an already established microthrombus within the vasculature. Because the major complication of heparin therapy is bleeding, some experts argue against heparin use in patients with an existing bleeding disorder. Although case reports have shown improvement in individual patients, heparin has not been shown to reduce morbidity or mortality in controlled clinical trials. Heparin rarely restores the coagulopathy to normal, although both the deficiency of coagulation factors and the thrombocytopenia may improve. If the patient does not respond to the replacement of coagulation factors, the addition of heparin may improve the coagulopathy by forming the heparin–antithrombin complex to inhibit thrombin.

Heparin is given subcutaneously or as a continuous IV infusion. The dosage of heparin for DIC is controversial, ranging anywhere from full-dose to low-dose heparin.⁸¹ Full-dose heparin in adults requires administration of 5,000 units as an IV bolus, followed by a continuous infusion at 1,000 units per hour or according to a weight-based heparin dosing regimen. Some experts advocate low-dose heparin, such as an infusion of 500 units per hour in adults, and adjusting the dose based on clinical and laboratory data. Low-dose heparin given subcutaneously has been used with success. Monitoring of heparin therapy is difficult because the aPTT often is elevated before initiation of heparin therapy, so following D-dimer and fibrinogen levels is best.

Anticoagulation is contraindicated in patients with life-threatening or serious bleeding (e.g., intracranial, retroperitoneal, or pericardial). Patients with symptomatic thromboemboli, extensive fibrin deposition, persistent coagulation abnormalities despite replacement of hemostatic factors, solid tumors, or chronic DIC may benefit from heparin therapy.^{81,84} Historically, an infusion of low-dose heparin at 7.5 units/kg/h has been used in patients with acute promyelocytic leukemia, along with administration of platelets, fresh-frozen plasma, and cryoprecipitate.⁸⁴ Patients with solid tumors who are symptomatic from a thrombosis should receive an infusion of heparin 15 units/kg/h. Once asymptomatic, heparin can be administered subcutaneously.

In two uncontrolled trials, patients tolerated the use of low-molecular-weight heparin well, and this approach showed a possible beneficial outcome.⁷⁹ A randomized, double-blind study compared

the efficacy of dalteparin with that of low-dose heparin. Dalteparin was more effective at improving bleeding symptoms, but no difference in mortality was observed.⁷⁹

Antifibrinolytics, such as aminocaproic acid, have been used in patients in whom excessive fibrinolysis was the dominant clinical picture.⁷⁹ Because aminocaproic acid can increase fibrin deposition, many experts believe that it usually is contraindicated. In patients with chronic liver disease who manifest dominant fibrinolysis, attempts to inhibit the fibrinolytic system have generally been unsuccessful. Patients with acute promyelocytic leukemia may benefit from an antifibrinolytic, as hyperfibrinolysis is the dominant clinical feature of their condition.⁷⁹

Critically ill patients may develop vitamin K deficiency. In addition, patients with DIC may consume vitamin K and may require supplementation to replenish stores. Other possible treatment may include use of protein C concentrate, lepirudin, anti-tissue factor antibody, tifacogin (recombinant tissue factor pathway inhibitor), or thrombin inhibitors such as dermatan sulfate, anti-plasminogen activator inhibitor type 1, and dithiocarbamates.^{79,85}

Activated protein C modulates coagulation (Fig. 105–5). Activation of protein C may be impaired during sepsis. Drotrecogin alfa (activated protein C) administration resulted in an absolute reduction in mortality of 6.1% from severe sepsis without undue bleeding in carefully chosen adult patients.⁸⁶ Strategies for use in adults have been developed to target appropriate patients.⁸⁷ The pediatric trials closed prematurely. Patients must be carefully chosen to minimize bleeding complications and optimize benefits.

Evaluation of Therapeutic Outcomes

The management of DIC is surrounded by controversy, and the optimal approach to these patients is still to be determined. Diagnosis and treatment of the underlying disease should be the goal in all cases. Determination of the dominant process (i.e., hemorrhage vs. thrombosis) can help focus the treatment approach but often is impossible, so clinicians institute replacement therapy of the deficient clotting factors and attempt to control the clotting problems with agents such as heparin.

Risk versus benefit, as well as any contraindications, should be considered at the start of any given therapy for each patient. Monitoring therapy for DIC with laboratory tests can be difficult because the underlying process can cause a variety of laboratory abnormalities. For example, monitoring the effect of heparin by using the aPTT can be a complex task, especially when the patient has an abnormal baseline aPTT. In this case, monitoring fibrinogen and D-dimer levels may be more useful in detecting any need to adjust therapy. In addition, it is important to combine laboratory parameters with clinical assessment to make rational treatment adjustments. Aggressive hemodynamic stabilization and other supportive measures to prevent organ failure also are important in the overall management and prognosis of patients with DIC.

VITAMIN K DEFICIENCY

Vitamin K is a cofactor for activation of factors II, VII, IX, and X.⁸⁸ Vitamin K is required for γ -carboxylation of these clotting factors. Without vitamin K, these factors cannot bind calcium or bind to negatively charge phospholipids membranes and thus remain inactive precursors. Vitamin K also is necessary for the active forms of proteins C and S, which inhibit factor Va and VIIIa. In most clinical situations, vitamin K deficiency causes a bleeding diathesis as a result of marked deficiency of factors II, VII, IX, and X.

Vitamin K is a fat-soluble vitamin. Vitamin K₁, phytonadione, is found in green vegetables. Bacteria in the large intestine produce vitamin K₂, the menaquinones, which require bile salts to be solubilized and absorbed.⁸⁸

Hemorrhagic Disease of the Newborn

Newborns are deficient in vitamin K at birth, as transplacental passage is insignificant.⁸⁹ The level may continue to fall during the neonatal period because the infant's gut has not had sufficient time to undergo bacterial colonization, so the infant lacks hepatic stores. Breast milk contains a low content of vitamin K in comparison to infant formulas; therefore, breast-fed infants are more vulnerable to developing vitamin K deficiency. In addition, the plasma concentrations of the vitamin K–dependent factors are physiologically low in infants.⁹⁰ Vitamin K deficiency in neonates can cause intracranial hemorrhage and bleeding from the umbilical cord or the gastrointestinal tract.⁸⁹

Bleeding within 24 hours of birth, early vitamin K–dependent bleeding, usually is the result of maternal ingestion of anticonvulsants, warfarin, rifampin, or isoniazid. Classic vitamin K–dependent bleeding usually appears during the first week of life and results from the lack of prophylactic vitamin K administration at birth. Risk factors for late vitamin K–dependent bleeding, which occurs at 2 to 12 weeks, include cholestatic liver disease, cystic fibrosis, α_1 -antitrypsin deficiency, exclusive breast-feeding, and failure to give adequate vitamin K at birth.⁸⁹ Use of oral vitamin K at birth is associated with a higher incidence of late vitamin K–dependent bleeding. It has been suggested that the intramuscular route of administration allows the vitamin K to act as a depot preparation and may explain the lower rate of late vitamin K–dependent bleeding with this route.⁸⁹

The levels of vitamin K–dependent coagulation factors are low at birth. Without adequate vitamin K, these levels may fall even further. In this situation, PT and aPTT are prolonged, but the thrombin time, fibrinogen level, and platelet count are normal. Most infants achieve adult levels by age 3 months if intramuscular phytonadione was given at birth.⁸⁹

8 In the United States, infants usually receive 1 mg of phytonadione intramuscularly at birth for prophylaxis. Most infants build up vitamin K₁ and K₂ stores in the liver during the first month of life. The speed of repletion depends on the amount of milk or formula received. Oral supplementation results in late vitamin K–dependent bleeding if vitamin K is not given daily for 3 months, which risks noncompliance. Controversy has arisen over whether the high plasma vitamin K levels achieved with intramuscular injection lead to an increased incidence of childhood cancer. This risk has not been substantiated, and the benefits of widespread use outweigh the minimal risk.⁹⁰ Fresh-frozen plasma is used to treat life-threatening hemorrhages.

Malabsorption

Patients may become deficient in vitamin K as a result of poor nutrition or malabsorption. A careful dietary history is important in this regard. Broad-spectrum antibiotics may sterilize the large intestine and prevent vitamin K₂ production.

Vitamin K absorption depends on both bile acids and pancreatic enzymes to create micelles. Malabsorption resulting from diseases of the small intestine or pancreas, such as cystic fibrosis, Crohn disease, ulcerative colitis, cholestatic liver disease, celiac disease, amyloidosis, Whipple disease, and short-bowel syndrome, may cause abnormal development in children, weight loss, muscle wasting, steatorrhea, vitamin deficiencies, and anemia. Significant malabsorption can occur even without the symptoms of diarrhea or steatorrhea.

TREATMENT

Vitamin K Deficiency

Phytonadione is used to treat vitamin K deficiency. The dose, frequency, and duration of vitamin K administration depend on the severity of the deficiency and the patient's response. Vitamin K can

be administered orally, intramuscularly, subcutaneously, or intravenously. After an oral dose of vitamin K₁, blood coagulation factors increase within 6 to 12 hours. When vitamin K₁ is administered parenterally, PT may take 12 to 24 hours to normalize, although improvement usually occurs within 1 to 2 hours. Failure of vitamin K₁ to correct PT after 48 hours should raise suspicion about the etiology of the coagulation abnormality (e.g., liver disease).

The appropriate route of administration depends on the severity and the cause of the vitamin K deficiency. For instance, in patients with severe hypoprothrombinemia, it is best to avoid the intramuscular route because of the risk of hematoma formation. Because of the rare anaphylactic reaction associated with intravenous administration, this route often is restricted to patients who are thrombocytopenic or unable to absorb the drug via the gastrointestinal tract.⁹¹ Vitamin K can be administered subcutaneously to patients without intravenous access. Patients with life-threatening bleeding should receive fresh-frozen plasma as a source of vitamin K–dependent factors to ensure immediate correction.

Patients with malabsorption or obstructive jaundice may require parenteral administration of vitamin K. Phytonadione 10 mg weekly usually is sufficient in adults. Patients on long-term total parenteral nutrition should receive daily supplementation.

COAGULOPATHY AND LIVER DISEASE

Bleeding disorders can be associated with acute or chronic liver disease. The degree of coagulopathy correlates with the degree of hepatocellular disease. The liver synthesizes the blood coagulation factors and inhibitors of coagulation (e.g., antithrombin and proteins C and S). All clotting factors except factor VIII are decreased in liver failure.⁹² The ability of the liver to clear activated clotting factors and their degradation products is reduced with liver failure.⁹² Primary fibrinolysis occurs due to decreased levels of the inhibitors of plasmin activation.⁹² Platelet count and function are decreased in patients with liver disease. The development of DIC may worsen the coagulopathy.

PT, aPTT, and thrombin time are useful in screening for a deficiency of liver-dependent factors. PT is sensitive to deficiencies in the vitamin K–dependent factors. aPTT helps to determine deficiencies in factor IX and other factors. Thrombin time can help to detect hypofibrinogenemia, dysfibrinogenemia, and the presence of FDPs that interfere with fibrin polymerization. Defects in polymerization may occur before severe hypofibrinogenemia and may be an indication of the degree of liver dysfunction. The level of D-dimer should be normal unless DIC is present.

Factor V is synthesized by hepatic cells but is not dependent on vitamin K. Therefore, it may be useful in distinguishing vitamin K deficiency from liver disease. Deficiency of antithrombin occurs with severe hepatocellular disease and may contribute to the development of DIC. In acute hepatic failure, the level of plasminogen may be low, reflecting decreased synthesis or increased catabolism associated with DIC. The level of factor VIII usually is normal or elevated in liver disease but is decreased in DIC.

TREATMENT

Coagulopathy and Liver Disease

Treatment of the coagulopathy associated with liver disease is recommended for overt bleeding or for correction of coagulation parameters (e.g., PT and aPTT) prior to an invasive procedure. Major bleeding may occur with normal coagulation parameters secondary to esophageal varices or peptic ulcer disease. To ensure that vitamin K deficiency is not contributing to the abnormalities, adults may receive 10 mg of vitamin K for one or more days.

When a patient bleeds in association with a coagulopathy, replacement therapy with platelets and fresh-frozen plasma may decrease bleeding. Fresh-frozen plasma supplies all of the missing coagulation factors, but fluid overload may be a serious problem. If fluid overload becomes an issue, plasma exchange may be considered. If the patient has ascites, the half-life of many of these factors is decreased, and correcting the coagulopathy is difficult. PCCs can be given, but they may increase the risk of intravascular coagulation and cause DIC if not already present. In general, use of these concentrates is not recommended. Only when administration of fresh-frozen plasma does not correct the coagulopathy and the patient continues to have serious bleeding should PCCs be considered.

The use of heparin and antifibrinolytic drugs is controversial. Administration of aminocaproic acid may be successful, especially with mucosal bleeding. Heparin has not been demonstrated to improve survival in patients with acute liver failure and may exacerbate bleeding. Antithrombin concentrates have been evaluated in fulminant liver failure. They had no benefit on mortality, clinical complications, or coagulation laboratory findings. Desmopressin may decrease the bleeding time in patients with liver failure.⁹² Administration of recombinant factor VIIa has successfully corrected coagulation parameters and stopped bleeding in patients with liver disease.⁹³

ABBREVIATIONS

aPCC: activated prothrombin complex concentrate

aPTT: activated partial thromboplastin time

BU: Bethesda unit

DIC: disseminated intravascular coagulation

FDP: fibrin degradation product

HIV: human immunodeficiency virus

PAI-1: plasminogen activator inhibitor type 1

PCC: prothrombin complex concentrate

PT: prothrombin time

vWF:Ag: von Willebrand factor antigen

C.Y. JENNIFER CHAN AND REGINALD MOORE

KEY CONCEPTS

- 1 Sickle cell disease is an inherited disorder caused by a defect in the gene for hemoglobin. Patients can have one defective gene (sickle cell trait) or two defective genes (sickle cell disease).
- 2 Although sickle cell disease usually occurs in persons of African ancestry, other ethnic groups can be affected. Different mutation variants can result in variation in clinical manifestations.
- 3 Sickle cell disease involves multiple organ systems. Usual clinical signs and symptoms include anemia, pain crisis, hepatosplenomegaly, and pulmonary diseases. Sickle cell disease can be identified by routine neonatal screening programs. Early diagnosis allows early comprehensive care.
- 4 Patients with sickle cell disease are at risk for infection. Prophylaxis against pneumococcal infection reduces death during childhood.
- 5 Hydroxyurea has been shown to decrease the incidence of painful crises, but patients treated with hydroxyurea should be carefully monitored.
- 6 Neurologic complications caused by vasoocclusion can lead to stroke. Chronic transfusion therapy programs have been shown to be beneficial in decreasing the occurrence of stroke in children with sickle cell disease.
- 7 Patients with fever greater than 38.5°C (101.3°F) should be evaluated and appropriate antibiotics should include coverage for encapsulated organisms, especially pneumococcal.
- 8 Pain episodes can usually be managed at home. Hospitalized patients usually require parenteral analgesics. Analgesic options include opioids, nonsteroidal antiinflammatory agents, and acetaminophen. The patient characteristics and the severity of the crisis should determine the choice of agent and regimen.

1 Sickle cell syndromes, which can be divided into sickle cell disease (SCD) and sickle cell trait (SCT), are a group of hereditary disorders characterized by the presence of sickle cell hemoglobin (HbS) in red blood cells. SCT is the heterozygous inheritance of one normal cell and one sickle cell hemoglobin (HbAS) gene. Individuals with SCT are usually asymptomatic. SCD can be of homozygous or compounded heterozygous inheritance. Homozygous HbS (HbSS) is called sickle cell anemia (SCA); heterozygous inheritance of HbS

compounded with another mutation results in sickle cell hemoglobin C (HbSC), sickle cell β -thalassemia (HbS β^+ -thal and HbS β^0 -thal), and some other rare phenotypes.

This complex disorder was first described in the literature by Herrick in 1910. Since that discovery was made, much progress has been made in identifying the molecular and functional defects and understanding the relationship between genotypes and clinical severity of the disease.^{1,2}

SCD is a chronic illness with significant burden for family and society.³ Frequent crisis episodes can interrupt schooling and result in employment difficulties. Acute complications of the disease can be unpredictable, rapidly progressive, and life-threatening. Later in life, chronic organ damage can develop. Because of the complexity and seriousness of the illness, it is essential that comprehensive care is available and that all providers involved have a good understanding of the disease and its management options.⁴

EPIDEMIOLOGY

More than 50,000 Americans have sickle cell disease, and approximately 2,000 infants with SCD are identified each year in the United States. In addition, for every 1 infant with SCD, approximately 50 infants are identified as carriers. The most common SCD genotype is HbSS (~45%), followed by HbSC (~25%), HbS β^+ -thal (~8%), and HbS β^0 -thal (~2%). Other variants account for less than 1% of patients.^{5,6}

Sickle cell gene mutation offers partial protection against serious malarial infection. Abnormal red blood cells (RBCs) are less easily parasitized by *Plasmodium falciparum* than normal RBCs. Consequently, persons with heterozygous sickle cell gene (i.e., SCT) have a selective advantage in regions (tropical areas) where malaria is endemic. The incidence of the sickle cell gene in a population correlates with the historical incidence of malaria.

2 SCD is most common in people with African heritage, with a frequency of approximately 1 in 400 for SCD and 8% for SCT in African Americans. The prevalence is higher in Africa, where an estimated 120,000 babies are born with SCD each year. The prevalence rate of SCT in Africa varies across regions, with a higher rate in western, central, and eastern Africa (10% to 30%) but lower rates in northern and southern Africa (0% to 5%). Hemoglobin C (HbC) appears primarily in the inhabitants of western and northern Africa or in descendants of people from this area. Approximately 2% to 3% of African Americans carry the HbC gene (HbC-trait).⁵⁻⁸

Other areas with sickle cell mutation are the Arabian Peninsula, the Indian subcontinent, and the Mediterranean region. HbS has been reported in up to 25% in certain Middle Eastern populations and greater than 30% in Greece and Cyprus. Genetic analysis shows that the mutation found in Arabic patients is different from those of African descent. Sickle cell gene mutation variants have been associated with different geographic locations and may be responsible for variations in clinical manifestations. In Africa, the variants are

FIGURE 106-1. Sickle cell gene inheritance scheme for both parents with sickle cell trait (SCT). Possibilities with each pregnancy: 25% normal (AA); 50% SCT (AS); 25% sickle cell anemia (SS). (A, normal hemoglobin; S, sickle cell hemoglobin.)

Senegal (Atlantic West Africa), Benin (Central West Africa), Bantu (Central African Republic), and Cameroon. Arab-Indian haplotype is seen in certain areas of Saudi Arabia and India.^{1,7-9}

ETIOLOGY

Normal hemoglobin (hemoglobin A [HbA]) is composed of two α chains and two β chains ($\alpha_2\beta_2$). The biochemical defect that leads to the development of HbS involves the substitution of valine for glutamic acid as the sixth amino acid in the β -polypeptide chain. Another type of abnormal hemoglobin, hemoglobin C (HbC), is produced by the substitution of lysine for glutamic acid as the sixth amino acid in the β -chain. Structurally, the α -chains of HbS, HbA, and HbC are identical. Therefore, it is the chemical differences in the β -chain that account for sickling and its related sequelae.^{1,2,7}

SCA is a form of SCD in which the patient has inherited both genes that code for formation of HbS, one from each parent (HbSS). Figures 106-1, 106-2, 106-3, and 106-4 show the probability of inheritance with each pregnancy for the offspring of parents with HbA, SCT, and SCA. If both parents are carriers, the offspring will have a 25% risk of having SCD and 50% risk of being a carrier (see Fig. 106-1). β -Thalassemia can be found in conjunction with HbS. Because patients with HbSS and HbS β^0 -thal do not have normal β -globulin production, they usually have a more severe course than those with HbSC and HbS β^{+} -thal. As discussed earlier, several haplotypes characterize the sickle cell gene, resulting in different clinical and hematologic courses. Included among these types are the three most commonly found in the United States: the Bantu haplotype, characterized by severe disease; the Senegal haplotype, characterized by mild disease; and the Benin haplotype, characterized by a course intermediate to that of the other two haplotypes.

FIGURE 106-2. Sickle cell gene inheritance scheme for one parent with sickle cell trait (SCT) and one parent with no sickle cell gene. Possibilities with each pregnancy: 50% normal (AA); 50% SCT (AS). (A, normal hemoglobin; S, sickle cell hemoglobin.)

FIGURE 106-3. Sickle cell gene inheritance scheme for one parent with sickle cell trait (SCT) and one parent with sickle cell anemia (SCA). Possibilities with each pregnancy: 50% SCA (SS); 50% SCT (AS). (A, normal hemoglobin; S, sickle cell hemoglobin.)

Although there are a number of other haplotypes seen around the world, the major types include Saudi Arabian and Cameroon. Both of these types usually follow milder courses of illness.^{2,7,9-10}

PATHOPHYSIOLOGY

To understand the pathophysiology of SCD, one must understand the normal physiology of RBC production. Normal adult RBCs contain 33 to 35 g/dL hemoglobin, predominantly HbA (96%). Other forms of hemoglobin are HbA₂ (2% to 3%) and fetal hemoglobin (less than 2%). Fetal hemoglobin (HbF) is present predominantly in fetal RBCs. Instead of β chains in HbA or HbS, HbF contains two γ chains ($\alpha_2\gamma_2$). The switch from production of γ chains to β chains occurs shortly before birth. A few red cell clones remain to produce HbF postnatally. Increased production of HbF is seen under severe erythroid stress, such as anemia, hematopoietic stem cell transplantation, or chemotherapy. Both water and hemoglobin content in the RBCs determine the mean corpuscular hemoglobin concentration (MCHC). Passive diffusion and active transport regulate intracellular cation and volume contents, which determine the intracellular viscosity of RBC. Normal RBCs are biconcave shape and able to deform to squeeze through capillaries. As RBCs age, MCHC increases, deformability decreases, and the cells are removed by the mononuclear phagocytic system.^{7,12}

In the pathogenesis of SCD, three known problems are primarily responsible for various clinical manifestations: impaired circulation, destruction of RBCs, and stasis of blood flow. These three problems probably relate directly to two major disturbances involving RBCs: polymerization and membrane damage (Fig. 106-5).

The solubility of HbS and HbA are the same when oxygenated. Because of increased hydrophobicity as a result of valine substituting

FIGURE 106-4. Sickle cell inheritance scheme for 1 parent without sickle cell gene and 1 parent with sickle cell anemia (SCA). Possibilities with each pregnancy: 100% SCT (AS). (A, normal hemoglobin; S, sickle cell hemoglobin.)

FIGURE 106-5. Pathophysiology of sickle cell disease. (Arg, arginine; ET-1, endothelin-1; Hb, hemoglobin; NO, nitric oxide; NOS, nitric oxide synthase; VCAM-1, vascular cell adhesion molecule 1; XO, xanthine oxidase.) (From Kato GJ, Gladwin MT. *Sickle cell disease*. In: Hall JB, Schmidt GA, Wood LDH. *Principles of Critical Care*, 3rd ed. New York: McGraw-Hill, 2005:1658.)

glutamic acid, solubility of deoxygenated HbS is reduced to 17 g/dL. Saturation of deoxy-HbS leads to intermolecular binding and formation of thin bundles of fibers, which initially are unstable, but increased binding of deoxy-HbS eventually results in cross-linking fibers and stable polymers. This process is influenced by MCHC, temperature, intracellular pH, and the amount of HbS. Polymerization allows deoxygenated hemoglobin molecules to exist as a semi-solid gel that protrudes into the cell membrane, leading to distortion of RBCs (sickled shape) and loss of deformability. The presence of sickled RBCs increases blood viscosity and encourages sludging in the capillaries and small venous vessels. Such obstructive events lead to local tissue hypoxia, which tends to accentuate the pathologic process.

When reoxygenated, polymers within the RBCs are lost, and the RBCs eventually return to normal shape. This process contributes to the vasoocclusive manifestation in that HbS is able to squeeze into microvasculature when oxygenated, but becomes sickled when deoxygenated. This cycle of sickling and unsickling results in damage to the cell membrane, loss of membrane flexibility, and rearrangement of surface phospholipids. Membrane damage also alters ion transport, resulting in potassium and water loss, which can lead to a dehydrated state that enhances the formation of sickled forms. After continual repetitions of the process, the RBC membrane develops into a more rigid form, irreversibly sickled cell (ISC). Unlike the reversible sickle cells, which have normal morphology when oxygenated, ISCs are elongated cells and remain sickled when oxygenated. More rigid membranes of HbS-containing RBC retard their flow, particularly through the microcirculation. In addition, sickled RBCs tend to adhere to vascular endothelial cells, which further increase polymerization and obstruction.

Intermolecular binding and polymer formation are reduced by HbF and to a lesser degree by HbA₂. RBCs that contain HbF sickle less readily than cells without. ISCs, not surprisingly, have a low HbF level. Increased levels of HbF, as in the case of the Saudi Arabian genotype, result in more benign forms of SCD. The amount of HbF and HbA₂ in relation to HbS influences clinical manifestations and accounts for the variability in severity among different SCD genotypes.

Intravascular destruction of sickle cells can occur at an accelerated rate. The stresses of circulation, and repetitive sickle-unsickle cycles are likely to lead to cell fragmentation. Damage to the cell

membrane promotes cell recognition by macrophages. Rigid ISCs are easily trapped, resulting in short circulatory survival and chronic hemolysis. The typical sickled cell survives for approximately 10 to 20 days, whereas the life span of a normal RBC is 100 to 120 days.

In addition to sickling, other factors are also responsible for the clinical manifestations associated with SCD. Obstruction of blood flow to the spleen by sickle cells can result in functional asplenia, defined as the loss of splenic function with an intact spleen. These patients can also have deficient opsonization. Impaired splenic function increases susceptibility to infection by encapsulated organisms, particularly pneumococcal disease. Coagulation abnormalities in SCD can be the result of continuous activation of the hemostatic system or disorganization of the membrane layer.^{7-9,12-14}

CLINICAL PRESENTATION

3 SCD is usually identified by routine neonatal screening programs. The sensitivity and specificity of screening methods, most commonly by isoelectric focusing, are excellent. For infants with a positive screening result, confirmation testing should be performed prior to 2 months of age. Even with universal screening, infants with SCD are sometimes not identified at birth because of extreme prematurity, prior blood transfusion, inability to contact family, or clerical errors.⁴

SCD involves multiple organ systems, and its clinical manifestations vary greatly between and among genotypes (Table 106-1). Persons with SCT are usually asymptomatic and are not considered to have clinical disease. However, some clinical signs and symptoms can occur, and patients should be cautious when participating in exercise under extreme conditions, such as high altitude or military training. Sickling of RBCs in the renal medulla can result in loss of ability to maximally concentrate urine. Patients with such impairment can be at risk of dehydration during periods in which the body normally conserves water. Microscopic hematuria has been observed, and gross hematuria can occur after heavy exercise. An increased incidence of urinary tract infection in women, especially during pregnancy, has been reported.^{1,5,7}

The feature presentations of SCD are hemolytic anemia and vasoocclusion. In patients who are homozygous for HbS, anemia usually appears from 4 to 6 months after birth. The delay in presenta-

TABLE 106-1 Clinical Features of Sickle Cell Trait and Common Types of Sickle Cell Disease

Type	Clinical Features
Sickle cell trait (SCT)	Rare painless hematuria; normal Hb level; heavy exercise under extreme conditions can provoke gross hematuria and complications
Sickle cell anemia (SCA)	Pain crises, microvascular disruption of organs (spleen, liver, bone marrow, kidney, brain, and lung), gallstone, priapism, leg ulcers; anemia (Hb 7–10 g/dL)
Sickle cell hemoglobin C	Painless hematuria and rare aseptic necrosis of bone; vasoocclusive crises are less common and occur later in life; other complications are ocular disease and pregnancy-related problems; mild anemia (Hb 10–12 g/dL)
Sickle cell β^+ -thalassemia	Rare crises; milder severity than sickle cell disease because production of HbA; Hb 10–14 g/dL with microcytosis
Sickle cell β^0 -thalassemia	No HbA production; severity similar to SCA; Hb 7–10 g/dL with microcytosis

HbA, hemoglobin; Hb, hemoglobin.

tion is because during those months, HbF in the infant’s RBC is gradually replaced by HbS, which typically leads to attacks of pain frequently accompanied by fever. Pneumonia and splenomegaly are also common findings. Infants can also present with pain and swelling of the hands and feet, commonly referred to as *hand-and-foot syndrome* or *dactylitis*.^{1,4,5,7}

The usual clinical signs and symptoms associated with SCA include chronic anemia; fever and pallor; arthralgia; scleral icterus; abdominal pain; weakness; anorexia; fatigue; enlargement of the liver, spleen, and heart; and hematuria. Laboratory findings include low hemoglobin level and increased reticulocyte, platelet, and white blood cell (WBC) counts. The peripheral blood smear demonstrates sickle cell forms.

Presentation of patients with HbSC disease is less severe than that of SCA and is characterized primarily by mild anemia (hemoglobin levels above 9 g/dL), infrequent episodes of pain, persistence of splenomegaly into adult life, and excessive target cells in the peripheral blood smear. In patients with heterozygous HbS and β -thalassemia gene, severity of disease depends on the thalassemia gene involved.^{1,5,7}

Patients with SCD experience delayed growth and sexual maturation. Both height and weight are usually below average, and the poor growth cannot be explained by nutritional factors alone. Fertility problems tend to occur more often, and some menstrual abnormalities are more common in female SCD patients than in normal women. Other typical physical characteristics include a protuberant abdomen with exaggerated lumbar lordosis, usually an asthenic appearance with rather long extremities and tapered fingers, and frequently a barrel-shaped chest.^{1,4,5,7}

The previously high mortality rate of early childhood has been reduced for patients with SCD with availability of public health programs and comprehensive care.⁴ The median survival rate is estimated to be 42 years for males and 48 years for females for HbA, and 60 years for males and 68 years for females for HbSC.⁵ Predictors for severe disease in children who are less than 10 years of age include dactylitis before 1 year of age, an average hemoglobin level less than 7 g/dL in the second year of life, and WBC count greater than 13,700 cells/mm³ in the absence of infection. Early acute chest syndrome during first 3 years of life is a predictor for recurrent episodes throughout childhood. Children with concomitant SCD and asthma have increased episodes of acute chest syndrome and stroke. Risk factors for early death in adults with SCD include acute complications such as pain crisis, anemic events, acute chest syndrome, renal failure, and pulmonary disease.^{3,5,15–19} Today,

with longer survival for SCD, chronic manifestations of the disease contribute to the morbidity later in life.

COMPLICATIONS

ACUTE COMPLICATIONS

Fever and Infection

Functional asplenia and failure to make antibodies against encapsulated organisms contribute to the high risk of overwhelming sepsis in patients with SCD. The most common pathogen is *Streptococcus pneumoniae*. Other encapsulated organisms are *Haemophilus influenzae* and *Salmonella*, and the latter has been known to cause osteomyelitis and pneumonia in SCD. *Mycoplasma pneumoniae* should be considered in older children with infiltrates on chest radiograph. Viral infections (e.g., influenza and parvovirus B19) can result in severe morbidity.^{1,5,20,21}

All SCD patients with fever greater than 38.5°C (101.3°F) must be evaluated to determine the extent of sepsis; workup can include physical examination, complete blood count with reticulocyte count, blood culture, chest radiograph, urinalysis, and urine culture. Lumbar puncture may be needed, especially in young children and toxic-looking children. A low threshold for empiric therapy compared to that in the general population is recommended.^{1,5,7,10}

Neurologic

Neurologic abnormalities can occur in both adults and children. Vasoocclusive processes occasionally lead to cerebrovascular occlusion that manifests itself as the signs and symptoms of stroke, such as drowsiness, paralysis, transitory or permanent blindness, aphasia, visual disturbances, spinal cord infarction, and convulsions. Behavioral and performance changes in patients with asymptomatic infarction. The cumulative risk of cerebral infarct in HbSS is 11% by age 20 years and 24% by age 45 years with a recurrence rate as high as 70% in 3 years. Some patients recover rapidly and completely, although others are left with permanent neurologic deficits. Evaluation of acute events include computed tomography (CT) scan and magnetic resonance imaging (MRI), magnetic resonance angiography (MRA) for asymptomatic infarction and transcranial Doppler (TCD) ultrasound to detect abnormal velocity and identify high-risk patients. In addition, electroencephalograph (EEG) can be used if there is a history of seizure. Some patients who have SCA with no prior history of stroke have been found to have changes on MRI of the brain consistent with infarction or ischemia. These “silent infarcts” have been reported to occur in up to 22% of HbSS patients and can be associated with increased risk of stroke and decreased neurocognitive functions.^{1,13,22–25}

Acute Chest Syndrome

Acute chest syndrome is the leading cause of death among patients with SCD. It is characterized by a new pulmonary infiltrate associated with one or more other symptoms (such as cough, dyspnea, tachypnea, chest pain, fever, wheezing, and new onset hypoxia), and an equivocal response to antibiotic therapy. As many as one-half of patients with SCD experience at least one episode of acute chest syndrome. Pulmonary infarcts often involve the lower lobes of the lungs and are a frequent cause of pleural effusions. Pneumonia occurs most often in the middle and upper lobes. These pulmonary manifestations must be recognized early and managed aggressively because the patient can rapidly progress to pulmonary failure and death.^{26–31}

Priapism

Sickling in the sinusoids of the penis can cause priapism, a sustained painful erection that can last several hours or days. Impotence has

TABLE 106-2 Sickle Cell Crisis**Vasooocclusive pain crisis^a**

Clinical features: Acute painful infarction without changes in Hb; almost all patients with SCA will have episodes of acute pain. Recurrent acute crises result in bone, joint, and organ damage and chronic pain. Vasooocclusive crisis most commonly involves the bones, liver, spleen, brain, lungs, and penis. Acute long bone pains can be accompanied by signs of inflammation, making it difficult to differentiate from osteomyelitis. Abdominal involvement can resemble a surgical abdomen. Precipitating factors include infection, extreme weather conditions, dehydration, and stresses.

Signs and symptoms: Deep throbbing pain; local tenderness, erythema, and swelling can be seen. Fever and leukocytosis are common. Dactylitis usually occurs in young infants. Jaundice and increased transaminases present if liver is involved.

Evaluation: Frequent physical examination, CBC, reticulocyte, and urinalysis; based on symptomatology, the following can be needed: needle aspiration to rule out osteomyelitis, abdominal studies (radiograph, computed tomography scan, etc.), liver function tests, bilirubin, culture, and chest radiograph.

Aplastic crisis^b

Clinical features: Acute decrease in Hb with decreased reticulocyte count (usually less than 1%); transient suppression of RBC production in response to bacterial or viral infection, most common being parvovirus B19

Signs and symptoms: Headache, fatigue, dyspnea, pallor, and tachycardia; can also present with fever, upper respiratory or gastrointestinal infection symptoms.

Evaluation: CBC, reticulocyte count, radiograph, cultures (blood, urine, and throat), evaluation of viral infection (e.g., parvovirus titers)

Acute splenic sequestration crisis^c

Clinical features: Acute exacerbation of anemia due to sequestration of large blood volume by the spleen. More commonly seen in patients with functioning spleens (e.g., infants and adults with HbSC disease); onset often is associated with viral or bacterial infections; recurrences are common and can be fatal.

Signs and symptoms: Sudden onset of fatigue, dyspnea, and distended abdomen; rapid decrease in Hb and HCT with elevated reticulocyte count, abdominal pain, splenomegaly, vomiting, hypotension, and shock

Evaluation: Close monitoring of vital signs, spleen size, and oxygen saturation, CBC, reticulocyte, and cultures

CBC, complete blood count; HbSC, sickle cell hemoglobin C; Hb, hemoglobin; HCT, hematocrit; RBC, red blood cell; SCA, sickle cell anemia.

^aFrom Fidler and Styles,¹ National Institutes of Health,⁵ Stuart and Nagel,⁷ and Heibel et al.¹²

^cFrom Fidler and Styles,¹ National Institutes of Health,⁵ and Stuart and Nagel.⁷

been reported after repeated episodes. Recurrent and severe priapism is a predictor for other end-organ damage. ASPEN (association of sickle cell disease, priapism, exchange transfusion, and neurologic events) syndrome has occurred in some patients with priapism 1 to 11 days after partial exchange transfusion. This syndrome can range from headaches and seizures to obtundation requiring ventilation.^{1,5,7}

Sickle Cell Crisis

Chronic hemolytic anemia in the SCD patient is periodically interrupted by crises, particularly in childhood (see Table 106–2). Patients with HbSS disease experience crises more often than do patients with HbSC disease or some other variants. Although fever, infections, dehydration, hypoxia, acidosis, and sudden temperature alterations can precipitate crises, multiple factors often contribute to development of a crisis.

Vasooocclusive Pain Crisis The most common type of crisis is the vasooocclusive crisis, which is usually characterized by pain affecting the involved areas, without changes in hemoglobin. Laboratory changes that can be seen include leukocytosis, increased fibrinogen levels, and decreased serum pH and bicarbonate level. Dactylitis (hand-and-foot syndrome) occurs in infancy and early childhood and is characterized by redness and swelling of the dorsal aspects of the hands, feet, fingers, and toes. The episodes are painful but usually do not result in permanent damage.^{1,5,7,12}

Aplastic Crisis Aplastic crisis is characterized by a decrease in the reticulocyte count and a rapidly developing severe anemia. The bone marrow is hypoplastic. There can be associated pain. The crisis is typically caused by a viral infection, particularly parvovirus B19.^{1,5,7,32}

Splenic Sequestration Crisis This is a sudden massive enlargement of the spleen resulting from the sequestration of blood from the mononuclear phagocytic system. There is a dramatic fall in hematocrit and hemoglobin concentrations, with no evidence of marrow failure or accelerated hemolysis. The trapping of the sickled RBCs by the spleen also leads to a decrease in circulating blood volume, which can result in hypotension and shock. The condition is most often seen in infants and children, as their spleens are intact. These crises can cause sudden death in young children. Repeated infarctions lead to autosplenectomy as the disease progresses; therefore, the incidence declines as adolescence approaches.^{1,5,7}

CHRONIC COMPLICATIONS

SCD manifests in a variety of chronic problems involving multiple organs. Pulmonary hypertension has been reported to be a risk factor for death in adult patients with SCD.^{16,33} Headache is a symptom associated with acute neurologic events, and pseudotumor cerebri presenting with severe headache and blurred vision has also been reported.³⁴ Destructive bone and joint problems are common. Aseptic necrosis, particularly of the femoral or humeral heads, causes permanent damage and disability. Patients with SCD also have an increased incidence of osteomyelitis; the organism most often responsible is *Salmonella*. In addition to necrosis of joints, chronic leg ulcers can become a difficult skeletal problem. The inner aspect of the lower leg just above the ankle is the site most often affected. Ulcers are often seen after trauma or infection and are usually slow to heal.^{1,5,7}

Ocular problems seen in patients with SCD include transient monocular blindness, visual field defects from retinal hemorrhage, retinal detachment, vitreous hemorrhage, venous microaneurysms, and neovascularization. The incidence of proliferative retinopathy in SCD patients varies from 5% to 10%. Vasooocclusion in the eye can occur as early as 20 months of age, and clinically detectable retinal diseases usually occur during adolescence and early adulthood. Despite the less systemic manifestations, patients with HbSC develop serious retinal complications more often and earlier. Annual examination with retinal evaluation is recommended for patients with SCD to prevent blindness from retinopathy and other complications.^{5,35,36}

Cholelithiasis is a common occurrence in the SCD patient. It is the result of the chronic hemolysis that results in increased bilirubin production, leading to biliary sludge and/or stone formation. The risk of gallstones increases with age, with 14% younger than age 10 years and 50% by age 22 years. Cholecystitis, exemplified by pain in the right iliac fossa, can be confused with abdominal pain crisis.^{1,5,37}

As with any anemia, cardiovascular abnormalities, including cardiac enlargement and various murmurs, can occur in patients with SCD. Patients complain of various degrees of exertional dyspnea, tachycardia, and palpitation owing to the decreased oxygen-carrying capacity of the blood. Acute myocardial infarction has also been reported in children with SCD.^{5,38,39}

Renal complications include hematuria, tubular acidosis, proteinuria and hyposthenuria (inability to concentrate urine maximally). Enuresis, as a result of increased urine production, is a common complaint. Death from renal disease is unusual among younger patients but does occur among older patients with SCD.^{1,5,40}

Depression can be more common than in the general population; especially in patients with unstable disease.⁴¹ Reduction of cognitive function has been reported even in children with no evidence of cerebral infarction.⁴² Delay in growth and sexual development are

seen in patients with SCD. Adults with SCD have decreased fertility. Finally, pregnancy introduces an increased risk for the mother with SCD and for the fetus. Some patients can experience increased frequency of pain crisis during pregnancy. The anemia of SCD can lead to intrauterine growth retardation. Preterm labor and premature delivery are common occurrences in mothers with SCD, and the risk of spontaneous abortion is increased. The incidence of preeclampsia is also higher when compared to mothers who do not have SCD.^{1,5,7,11}

TREATMENT

Sickle Cell Disease

Patients with SCD require lifelong multidisciplinary care. All patients with SCD should receive regularly scheduled comprehensive medical evaluations. The goal of comprehensive care is to reduce hospitalizations, complications, and mortality. Because of the complexity of the disease, a multidisciplinary team is needed to provide medical care, education, counseling, and psychosocial support. Appropriate comprehensive care can have a positive impact on both longevity and general quality of life. This care includes the use of traditional prophylactic and general symptomatic supportive care and the use of newer, more specific therapies aimed at altering hematologic capacity and function.^{1,5,7,10,11}

Treatment for patients with SCD involves the use of general measures to meet the unique demands for increased erythropoiesis. Additional interventions can be aimed at preventing or treating complications of the disease. When crises occur, the type and severity of the crisis determine the appropriate therapeutic plan.

HEALTH MAINTENANCE Immunizations

Administration of routine immunizations as recommended by the American Academy of Pediatrics is crucial. In addition to the routine immunizations, SCD patients 6 months and older should receive influenza vaccine annually. Meningococcal vaccine is also recommended for patients older than 2 years of age undergoing splenectomy.⁴³⁻⁴⁵

Patients with SCD have impaired splenic function, which increases their susceptibility to infection by encapsulated organisms, particularly pneumococci. Prior to the routine use of penicillin prophylaxis and the development of pneumococcal vaccines, invasive pneumococcal disease was 20- to 100-fold more common in children with SCD than in healthy children. Even with these interventions, some groups of children with SCD continue to have a high rate of invasive pneumococcal infections.^{20,43}

④ Two different pneumococcal vaccines are available. The 7-valent pneumococcal conjugate vaccine (PCV7; Prevnar) induces good antibody responses in infants. Immunization with the PCV7 is recommended for all children younger than 24 months of age. Infants should receive the first dose between 6 weeks and 6 months. Two additional doses should be given at 2-month intervals, followed by a fourth dose at age 12 to 15 months. The 23-valent pneumococcal polysaccharide vaccine (PPV 23; Pneumovax 23) is not recommended for use in children younger than 2 years of age because of poor antibody response. To cover for different serotypes, the immunization schedule for children with SCD should include both pneumococcal vaccines. PPV 23 should be given at 2 years of age or older, administered about 2 months after the last dose of the PCV7. An additional dose of the PPV 23 administered 3 to 5 years later should be considered. The recommended immunization schedule and catch-up schedule for PCV7 and PPV 23 are presented in Table 106-3.^{44,46} In addition to pneumococcal disease, the risk of menin-

TABLE 106-3 Pneumococcal Immunization for Children with Sickle Cell Disease

Recommended Schedule	
Previously unvaccinated	
Age 2–6 months	PCV7 (Prevnar): 3 doses 6–8 wk apart; then 1 dose at 12–15 months
Age 7–11 months	PCV7 (Prevnar): 2 doses 6–8 wk apart; then 1 dose at 12–15 months
Age ≥12–23 months	PCV7 (Prevnar): 2 doses 6–8 wk apart
Age 24–59 months	PCV7 (Prevnar): 2 doses 6–8 wk apart PPV 23 (Pneumovax): 2 doses; first dose at least 6–8 wk after last PCV7 dose; second dose 3–5 years after the first PPV 23 dose
Age 5 years or older	PCV7 (Prevnar): 1 dose PPV 23 (Pneumovax): 2 doses; first dose at least 6–8 wk after last PCV7 dose; second dose 3–5 years (for those age 10 years or younger) or more than 5 years (for those age 10 years or older) after the first PPV 23 dose
Previously vaccinated	
Age 12–23 months, incomplete PCV7 series	PCV7 (Prevnar): 2 doses 6–8 wk apart
Age 24–59 months, received four doses of PCV7	PPV 23 (Pneumovax): 2 doses; first dose at least 6–8 wk after last PCV7 dose; second dose 3–5 years after the first PPV 23 dose
Age 24–59 months, three doses PCV7 given before 24 months of age	PCV7 (Prevnar): 1 dose PPV 23 (Pneumovax): 2 doses; first dose at least 6–8 wk after last PCV7 dose; second dose 3–5 y after the first PPV 23 dose
Age 24–59 months, 1 dose PPV 23 given	PCV7 (Prevnar): 2 doses 6–8 wk apart; first dose at least 8 wk after PPV 23 dose PPV 23 (Pneumovax): second dose 3–5 years after first PPV 23
Age 5 years or older, received PPV 23	PCV7 (Prevnar): 1 dose 6–8 wk after PPV 23 If only received 1 dose of PPV 23 (Pneumovax): Second dose 6–8 wk after PCV7 and 3–5 years (for those age 10 years or less) or more than 5 years (for those age 10 years or older) after the first PPV 23 dose

PCV7, 7-valent pneumococcal conjugated vaccine; PPV 23, 23-valent pneumococcal polysaccharide vaccine.
From Advisory Committee on Immunization Practices⁴⁴ and Sickle Cell Disease Care Consortium.⁴⁶

gococcal disease can also be higher in SCD, and routine vaccination is recommended.⁴⁵

Penicillin

④ Penicillin prophylaxis until at least 5 years of age is recommended in children with SCD, even if they have been immunized with PCV7 as prophylaxis against pneumococcal infections. Prophylactic treatment should begin at 2 months of age or earlier. An effective regimen that reduces the risk of pneumococcal infections by 84% is penicillin V potassium at a dosage of 125 mg orally twice daily until the age of 3 years, followed by 250 mg twice daily until the age of 5 years. An alternate regimen is benzathine penicillin, 600,000 units given intramuscularly every 4 weeks for children age 6 months to 6 years, and 1.2 million units every 4 weeks for those over 6 years of age for whom continued therapy is warranted. Patients who are allergic to penicillin can be given erythromycin 20 mg/kg per day twice daily. Penicillin prophylaxis is not routinely given in older children, based on a study demonstrating no benefit over placebo beyond the age of 5 years. However, continuation of oral pneumococcal prophylaxis should be evaluated on a case-by-case basis, especially in patients with a history of invasive pneumococcal infection or surgical splenectomy.^{1,5,7,43,44,46,47}

CLINICAL CONTROVERSY

The need for routine penicillin prophylaxis is controversial in HbS β^+ -thal patients because these patients have less severe disease.

Folic Acid

Patients with SCD have an increased demand for folic acid because of accelerated erythropoiesis. Megaloblastic changes have been reported, but the actual prevalence of megaloblastic anemia in patients with SCD is unknown. Conflicting data on serum folate levels have been reported. In children and adolescents, one study reported normal folate stores in SCD patients without receiving supplemental folic acid, and another study reported that 15% of patients had low folate levels despite daily supplementation. Conversion of homocysteine (Hcy) to methionine depends on folate, and vitamins B₆ and B₁₂. Plasma homocysteine level has been used as a marker for folate and vitamins B₆ and B₁₂ status, and increased homocysteine levels have been associated with endothelial damage in pediatric SCD patients. In general, folic acid supplementation at a dose of 1 mg/day is recommended in adult patients, women who are contemplating pregnancy, and patients of all ages with chronic hemolysis. Daily supplementation with folic acid (1 mg), vitamin B₁₂ (6 mcg) and vitamin B₆ (6 mg) has also been suggested for patients with increased homocysteine levels to reduce risk of endothelial damage.^{5,7,48–50}

FETAL HEMOGLOBIN INDUCERS

HbF has a direct effect on polymer formation. Increases in HbF levels significantly correlate with decreased RBC sickling and RBC adhesion. Epidemiologic studies show a relationship between HbF concentration and severity of the disease. Patients with low HbF levels have more frequent crises and higher mortality. Based on these observations, HbF induction has become a treatment modality for patients with SCD.^{6,13}

Hydroxyurea

Hydroxyurea, a chemotherapeutic agent, increases HbF levels by stimulating the production of HbF. It also increases in the number of HbF-containing reticulocytes and intracellular HbF. Its antineoplastic activity is related to inhibition of DNA synthesis by blocking the conversion of ribonucleoside to deoxyribonucleotides. The exact mechanism on HbF production is unknown, but it alters RBC differentiation toward macrocytosis and HbF production as part of the erythropoietic response to cytorreduction in the bone marrow. In addition, hydroxyurea increases nitric oxide (NO) levels, which provides the rationale for the development of NO as a treatment modality for SCD.^{51–54} Hydroxyurea also reduces neutrophils and monocytes, has antioxidant properties, alters RBC membrane properties, increases RBC deformability by increasing intracellular water content, and decreases RBC adhesion to endothelium.^{5,51–53}

Hydroxyurea can prevent painful crises and is FDA-approved for adult patients based on a double-blind, placebo-controlled study called the Multicenter Study of Hydroxyurea in Sickle Cell Anemia (MSH). In that study of 299 adults with moderate-to-severe SCD, hydroxyurea significantly reduced the frequency of painful episodes, incidence of acute chest syndrome, need for blood transfusions, and number of hospitalizations.⁵¹ The average number of crises was 44% lower in those who received hydroxyurea, declining from 4.5 to 2.5 crises per year. The incidence of severe crises, defined as those requiring hospitalization, was also lower, with a median rate of 2.4 severe crises per year in the placebo group versus one severe crisis per year in the hydroxyurea group. The risk of acute chest syndrome was also significantly reduced in patients receiving hydroxyurea. Of the 152 patients in the hydroxyurea group, 25 (16%) developed acute

chest syndrome, as compared with 51 (35%) of the 147 patients in the placebo group. Blood transfusion requirements were decreased by 34% in the hydroxyurea group. The study was terminated early after interim analyses revealed the significant benefits. The incidence of death, stroke, and hepatic sequestration in the hydroxyurea and placebo groups was not significantly different during the 29-month evaluation period. However, the followup study of 233 of the 299 patients showed a 40% reduction in mortality with hydroxyurea over a 9-year period.⁵⁵ It is not clear whether the beneficial results can be extrapolated to patients with milder disease, such as HbSC.

Hydroxyurea is also used in selected children and adolescents with SCD, although its use is not FDA-approved in this patient population. Studies in pediatric patients (Pediatric Hydroxyurea in Sickle Cell Anemia) showed similar benefits as in adults with no adverse effects on growth and development. In addition, patients treated with 4 years of hydroxyurea therapy had possible delayed progression of organ dysfunction, such as splenic function. The results of another study, Pediatric Hydroxyurea Phase III Clinical Trial (BABY HUG), supported by the National Heart, Lung and Blood Institute will be available in the next few years to evaluate if hydroxyurea therapy is effective in prevention of chronic end-organ damage in young children with SCA.^{5,51,52,56–59}

The most common side effect of hydroxyurea is bone marrow suppression. In the MSH trial, 14 of 152 patients in the hydroxyurea group and 6 of 147 patients in the placebo group required permanent discontinuation of treatment because of medical reasons. Temporary discontinuation of therapy occurred in almost all patients because of bone marrow suppression, which usually recovered within 2 weeks.⁵¹ Alteration of magnesium levels, an cofactor in cation transport, has been reported in children.⁶⁰ Long-term side effects of hydroxyurea therapy in patients with SCD are not fully known. Myelodysplasia, acute leukemia, and chronic opportunistic infection associated with T-lymphocyte abnormalities have been reported.^{7,46,59} In the 9-year followup study, 3 of 233 patients treated with hydroxyurea have developed cancer.⁵⁵ However, only 23 of those patients received therapy for more than 8 years, a duration that had been associated with an increased risk of acute leukemia.⁶¹ Although no increased risk of cancer has been associated with hydroxyurea use of 2 to 15 years, a pilot study reported acquired DNA mutations in children.⁵¹ Longer followup is needed to determine its carcinogenic or leukemogenic effects. Teratogenicity is another concern, as high-dose hydroxyurea has been shown to be teratogenic in animals. Normal pregnancies resulting in no birth defects have been reported in at least 15 women receiving hydroxyurea.^{7,46}

Clinical indications for hydroxyurea use include frequent painful episodes, severe symptomatic anemia, a history of acute chest syndrome, or other severe vasoocclusive complications.^{7,46} It is not clear whether hydroxyurea prevents organ damage or reverses previous damage. Splenic regeneration, however, has been reported in adult patients who received the agent. Hydroxyurea does not appear to prevent neurologic complications but can preserve cognitive performance. Hydroxyurea does not prevent strokes, but when given with a transfusion program, it can play an important role in preventing recurrent strokes and reducing iron overload from transfusion.⁶² As discussed previously, hydroxyurea has been shown to decrease mortality in adult sickle cell patients in a 9-year followup study.^{33,55}

Hydroxyurea is available in 200-, 300-, 400-, and 500-mg capsules. For children who are unable to swallow capsules, liquid preparations (100 mg/mL) can be prepared extemporaneously. The starting dose for hydroxyurea is 10 to 15 mg/kg per day as a single daily dose (Fig. 106–6). The dosage can be increased after 8 to 12 weeks if the patient can tolerate the adverse effects and blood counts are stable. Hydroxyurea dosage should be individualized based on response and toxicity. In general, 3 to 6 months of daily administration are required before improvement is observed. Medication adherence can be an issue.

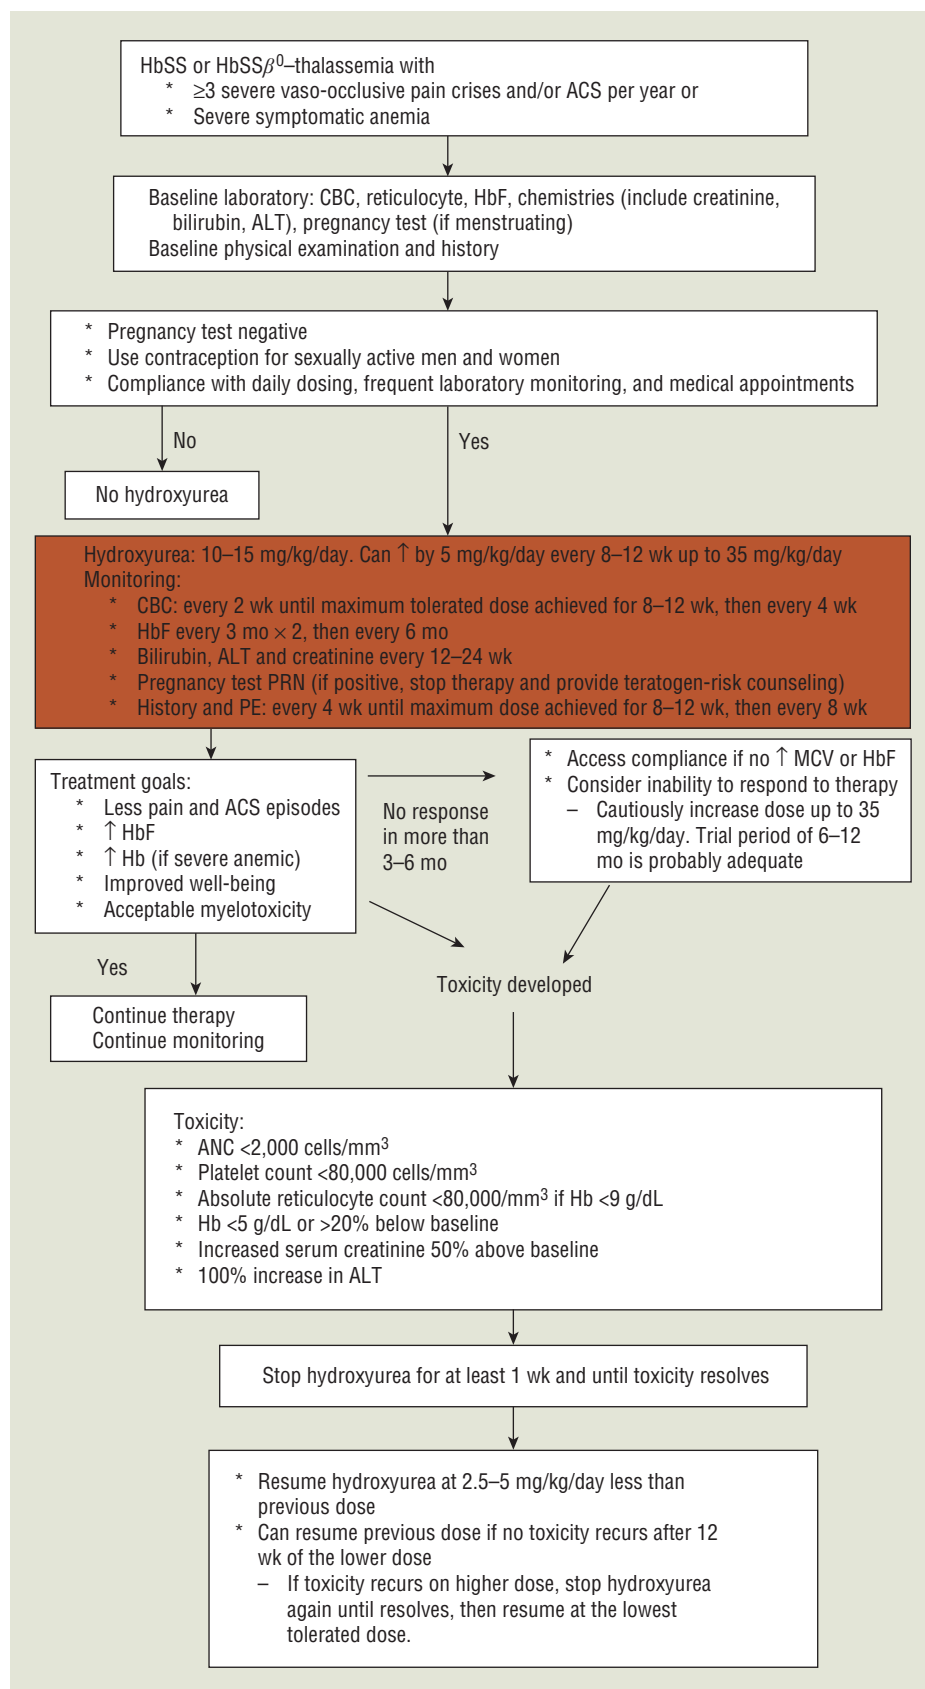

FIGURE 106-6. Hydroxyurea use in sickle cell disease. (ACS, acute chest syndrome; ALT, alanine aminotransferase; ANC, absolute neutrophil count; CBC, complete blood cell count; HbF, fetal hemoglobin; Hb, hemoglobin; HbSS, homozygous sickle cell hemoglobin; HbSS β^0 , sickle cell β^0 -thalassemia; MCV, mean corpuscular volume; PE, physical examination; PRN, as needed; RBC, red blood cell.) (From Stuart *et al.*,⁷ Sickle Cell Disease Care Consortium,⁴⁶ and Halsey and Roberts.⁵¹)

Since the mean corpuscular volume (MCV) generally increases as the level of HbF increases, monitoring the MCV is an inexpensive and convenient method of monitoring response. With close monitoring, hydroxyurea can be increased by 5 mg/kg per day up to 35 mg/kg per day, the maximal prescribed dose in the MSH study.^{7,46,51}

5 Patients receiving hydroxyurea should be closely monitored for toxicity. Blood counts should be checked every 2 weeks during dose titration and every 4 to 6 weeks thereafter. Treatment should be interrupted if hematologic indices fall below the following values: absolute neutrophil count, 2,000 cells/mm³; platelet count, 80,000

cells/mm³; hemoglobin, 5 g/dL; or reticulocytes, 80,000 cells/mm³ if the hemoglobin concentration is less than 9 g/dL. Other laboratory abnormalities warranting temporary discontinuation of therapy are a 50% increase in serum creatinine and a 100% increase in transaminase. After recovery has occurred, treatment should be resumed at a dose that is 2.5 to 5 mg/kg per day lower than the dose associated with toxicity. If no toxicity occurs after 12 weeks with the lower dose, the dose can be increased by 2.5 to 5 mg/kg per day. A given dose that twice produces a toxic hematologic response should not be tried again. Failure to see an increase in the MCV with hydroxyurea therapy can indicate that the marrow is unable to respond, the hydroxyurea dose is inadequate, or the patient is noncompliant.^{7,46,51}

Butyrate

Butyrate, a naturally occurring fatty acid, increases HbF by altering gene expression, which leads to increased γ -globin chain production. Unlike hydroxyurea, butyrate does not appear to be cytotoxic.

Butyrate has been studied in small number of adult patients. Initial trials with continuous infusion butyrate showed an increase in not only HbF, but also in total hemoglobin and in the number of cells containing HbF. However, a sustained effect or an associated clinical benefit has not been observed. A later study with arginine butyrate in a pulse regimen reported a sustained increase in HbF and reduction of hospitalized days in a small number of adult patients. In that study, adult patients received a 4-day course of arginine butyrate, followed by a 10- to 24-day drug-free period before the administration of the next dose. Arginine butyrate was given at a daily dose of 250 to 500 mg/kg over 6 to 12 hours. Although the results are encouraging, the need for intravenous administration can limit widespread use of the regimen.⁶³

Oral sodium phenylbutyrate has been used for years in young children with urea cycle disorders. At high doses, side effects include transient fluid retention, rashes, and unusual body odor. Increased HbF levels were seen in patients with SCA who received both high-dose (15 to 20 g/day) and low-dose (1 to 11 g/day) regimens. In the study of low-dose sodium phenylbutyrate, increased HbF was seen within 5 weeks but may not be sustained. The studies of butyrate involved a small number of patients. More clinical trials are needed to determine the optimal dosage and regimen.^{5,63}

5-Aza-2'-Deoxycytidine (Decitabine)

5-Azacytidine and 5-aza-2'-deoxycytidine (decitabine) induce HbF by inhibiting methylation of DNA, thus preventing the switch from γ - to β -globin production. Compared with 5-azacytidine, decitabine has a more favorable safety profile and is a more potent methylation inhibitor. Virtually abandoned in the past because of concerns regarding the cytotoxicity of 5-azacytidine, decitabine has been studied in a small number of patients with SCD who did not respond to hydroxyurea. In one study of eight patients who were resistant or intolerant to hydroxyurea, 5-aza-2'-deoxycytidine was given at a dose of 0.2 mg/kg one to three times a week subcutaneously. An increase in HbF was seen in all patients. In addition, reduction of adhesion was reported in the RBC adhesion study. The only significant toxicity observed was neutropenia. This agent may have a role in treating patients who fail to respond to hydroxyurea.^{5,64}

Combinations of Hemoglobin F Inducers

Erythropoietin therapy has been used in only a limited number of patients with SCD, and the clinical results have been inconsistent; therefore, its routine use in these patients cannot be recommended. When used in combination with hydroxyurea, erythropoietin increases HbF levels to a greater extent than hydroxyurea alone. This suggests that there may be a role for addition of erythropoietin therapy in patients who do not respond to hydroxyurea alone,

although more studies are needed. Other proposed combinations are hydroxyurea combined with either phenylbutyrate or clotrimazole, based on their different mechanisms of action.^{7,52,57,63}

■ CLOTRIMAZOLE

Clotrimazole, an antifungal agent, decreases cell density by blocking cation transport channels in the erythrocyte membrane. The decrease seen, however, is less than that demonstrated with hydroxyurea therapy. It is unclear whether this agent will be clinically useful in the treatment of SCA.⁵² Its analog, ICA-17043, is more specific for potassium efflux and is currently undergoing clinical trials for vasoocclusive event reduction.⁶⁵

■ CHRONIC TRANSFUSION THERAPY

Transfusions play an important role in the management of SCD. In acute illness, transfusions can be life-saving and will be discussed in a later section (see Chronic Transfusion Therapy). Maintenance transfusion programs are used to prevent serious complications of SCD. The primary indication for chronic transfusion is stroke prevention and amelioration of other organ damage. Transfusion can be done by simple or exchange transfusions. Exchange transfusion is associated with higher cost but has the advantage of limiting volume, and minimizing hyperviscosity and iron overload.⁶⁶

6 In children who had a stroke, chronic transfusions are successful in reducing stroke recurrence from approximately 50% to approximately 10% over 3 years. As the initial stroke in SCD can be devastating, transfusions are usually to prevent the initial stroke. In one trial, prophylactic transfusions significantly reduced the incidence of first stroke over a 2-year period in children 2 to 16 years of age with abnormal TCD ultrasonography. Stroke occurrence rate was reduced from 16% in patients receiving usual care to 2% in those who received prophylactic transfusions.^{66–68}

Chronic transfusions can also reduce the risk of vasoocclusive pain and acute chest syndrome, and prevent or delay progression of organ damage. They can also reverse preexisting organ dysfunction and improve quality of life, energy levels, exercise tolerance, growth, and sexual development. Selected patients in whom chronic transfusion should be considered are patients with transient ischemic attack, abnormal TCD, severe or recurrent acute chest syndrome, debilitating pain, splenic sequestration, recurrent priapism, chronic organ failure, intractable leg ulcers, severe chronic anemia with cardiac failure, and complicated pregnancies.^{5,46,66}

The goal of transfusions is to achieve and maintain an HbS concentration of less than 30% of total hemoglobin. Transfusions are usually given every 3 to 4 weeks, but the frequency of transfusion is adjusted to maintain the desired HbS levels. After 4 years of therapy without development of complications, many clinicians give transfusions less frequently and allow the HbS concentration to increase to 50% of total hemoglobin.^{4,5,46,66} The optimal duration of chronic primary prophylactic transfusion therapy is not clear, but discontinuation of transfusions has been associated with a 50% recurrence rate within 12 months and abnormal blood flow velocity in children. For secondary prevention, current recommendations are to continue transfusion for at least 5 years if there has been no neurologic event and imaging studies have been normalized or until age 18 years. A pilot study suggests that hydroxyurea should be started prior to discontinuation of transfusion for secondary stroke prevention.^{5,66–71}

Although the benefits of transfusion therapy are clear in some clinical situations, its role in other situations such as priapism and leg ulcer remains controversial.⁶⁶ The risks of transfusion therapy must be weighed against possible benefits. The risks associated with transfusion therapy include alloimmunization (sensitization to the blood received), hyperviscosity, viral transmission, volume overload, iron overload, and transfusion reactions. Alloimmunization occurs in 18% to 36% of SCD

patients who receive blood transfusions. The use of leukocyte-reduced RBC transfusions or human leukocyte antigen (HLA)-matched units in chronically transfused patients can reduce the risk of alloimmunization. Transfusion-related infections also remain a concern. All patients should be immunized with hepatitis A and B vaccines. Presently, hepatitis C is considered the most serious risk associated with transfusion therapy, with an infection rate of approximately 1 in every 100,000 transfusions. The risk of contracting acquired immune deficiency syndrome (AIDS) from blood transfusions, although still of concern, has decreased with routine blood screening. Iron overload is another complication of transfusions, and patients should be counseled to avoid excess dietary iron. Abnormal liver biopsy results showing mild to moderate inflammation or fibrosis have been reported. Chelation therapy with deferoxamine should be considered after more than 1 year of chronic transfusions or when serum ferritin is greater than 1,500 to 2,000 ng/mL.^{5,7,46,66} Deferoxamine has been associated with oto- and ocular toxicity and growth failure. Therefore, patients receiving chelation therapy should have yearly ophthalmologic and auditory examinations. Deferasirox, a new oral chelator, has shown effectiveness in management of iron overload in SCD. It has an advantage of being available as an oral dosage form.^{46,66,72,73}

Unique to the population with SCD is a constellation of features that can occur in response to blood transfusion; this is often referred to as the sickle cell hemolytic transfusion reaction syndrome. This syndrome includes manifestations of an acute or delayed transfusion reaction caused by alloimmunization. Delayed reaction can occur 2 to 20 days after transfusion. During the hemolytic reaction, the patient develops symptoms suggestive of a pain crisis, or symptoms worsen if the patient is already in crisis. The patient can also develop an anemia posttransfusion that is more severe than previously observed because of the rapid decline in hemoglobin and hematocrit, accompanied by a suppressed erythropoiesis. Reticulocytopenia is often seen in delayed hemolytic transfusion reactions. Alloantibodies and autoantibodies that formed as a result of past transfusions can serve as a trigger, causing a return of symptoms in the postrecovery period. Subsequent transfusions can further worsen the clinical situation because of the presence of autoimmune antibodies. Life-threatening events can be treated with steroids and intravenous immunoglobulin. Erythropoietin has been used in patients with reticulocytopenia. Recovery, as evidenced by reticulocytosis with a gradual increase in the hemoglobin level, may occur only after further transfusions are withheld. Although some patients tolerate further transfusions after recovery, others experience a recurrence of the hemolytic transfusion reaction.^{3,5,13,46,66,74}

■ ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION

Allogeneic hematopoietic stem cell transplantation (HSCT) is currently the only therapy that can cure patients with SCD.⁷⁵⁻⁷⁷ A report of a multicenter trial of allogeneic HSCT in 50 patients with SCD showed a 94% survival rate and 84% event-free survival. All of the patients in the study were younger than 16 years of age, had symptomatic SCD, and had an HLA-identical sibling donor. Two patients died from chronic graft-versus-host disease, and one died of intracranial hemorrhage. Of the 47 surviving patients, 5 experienced graft rejection and recurrent SCD. These rejections occurred a median of 5.1 months after transplantation.⁷⁵⁻⁷⁷ Pretransplant use of hydroxyurea has been associated with a lower incidence of rejection or failure of engraftment in a study of children with severe SCD.⁷⁸

The best candidates for allogeneic HSCT are SCD patients who are younger than 16 years of age; have severe complications such as refractory pain, stroke, or recurrent acute chest syndrome; and have an HLA-matched donor. Although allogeneic HSCT in young children before organ damage and alloimmunization occur can be associated with an increased success rate, disease progression is

unpredictable, making it difficult to determine the optimal time for transplantation. The risks associated with allogeneic HSCT must be carefully considered, as the transplant-related mortality rate is approximately 5% to 10%, and graft rejection is approximately 10%. The risk of acute or extensive chronic graft-versus-host disease ranges from 6% to more than 50% in various studies. Other risks associated with allogeneic HSCT include secondary malignancies. Neurologic events, such as intracranial hemorrhage and seizures during transplant were seen more frequently in patients with a history of stroke. In addition, transmission of chronic myeloid leukemia has been reported in a sickle cell patient who received a peripheral blood stem cell transplant. Efforts to decrease the posttransplant risk of seizures or intracranial bleeding include prophylactic anticonvulsant therapy, aggressive platelet support, and stringent patient selection.^{5,75-79}

Experience with unrelated HLA-matched or related HLA-mismatched donor transplants is very limited. Studies in thalassemia patients do not support the use of these alternate donors at this time. Umbilical cord blood is another donor source. Its advantages include a lower incidence of severe graft-versus-host disease and the potential of using umbilical cord blood from unrelated donors, but such advantages are balanced by longer duration for engraftment and a higher rate of graft rejection.^{5,75-79}

TREATMENT OF COMPLICATIONS

■ GENERAL MANAGEMENT

Parents and older children should be educated on the signs and symptoms of complications and conditions that require urgent evaluation. During acute illness, patients should be evaluated promptly, as deterioration can occur rapidly. It is essential to maintain a balanced fluid status because dehydration and fluid overload can worsen complications associated with SCD. Oxygen saturation by pulse oximetry should be maintained at least 92% or at baseline. New or increasing supplemental oxygen requirements should be investigated.^{5,7,46}

■ EPISODIC TRANSFUSIONS FOR ACUTE COMPLICATIONS

Indications for RBC transfusions include (1) acute exacerbation of baseline anemia, such as aplastic crisis if the anemia is severe, hepatic or splenic sequestration, or severe hemolysis; (2) severe vasoocclusive episodes, such as acute chest syndrome, stroke, or acute multi-organ failure; and (3) preparation for procedures that require the use of general anesthesia or ionic contrast. Other patients in whom transfusions can be useful include patients with complicated obstetric problems, refractory leg ulcers, or refractory and protracted painful episodes or severe priapism. Transfusion can be done by simple transfusion or partial exchange transfusion. If simple transfusion is used, volume overload leading to congestive heart failure can occur if anemia is corrected too rapidly in patients with severe anemia. In addition, increases in hemoglobin levels to greater than 10 to 11 g/dL can cause hyperviscosity and should be avoided.^{5,46,66}

■ INFECTION AND FEVER

Patients with SCD should be evaluated as soon as possible for any fever greater than 38.5°C (101.3°F). Criteria for hospitalization include an infant younger than 1 year old, history of previous bacteremia or sepsis, temperature greater than 40°C (104°F), WBC greater than 30,000 cells/mm³ or less than 5,000 cells/mm³ and/or platelets less than 100,000 cells/mm³, and evidence of other acute complications or toxic appearance. Outpatient management can be considered in older non-toxic children with reliable family caregivers. Antibiotic choice should provide adequate coverage for encapsulated organisms.

7 Ceftriaxone should be used for outpatient management because it provides coverage for 24 hours. If admitted, cefotaxime can also be used. For patients with cephalosporin allergy, clindamycin can be used. Vancomycin should be considered for acutely ill children or if staphylococcus is suspected. A macrolide antibiotic should be added if mycoplasma pneumonia is suspected. Penicillin prophylaxis should be discontinued while receiving broad-spectrum antibiotics. Acetaminophen or ibuprofen can be used for fever control. Increased fluid requirements can be needed because of dehydration and/or increased insensible loss.^{1,4,5,7,46}

■ CEREBROVASCULAR ACCIDENTS

Patients with acute neurologic events must be hospitalized and monitored closely. Physical and neurologic examination should be performed every 2 hours. Acute treatment for children should include exchange transfusion or simple transfusion to maintain hemoglobin at approximately 10 g/dL and HbS less than 30%, anticonvulsants for patients with a seizure history, and therapy for increased intracranial pressure if needed. Chronic transfusion therapy should be initiated for children with ischemic stroke as discussed above. In adults presenting with ischemic stroke, thrombolytic therapy should be considered if it is less than 3 hours since the onset of symptoms.^{1,4,5,7,24,46,67}

■ ACUTE CHEST SYNDROME

Patients with acute chest syndrome should use incentive spirometry frequently (e.g., at least every 2 hours while awake) to reduce atelectasis development. In addition, proper management of pain is important. The goal is to provide relief while avoiding analgesic-induced hypoventilation. Appropriate fluid therapy is important as overhydration can cause pulmonary edema and exacerbate respiratory distress. Early use of broad-spectrum antibiotics, including a macrolide or quinolone, is also recommended. Studies indicate that infection is common with acute chest syndrome, and can involve gram-positive, gram-negative, or atypical bacteria. Oxygen therapy is indicated for all patients who are hypoxic or in acute distress. In a patient with a history of reactive airway disease or wheezing on examination, a trial of bronchodilators is appropriate. Transfusions are often used in the treatment of acute lung disease.^{5,7,30,31,80}

Steroids can decrease inflammation and endothelial cell adhesion. Glucocorticoids can decrease the duration of hospitalization, transfusions, and need for other supportive care but can increase the readmission rate for SCA-related complications. Another promising therapy is the use of NO. NO inhalation relaxes and dilates blood vessels. Its hematologic effects include inhibition of platelet aggregation and reduction in the polymerization tendency of HbS. Marked improvement of pulmonary status and cardiac output has been reported in a patient with acute chest syndrome. Both inhaled NO and oral L-arginine, the precursor of NO, are being evaluated for management of acute chest syndrome.^{30,31,80}

■ PRIAPISM

Stuttering priapism, episodes that last a few minutes to 2 hours, resolve spontaneously. Prolonged episodes lasting more than 2 to 3 hours require prompt medical attention. The initial goals of treatment are to provide appropriate analgesic therapy, reduce anxiety, produce detumescence, and preserve testicular function and fertility. Treatment given within 4 to 6 hours can usually reduce erection. Aggressive hydration and adequate pain control should be initiated. Use of ice packs is not recommended. Heat (hot water bottles, hot packs, or sitz baths) can provide comfort without precipitating pain crisis. Although transfusions have been given to these patients, the efficacy of this therapeutic intervention has not been established.^{1,5,81,82}

Clinicians have used both vasoconstrictors and vasodilators in the treatment of priapism. Vasoconstrictors, such as diluted phenylephrine (10 microgram/mL) or epinephrine (1:1,000,000), are thought to work by forcing blood out of the corpus cavernosum into the venous return. In one uncontrolled open-label study, aspiration followed by intrapenile irrigation with epinephrine was effective and well tolerated. In that study, blood was first aspirated from the corpus cavernosum, and then the area was irrigated with a 1:1,000,000 solution of epinephrine. The priapism resolved in 37 of the 39 occasions. A followup study reported that 3 out of 20 patients required a repeat procedure within 24 hours. The therapy was well tolerated with no serious immediate or long-term side effects but on two occasions, a small intrapenile hematoma formed after treatment.⁸²

Vasodilators, such as terbutaline and hydralazine, relax the smooth muscle of the vasculature. This relaxation allows oxygenated arterial blood to enter the corpus cavernosum, which displaces or washes out the damaged sickle cells that are stagnant in the corpus cavernosum. Terbutaline has been used to treat priapism, but it has not been formally studied in patients with SCA. In one case report, a single oral sildenafil dose at onset of priapism aborted episodes. Surgical interventions used in severe refractory priapism have included a variety of shunt procedures. These surgical procedures have been successful in some cases, but they have a high failure rate and potential serious complications, which include impotence, skin sloughing, cellulitis, and urethral fistulas.^{5,7,82}

Modalities to prevent priapism are limited and not well studied. Pseudoephedrine (30 or 60 mg/day given orally at bedtime) and leuprolide, a gonadotropin-releasing hormone, have been used to decrease the number of recurrent episodes of priapism. Hydroxyurea therapy can also be useful. Finally, low-doses of an antiandrogen, bicalutamide, have been used in two patients with SCD and one patient with spinal cord injury for treatment of recurrent and refractory priapism without major side effects.^{5,7,46,82,83} The role of RBC transfusion in preventing priapism remains unclear.^{66,82}

CLINICAL CONTROVERSY

Some clinicians transfuse patients to maintain an HbS level less than 30% to prevent recurrent priapism. Duration of such regimens should be limited to 6 to 12 months.

■ MANAGEMENT OF CRISES

Aplastic Crisis

Treatment of aplastic crisis is primarily supportive, and most patients recover spontaneously. The patient can need blood transfusions if the anemia is severe or symptomatic. Reticulocyte count helps to determine if there is red cell production and the need for transfusions. The most common cause for aplastic crisis is acute infection with human parvovirus B19. As parvovirus is contagious, infected patients should be placed in isolation. In addition, contact with pregnant healthcare providers should be avoided because parvovirus infection during the midtrimester of pregnancy can result in hydrops fetalis and stillbirth.^{4,5,7,46}

Sequestration Crisis

Splenic sequestration crisis is a major cause of mortality in young patients with SCD. The sequestration of RBCs in the spleen can result in a rapid drop of hematocrit, leading to hypovolemia, shock, and death. Immediate treatment is RBC transfusion to correct hypovolemia. Broad-spectrum antibiotic therapy, which includes coverage for pneumococci and *H. influenzae*, can also be beneficial because infection can precipitate crises.^{4,5,7,46}

Recurrent episodes occur in approximately one-half of patients and are associated with increased mortality. Options for management of recurrence include observation, chronic transfusion, and splenectomy. Adults are often observed because they tend to have milder episodes. Increased risk of invasive infection after splenectomy is a concern in young children. Chronic transfusions delay splenectomy and temporarily restore splenic function, but it is associated with its own risks. Splenectomy is probably indicated, even after a single sequestration crisis, if that event is life-threatening. Splenectomy should be considered after repetitive episodes, even if they are less serious. For children younger than 2 years of age, chronic blood transfusions are recommended to prevent sequestration and delay splenectomy until the age of 2 years, when the risk of postsplenectomy septicemia is less. Finally, splenectomy should also be considered for patients with chronic hypersplenism.^{1,4,5,7,46}

Vasoocclusive Pain Crisis

Hydration and analgesia are the mainstays of treatment for vasoocclusive (painful) crises (Table 106-4). Patients with mild pain crisis can be treated as outpatients with rest, increased fluid intake, warm compresses, and oral analgesics. Hospitalization is necessary for moderate to severe crisis. As infection can precipitate crises, an infectious etiology should be ruled out and appropriate empiric therapy should be initiated in patients who have fever or are critically ill. In anemic patients, transfusion to maintain the hemoglobin level at baseline can be needed. Fluid replacement given intravenously or orally at 1.5 times the maintenance requirement is recommended. Close monitoring of fluid status is essential as aggressive hydration, particularly with sodium-containing fluids, can lead to volume overload, acute chest syndrome, and heart failure.^{4,5,7,46}

The frequency and severity of acute pain episodes associated with SCD are variable, and pain should be assessed, and analgesic therapy should be tailored for each patient. Several pain assessment tools are available and should be used to quantify the degree of pain. Unfortunately, they have not been validated for sickle cell pain. The healthcare provider should choose one tool appropriate for age and use it routinely to assess pain. Other useful information to guide choice of analgesics should include previous effective agents and their dosages, response to therapy and previous clinical course, and duration of pain crisis.⁸⁴⁻⁸⁵

8 Aggressive therapy that relieves pain and enables the patient to attain maximum functional ability should be initiated in patients with pain crisis. Treatment of mild-to-moderate pain should include the use of nonsteroidal antiinflammatory drugs (NSAIDs) or acetaminophen, unless there are contraindications to their use. Ketorolac is the only injectable NSAID available and is useful for patients requiring intravenous therapy. Because of concerns about gastrointestinal bleeding, it is recommended to limit the duration of therapy to 5 days or less. When acetaminophen is used, it is important to review the total dose of acetaminophen administered in patients who may also be receiving the agent for fever or another acetaminophen-containing product for pain. If mild-to-moderate pain persists, an opioid should be added. Effective combination therapy, such as an NSAID combined with an opioid, can enhance analgesic efficacy while decreasing side effects.^{7,84-86}

Severe pain should be treated aggressively until the pain is tolerable. Commonly used opioids include morphine, hydromorphone, fentanyl, and methadone. The weak opioids, codeine and hydrocodone, are used to manage mild-to-moderate pain. Meperidine has no advantages as an analgesic. Its duration of action is short compared to the half-life of the metabolite, normeperidine. The accumulation of normeperidine can cause central nervous system side effects, ranging from dysphoria to seizures. Therefore, meperidine should be avoided if possible and used only for a very brief duration in patients who are allergic or intolerant to other opioids.^{7,84-86}

TABLE 106-4 Management of Acute Pain of Sickle Cell Disease

Principles

- Treat underlying precipitating factors
- Avoid delays in analgesia administration
- Use pain scale to assess severity
- Choice of initial analgesic should be based on previous pain crisis pattern, history of response, current status, and other medical conditions
- Schedule pain medication; avoid as-needed dosing
- Provide rescue dose for breakthrough pain
- If adequate pain relief can be achieved with one or two doses of morphine, consider outpatient management with a weak opioid; otherwise hospitalization is needed for parenteral analgesics
- Frequently assess to evaluate pain severity and side effects; titrate dose as needed
- Treating adverse effects of opioids is part of pain management
- Consider nonpharmacologic intervention (e.g., relaxation techniques, guided imagery, deep breathing)
- Transition to oral analgesics as the patient improves; choose an oral agent based on previous history, anticipated duration, and ability to swallow tablets; if sustained-release products are used, a product with a rapid onset is also needed for breakthrough pain

Analgesic regimens

Mild-to-moderate pain: nonopioid ± weak opioid

Moderate-to-severe pain: weak opioid or low dose of a strong opioid ± nonopioid

Severe pain: strong opioid + nonopioid

Weak opioid

Acetaminophen with codeine

Dose based on codeine—children: 1 mg/kg per dose every 6 hours; adult: 30 to 60 mg/dose

Hydrocodone + acetaminophen

Dose based on hydrocodone—children: 0.2 mg/kg per dose every 6 hours; adults: 5 to 10 mg/dose

Nonopioid

Oral antiinflammatory agents

Use with caution in patients with renal failure (dehydration) and bleeding

Ibuprofen—children: 10 mg/kg every 6 to 8 hours; adult: 200 to 400 mg/dose

Naproxen: 5 mg/kg every 12 hours; adult 250 to 500 mg/dose

Intravenous antiinflammatory agents:

Ketorolac: 0.5 mg/kg up to 30 mg/dose every 6 hours

Strong opioid

Morphine: 0.1 to 0.15 mg/kg per dose every 3 to 4 hours for children; 5 to 10 mg/dose for adults

Continuous infusion: 0.04 to 0.05 mg/kg per hour; titrate to effect

Hydromorphone: 0.015 mg/kg per dose every 3 to 4 hours for children; 1.5 to 2 mg/dose for adults

Continuous infusion: 0.004 mg/kg per hour; titrate to effect

Patient-controlled analgesics:

Morphine: 0.01 to 0.03 mg/kg per hours basal; demand 0.01 to 0.03 mg/kg every 6 to 10 min; 4-hour lock out 0.4 to 0.6 mg/kg

Hydromorphone: 0.003 to 0.005 mg/kg per hour basal; demand 0.03 to 0.05 mg/kg every 6–10 minutes; 4 hour lock out 0.06 to 0.08 mg/kg

Rescue therapy:

For breakthrough, give 1/4 to 1/2 of the scheduled dose as bolus every 1 to 2 hour; assess amount of rescue dose used in 8 to 12 hours and readjust scheduled dose or infusion rate as needed

Other adjunct therapy:

Hydration, heating pads, relaxation, and distraction

Stool softener and/or stimulants for constipation

Antihistamine for itching

Antiemetics for nausea or vomiting

From Jacob et al,⁸⁴ Stinson and Naser,⁸⁵ Dumaplin,⁸⁶ and Elander et al.⁸⁷

Both prior history and current assessment should be considered in the management of pain crisis. For patients whose typical crisis improves in a short time, preparations with a short duration of action are appropriate. For patients whose crises require many days to resolve, sustained-release preparations combined with a short-acting product for breakthrough pain are more appropriate. If the patient has been on long-term opioid therapy at home, tolerance can develop. In these cases, the pain of acute crises can be treated with a different potent opioid or a larger dose of the same medication.

Intravenous administration provides a rapid onset of action and therefore is preferred for severe pain. Intramuscular injections should be avoided. Children might actually deny pain because of fear of injections. Analgesics should be titrated to pain relief. In patients with continuous pain, the analgesic should be given as a scheduled dose or continuous infusion. Continuous infusion has the advantage of less fluctuation of blood levels between dosing intervals. As-needed dosing is only appropriate for breakthrough pain. Patient-controlled analgesia (PCA) is commonly used. When used properly, PCA allows patients to have control over pain therapy and minimizes the lag time between perception of pain and administration of analgesics. The transdermal fentanyl patch has also been used successfully, but its role in sickle cell pain crisis is unclear because of its long time of onset of pain relief (12 to 16 hours) and fixed dosage form, which makes it difficult to titrate the dose. Other alternative pain management techniques such as physical therapy and relaxation therapy can be helpful as adjunct therapy.^{7,84–86}

The most common cause of suboptimal pain control in children with SCA is the suspicion of addiction. This obstacle is especially common in adolescents. In one study, 53% of emergency physicians believed that 20% of SCD patients are addicted to analgesics. Elander and associates interviewed 51 SCD patients and used symptoms described in the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition* to assess substance dependence. They reported that when pain-related symptoms are included, 31% met criteria for substance dependence, but when symptoms are restricted to those that are not pain related, only 2% met the criteria for substance dependence. Another barrier for effective pain control is the difference in perception between patients, family, and healthcare providers. Patients with SCD often suffer from chronic pain, and they may cope with the pain by being inactive. Patients who have inadequate pain control can exhibit anxiety and drug-seeking behavior for fear of pain. Tolerance to narcotics can also be misinterpreted as drug addiction by healthcare providers and families. Aggressive pain control, frequent monitoring of pain during crises, and tapering medication according to response are factors that minimize physical dependence.^{84–89}

Poloxamer 188 (FloCor), a highly purified poloxamer, is an agent currently being evaluated under orphan drug status for the management of vasoocclusive pain crisis in SCD. It acts as a surfactant and normalizes the RBC to its nonadhesive state. In addition, it enhances blood flow in ischemic areas by blocking RBC aggregation. The antiadhesive and hemorheologic properties result in improved blood flow, increased oxygen delivery, and decreased cell injury. A phase III clinical study conducted in adults and children aged 8 to 65 years old with vasoocclusive crises reported more rapid resolution in those treated with poloxamer 188. Patients younger than 15 years and those who were receiving hydroxyurea therapy were two groups that appeared to have the most beneficial effect.⁹⁰

Intracellular adhesion of RBCs contributes to vasoocclusion in SCD. Agents that can alter adhesion molecules on RBCs can potentially reduce or ameliorate clinical manifestation of SCD. Omega-3 fatty acids are important components of cell membrane and organelles and may be important for erythrocyte integrity and play a role in reducing hemolysis. In addition, omega-3 fatty acids have anti-adhesion activity by modulating adhesive molecules in membrane. Reduction of disease severity has been reported in clinical trials.⁹¹

PHARMACOECONOMIC CONSIDERATIONS

Patients with SCD incur considerable healthcare costs. Pharmacoeconomic considerations should include newborn screening, cost of managing acute and chronic complications, and the economic impact of new treatment modalities. Early penicillin prophylaxis prevents pneumococcal sepsis in infants. Newborn screening targeted at Afri-

can Americans has been shown to be cost-effective. Whether it is cost-effective to screen all infants depends on the prevalence of high-risk infants in the area. The estimated annual cost through universal screening programs ranged from \$1,402 in Mississippi to \$304,215 in Vermont per case identified. In general, universal screening identifies more infants with disease, prevents more deaths, and can provide for a certain degree of cost-effectiveness because targeted screening might not detect all infants with the disease.^{8,92}

Hospitalization is an important societal financial burden. A 1996 national estimate reported the average cost per hospitalization to be \$6,300, which totals a cost of \$475 million per year. Studies conducted in various regions have shown that a small number of patients consume a disproportionate amount of care as a result of severe illness, and most of the total cost is related to hospitalizations. Patients who are not being followed in settings that provide comprehensive medical care tend to acquire higher costs for emergency room and hospital visits. Another study examining relationships between socioeconomic factors and geographic distribution in Alabama reported that use of comprehensive care was lower for those living in rural areas. Using a mathematical model and data available from studies, researchers estimated lifetime costs for SCA and other hemoglobinopathies to be \$83,200 for patients with early diagnoses and \$78,400 for late diagnosis.^{3,8,93,94}

Newer therapies, diagnostic methods such as TCD, and chronic transfusions further increase cost. Using the data from the MSH trial, Moore and colleagues estimated that the average annual cost for medical care was lower in the hydroxyurea group as compared with the placebo group (\$12,160 vs. \$22,020). Hospitalization because of pain crisis accounted for the highest cost in both groups and a saving of more than 5,000 per patient per year of medical costs can be achieved if every eligible patient was to receive the agent.⁹⁴ However, this cost-saving was not demonstrated in one analysis performed in Maryland.⁹⁵ Allogeneic HSCT can potentially cure the disease, and if successful can reduce long-term costs, but it requires a high up-front cost. The new therapies, although expensive, might reduce visits to emergency departments and inpatient hospitalizations, improving the cost-effectiveness of those therapies over a patient's lifetime.⁷

EVALUATION OF THERAPEUTIC OUTCOMES

SCD is a complex disorder that requires multidisciplinary comprehensive care. All patients should be medically evaluated regularly to establish baseline, monitor changes, and provide education appropriate for age. For infants younger than 1 year old, medical evaluations every 2 to 4 months are needed. Beyond 1 year of age, evaluation can be extended to every 6 to 12 months with modifications depending on severity of the illness.⁴⁶

It is important to establish baseline laboratory values and imaging studies. Routine laboratory evaluation includes complete blood cell counts and reticulocyte counts every 3 months up to 2 years of age, then every 6 months; HbF level should be taken every 6 months until 2 years of age, then annually. Evaluation of renal, hepatobiliary, and pulmonary function should be done annually. TCD screening is recommended to start at age 2 years, then annually. Ophthalmologic examination to screen for retinopathy is recommended at around age 10 years. In patients with recurrent acute chest syndrome, pulmonary function tests should be done to establish baseline values and identify declines in lung function.

It is essential that prophylactic immunizations and antibiotics are given. When infections do occur, appropriate antibiotic therapy should be initiated, and the patient should be monitored for laboratory and clinical improvement. The efficacy of hydroxyurea can best be assessed in terms of the decrease in number, severity, and duration of sickle cell pain crises. HbF concentrations or MCV values can also provide some indication of the patient's response to therapy. When painful crises do occur, the effectiveness of analge-

sics can be measured by subjective assessments made by the patient, family, and healthcare practitioners. The success of poststroke blood transfusions can be measured by clinical progression or the occurrence of subsequent strokes.

CONCLUSIONS

The goals of the general management of SCA are to decrease the number of sickle cell crises, decrease the complications arising from the disease, and improve the overall quality of the patient's life. The general care of SCA patients still includes early penicillin prophylaxis and appropriate immunization. HbF inducers such as hydroxyurea can decrease the frequency and severity of painful episodes. Continued studies of other possible agents and treatment modalities that can reduce crises or reverse organ damage are warranted.

ABBREVIATIONS

ASPEN syndrome: association of sickle cell disease, priapism, exchange transfusion, and neurologic events
 HbAS: one normal (hemoglobin A) and one sickle cell hemoglobin (hemoglobin S) geneHbC: Hemoglobin C
 HbF: fetal hemoglobin
 HbS β^+ -thal, HbS β^0 -thal: hemoglobin sickle cell β^+ -thalassemia and hemoglobin sickle cell β^0 -thalassemia
 HbSC: sickle cell hemoglobin C
 HbSS: homozygous sickle cell hemoglobin (hemoglobin S)
 HbS: sickle cell hemoglobin
 HLA: human leukocyte antigen
 HSCT: hematopoietic stem cell transplantation
 ISC: irreversibly sickled cell
 MCHC: mean corpuscular hemoglobin concentration
 MCV: mean corpuscular volume
 MSH: Multicenter Study of Hydroxyurea in Sickle Cell Anemia
 NO: nitric oxide
 NSAID: nonsteroidal antiinflammatory drug
 PCA: patient-controlled analgesia
 PCV7: 7-valent pneumococcal conjugate vaccine
 PPV 23: 23-valent pneumococcal polysaccharide vaccine
 RBC: red blood cell
 SCA: sickle cell anemia
 SCD: sickle cell disease
 SCT: sickle cell trait
 TCD: transcranial Doppler
 WBC: white blood cell

KEY CONCEPTS

- 1 The most common drug-induced hematologic disorders include aplastic anemia, agranulocytosis, megaloblastic anemia, hemolytic anemia, and thrombocytopenia.
- 2 Drug-induced hematologic disorders are generally rare adverse effects associated with drug therapy.
- 3 Reporting during postmarketing surveillance of a drug is usually the method by which the incidence of rare adverse drug reactions is established.
- 4 Because drug-induced blood disorders are potentially dangerous, rechallenging a patient with a suspected agent in an attempt to confirm a diagnosis may not be ethical.
- 5 The mechanisms of drug-induced hematologic disorders are the result of direct toxicity or an immune reaction.
- 6 The primary treatment of drug-induced hematologic disorders is removal of the drug in question and symptomatic support of the patient.
- 7 Frequent laboratory monitoring may be warranted for agents commonly demonstrating severe hematologic reactions.

1 Hematologic disorders have long been a potential risk of modern pharmacotherapy. Granulocytopenia (agranulocytosis) was reported in association with one of medicine's early therapeutic agents, sulfanilamide, in 1938.¹ Some agents cause predictable hematologic disease (e.g., antineoplastics), but others induce idiosyncratic reactions not directly related to the drugs' pharmacology. The most common drug-induced hematologic disorders include aplastic anemia, agranulocytosis, megaloblastic anemia, hemolytic anemia, and thrombocytopenia.

2 The incidence of idiosyncratic drug-induced hematologic disorders varies depending on the condition and the associated drug. Few epidemiologic studies have evaluated the actual incidence of these adverse reactions, but these reactions appear to be rare. A report from the Netherlands estimated the incidence of drug-associated agranulocytosis as 1.6 to 2.5 cases per million inhabitants per year.² Similar results were reported in epidemiologic studies conducted in Thailand and Brazil.^{3,4} However, the incidence of drug-induced thrombocytopenia is more frequent, with some reports

suggesting that as many as 5% of patients who receive heparin develop heparin-induced thrombocytopenia.⁵

Although drug-induced hematologic disorders are less common than other types of adverse reactions, they are important because they are associated with significant morbidity and mortality. An epidemiologic study conducted in the United States estimated that 4,490 deaths in 1984 were attributable to blood dyscrasias from all causes. Aplastic anemia was the leading cause of death, followed by thrombocytopenia, agranulocytosis, and hemolytic anemia.⁶ Like most other adverse drug reactions, drug-induced hematologic disorders are more common in the elderly than in the young; the risk of death also appears to be greater with increasing age. The risk of agranulocytosis has been reported to be higher in women than in men.⁴

3 Because of the seriousness of drug-induced hematologic disorders, it is necessary to track the development of these disorders to predict their occurrence and to estimate their incidence. Reporting during postmarketing surveillance of a drug is the most common method of establishing the incidence of adverse drug reactions. The MedWatch program supported by the Food and Drug Administration is one such program.⁷ Many facilities have similar drug-reporting programs to follow adverse drug reaction trends and to determine whether an association between a drug and an adverse drug reaction is causal or coincidental. In the case of drug-induced hematologic disorders, these programs can enable practitioners to confirm that an adverse event is indeed the result of drug therapy rather than one of many other potential causes; general guidelines are readily available.^{8,9}

4 Because drug-induced blood disorders are potentially dangerous, rechallenging a patient with a suspected agent in an attempt to confirm a diagnosis may not be ethical. In-vitro studies with the offending agent and cells or plasma from the patient's blood can be performed to determine causality.¹⁰ These methods are often expensive, however, and require facilities and expertise that are not generally available. Therefore, it is extremely important that practitioners be able to clinically evaluate suspect drugs quickly and to interrupt therapy when necessary.

Throughout the past decades, lists of drugs that have been associated with adverse events have been developed to help clinicians identify possible causes. Unfortunately, these lists are comprehensive and include commonly used drugs, making it difficult to determine the cause of any abnormality. Furthermore, the absence of a drug from such a list should not discourage the investigation and reporting of an agent associated with an adverse event. It is imperative that clinicians use a rational approach to determine causality and identify the agents associated with a reaction. The clinician should focus on the issue, perform a rigorous investigation, develop appropriate criteria, use objective criteria to grade the response, and complete a quantitative summary. A systematic approach to evaluate the information available in the literature also helps the clinician to focus and intervene in the cause of the disorder.

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

A common tool employed by clinicians to rate the likelihood of causality in adverse drug reaction (ADR) investigations is an ADR probability scale (algorithm). One such scale was developed and tested by Naranjo and colleagues.¹¹ This tool provides a series of scored questions that lead an investigator to the likelihood that an ADR was caused by the suspected medication. Depending on the aggregate score, the causality is rated as *doubtful*, *possible*, *probable*, or *definite*. The scale gives the most weight to the temporal relationship of the reaction with relation to administration of the drug, observations following a rechallenge of the suspected medication, and alternate explanations for the ADR. As mentioned above, it is often unethical to rechallenge patients who experience severe hematologic toxicities. Thus without a rechallenge it is difficult to achieve a causality rating of *definite* with such an algorithm.

In determining the likelihood that an observed reaction is caused by a particular medication, clinicians should review the medical literature for past reports supporting the observation. Using an evidence-based approach such as that proposed by Sackett,¹² the investigator assigns greater weight to prospective study designs such as clinical trials or cohort studies than to case reports or expert opinion. This will provide a framework for the investigator's confidence in published literature describing ADRs.

In this chapter, we use both methods described to review and present published information on hematologic drug toxicities. When only case reports were available, the Naranjo algorithm was applied to the cases (if not already used). *Definite* and those rated as *probable* when only a lack of rechallenge prevented a rating of *definite* were included in the lists. An evidence-based approach was incorporated through a review of the medical literature for prospective and retrospective studies of the adverse reactions and medications of interest. Drugs significantly associated with an adverse reaction of interest through studies were also deemed to have a causal relationship to the reaction.

The understanding of drug-induced hematologic disorders requires a basic understanding of hematopoiesis (see Chap. 103 on hematopoiesis). The pluripotential hematopoietic stem cells in the bone marrow, which have the ability to self-reproduce, maintain the blood. These pluripotential hematopoietic stem cells further differentiate to intermediate precursor cells, which are also called *progenitor cells* or *colony-forming cells*. Committed to a particular cell line, these intermediate stem cells differentiate into colonies of each type of blood cell in response to specific colony-stimulating factors (Fig. 107-1).

Drug-induced hematologic disorders can affect any cell line, including white blood cells (WBCs), red blood cells (RBCs), and platelets. When a drug causes decreases in all three cell lines accompanied by a hypoplastic bone marrow, the result is drug-induced aplastic anemia. The decrease in WBC count alone by a medication is drug-induced agranulocytosis. Drugs can affect RBCs by causing a number of different anemias, including drug-induced immune hemolytic anemia, drug-induced oxidative hemolytic anemia, or drug-induced megaloblastic anemia. A drug-induced decrease in platelet count is drug-induced thrombocytopenia.

DRUG-INDUCED APLASTIC ANEMIA

Aplastic anemia is a rare, serious disease of unclear etiology. It was first described by Ehrlich in 1888 following an episode of failed hematopoiesis identified during the autopsy of a pregnant woman.¹³ Since that first report, numerous cases of aplastic anemia have been described, but the true incidence of the disease remains uncertain. Best estimates report an incidence of two to seven cases per million inhabitants.¹⁴⁻¹⁶ Interestingly, the incidence of aplastic anemia is different in different regions, which suggests an environmental component to the etiology of this condition.^{14,15,17} There is also debate regarding the peak age at

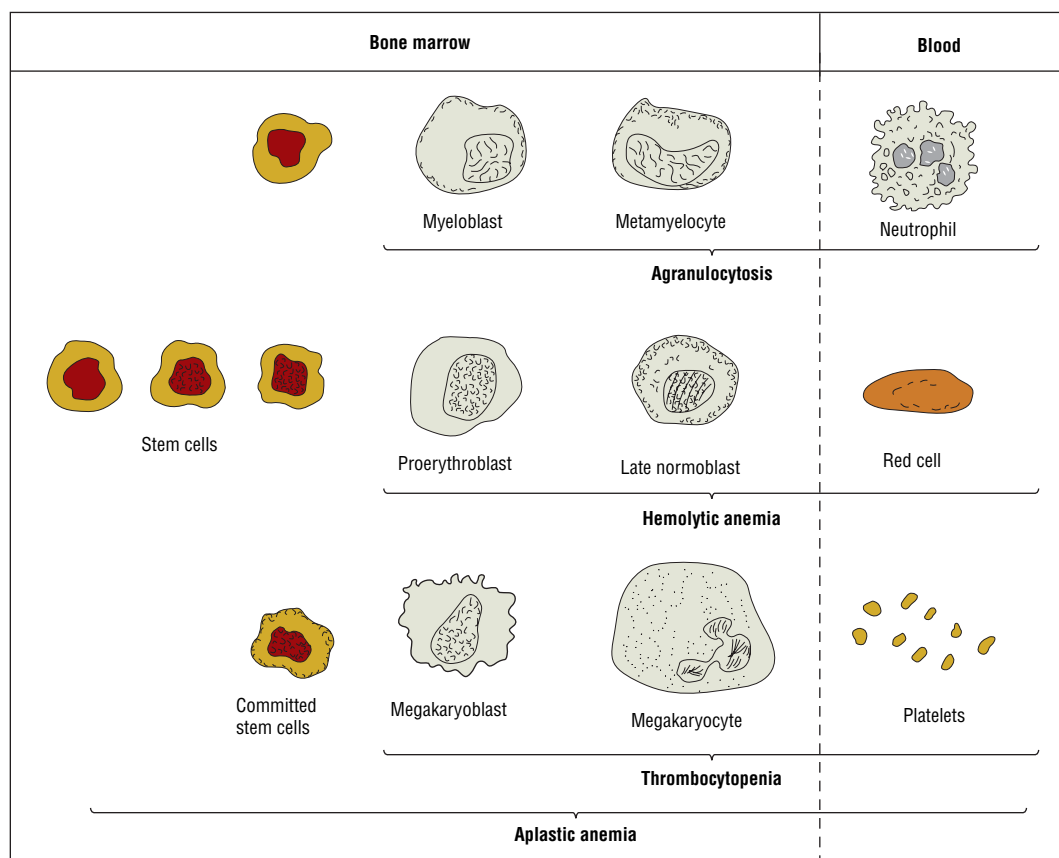

FIGURE 107-1. Differentiation of the stem cell into committed cell lines, illustrating the origins of various drug-induced hematologic disorders.

which aplastic anemia is most common. Some authors have reported a peak incidence in patients younger than 30 years of age, although others report the highest incidence in those older than 60 years of age.^{14,17–19} When the results of all studies are considered, the young and elderly appear to be at increased risk for the development of aplastic anemia.

Aplastic anemia can be broken down into two very broad categories—inherited and acquired. Although this chapter will focus on one specific type of acquired aplastic anemia, it is important to be aware of inherited disorders of bone marrow failure because they can be misdiagnosed as acquired.¹⁸ Inherited types of bone marrow failure typically present in the first decade of life, are often associated with physical anomalies (e.g., short stature and café-au-lait spots), and rarely respond to immunosuppressive therapies.¹⁸ Acquired aplastic anemia accounts for the large majority of cases, and as with many other autoimmune disorders, genetic factors may predispose some patients to acquire aplastic anemia.^{20,21} A number of variables can incite immune destruction of the bone marrow; the most common are drugs, insecticides, benzene and other chemical exposure, viruses, and radiation. It has been estimated that 25% to 40% of aplastic anemia cases are related to one of these external factors.²² However, in the large majority of modern cases, a definitive causative agent cannot be identified.^{18,23}

Aplastic anemia is characterized by pancytopenia (presence of anemia, neutropenia, and thrombocytopenia) with a hypocellular bone marrow and no gross evidence of increased peripheral blood cell destruction.²⁴ A diagnosis of aplastic anemia can be made by the presence of two of the following criteria: a WBC count of 3,500 cells/mm³ or less, a platelet count of 55,000 cells/mm³ or less, or a hemoglobin value of 10 g/dL or less with a reticulocyte count of 30,000 cells/mm³ or less.²⁵ However, all of these blood counts do not decrease at the same rate.

Once diagnosed, acquired aplastic anemia can be classified as nonsevere, severe, or very severe based on the degree of bone marrow cellularity and peripheral neutrophil, platelet, and reticulocyte counts. Severe aplastic anemia is defined by at least two of the following three peripheral blood findings: neutrophil count of less than 500 cells/mm³, platelet count of less than 20,000 cells/mm³, and anemia with a corrected reticulocyte index of less than 1%.^{26,27} The prognosis is poor if the neutrophil count declines to less than 200 cells/mm³.^{32,28} A bone marrow aspirate and biopsy are required to exclude other causes of pancytopenia, including neoplastic infiltration or significant myelofibrosis.²⁹ There must also be no history of iatrogenic exposure to cytotoxic chemotherapy that is known to cause transient bone marrow suppression or to intensive radiation.

Aplastic anemia is considered the most serious drug-induced blood dyscrasia because of the associated high mortality rate as compared to other blood dyscrasias.^{26,30} The onset of drug-induced aplastic anemia is variable and insidious. Symptoms have been reported to appear from days to months after initiation of the offending drug, with the average being approximately 6.5 weeks.²⁸ In some instances, symptoms appear after the drug has been discontinued. Neutropenia typically presents first, followed by thrombocytopenia and finally, because of the longer life span of the RBCs, anemia evolves slowly.³¹ Clinical features of drug-induced aplastic anemia depend on the degree to which each cell line is suppressed, similar to idiopathic disease. Symptoms of anemia include pallor, fatigue and weakness, whereas fever, chills, pharyngitis, or other signs of infection can characterize neutropenia. Thrombocytopenia, often the initial clue to diagnosis, is manifest by easy bruisability, petechiae, and bleeding.

5 The cause of drug-induced aplastic anemia is damage to the pluripotential hematopoietic stem cells before their differentiation to committed stem cells. This damage effectively reduces the normal levels of circulating erythrocytes, neutrophils, and platelets. Three mechanisms have been proposed as causes of damage to the pluripo-

tential hematopoietic stem cells.³² The first is direct, dose-dependent drug toxicity. This type of injury leads to transient marrow failure secondary to direct suppression of proliferating cell lines, and hematopoietic suppression continues with dose escalation. Most often caused by chemotherapy or radiotherapy, this injury is frequently iatrogenic. The second mechanism is idiosyncratic and may operate through toxic metabolites of the parent drug. Furthermore, individual variations in the pharmacokinetics of the suspected drug, genetic polymorphisms altering metabolism or a hypersensitivity of the stem cells to the destructive effects of the implicated drug may increase the potential for toxicity. The third mechanism is a drug- or metabolite-induced immune reaction specific to the stem-cell population, and it is this mechanism that has received much attention over the past few decades. Currently, it is believed that most cases of aplastic anemia are immune mediated.¹⁶ It is proposed that exposure to an inciting antigen (drug), activates cells and cytokines of the immune system, leading to the death of stem cells.³² Table 107–1 lists drugs that have been associated with drug-induced aplastic anemia.

The antineoplastic agents exemplify the dose-dependent mechanism for the development of aplastic anemia. Many of these agents have the ability to suppress one or more cell lines in a reversible manner. The degree of suppression and the cell line involved depend on the nature of the particular drug and its potential for inhibiting marrow proliferation. Chloramphenicol, an antimicrobial agent, also causes a bone marrow depression that is dose-dependent and reversible.³³

Idiosyncratic drug-induced aplastic anemia secondary to direct toxicity can be characterized by dose independence, a latent period prior to the onset of anemia, and continued marrow injury following

drug discontinuation.³⁴ Chloramphenicol, already known to cause a dose-dependent reaction, is the prototype drug for the idiosyncratic mechanism, with an estimated incidence of 1 case per 20,000 patients treated;²⁸ however, the overall prevalence has fallen with decreased use of this agent.³⁴ The idiosyncratic mechanism is believed to result from abnormal metabolism of chloramphenicol. The nitrobenzene ring on chloramphenicol is thought to be reduced to form a nitroso group on the chloramphenicol molecule.³³ The nitroso group may then interact with DNA in the stem cell, causing damage to the chromosomes, and eventually cell death. Other investigators have hypothesized that bacteria from the gastrointestinal tract may metabolize chloramphenicol to marrow-toxic metabolites.³⁵ There appears to be no relationship between the dose-dependent and idiosyncratic reactions seen with chloramphenicol.

Other drugs thought to induce aplastic anemia through toxic metabolites include phenytoin and carbamazepine. Investigators have theorized that metabolites of phenytoin and carbamazepine bind covalently to macromolecules in the cell and then cause cell death either by exerting a direct toxic effect on the stem cell or by causing the death of lymphocytes involved in regulating hematopoiesis.³⁶

Of the three potential mechanisms, the most common cause of drug-induced aplastic anemia is the development of an immune reaction. Early laboratory studies showed that removal of T lymphocytes from patients with aplastic anemia improved in-vitro colony formation.³⁷ Furthermore, overproduction of cytokines (e.g., tumor necrosis factor and interferon- γ) from activated T lymphocytes appears to be responsible for hematopoietic failure, as well as for the initiation of apoptosis.^{16,38} The observation of improved hematopoiesis in aplastic anemia patients who receive a conditioning regimen with antithymocyte globulin and cyclophosphamide prior to allogeneic hematopoietic stem cell transplantation (HSCT) supports this hypothesis.³⁹ After the initiation of immunosuppressive therapy, bone marrow concentrations of interferon- γ decreased whereas all cell lines improved.⁴⁰

Additional support for an immunologic basis as a mechanism of aplastic anemia comes from a prospective, randomized, placebo-controlled trial evaluating the efficacy of antilymphocyte globulin and methylprednisolone, with or without cyclosporine, in patients with severe aplastic anemia.⁴¹ The primary response variable was an improvement in blood counts (i.e., platelets, erythrocytes, and leukocytes) at 3 months. Patients receiving therapy with antilymphocyte globulin, methylprednisolone, and cyclosporine had a response rate of 65% versus a response rate of 39% in the group not receiving cyclosporine. The favorable response rate from this study, using immunosuppressant drugs, supports the overall hypothesis of an immune-based mechanism for aplastic anemia. One can also conclude that the degree of immunosuppression is related to a better response rate.

Genetic predisposition can also influence the development of drug-induced aplastic anemia. Studies in animals and a case report of chloramphenicol-induced aplastic anemia in identical twins suggest a genetic predisposition to the development of drug-induced aplastic anemia.^{28,33} Furthermore, pharmacogenetic research that focuses on patients who may be slow or normal metabolizers of drugs can increase the clinician's ability to predict the development of aplastic anemia. Initial case-control studies have not had the statistical power necessary to identify a significant difference between controls and cases, but continued research may establish the role of altered metabolism in patients with aplastic anemia.⁴²

anemia be diagnosed quickly and therapy initiated immediately. Treatment should be based on the degree of cytopenia, and the goals of therapy are to improve peripheral blood counts, which limits the requirement for transfusions and minimizes the risk for opportunistic infections.

6 As with all cases of drug-induced hematologic disorders, the first step is to remove the suspected offending agent. Early withdrawal of the drug can allow for reversal of the aplastic anemia.²⁸ The next step is to provide adequate supportive care, including appropriate antimicrobial therapy for the treatment of infection and transfusion support with erythrocytes and platelets. Appropriate supportive care is essential because the major causes of mortality in patients with aplastic anemia are bacterial or fungal infections and bleeding. Current treatment guidelines for aplastic anemia do not include chemoprophylaxis, except in patients undergoing allogeneic HSCT. Therefore, fever of unknown origin should be initially managed with broad-spectrum antibiotics.

The clinical course of aplastic anemia is variable. The condition can progress to severe or very severe disease in some patients, although it can remain relatively stable or even resolve in others.¹⁶ The treatment of moderate disease ranges from no clinical intervention to immunosuppressive regimens, and treatment should be based on the degree of cytopenias.^{16,18}

For patients with disease requiring treatment, the two major treatment options for patients with drug-induced aplastic anemia are allogeneic HSCT and immunosuppressive therapy. Most experts consider allogeneic HSCT the treatment of choice for young patients who have human leukocyte antigen (HLA)-matched sibling donors.¹⁸ Most patients are cured after HSCT, and the 5-year survival of patients following a matched sibling donor transplant has been reported to be 77% for adults and up to 80% to 90% in children.^{16,43} Despite these promising results, relatively few patients are eligible for HSCT because less than 30% of patients have a matched sibling donor.¹⁸ For those patients who do not have a matched sibling donor, mismatched related and matched unrelated donor transplants may be an option, but the prognosis is less optimistic. In one recent study reporting the results of 318 mismatched related or matched unrelated donor transplants for aplastic anemia, the 5-year survival rate ranged from 30% to 49%.⁴⁴ The highest mortality rate was seen in older patients and those with poorer clinical status at the time of transplantation. Complications for HSCT, such as graft-versus-host disease (GVHD) and graft rejection, require all patients to be closely monitored for an extended period of time.

An alternative to allogeneic HSCT is immunosuppressive therapy, which tends to be first-line therapy for older patients and those who are not candidates for HSCT. The current standard regimen against which new therapies are measured is combination therapy with antithymocyte globulin (ATG) and cyclosporine.⁴⁵ ATG is composed of polyclonal immunoglobulin G (IgG) against human T-lymphocytes derived from either horses or rabbits, and it has been a standard component of immunosuppressive therapy for aplastic anemia for many years. Monotherapy may achieve response rates of 40% to 70%, and long-term survival rates are similar to those receiving allogeneic HSCT.⁴⁶ Most of these studies used horse-derived ATG, and one recent trial showed a lower response rate in patients whose regimen contained rabbit-derived ATG versus those who received horse-derived ATG.⁴⁷ More data are needed to determine the role of rabbit-derived ATG in the treatment of aplastic anemia. Recommended dosing of antithymocyte globulin (horse-derived) has varied from 40 mg/kg per day for 4 days to 10 to 20 mg/kg per day for 8 to 14 days. Shorter, more intense regimens are preferred, as they are associated with fewer adverse events (i.e., serum sickness).¹⁶

Cyclosporine plays a key role in immunosuppressant therapy for aplastic anemia. Although cyclosporine monotherapy has been used in moderate cases of aplastic anemia, it is more often used in

TREATMENT

Drug-Induced Aplastic Anemia

Because of the high mortality rate associated with severe and very severe aplastic anemia, it is imperative that drug-induced aplastic

combination with ATG. The addition of cyclosporine to ATG therapy has been shown to increase response rate, improve failure-free survival, and reduce the number of immunosuppressive courses needed.^{45,47} Cyclosporine inhibits interleukin-2 production and release and subsequent activation of resting T cells. Cyclosporine dosing has varied from 4 to 6 mg/kg per day to 10 to 12 mg/kg per day, with the most frequently reported initial dose of 5 mg/kg per day in two divided doses. Cyclosporine doses are titrated to a target blood concentration that can be patient- and institution-specific but is usually in the range of 200 to 400 ng/mL. Although it does not provide a cure for the disease, immunosuppressive therapy with regimens that include ATG and cyclosporine provides a response rate between 60% and 80% with a 5-year survival rate similar to allogeneic HSCT.¹⁸

Corticosteroids are sometimes added to ATG-based immunosuppression. Although the addition of corticosteroids does not clearly improve the efficacy of regimens that include ATG and cyclosporine, they are still commonly used today because they reduce adverse reactions to the ATG portion of the therapy. For this reason, some practitioners currently use abbreviated courses (e.g., 2 weeks). Several dosing regimens of methylprednisolone or prednisolone have been used including 1 mg/kg per day for 2 to 4 weeks or a tapered therapy using higher doses (e.g., 2 mg/kg/day) during the initial weeks of therapy followed by lower doses. Despite the abbreviated regimen used, all patients receiving immunosuppressive therapy must be monitored for long-term complications including infection, relapse, and conversion to other stem-cell disorders (e.g., myelodysplastic syndrome, acute myelogenous leukemia, and paroxysmal nocturnal hemoglobinuria).

In an effort to improve outcomes, several other agents have also been investigated in the treatment of aplastic anemia. The additive benefits of other immunosuppressive agents such as mycophenolate, cyclophosphamide, and sirolimus have been evaluated.¹⁶ However, they have not been shown to be superior to the combination of ATG and cyclosporine, and their place in therapy is not defined. Granulocyte colony-stimulating factor (G-CSF),⁴⁸ granulocyte-macrophage colony-stimulating factor (GM-CSF),⁴⁷ and erythropoietin,⁴⁷ have also been investigated in the supportive care of aplastic anemia. Results of these trials have varied. Some patients have had a faster neutrophil recovery, whereas others showed no difference in hematopoietic recovery. No improvement in survival has been observed.^{18,47,48} If long-term bone-marrow suppression continues after initial treatment with optimal immunosuppression, the only viable available option is allogeneic HSCT.

CLINICAL CONTROVERSY

HSCT has long been the established treatment of drug-induced aplastic anemia. More recently, immunosuppressive regimens combining antithymocyte globulin, glucocorticoids, and cyclosporine are gaining favor. The usefulness of each treatment modality is limited by various factors. Clinical data suggest that there is no difference in survival achieved with the two treatments among patients followed for 6 years. Parity between the treatments will necessitate that clinicians individualize treatment decisions, while considering risk factors, economics, and quality of life.

DRUG-INDUCED AGRANULOCYTOSIS

Agranulocytosis is defined as a reduction in the number of mature myeloid cells in the blood (granulocytes and immature granulocytes [bands]) to a total count of 500 cells/mm³ or less. It occurs most commonly in females and the elderly (i.e. >60 years of age),⁴⁹ with an estimated annual incidence of 1.1 to 12 cases per million popula-

tion.^{15,50} The overall mortality rate of agranulocytosis is estimated to be 3.5% to 16%, and that rate is highest among the elderly and patients with renal failure, bacteremia, or shock at the time of diagnosis.^{15,50} Of those cases reported since 1990, approximately 5% to 6% have resulted in fatal outcomes.⁵¹ Symptoms of agranulocytosis include sore throat, fever, malaise, weakness, chills, and other signs and symptoms of infection. These symptoms can appear rapidly, within days to weeks after the initiation of the offending drug. The median duration of exposure prior to the development of agranulocytosis ranges from 19 to 60 days for most drugs associated with this adverse event, but the time to onset is greater than 1 month for most of these agents.⁵¹ Drug-induced agranulocytosis will usually resolve over time with supportive care and management of infection. Time to neutrophil recovery typically has been reported to range from 4 to 24 days.⁵¹ Table 107-2 provides a list of medications that have been associated with drug-induced agranulocytosis.

The cause of drug-induced agranulocytosis is not fully understood, and several mechanisms have been proposed. Initially, it was thought that drugs affected only the mature granulocytes, causing a *maturation arrest*. However, more recent studies have demonstrated that drugs may have either a direct toxic effect or an antibody-mediated effect on the bone marrow, neutrophils, or stem cells. Several immune-mediated mechanisms have been proposed.⁴⁹

The first type of immune-mediated mechanism involves the drug or drug metabolite, antibodies, and neutrophils. This mechanism involves drug adsorption on the membrane of the neutrophil. The drug-membrane complex then acts as a hapten to stimulate antibody formation. The antibodies produced bind to the drug-membrane complex, causing WBC destruction through complement activation and removal by the phagocytic system (Fig. 107-2). This hapten-type reaction is often seen when drugs, such as the penicillin derivatives, are given in large doses. Continuous presence of the drug is required for the destruction of neutrophils in this type of reaction.

The second mechanism of immune-mediated agranulocytosis is called the *innocent bystander phenomenon*. In this reaction, the drug combines with a drug-specific antibody. The complex is nonspecifically adsorbed to the neutrophil membrane, resulting in complement activation. The activated complement then destroys the cell (Fig. 107-3). Quinidine has been associated with this type of reaction. Functioning in a manner somewhat similar to that of the second mechanism, the third mechanism of immune response involves a protein carrier that combines with the drug and then attaches to the cell membrane. This in turn causes antibody formation. The antibodies bind to the drug protein carrier-membrane complex and activate complement. The cells are then cleared by the phagocytic system (Fig. 107-4).

In addition, there are several other immune-mediated mechanisms that have been identified. The production of autoantibodies to a *spoiled membrane* is a mechanism in which the offending drug alters the neutrophil membrane. This alteration induces the formation of autoantibodies (antibodies that attach directly to the neutrophil), which causes cellular destruction by the phagocytic system. High concentrations of β -lactam antibiotics, carbamazepine, and valproic acid have been associated with inhibition of colony-forming units of granulocytes and macrophages. Finally, drug-induced apoptosis and direct toxicity for pluripotent or bipotent hematopoietic progenitor stem cells have also been associated with clozapine and ticlopidine respectively.⁴⁹

In the case of penicillin-induced agranulocytosis, the patient can often begin taking penicillin again, at a lower dosage, after the neutropenia has resolved without any relapse of drug-induced agranulocytosis.⁵² Because of the rapid onset of symptoms and the dose-related phenomenon, a second mechanism could possibly be involved with penicillin-induced agranulocytosis. That mechanism involves an accumulation of drug to toxic concentrations in hyper-

TABLE 107-2 Drugs Associated with Agranulocytosis

Observational Study Evidence	Case Report Evidence (probable or definite causality rating)

NSAID, nonsteroidal antiinflammatory drug.

sensitive individuals. Researchers have shown with in-vitro cell cultures that penicillin derivatives in high concentrations inhibit the growth of myeloid colony-forming units in patients recovering from drug-induced agranulocytosis.⁵³ Penicillin derivatives, therefore, may suppress WBCs by several mechanisms.

Antithyroid medications, such as propylthiouracil and methimazole, have been reported to cause agranulocytosis. The current incidence of this adverse effect is unknown, but early publications report agranulocytosis in approximately 0.3% to 0.6% of patients.⁵⁴ In two more recent reports, antithyroid medications accounted for 7% to 23% of drug-induced agranulocytosis cases investigated.^{55,56} The mechanism by which antithyroid agents cause agranulocytosis is unknown, but antineutrophil cytoplasmic antibodies have been identified.⁵⁷ In a study by Cooper and coworkers,⁵⁴ agranulocytosis occurred more frequently in older patients (>40 years old), and it appeared within 2 months after the initiation of therapy. The investigators also reported a possible dose-response relationship with methimazole.⁵⁴ For patients receiving less than 30 mg/day of methimazole, no agranulocytosis occurred, but in patients receiving

higher doses, neutropenia was evident. No dose-response relationship has been observed with conventional doses of propylthiouracil. However, another study demonstrated no relationship between age or dose and the incidence of thionamide-induced agranulocytosis.⁵⁸

Ticlopidine is an antiplatelet agent indicated for the treatment of cerebrovascular disease and the prevention of reocclusion associated with stent placement. It produces neutropenia in approximately 2.4% of patients and agranulocytosis in 0.8%,⁵⁹ possibly by inhibiting hematopoietic progenitor stem cells.⁴⁹ Patient factors that can be associated with the development of agranulocytosis include poor bone marrow reserve and age. Agranulocytosis most commonly occurs within 1 to 3 months from the initiation of ticlopidine. Removal of the drug is the best treatment option with counts usually returning to normal within 2 to 4 weeks.

The phenothiazine class of drugs is known to cause drug-induced agranulocytosis by the innocent bystander mechanism. The onset of phenothiazine-induced agranulocytosis is approximately 2 to 15

FIGURE 107-2. Drug adsorption mechanism. The drug binds to the membrane of the blood cell. Antibodies are formed to the drug-membrane complex (hapten). The antibodies then attach to the complex, and cell toxicity occurs. (Reproduced with permission from Petz LD. Drug-induced autoimmune hemolytic anaemia. *Transfus Med Rev* Oct 1993;7:242–254.)

FIGURE 107-4. Protein carrier mechanism. The drug combines with a plasma protein. The complex then attaches to the cell membrane, and antibody formation is stimulated. Antibodies later attach to the complex and activate complement. The cell is then lysed by the complement. (Reproduced with permission from Young GA, Vincent PC. Drug-induced agranulocytosis. *Clin Haematol* 1980 Oct;9:483–504.)

weeks after the initiation of therapy, with a peak onset between 3 and 4 weeks.^{60,61} The mechanism by which phenothiazines cause drug-induced agranulocytosis has been studied primarily with chlorpromazine,⁶² which is thought to affect cells in the cell cycle phase that manufactures enzymes needed for DNA synthesis (G_1 phase), or the phase in which cells are resting and not committed to cell division (G_0 phase).⁶² The antipsychotic agents are known to precipitate proteins and may coprecipitate polynucleotides so they can no longer participate in nucleic acid synthesis. Chlorpromazine also increases the loss of macromolecules from the intracellular pools that are essential for cellular replication.⁶² When the bone marrow from a patient with phenothiazine-induced agranulocytosis is examined, it initially appears to have no cellularity (aplastic), but over time it becomes hyperplastic. It is believed that toxic effects of the phenothiazines are not seen in all patients taking the medications because most patients have enough bone marrow reserve to overcome the toxic effects.⁶²

Clozapine, an antipsychotic agent, is associated with a significantly higher risk of agranulocytosis as compared to other antipsychotic medications and has received much attention over recent years.⁶³ The annual incidence of clozapine-induced agranulocytosis in the United States is reported to be 1.3% and can occur at any time during treatment, although the risk is highest at around 3 months after initiation.⁶⁴ Because of the frequency and seriousness of clozapine-induced agranulocytosis and because of its reversible nature if detected early in therapy, clozapine is currently only available through a limited distribution program which requires strict WBC count monitoring.⁶⁴ In-vitro studies have suggested that the formation of a nitrenium ion unstable metabolite may be responsible for clozapine-induced agranulocytosis.⁴⁹ The resulting oxidative stress caused by this metabolite may cause cytotoxicity or an immune reaction.⁶⁵

TREATMENT

Drug-Induced Agranulocytosis

The primary treatment of drug-induced agranulocytosis is the removal of the offending drug. Following discontinuation of the drug, most cases of neutropenia resolve over time, and only symptomatic treatment (e.g., antimicrobials for infections) and appropriate vigilant hygiene practices are necessary. Sargramostim (GM-CSF) and filgrastim (G-CSF) have been shown to shorten the duration of neutropenia, length of antibiotic therapy, and hospital length of stay.⁵⁰ Although the use of both agents has been reported in the literature, a commonly reported regimen is G-CSF 300 mcg/day via

subcutaneous injection. The only prospective, randomized trial to date did not confirm the benefit of these growth factors.⁶⁶ However, some experts have questioned the validity of these results based on the small sample size ($n = 24$) and the lower than standard dose of filgrastim used (i.e., 100–200 mcg/day). One systematic review found that patients with a neutrophil nadir less than 100 cells/mm³ had a higher rate of infections and fatal complications as compared to those with a higher nadir.⁵¹ Therefore, some clinicians recommend the use of growth factors in patients with a neutrophil nadir less than 100 cells/mm³, regardless of the presence of infection.

DRUG-INDUCED HEMOLYTIC ANEMIA

Following their release from the bone marrow, normal RBCs survive for approximately 120 days before they are removed by phagocytic cells of the spleen and liver. The process of premature RBC destruction is referred to as hemolysis, which can occur either because of defective RBCs or abnormal changes in the intravascular environment. Drugs can promote hemolysis by both processes.

The causes of drug-induced hemolytic anemia can be divided into two categories: immune or metabolic. Those in the first category may operate much like the process that leads to immune-mediated agranulocytosis, or they can suppress regulator cells, which can lead to the production of autoantibodies. The second category involves the induction of hemolysis by metabolic abnormalities in the RBCs.

Patients with drug-induced hemolytic anemia can present with signs of intravascular or extravascular hemolysis. Intravascular hemolysis, the lysis of RBCs in the circulation, can result from trauma, complement fixation to the RBC, or exogenous toxic factors. Extravascular hemolysis refers to the ingestion of RBCs by macrophages in the spleen and liver, a process that requires the presence of surface abnormalities on RBCs, such as bound immunoglobulin.⁶⁷

The onset of drug-induced hemolytic anemia is variable and depends on the drug and mechanism of the hemolysis. Symptoms of hemolytic anemia can include fatigue, malaise, pallor, and shortness of breath. Table 107–3 provides a list of drugs that have been associated with drug-induced immune hemolytic anemia.

DRUG-INDUCED IMMUNE HEMOLYTIC ANEMIA

In immune hemolytic anemia, IgG and/or immunoglobulin M (IgM) bind to antigens on the surface of RBCs and initiate their destruction through the complement and mononuclear phagocytic systems.⁶⁸ Depending on the antigenic stimulus, immune hemolytic anemia is either classified as autoimmune, alloimmune, or drug-induced.⁶⁸ Drug-induced antibodies may recognize the host's intrinsic RBC antigens or RBCs bound to drug. If the antibodies react against RBC-bound drug, then the drug must be present to induce hemolysis.⁶⁸

A laboratory test called the direct Coombs test (or direct antiglobulin test [DAT]), which identifies foreign immunoglobulins either in the patient's serum or on the RBCs themselves, is the best means to diagnose drug-induced immune hemolytic anemia. The Coombs test begins with the antiglobulin serum, which is produced by injecting rabbits with preparations of human complement, crystallizable fragment (of immunoglobulin) (Fc), or immunoglobulins. The rabbits produce antibodies that are foreign to human immunoglobulins and complement. The direct Coombs test involves combining the patient's RBCs with the antiglobulin serum. If the patient's RBCs are coated with antibody or complement (as a result of a drug-induced process), the antibodies in the serum (produced by the rabbit) will attach to the Fc regions of the autoimmune globulins on two separate RBCs, creating a lattice formation called agglutination.⁶⁹ This agglutination is considered positive for the presence of IgG or complement on the cell surfaces.

An indirect Coombs test can identify antibodies in a patient’s serum. This test is performed by combining the patient’s serum with normal RBCs, then subjecting them to the direct Coombs test. Antibodies that have attached to the normal RBCs will be identified. This process is important in blood bank procedures.

The mechanisms that have been proposed to explain how drugs can induce immune hemolytic anemia are similar to the mechanisms that produce drug-induced agranulocytosis. The first mechanism is the adsorption of the drug to the RBC membrane to form a hapten, and subsequently, an antibody. The antibody attaches to the drug without direct interaction with the erythrocyte. The extravascular anemia that follows is usually caused by IgG, and generally complement is not activated. The anemia usually develops gradually over 7 to 10 days and reverses over a couple of weeks after the offending drug is discontinued. The direct Coombs test may remain positive for several weeks. The penicillin and cephalosporin derivatives given in high doses are primarily associated with this type of immune reaction.⁷⁰ Other drugs that have been reported to cause drug-induced immune hemolytic anemia by this process include minocycline, tolbutamide, and semi-synthetic penicillins.⁷⁰ Streptomycin is also associated with this type of reaction and is associated with activation of the complement system.⁷¹

Like drug-induced agranulocytosis, immune hemolytic anemia has been associated with the formation of immune complexes in a reaction formally known as the *innocent bystander phenomenon*. Quinidine and phenacetin are the prototype drugs of this reaction, but many other

drugs have been implicated, including quinine and several sulfonamides. Drugs that induce this reaction bind weakly to a normal RBC component. The immune system identifies this complex as foreign, a *neoantigen*, and initiates lysis of the RBC via the complement system.⁶⁸ As soon as complement is activated, the complex can detach and move on to other RBCs, and to WBCs or platelets. Because of this low affinity, only a small amount of drug is needed to cause the reaction, and the direct Coombs test is positive for complement only. RBCs are essentially victims, or “innocent bystanders,” of the immunologic reaction. This type of mechanism is associated with acute intravascular hemolysis that can be severe, sometimes leading to hemoglobinuria and renal failure. Following discontinuation and clearance of the drug from the circulation, the direct Coombs test will become negative.

The third mechanism is drug-induced autoimmune hemolytic anemia. The first drug implicated in this type of hemolytic anemia was methyldopa.⁷² Like some other drugs, methyldopa is known to induce true autoantibodies to RBCs; the antibodies can be identified without the presence of the offending drug or its metabolites. Approximately 10% to 20% of patients receiving methyldopa will develop a positive Coombs test, usually within 6 to 12 months of initiating therapy.⁷³ However, less than 1% of these patients experience hemolysis, and hemolysis can develop from 4 to 6 months to more than 2 years after the start of therapy. After the withdrawal of the drug, results of the Coombs test can remain positive for many months.⁷¹ The mechanism by which methyldopa induces antibody production is not completely known, but there are two main hypotheses.⁷² The first suggests that methyldopa or its metabolites acts on the immune system and impairs immune tolerance. An alternative hypothesis suggests that the offending drug may bind to immature RBCs, altering the membrane antigens and inducing autoantibodies.

It is not known why only some patients develop autoantibodies, and why only some of the patients who have autoantibodies develop hemolytic disease. In an effort to explain why patients have a positive result from a Coombs test and no hemolysis, Kelton demonstrated that methyldopa impairs the ability of these patients to remove antibody-sensitized cells.⁷⁴ In Coombs-positive patients receiving methyldopa, patients with impairment of the mononuclear phagocytic system could not clear the RBCs coated with autoantibodies from their bloodstream, and therefore hemolysis did not occur. Patients with hemolysis had no impairment of the mononuclear phagocytic system. Procainamide has also been reported to cause a positive result on the indirect Coombs test and hemolytic anemia.⁷⁵ Other drugs that have been reported to cause autoimmune hemolytic anemia include levodopa, mefenamic acid, and diclofenac.⁷⁶

DRUG-INDUCED OXIDATIVE HEMOLYTIC ANEMIA

A hereditary condition, drug-induced oxidative hemolytic anemia, most often accompanies a glucose-6-phosphate dehydrogenase (G6PD) enzyme deficiency, but it can occur because of other enzyme defects (reduced nicotinamide adenine dinucleotide phosphate [NADPH] methemoglobin reductase or reduced glutathione peroxidase). A G6PD deficiency is a disorder of the hexose monophosphate shunt, which is responsible for producing NADPH in RBCs, which in turn keeps glutathione in a reduced state. Reduced glutathione is a substrate for glutathione peroxidase, an enzyme that removes peroxide from RBCs, thus protecting them from oxidative stress.⁷⁷ Without reduced glutathione, oxidative drugs can oxidize the sulfhydryl groups of hemoglobin, removing them prematurely from the circulation (i.e., causing hemolysis).

A G6PD deficiency is the most common of all enzyme defects, affecting millions of people. Because the G6PD gene is located on the X chromosome, the disorder is therefore inherited through a sex-linked mode. Both homozygotes and heterozygotes can be symptomatic, but

homozygotes tend to have the most severe cases.⁷⁸ There are many G6PD variants, but the most common types occur in American and African blacks (approximately 10%), people from Mediterranean areas (e.g., Greeks, Sardinians, and Khurdic and Sephardic Jews), and Asians.⁷⁸

The degree of hemolysis depends on the severity of the enzyme deficiency and the amount of oxidative stress. However, the dose required for hemolysis to occur is often less than prescribed quantities of the suspected drug.^{71,77} Although severe hemolysis is rare, any drug that places oxidative stress on RBCs can cause drug-induced oxidative hemolytic anemia. One case of drug-induced oxidative hemolytic anemia has been reported in a child when dapsone (an oxidizing agent) was transferred through the breast milk of the mother, who was taking the drug.⁷⁹ For a list of agents associated with drug-induced oxidative hemolytic anemia, refer to Table 107-4.

TREATMENT

Drug-Induced Hemolytic Anemia

■ DRUG-INDUCED IMMUNE HEMOLYTIC ANEMIA

The severity of drug-induced immune hemolytic anemia depends on the rate of hemolysis. Hemolytic anemia caused by drugs through the hapten/adsorption and autoimmune mechanisms tend to be slower in onset and mild to moderate in severity. Conversely, hemolysis prompted through the neoantigen mechanism (innocent bystander) phenomenon can have a sudden onset, lead to severe hemolysis, and result in renal failure. The treatment of drug-induced immune hemolytic anemia includes the removal of the offending agent and supportive care. In severe cases, glucocorticoids can be helpful,⁶⁸ but some practitioners have questioned their efficacy.⁷⁶ Other agents such as the chimeric anti-CD20 monoclonal antibody rituximab and immunoglobulin treatments have been used, but their role is yet to be clearly defined.^{80,81}

■ DRUG-INDUCED OXIDATIVE HEMOLYTIC ANEMIA

Removal of the offending drug is the primary treatment for drug-induced oxidative hemolytic anemia. No other therapy is usually necessary, as most cases of drug-induced oxidative hemolytic anemia are mild in severity. Patients with these enzyme deficiencies should be advised to avoid medications capable of inducing the hemolysis.

DRUG-INDUCED MEGALOBlastic ANEMIA

In drug-induced megaloblastic anemia, the development of RBC precursors called megaloblasts in the bone marrow is abnormal.

Vinblastine

Deficiencies in either vitamin B₁₂ or folate are responsible for the impaired proliferation and maturation of hematopoietic cells, resulting in cell arrest and subsequent sequestration. Examination of peripheral blood shows an increase in the mean corpuscular hemoglobin concentration. These megaloblastic changes are caused by the direct or indirect effects of the drug on DNA synthesis. Some patients can have a normal-appearing cell line, and the diagnosis must be made by measurement of vitamin B₁₂ and folate concentrations. The abnormality can be seen in any portion of the replication process, including DNA assembly, base precursor metabolism, or RNA synthesis.⁸²

Because of their pharmacologic action on DNA replication, the antimetabolite class of chemotherapeutic agents is most frequently associated with drug-induced megaloblastic anemia. Methotrexate, an irreversible inhibitor of dihydrofolate reductase, causes megaloblastic anemia in 3% to 9% of patients.⁸³ Dihydrofolate reductase is an enzyme responsible for generating tetrahydrofolate, an essential factor in making deoxythymidine triphosphate, which is necessary for DNA synthesis. Other drugs such as cotrimoxazole, phenytoin, or the barbiturates have also been implicated in megaloblastic anemia. Cotrimoxazole, for example, has been reported to cause drug-induced megaloblastic anemia with both low and high doses,^{84,85} particularly in patients with a partial vitamin B₁₂ or folate deficiency.⁸² Because the drug's affinity for human dihydrofolate reductase is low, patients with adequate stores of these vitamins are at low risk of developing drug-induced megaloblastic anemia. It has been postulated that phenytoin, primidone, and phenobarbital cause drug-induced megaloblastic anemia by either inhibiting folate absorption or by increasing folate catabolism. In both instances, the patient develops a relative deficiency of folate. Table 107-5 provides a list of drugs that have been suggested as causative factors in drug-induced megaloblastic anemia.

TREATMENT

Drug-Induced Megaloblastic Anemia

When drug-induced megaloblastic anemia is related to chemotherapy, no real therapeutic option is available, and the anemia becomes an accepted side effect of therapy. If drug-induced megaloblastic anemia results from cotrimoxazole, a trial course of folinic acid, 5 to 10 mg up to four times a day, can correct the anemia.^{84,85} Folic acid supplementation of 1 mg every day often corrects the drug-induced

megaloblastic anemia produced by either phenytoin or phenobarbital, but some clinicians suggest that folic acid supplementation can decrease the effectiveness of the antiepileptic medications.⁸⁶

DRUG-INDUCED THROMBOCYTOPENIA

Thrombocytopenia is usually defined as a platelet count below 100,000 cells/mm³ or >50% reduction from baseline values. Thrombocytopenia can be caused by numerous conditions such as blood loss, infection, diffuse intravascular coagulation, and the use of some medications. The annual incidence of drug-induced thrombocytopenia is approximately 10 cases per 1,000,000 population (excluding those cases associated with heparin).⁸⁷ Although numerous epidemiologic studies have been reported, none of them have identified patient-specific risk factors, other than exposure to certain classes of medications, that increase the risk for the development of drug-induced thrombocytopenia.⁸⁷

Several mechanisms have been proposed for the development of drug-induced thrombocytopenia: direct toxicity reactions, hapten-type immune reactions, platelet-reactive autoantibodies, and drug-dependent antibodies. Direct toxicity reactions, as often associated with chemotherapeutic agents, result in suppressed thrombopoiesis and produce a decrease in the number of megakaryocytes in the bone marrow. In contrast, immune reactions result in an increased peripheral destruction of platelets and an increased number of megakaryocytes. Early symptoms of drug-induced thrombocytopenia include increased bruising, petechiae, ecchymoses, and epistaxis. Bleeding from mucous membranes and severe purpura can appear later in the disorder. A list of medications associated with drug-induced thrombocytopenia can be found in Table 107-6.

Most of the drugs that induce thrombocytopenia by their toxic effects are cancer chemotherapy agents, but organic solvents, pesticides, drugs that influence folic acid metabolism, and inamrinone (formally named amrinone) have also been implicated. Although orally administered inamrinone has been reported to cause thrombo-

cytopenia in up to 18.6% of patients,⁸⁸ only the intravenous formulation is currently commercially available in the United States. Some studies suggest that this toxic effect might be caused by the metabolite of inamrinone, instead of the parent drug.⁸⁹ Regardless of the cause, inamrinone use has been largely replaced by other phosphodiesterase-3 inhibitors that are not associated with the same high risk of side effects.

Drug-induced thrombocytopenia usually develops through an immunologic mechanism. The agents most commonly implicated are quinine, quinidine, gold salts, sulfonamide antibiotics, rifampin, glycoprotein IIb/IIIa (GPIIb/IIIa) receptor antagonists, and heparin.⁸⁷ Studies of these agents have helped to elucidate the mechanisms of drug-induced immune thrombocytopenia. In hapten-type reactions, the offending drug binds to certain platelet glycoproteins. Antibodies are generated that bind to these drug-bound glycoprotein epitopes. After the binding of drug-dependent antibodies to the platelet surface, lysis occurs through complement activation or through clearance from the circulation by macrophages.⁹⁰ Hapten-mediated immune thrombocytopenia usually occurs at least 7 days after the initiation of the drug, although it can occur much sooner if the exposure is actually a reexposure to a previously administered drug. The recovery period, once the suspected drug is discontinued, is often short in duration with a median recovery time within 1 week.⁹¹ A recently published study suggests that vancomycin-induced thrombocytopenia is related to drug-dependent antibodies,⁹² and although relatively rare, penicillins and cephalosporins can cause thrombocytopenia through this mechanism.⁸⁷

Gold compounds and procainamide appear to induce thrombocytopenia through the platelet-specific autoantibody type reaction.⁸⁷ In this type of reaction, a drug induces the production of autoantibodies that bind to platelet membranes and cause destruction, but the causative drug does not have to be present for the reaction to occur. In contrast, the drug-dependent antibody reaction requires the presence of the drug to allow antibody binding. Although several mechanisms of drug-induced thrombocytopenia have been proposed, it is often not possible to determine the

mechanism for an individual drug or patient and more than one mechanism can be responsible for the condition.

Approximately 1% of patients who receive the GPIIb/IIIa receptor antagonist abciximab develop acute thrombocytopenia, and that rate increases to approximately 4% after a second exposure.⁹³ Three GPIIb/IIIa receptor antagonists are currently marketed in the United States, abciximab, eptifibatide, and tirofiban, and all three agents have been associated with thrombocytopenia. The pathogenesis of GPIIb/IIIa-induced thrombocytopenia remains unclear, and one of the unique aspects is the varying presentations. Some patients develop a precipitous drop in platelets within hours of their first exposure to the medication, which can be associated with fever, dyspnea, hypotension, and even anaphylaxis in some cases.^{93,94} Several authors have proposed a nonimmune mechanism for this type of drug-induced thrombocytopenia because of the acute nature of the platelet drop.⁹³ In addition to the acute thrombocytopenia that can occur with GPIIb/IIIa receptor antagonists, delayed thrombocytopenia has also been reported, which suggests an immune-based reaction.^{64,95} Although the exact mechanism is unknown, growing evidence suggests that the binding of GPIIb/IIIa receptor antagonists to the GPIIb/IIIa receptors can induce the expression of ligand-induced binding sites.⁹³ These new binding sites may then react with antibodies, leading to an increased clearance of platelets.^{96,97}

Because GPIIb/IIIa receptor antagonists are coadministered with heparin, it is important to distinguish between GPIIb/IIIa receptor antagonist-induced and heparin-induced thrombocytopenia. A heparin-induced platelet aggregation study can help to determine the offending agent.

CLINICAL CONTROVERSY

Profound thrombocytopenia (i.e., platelet count less than 20,000 cells/mm³) has been reported with the GPIIb/IIIa receptor antagonists. Before this effect was fully appreciated, many clinicians attributed this event to heparin. The current challenge for clinicians is to distinguish between GPIIb/IIIa receptor antagonist-induced and heparin-induced thrombocytopenia, so that the patient's adverse event is documented properly. Thrombocytopenia associated with GPIIb/IIIa receptor antagonists can present with a nadir of platelet counts of 1,000 to 4,000 cells/mm³ occurring from 2 to 31 hours following bolus infusion, which is much sooner than the 5 to 10 days observed with initial heparin exposure. However, reexposure to heparin can produce profound thrombocytopenia within hours. The ubiquity of heparin use for flushing catheters makes it difficult to determine previous exposure in many cases. Clinicians can choose from several types of assays to aid in the diagnosis of heparin-induced thrombocytopenia, including platelet activation assays, platelet aggregation studies, and enzyme-linked immunosorbent assay methods, each with varying sensitivity, specificity, and availability.

Pseudothrombocytopenia, defined as in-vitro platelet aggregation in blood anticoagulated with ethylenediamine tetraacetic acid (EDTA), is clinically insignificant, but it must also be differentiated from thrombocytopenia induced by GPIIb/IIIa receptor antagonists. In this case, microscopic examination of a peripheral blood smear, along with repeated platelet counts in citrate-anticoagulated blood samples, makes the distinction possible.⁹³

Probably the most recognized, complex type of drug-induced thrombocytopenia is that associated with heparin. At least two types of heparin-induced thrombocytopenia (HIT) have been identified. The most common, type I, occurs in approximately 10% to 20% of patients treated with heparin.⁹⁸ It is a mild, reversible, nonimmune-mediated reaction that usually occurs within the first 2 days of therapy.⁵ The platelet count slowly returns to baseline following an

initial decline, despite continued heparin therapy. HIT type I is usually an asymptomatic condition and is thought to be related to platelet aggregation.⁵

HIT type II is less common but more severe and can be associated with more complications. Approximately 1 to 5% of patients receiving unfractionated heparin and up to 0.8% of patients receiving low-molecular-weight heparin (LMWH) can develop HIT.^{5,98} Patients typically present with a low platelet count (e.g., below 150,000 cells/mm³) or a 50% or more decrease in platelet count from baseline and thrombosis can occur.⁹⁹ The platelet count generally begins to decline 5 to 10 days after the start of heparin therapy. However, this decline can occur within hours of receiving heparin if the patient has recently received heparin (i.e., within 100 days).⁹⁹ Thrombocytopenia and thrombosis can develop with low-dose heparin,¹⁰⁰ heparin-coated catheters,¹⁰¹ or even heparin flushes. Certain patient populations have a higher risk for developing HIT than others; patients who have had recent, major surgery are one of the highest risk groups.⁹⁸ The next highest risk groups include patients receiving heparin for thrombosis prophylaxis following peripheral vascular surgery, cardiac surgery, and orthopedic surgery.¹⁰² A lower incidence is seen in medical, obstetric, and pediatric patients, especially those receiving LMWH instead of unfractionated heparin.⁹⁸ The most recent practice guidelines by the American College of Chest Physicians recommend varying degrees of platelet monitoring based on the relative risk of developing HIT.¹⁰³

HIT is caused by the development of antibodies against platelet factor-4 (PF-4) and heparin complexes⁹⁹ (Fig. 107-5). Low-molecular-weight heparins bind less well to PF-4 than unfractionated heparin, and therefore antibody formation is less common. However, there is cross-reactivity between antibodies developed by patients receiving unfractionated heparin and LMWH, and LMWH should therefore not be used in patients with HIT.⁹⁸ Once the antibodies bind to the complexes, platelet activation and aggregation occur, with subsequent release of more circulating PF-4 to interact with heparin. In addition, procoagulant microparticles are also released that increase the risk of thrombosis.⁹⁸ Thrombosis is one of the major complications of HIT and can occur in up to 20% to 50% of patients with HIT.⁹⁹ In fact, thrombosis is the precipitating factor that leads the clinician to diagnose HIT in many patients. This high risk of thrombosis continues for days to weeks after heparin discontinuation and platelet recovery, and continued anticoagulation with an alternative agent is essential during this time period.⁹⁹ Other less frequent manifestations of HIT include heparin-induced skin necrosis and venous gangrene of the limbs.^{98,99} The diagnosis of HIT is frequently a clinical one, supported by laboratory testing. Several types of assays are available to aid in the diagnosis of HIT, including platelet activation assays, platelet aggregation studies, and enzyme-linked immunosorbent assay methods, each with varying sensitivities and specificities.⁵

TREATMENT

Drug-Induced Thrombocytopenia

The primary treatment of drug-induced thrombocytopenia is removal of the offending drug and symptomatic treatment of the patient. The use of corticosteroid therapy in the treatment of drug-induced thrombocytopenia is controversial, although some authors recommend it in severe symptomatic cases.¹⁰⁴

In the case of HIT, the main goal of management is to reduce the risk of thrombosis or reduce thrombosis-associated complications in patients who have already developed a clot. All forms of heparin must be discontinued, including heparin flushes, and alternative

FIGURE 107-5. Proposed explanation for the presence of both thrombocytopenia and thrombosis in heparin-sensitive patients who are treated with heparin. Injected heparin reacts with platelet factor-4 (PF-4), which is normally present on the surface of endothelial cells (ECs) or released in small quantities from circulating platelets, to form PF-4-heparin complexes (1). Specific immunoglobulin G (IgG) antibodies react with these conjugates to form immune complexes (2) that bind to crystallizable fragment (Fc) receptors on circulating platelets. Fc-mediated platelet activation (3) releases PF-4 from α -granules in platelets (4). Newly released PF-4 binds to additional heparin, and the antibody forms more immune complexes, establishing a cycle of platelet activation. PF-4 released in excess of the amount that can be neutralized by available heparin binds to heparin-like molecules (glycosaminoglycans) on the surface of ECs to provide targets for antibody binding. This process leads to immune-mediated EC injury (5) and heightens the risk of thrombosis and disseminated intravascular coagulation. (Reproduced with permission from Aster RH. Heparin-induced thrombocytopenia and thrombosis. *N Engl J Med* 1995;332:1374–1376. Copyright © 1995 Massachusetts Medical Society. All rights reserved.)

anticoagulation must begin immediately.¹⁰⁵ The direct thrombin inhibitors are the alternative anticoagulants most commonly used in current practice. Three direct thrombin inhibitors are currently available: lepirudin, argatroban, and bivalirudin. Lepirudin, the first

drug that was approved for the treatment of HIT, is a recombinant analogue of hirudin, a natural anticoagulant found in leeches. Lepirudin is renally eliminated and requires dosage adjustment in those patients with kidney dysfunction. It is also important to note that antibodies to lepirudin develop in approximately 30% of patients who receive this agent for the first time, and it is therefore recommended that patients receive only one treatment course of lepirudin.⁹⁹ Argatroban is another intravenous thrombin inhibitor indicated for the management of HIT. But unlike lepirudin, argatroban is metabolized in the liver and can be used in patients with end-stage renal disease. However, dosage adjustment is needed for patients with significant hepatic impairment. The most recently approved direct thrombin inhibitor is bivalirudin. It is similar to lepirudin in that is parenteral bivalent analog of hirudin. It requires dosage adjustment only in severe renal failure. These agents should also be considered for the treatment of patients who have acute HIT without thrombosis because of the increased risk of thrombosis occurring in these patients. Because of the increased risk of venous limb gangrene, warfarin should not be used alone to treat acute HIT complicated by deep vein thrombosis.¹⁰³

SUMMARY

6 Drug-induced hematologic disorders are rare but potentially life-threatening conditions. Clinicians should be cognizant of medications with the potential of causing hematologic disorders and educate patients to recognize the symptoms associated with such events. Frequent laboratory monitoring of patients taking medications associated with severe hematologic events can facilitate diagnosis and treatment. Identifying the etiology of the event and documenting the causative agents can serve to prevent a recurrence secondary to the use of a related medication. Reporting these events to national adverse event reporting services and in the peer-reviewed medical literature can serve to improve the understanding of the prevalence and risk factors for this disorder.

ABBREVIATIONS

- ADR: adverse drug reaction
- ATG: antithymocyte globulin
- DAT: direct antiglobulin test
- EDTA: ethylenediamine tetraacetic acid
- Fc: crystallizable fragment (of immunoglobulin)
- G6PD: glucose-6-phosphate dehydrogenase
- G-CSF: granulocyte colony-stimulating factor
- GM-CSF: granulocyte-macrophage colony-stimulating factor
- GPIIb/IIIa: glycoprotein IIb/IIIa
- GVHD: graft-versus-host disease
- HIT: heparin-induced thrombocytopenia
- HLA: human leukocyte antigen
- HSCT: hematopoietic stem cell transplantation
- IgG: immunoglobulin G
- IgM: immunoglobulin M
- LMWH: low-molecular-weight heparin
- NADPH: reduced nicotinamide adenine dinucleotide phosphate
- PF-4: platelet factor-4
- RBC: red blood cell
- WBC: white blood cell

INFECTIOUS DISEASES

CHAPTER

108

Laboratory Tests to Direct Antimicrobial Pharmacotherapy

MICHAEL J. RYBAK AND JEFFREY R. AESCHLIMANN

KEY CONCEPTS

- 1 Familiarity with normal host flora and typical pathogens will help to determine whether a patient is truly infected or merely colonized.
- 2 Direct examination of tissue and body fluids by Gram stain provides simple and rapid information about the potential pathogen.
- 3 Isolation of the offending organism by culture assists in the diagnosis of infection and allows for more definitive directed treatment.
- 4 The development of molecular testing systems has improved our ability to diagnose infection and determine the antimicrobial susceptibilities for numerous fastidious or slow-growing pathogens, such as mycobacteria and viruses.
- 5 Although highly standardized, in-vitro antimicrobial susceptibility testing has limitations and often cannot truly mimic the conditions found at the site of an infection. This can cause discordance between in-vitro susceptibility results and in-vivo response to therapy.
- 6 The laboratory evaluation of antimicrobial activity is an important component of the pharmacotherapeutic management of infectious diseases.
- 7 Antimicrobial pharmacodynamics have become a crucial consideration for the clinician during the selection of both empirical and pathogen-directed therapy in the current era of antimicrobial resistance.
- 8 When used appropriately, rapid automated susceptibility test systems appear to improve therapeutic outcomes of patients with infection, especially when they are linked with other clinical information systems.
- 9 Laboratory tests such as minimal bactericidal concentration tests, timed-kill tests, post-antibiotic-effect tests, and antimicrobial combination testing are important for the clinician to understand because they help to determine an antimicrobial's pharmacodynamic properties.
- 10 Routine monitoring of serum concentrations is currently used for a select few antimicrobials (e.g., aminoglycosides, chloramphenicol, and vancomycin) in an attempt to minimize toxicity and maximize efficacy.
- 11 Appropriate timing for the collection of serum samples when measuring antimicrobial serum concentrations is crucial to ensure that proper data are generated on the pharmacokinetics of antimicrobials.
- 12 The monitoring of serum concentrations of aminoglycosides and the use of extended-interval doses of aminoglycosides can help to maximize the probability of therapeutic success and minimize the probability of aminoglycoside-related toxicity.
- 13 Vancomycin serum concentration monitoring should be routinely done to ensure adequate serum concentrations, minimize toxicity, and avoid the potential for resistance.
- 14 Optimization of antimicrobial pharmacodynamic parameters such as the ratio of the peak serum concentration to minimum inhibitory concentration or the time that the serum concentration remains above the minimum inhibitory concentration can improve infection treatment outcomes.

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

Appropriate antimicrobial pharmacotherapy for a given infectious disease requires knowledge of the infecting pathogen, host characteristics, and the drug's expected activity against the pathogen. The most fundamental aspect of therapy starts with an appropriate diagnosis. A vast array of laboratory tests is available to assist the clinician in verifying the presence of infection and for monitoring the response to therapy. Although useful, these tests are subject to interpretation and cannot be substituted for sound clinical judgment. Organism susceptibility to the administered antimicrobials is key to determining the outcome from a patient's therapy. Host characteristics, however, such as immune status, infection-site location, and body-organ function, play a significant role in selecting

the most appropriate antimicrobial for a given individual.¹ This chapter reviews the routine laboratory tests that are used to assist in the diagnosis and treatment of infection.

LABORATORY TESTS CONFIRMING THE PRESENCE OF INFECTION

NONSPECIFIC TESTS

Many tests are used by clinicians to determine whether a patient has an infection. Although no single test can prove that a patient is infected, when used in combination with clinical findings, tests are helpful to establish the diagnosis of infection. Because many tests are nonspecific, there are often factors other than infection that can cause a test to be reported as positive when no infection exists. Therefore, the importance of careful interpretation and sound clinical judgment cannot be overemphasized. This chapter reviews the commonly employed tests and their interpretation and application for the diagnosis and management of infection.

White Blood Cell Count and Differential

1 Understanding the role of the white blood cell (WBC) in fighting infection is important in the diagnosis of infection, the selection of drug therapy, and the monitoring of patient progress. The major role of the WBC is to defend the body against invading organisms such as bacteria, viruses, and fungi. The normal range of the WBC is 4,500 to 10,000 cells/mm³. WBCs usually are elevated in response to infection. The WBC count can become elevated in response to a number of noninfectious causes, including stress, inflammatory conditions such as rheumatoid arthritis, and leukemia or in response to certain drugs (e.g., corticosteroids).

WBCs are divided into two groups: the granulocytes, which have prominent cytoplasmic granules, and the agranulocytes, which lack granules. Polymorphonuclear (PMN) granulocytes are made up of neutrophils, basophils, and eosinophils. The two other classes of WBCs are the monocytes and lymphocytes. Neutrophils are the most common type of WBCs in the blood, comprising approximately 70% of the total WBC count. In response to infection, they leave the bloodstream and enter the tissue to interact with and phagocytize offending pathogens. Mature neutrophils sometimes are referred to as *segs* because of their segmented nucleus, which usually consists of two to five lobes. Immature neutrophils lack this segmented feature and are referred to as *bands*. During an acute infection, immature neutrophils, such as bands (single-lobed nucleus), are released from the bone marrow into the bloodstream at an increased rate, and the percentage of bands (usually 5%) can

increase in relationship to mature cells. The change in the ratio of mature to immature cells is often referred to as a *shift to the left* because of the way the cells were counted by hand with a microscope and charted from immature to mature cells.

Leukocytosis is a normal host defense to infection and is an important adjunct to antimicrobial therapy. Unfortunately, bacterial infection is a common complication of neutropenia from cancer chemotherapy. These patients are incapable of increasing their WBCs in response to infection. In fact, susceptibility to infection in these patients is highly dependent on their WBC status. Patients with neutrophil counts of less than 500 cells/mm³ are at high risk for the development of bacterial or fungal infections. The absence of leukocytosis also occurs in the elderly and in severe cases of sepsis.^{2,3}

Lymphocytes comprise 15% to 40% of all WBCs and are of central importance to the immune system. Two functional types of lymphocytes are the T cell, which is involved in cell-mediated immunity, and the B cell, which produces antibodies involved in humoral immunity. Lymphocytosis frequently is associated with acute viral infections such as Epstein-Barr virus infection (mononucleosis) and Cytomegalovirus (CMV) infection and rarely with unusual bacterial infections (i.e., *Brucella* species infections).

T lymphocytes are characterized on the basis of function (type 1 or type 2) and on the basis of surface antigen. Most type 1 and type 2 T cells carry a T4 (CD4) marker that recognizes class II major histocompatibility complex (MHC) antigens, and most cytotoxic T cells carry a T8 (CD8) marker that recognizes class I MHC antigens. A severe deficiency of CD4 cells is associated with human immunodeficiency virus (HIV) infection.⁴ Malignancies also can adversely affect cellular immunity. Patients with Hodgkin's disease and other types of lymphoma exhibit defective cell-mediated immunity that predisposes them to a variety of infections, notably fungal diseases and infections by the *Listeria* species. Drug treatment with cytotoxic chemotherapy and corticosteroids also can have profound deleterious effects on cell-mediated immunity.⁵ Defects in cell-mediated immune function can be demonstrated by a variety of simple laboratory tests, including quantification of lymphocytes on a routine complete blood cell count and skin testing for anergy. A more detailed investigation includes quantitative measurements of CD4+ and CD8+ cells. Monocytosis is correlated less frequently with acute bacterial infection, although its presence has been associated with the response of certain infections (e.g., tuberculosis) to chemotherapy. Eosinophilia can result from parasitic infection.⁶ Figure 108–1 describes a number of cell types and their biologic function.

Other Tests

Some nonspecific laboratory tests are useful to support the diagnosis of infection. The inflammatory process initiated by an infection sets

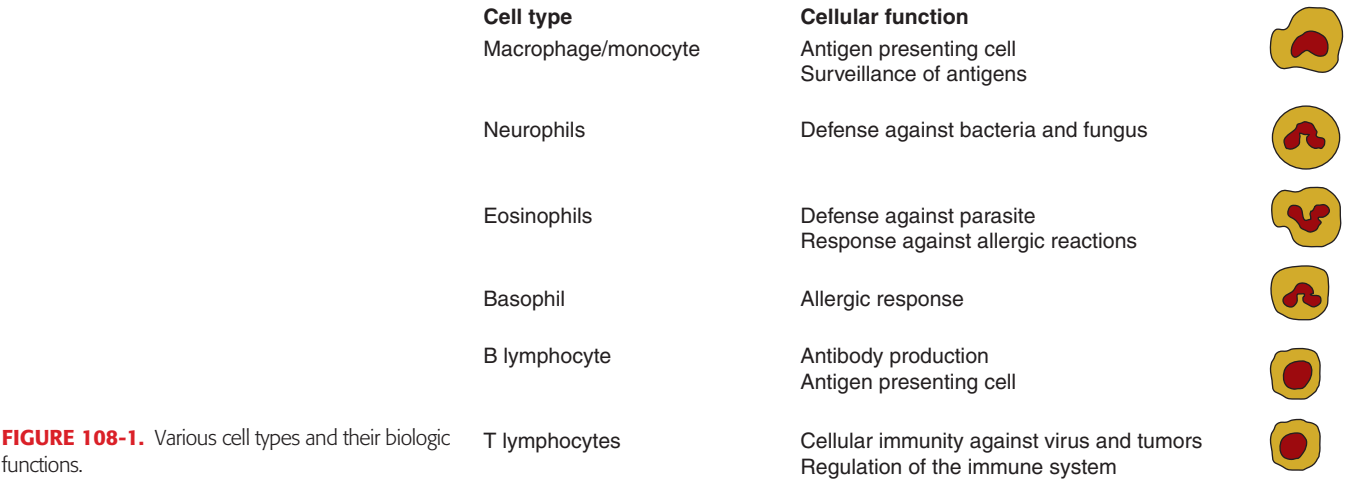

FIGURE 108-1. Various cell types and their biologic functions.

up a complex host response. Activation of complements, such as C3a and C5a, initiates inflammation and sets off a cascade of changes and the subsequent release of mediators, all of which can be measured and monitored. Serum complement concentrations, particularly C3, usually are consumed as part of the host defense mechanism and subsequently are reduced during the early stages of an acute infectious process.⁷ Acute-phase reactants, such as the erythrocyte sedimentation rate (ESR) and the C-reactive protein concentration, are elevated in the presence of an inflammatory process but do not confirm the presence of infection because they are often elevated in noninfectious conditions, such as collagen-vascular diseases and arthritis. Large elevations in ESR are associated with infections such as endocarditis, osteomyelitis, and intraabdominal infections.^{8,9}

Changes in endothelial membranes and the presence of a foreign pathogen and its endotoxins cause certain cytokines, such as interleukin 1 (IL-1), IL-6, and IL-8 and tumor necrosis factor- α (TNF- α), to be produced by macrophages or lymphocytes. Fluctuations in cytokine levels occur during the course of an infection, which can be useful in staging and monitoring the response to therapy. Although abnormally high levels of TNF have been associated with a variety of noninfectious causes, spiked elevations in TNF are found in patients with serious infections, such as sepsis. Studies of the relationship of circulating mediators to patient outcome have determined the value of endotoxin and cytokine measurements in patients with sepsis. Although the combination of elevations in endotoxin and individual cytokines has correlated well with the mortality rate, measurement of IL-6 was by far the best individual cytokine that predicted patient outcome.⁹ There is a significant relationship between monocyte human leukocyte antigen (HLA)-DR expression and the risk of mortality in patients with community-acquired severe infections.¹⁰ Understanding the balance between these proinflammatory and antiinflammatory processes likely will lead to interventions that can have a direct impact on the outcome of patients with sepsis.¹¹

LABORATORY IDENTIFICATION OF PATHOGENS

COLONIZATION VERSUS INFECTION

2 Pathogens are organisms that are capable of damaging host tissues and that elicit specific host responses and symptoms that are consistent with an infectious process. These organisms are transferred from patient to patient, vector to patient (animals, insects, and so on), environment to patient (e.g., hospital settings) or are derived from the patient's own flora. Conversely, the human body contains a vast variety of microorganisms that colonize body systems and make up the so-called *normal flora*. These organisms occur naturally in the tissues of the host and provide some benefits, including defense by occupying space, competing for essential nutrients, stimulating cross-protective antibodies, and suppressing the growth of potentially pathogenic bacteria and fungi (Table 108-1).

Organisms that comprise the normal flora can become pathogenic when host defenses become impaired or if they are translo-

cated to other body sites during trauma. The identification of an organism that is considered to be normal flora in a wound or otherwise sterile body cavity or fluid often becomes a dilemma for the clinician in deciding whether or not a patient is infected and whether or not the patient requires treatment. Such is the case with *Staphylococcus epidermidis* when it is identified in the blood of a hospitalized patient. *S. epidermidis* is considered normal skin flora and commonly colonizes intravenous catheters. In these conditions, identification of the organism must be taken in light of the patient circumstances (signs and symptoms, laboratory indices supporting infection) and the probability of the organism being responsible for the infection. Often the simple removal of the catheter can eliminate the organism from the bloodstream, thereby preventing misdiagnosis and unnecessary application of antimicrobials.¹²

DIRECT EXAMINATION

3 Direct examination of tissue or body fluids believed to be infected can provide simple, rapid information to the clinician. Microscopic examination of wet-mount specimen preparations can provide valuable information regarding potential pathogens. Applications of this procedure with or without staining preparations include direct examination of sputum, bronchial aspirates, scrapings of mucosal lesions, and urinary sediment. The Gram stain is one of the first identification tests run on a specimen brought to the laboratory. For this procedure, crystal violet is applied as the primary stain, with iodine added to enhance the staining process and to form a crystal violet-iodine complex. Alcohol decolorization is the next step in the procedure. Gram-negative cells are decolorized by the addition of alcohol, and they take in a red color when counterstained by safranin. Gram-positive cells are not decolorized by alcohol and retain the crystal violet color and appear purple. Gram staining in conjunction with microscopic examination can provide a presumptive diagnosis and some indication of the organism's characteristics (gram-positive, gram-negative, gram-variable, bacillus, or cocci). This is extremely useful information for the selection of empirical antibiotic therapy.

Gram stains are performed routinely on cerebrospinal fluid (CSF) in cases of suspected meningitis, on urethral smears for venereal diseases, and on abscess or effusion specimens. They are helpful in identifying organisms that may not grow on culture and which otherwise would be missed. Although Gram stains of sputum are performed routinely when respiratory tract infections are suspected, there is controversy regarding the usefulness of this test because the sputum is often contaminated with mixed or normal flora. The predominance of one particular organism, the overall number of organisms present, the amount of PMN granulocyte present, and the presence or absence of a significant amount of squamous epithelial cells (<10 per low-power field) can improve the significance of the sputum Gram stain specimen. Figure 108-2 lists some common infecting pathogens grouped according to Gram stain and other characteristics.

Other staining techniques are used to identify pathogens such as those that are best identified microscopically because of their poor growth characteristics in the laboratory setting. The best examples

of these are the Ziehl-Neelsen stain for acid-fast bacilli, which is used for the identification of mycobacteria, and the India ink, potassium hydroxide (KOH), and Giemsa stains, which are useful for detecting certain fungi.¹³

CULTURES

4 Isolation of the etiologic agent by culture is the most definitive method available for the diagnosis and eventual treatment of infection. Although suspicion of a specific pathogen or group of pathogens is helpful to the laboratory for the selection of a specific cultivating medium, the more common procedure for the laboratory is to screen for the presence of any potential pathogen. After receipt of a clinical specimen, the laboratory will inoculate the specimen in a variety of artificial media. Some culture media are designed to differentiate various organisms on the basis of biochemical characteristics or to select specific organisms on the basis of resistance to certain antimicrobials. Other media are employed commonly for the isolation of more fastidious organisms, such as *Listeria*, *Legionella*, *Mycobacterium*, or *Chlamydia*. Cultures for viruses are more difficult to perform and are undertaken primarily by larger institutions or outside laboratories because of the technical expense and time involved in processing samples.

When a culture is obtained, careful attention must be paid to ensuring that specimens are collected and transported appropriately to the laboratory. Every effort should be made to avoid contamination with normal flora and to ensure that the specimen is placed in the appropriate transport medium. Culture specimens should be transported to the laboratory as soon as possible because organisms can perish from prolonged exposure to air or drying. This is especially important for swab specimen preparations. Transport media may not be ideal for all organisms. Specimens that contain fastidious organisms or anaerobes require special transport media and should be forwarded immediately to the laboratory for processing. Finally, the source of the specimen should be clearly recorded and forwarded along with the culture to the laboratory. This process will aid the laboratory in differentiating true pathogens from the expected normal flora, and it will help in the selection of the appropriate culture media. Detection of microorganisms in the bloodstream by standard culturing techniques is difficult because of the inherently low yield of organisms diluted by blood, humoral factors with bactericidal activity, and the potential of antimicrobial pretreatment affecting organism growth. Newer automated systems employing the use of medium-containing culture bottles and innovative organism-detection techniques have improved this situation. Most blood collection bottles dilute the blood specimen 1:10 with

growth medium to neutralize the bactericidal properties of blood and antimicrobials. The addition of a polyanionic anticoagulant abolishes the effect of complement and antiphagocytic activity in the specimen. Some laboratories also add β -lactamase to their blood collection bottles. Antibiotic-binding resin bottles, such as BACTEC 16B, are also commercially available. Rapid detection of bacteria or fungi within a few hours of specimen collection is now possible by the use of automated culturing systems, such as BACTEC (Becton Dickinson Diagnostic Instruments, Sparks, MD), that use bottles of growth medium containing a fluorescent sensor to monitor culture bottles for the presence of carbon dioxide (CO_2) every 10 minutes as a by-product of microorganism growth. Computers monitoring the system alert laboratory personnel of positive culture results by both audible and visual alarms. Once detected, a battery of testing can be performed rapidly that shortens the reporting time and that enables clinicians to obtain preliminary information about the organism.^{13,14} The initial identity of the organism can be determined by a variety of testing procedures. General schemes differentiate organisms into primary groups, such as gram-positive and gram-negative bacteria. This can be accomplished by simple Gram staining, as described previously, by evaluating organism growth patterns on selective media, and by testing for the presence or absence of specific enzymes and chemical characteristics, such as hemolytic and fermentation properties. For example, non-lactose-fermenting gram-negative bacilli that are oxidase-positive can suggest *Pseudomonas aeruginosa* as opposed to a variety of other potential gram-negative organisms. This preliminary information, which is readily obtainable from the laboratory, can greatly assist the clinician in choosing the appropriate empirical therapy. Definitive identification of organisms requires more complex testing procedures and devices that can further differentiate the organism on the basis of specific fermentation and biochemical reactive properties. Commercially available automated systems can inoculate the test organism into a series of panels containing a variety of test media, sugars, and other reagents. The system can then photometrically determine the results and compare the findings to a library of organism characteristics to produce a definitive identification.¹⁴ Viral agents can be detected by direct observation of inoculated culture cells for cytopathic effects or by detection of antigens after incubation by immunofluorescent methods. The culture method is most useful for organisms such as CMV or herpes simplex virus because these viral agents are rapidly propagated in culture cells, making them easily detected.¹⁵

DIAGNOSIS OF INFECTION USING IMMUNOLOGIC AND MOLECULAR METHODS

ANTIBODY AND ANTIGEN DETECTION

5 The use of immunologic methods for the diagnosis and monitoring of human host immune response to infection has become an indispensable laboratory tool. This is especially important in the detection of microorganisms, such as bacteria, fungi, and viruses, that otherwise would elude detection or severely delay results from conventional culturing techniques. These methods have the advantage of a rapid turnaround time and an acceptable level of sensitivity and specificity. Some tests (e.g., identification of group A streptococci) are simple to use, can be performed conveniently in the physician's office, and often can be used to decide whether antibiotics should be administered for a suspected upper respiratory infection.

The primary immunologic methods involve the detection and quantification of antibodies directed against a specific pathogen or its components (i.e., surface proteins of HIV, such as p24 antigen). The commercial availability of specific monoclonal antibodies in a

variety of testing formats has led to an increased use of these methods for direct pathogen detection. Although pathogen antigenic proteins can be increased and, therefore, detected easily during acute infection, detection of past or asymptomatic infection can be difficult because of undetectable levels of antigen and, therefore, low antibody titers. Continued advancement in test sensitivity (the capability to detect a true-positive state) and specificity (the capability to detect a negative state), as well as the use of amplification techniques, likely will improve these tests in the near future.

Antibody or antigen detection can be accomplished by a variety of techniques, including immunofluorescence, which has been used routinely for the detection of CMV, respiratory syncytial virus, varicella-zoster virus, *Treponema pallidum* (syphilis), *Borrelia burgdorferi* (Lyme disease), and *Chlamydia trachomatis*. Latex agglutination is useful for detecting meningococcal capsular antigens in CSF of patients suspected of having bacterial meningitis and as an aid in the diagnosis of *Legionella pneumophila*. Enzyme-linked immunosorbent assay (ELISA) is a commonly employed method for detecting HIV, herpes simplex virus, respiratory syncytial virus, pneumococcal serum antibody, *Neisseria gonorrhoeae*, and *Haemophilus pylori*.¹⁵

MOLECULAR TECHNIQUES FOR THE DETECTION OF MICROORGANISMS

Hybridization DNA Probes

Highly sensitive and specific molecular methods are now available for the rapid detection and identification of a variety of pathogens. The two primary molecular techniques used commonly are nucleic acid hybridization, which involves the binding of a specific DNA or RNA probe to its target, and DNA amplification schemes. Probe-based methods require the extraction of DNA or RNA from a clinical specimen (i.e., body fluid, tissue, or WBC) or directly from a microorganism culture. The extract is then tested for the presence of pathogen DNA or RNA using a probe that contains a specific oligonucleic acid-based sequence for the organism. For example, a probe with a sequence of ACTGTT would bind to the complementary organism nucleic acid sequence of TGACAA. Because the probe is labeled with a signal-emitting molecule (i.e., radiolabeled, colorimetric, or chemoluminescent), a match would be detected. The primary means for detection involves the use of separation of the organism DNA into specific fragments (gel electrophoresis), transfer and fixation of the mixture to specialized paper or nylon membranes (Southern or Northern blotting), the mixing of the DNA fragments with the labeled probe (hybridization), and transfer to radiographic or photographic film for processing. These techniques have been used for many years and are fairly standardized methods for the detection of a variety of organisms. Hybridization probes are useful for a variety of diagnostic and clinical applications, including the direct examination of organisms in tissue, which enables the evaluation and documentation of organism infestation, location, distribution, and host response. The use of hybridization probes is particularly helpful for the detection of slow-growing organisms such as *Mycobacterium tuberculosis*, *N. gonorrhoeae*, and certain species of fungi. This technique is also used to document the presence or absence of antimicrobial-resistant genes in a cell culture and to track the spread of resistant microorganisms in hospital and outpatient settings. Although employed widely, the use of hybridization probes is often limited by their lack of sensitivity. Probe amplification methods are available that improve the sensitivity of these assays. The principle of these probe-amplification schemes is to boost the probe's signal-emitting molecule to make it more easily detected. The most advanced signal-amplification system available is the branched DNA (bDNA) probe system (Chiron Corp., Emeryville, CA). This system uses multiple probes and multiple signal-emitting molecules (report-

ers). The target-binding probe contains two hybridization regions. One region is complementary to the target, and the other region is capable of binding with the bDNA amplification multimer. The amplification multimer binds multiple reporter molecules (as many as 3,000), which provides a significant boost in the probe's signal. Branched DNA probe systems are being developed for rapid detection of hepatitis B and C, HIV-1, and CMV. Because of the system's high specificity and quantitative ability, bDNA probe assays can be useful for therapeutic monitoring, such as in the case of monitoring the response to antiretroviral therapy in acquired immunodeficiency syndrome (AIDS).^{16,17}

Nucleic Acid Amplification Methods

Nucleic acid amplification methods are now considered a standard laboratory tool. They have had a tremendous impact on the diagnosis and treatment of infectious diseases. These highly sensitive methods have the capability to detect and quantitate minute amounts of target nucleic acid in a rapid manner. The polymerase chain reaction (PCR) is based on the capability of a DNA polymerase to copy and elongate a targeted strand of DNA. This is accomplished by the use of short oligonucleotide primers (20 to 25 nucleotides long) that correspond to the DNA targeted to be expanded. After an excess of primers and heat-stable DNA polymerases are added to the targeted DNA mixture, the targeted DNA is denatured and separated by a process of cycling hot and cool temperatures. The heat-stable DNA polymerase elongates the primers on the two separate strands of DNA, thereby generating two new strands of targeted DNA. The process of cycling typically is repeated 20 to 35 times. Each cycle doubles the amount of DNA originally present at the start of the cycle, thereby exponentially increasing the overall number of DNA copies. In theory, more than 1 million copies of the original DNA can be generated from as few as 20 cycles. Although this amplification technique is very sensitive and has tremendous application potential, it is not without problems. The powerful amplification procedure can yield false-positive results when samples are contaminated by nucleic acid left over from previously amplified DNA. Other problems include primer artifact formation and nonspecific hybridization of primers to DNA samples. Several modifications to the original PCR technology have been made over the years to improve the sensitivity and application potential for PCR, including the use of multiple sets of amplification primers, multiplex PCR, PCR amplification of RNA by converting targeted RNA with reverse transcriptase to complementary DNA templates (which are then suitable for DNA amplification by traditional PCR techniques), and real-time quantitative PCR. The cost-benefit ratio of PCR as compared with traditional microbiologic methods must be evaluated. Molecular amplification schemes such as PCR have become routine in situations in which rapid turnaround time is essential to improve patient diagnosis and outcome, for example, real-time universal screening for acute HIV infection and routine testing and monitoring of patients receiving treatment for HIV infection, and the isolation and detection of fastidious or slow-growing organisms such as *M. tuberculosis*, *B. burgdorferi*, and *Helicobacter pylori*. Another potential application for this technology is the early detection of multidrug-resistant organisms. Amplification of resistant gene markers would aid in rapid selection of the most appropriate therapy in the treatment of organisms in which days or weeks traditionally are required for culturing and determining basic susceptibility. Examples fitting this description include the rapid detection of isoniazid and rifampin gene markers for *M. tuberculosis*, early detection of the *mec* gene responsible for methicillin resistance in *Staphylococcus aureus*, and identification of resistant genes responsible for production of β -lactamase capable of destroying specific cephalosporins and multidrug resistant *H. pylori*.¹⁷⁻²⁰

EVALUATION OF ANTIMICROBIAL ACTIVITY AND DETERMINATION OF ANTIMICROBIAL PHARMACODYNAMICS

6 The laboratory evaluation of antimicrobial activity is an important component of the pharmacotherapeutic management of infectious diseases. The integration of this activity with various pharmacokinetic properties of the antimicrobial agent determines the 7 drug's pharmacodynamic characteristics. Antimicrobial pharmacodynamics have become a crucial consideration for the clinician for selecting both empirical and pathogen-directed therapy, formulary decision-making, developing antimicrobial streamlining programs, and for intravenous-to-oral antimicrobial switch protocols.

5 Most antimicrobial susceptibility testing methods that are used in the clinical laboratory are well characterized and have been standardized by the Clinical and Laboratory Standards Institute (CLSI). However, controversies exist about which test methods provide the most useful information, how to report these results, and how to apply them to the treatment of patients.²¹ Nevertheless, there are many investigations that show that the general antimicrobial susceptibility or resistance profile of an infecting organism correlates with clinical and/or microbiologic responses to therapy.

Most of the standardized and well-accepted test methods evaluate the susceptibility of aerobic, nonfastidious bacteria. However, substantial progress has been made to develop sensitive, specific, reproducible, and clinically useful susceptibility tests for anaerobic bacteria, yeasts, mycobacteria, and viruses. Continued advances in technology should further improve test methods and the rapidity with which the results can be applied to the management of patients. Although these newer systems are often very expensive, the increased quality and decreased overall costs of patient care can determine their cost-effectiveness.

QUANTITATIVE ANTIMICROBIAL SUSCEPTIBILITY TESTING

MINIMAL INHIBITORY CONCENTRATIONS

The *minimal inhibitory concentration* (MIC) is defined as the lowest antimicrobial concentration that prevents visible growth of an organism after approximately 24 hours of incubation in a specified growth medium. The MIC quantitatively determines in-vitro antibacterial activity. Classically, MICs were determined through the macrotube dilution method, which uses liquid growth medium (broth), doubling serial dilutions of antimicrobials in test tubes, and a standard inoculum of bacteria (approximately 10^5 colony-forming units [CFU]/mL). The tubes (up to 10 mL) were incubated at approximately 35°C (95°F) for 18 to 24 hours and then examined for visible bacterial growth (Fig. 108-3). Because macrodilution MIC testing is laborious and supply-intensive, it is not used often in the contemporary clinical microbiology laboratory. However, one advantage of this method is that it tests a large inoculum of bacteria—a factor that can improve the detection of small numbers of resistant subpopulations or document the presence of inducible resistance.²²

The use of 96-well microtiter plates substantially reduces the amount of growth medium and preparation time needed for broth-dilution MIC testing in the clinical laboratory. Volumes of 100 to 200 microliters (mL) or less of medium are used, and multichannel pipets and/or automated systems allow efficient preparation of numerous tests (Fig. 108-4). The microdilution MIC test method is currently the most commonly-used susceptibility test method in the clinical microbiology laboratory. Although microdilution MIC testing is a vast improvement over macrodilution MIC testing, it still has important shortcomings. These include both limitations in the

FIGURE 108-3. Macrotube minimal inhibitory concentration (MIC) determination. The growth control (C), 0.5 mg/L, and 1 mg/L tubes are visibly turbid, indicating bacterial growth. The MIC is read as the first clear test tube (2 mg/L).

numbers and various types of antimicrobials to use in the test (especially with premade or premanufactured trays) and a limited ability to detect some forms of antimicrobial resistance (e.g., β -lactamases in gram-negative bacteria).²³

The MIC also can be determined using solid agar growth medium. For the agar dilution MICs, the test antimicrobial is added to the molten agar at the desired concentration just prior to its solidification. After the agar has hardened, suspensions of test bacteria are applied to the agar. As with broth MICs, the agar dilution MIC is defined as the lowest concentration that prevents the visible growth of the organism after an overnight incubation period. The primary advantages of the agar dilution MICs are the ability to test many bacteria on the same agar plate and the flexibility to choose specific antimicrobials. These advantages often are outweighed by the need to prepare agar plates manually and the instability of the antimicrobial in the agar as compared with commercially prepared microtiter MIC trays. Although agar dilution MIC once was considered the standard susceptibility test for many bacteria and for certain slow-growing organisms such as *M. tuberculosis*, its use has declined in most clinical laboratories with the advent of more rapidly performed and less cumbersome susceptibility testing methods (e.g., microtiter MICs, PCR, radiometric, and/or fluorometric tests).

LIMITATIONS AND PROBLEMS WITH MIC TESTING

Some of the limitations and problems of MIC testing are academic in nature, whereas others can have important implications for the clinician's everyday management of patients with serious infections. For

FIGURE 108-4. A prepared microtiter minimal inhibitory concentration (MIC) panel represents antibiotics tested commonly against gram-negative pathogens. This tray indicates that the organism is resistant to ampicillin (AM), cefazolin (CFZ), cefotetan (CTN), cefuroxime (CRM), ceftriaxone (CAX), and gentamicin (GM). The isolate is susceptible to mezlocillin (MZ), piperacillin (PIP), ceftazidime (CAZ), and tobramycin (TO). The isolate would be considered intermediately susceptible to ceftizoxime (CZ).

example, because the MIC only represents the concentration of antimicrobial that is needed to inhibit visual growth of the most resistant cells within the tested bacterial population, there can be small numbers of cells present within the large numbers of cells within the infection that are more antimicrobial-resistant than the MIC would indicate. Use of the antimicrobial then could select these more resistant subpopulations, resulting in poor clinical response. This phenomenon can be observed with intermediate vancomycin resistance in *S. aureus*, as well as in strains of gram-negative bacteria such as the *Enterobacteriaceae* species that produce both plasmid-borne and chromosomal β -lactamases.^{23,24}

8 Many other factors also can influence the in-vitro MIC value obtained and its subsequent application to the in-vivo situation. The bacterial growth medium used and cation content can affect the activity of many drugs significantly. For example, aminoglycosides are more active against *P. aeruginosa* in a medium supplemented with physiologic concentrations of magnesium and calcium (CLSI standardized method) than in a medium without these cations. MIC values of antibiotics that are highly bound to plasma proteins are significantly higher when the test medium contains human serum. As testing of these drugs in a serum-supplemented medium has not gained widespread acceptance, their in-vivo activity can be overestimated by in-vitro MIC test results. Fortunately, the standardized guidelines for testing and quality assurance procedures proposed by the CLSI attempt to minimize the impact of these problems and are followed by most clinical and research laboratories.²⁵ However, when a patient infected with an apparently susceptible organism fails therapy, it is important for the clinician to consider these potential confounding factors as possibly being related to the observed failure. In such situations, consideration of antimicrobial pharmacokinetics and pharmacodynamics also often can help to better predict therapeutic response as compared with organism susceptibility alone.

QUALITATIVE ANTIMICROBIAL SUSCEPTIBILITY TEST METHODS

DISK DIFFUSION ASSAY

The disk diffusion assay method for susceptibility testing (Bauer-Kirby method) was developed in the 1960s by Bauer and coworkers as a way to reduce the labor needed for tube dilution susceptibility testing.²⁶ It still remains one of the more common susceptibility test methods used in the clinical microbiology laboratory owing to its high degree of standardization, reliability, flexibility, low cost, and simplicity of test interpretation. Up to 12 user-selected antibiotic-impregnated disks are placed on an agar plate previously streaked with a standard suspension of bacteria ($1-2 \times 10^8$ CFU/mL). The drug contained in the disk diffuses in a concentration gradient out into the agar. The plate is incubated (18 to 24 hours at 35°C), and visual bacterial growth occurs only in areas in which the drug concentrations are below those required for growth inhibition. The diameters of the zones of inhibition are measured via calipers or automated scanners and are compared with standard zone size ranges that determine susceptibility, intermediate susceptibility, or resistance to the antimicrobials that were tested (Fig. 108-5). Although factors such as agar composition, incubation temperature, bacterial inoculum, and antibiotic paper disk composition can influence results, the standards for testing conditions and interpretive zone sizes are well defined by the CLSI.

QUALITATIVE VERSUS QUANTITATIVE SUSCEPTIBILITY TESTING OF MICROORGANISMS

Quantitative MIC data often are reported to the clinician qualitatively by deeming an organism “susceptible,” “intermediate or

FIGURE 108-5. Disk diffusion susceptibility test. Antibiotic-impregnated disks are placed on the surface of a plate previously inoculated with the test organism. The plate is incubated for 18 hours, and the subsequent zones of inhibition are measured. The zone size correlates with the sensitivity of the organism. The larger the zone, the more sensitive is the organism to the specific antibiotic. On the basis of predetermined zone breakpoints, organisms can be classified as susceptible, resistant, or intermediately susceptible to the antibiotic. (Photograph courtesy of the Anti-Infective Research Laboratory, Wayne State University, Detroit, Michigan.)

indeterminate” or “moderately susceptible,” or “resistant” to a given antimicrobial agent. Many factors are considered to determine these qualitative susceptibility classifications, including pharmacokinetic properties, the distribution of MICs for the organisms, and the clinical and bacteriologic responses observed for the antimicrobial against strains of bacteria with various MIC values. This simplification makes the susceptibility data easily interpretable by non-infectious-disease clinicians. Pathogens classified as susceptible to an antibiotic are those with the lowest MICs, and they are the most likely to be eradicated during therapy of infections using typical drug doses. Conversely, resistant organisms are bacteria with significantly higher MICs that, when treated with the antimicrobial, will result in a less-than-optimal clinical response, even at the highest doses. The indeterminate classification exists when the number of strains with MICs in the given range is too small to derive robust conclusions on susceptibility or resistance to the antimicrobial. Responses to therapy for organisms that are moderately susceptible/intermediately susceptible/indeterminate can be variable. These organisms can respond to treatment with maximal doses of the antimicrobial or can respond when the drug is known to be concentrated at the site of infection (e.g., urinary tract infections treated by drugs excreted by the kidneys).

There are concerns that the “user friendly” susceptible/resistant classification system can oversimplify the decision-making process for treating infections. For example, a critically ill patient may not respond to the antimicrobial therapy of a susceptible organism at the usual doses. If serum concentrations or concentrations at the site of infection could be assayed (not practically done), one might discover suboptimal concentrations as a result of inadequate tissue perfusion. Likewise, a patient with severe vascular insufficiency and a diabetic foot infection may fail a course of therapy with normal doses of an antimicrobial and a susceptible organism because of inadequate drug delivery. Additionally, some investigators have shown that different outcomes can be achieved for “susceptible” organisms with different MIC values²⁷ and also that substantial (although not clinically acceptable) clinical and/or microbiologic cure rates can occur for infections

that are caused by resistant organisms.²⁸ These reports emphasize that in-vitro susceptibility does not correlate unequivocally with clinical success and that resistant organisms do not always equate with impending clinical failure.

Similarities in the spectrum of activity for classes of antibiotics have led to the concept of *class testing*. Thus cephalothin susceptibility results are extrapolated to other first-generation cephalosporins, such as cephalexin or cefazolin. Likewise, susceptibility to an antibiotic that typically has minimal activity usually ensures that other more potent agents in its class will have activity as well. However, many gram-negative organisms have now developed extended-spectrum β -lactamases (ESBLs) that often have different activity against members of the same drug class. These developments significantly limit the utility of class testing to reduce susceptibility testing workload.

CLINICAL CONTROVERSY

Some clinicians believe that the MICs of all antimicrobials for which susceptibility testing was performed should be reported to allow for proper selection of the best antimicrobial for a given infection in a patient. However, other clinicians argue that the additional information can be misapplied or that the nonselective reporting of all antimicrobial susceptibility data will result in the increased use of more costly broad-spectrum antimicrobials.

OTHER SUSCEPTIBILITY TESTS

EPSILOMETER TEST

8 The Epsilon meter test (Etest; AB Biodisk, Solna, Sweden) combines the benefits of quantitative MIC test methods with the ease of agar diffusion testing. The E-test is a plastic strip impregnated with a known, prefixed concentration gradient of antibiotic that is placed on an agar plate streaked with a suspension of known bacterial inoculum. The drug instantly diffuses from the plastic strip to form an effective concentration gradient within the agar. After overnight incubation, elliptical zones of inhibition are formed; the point where the bottom of the ellipse crosses the plastic strip is correlated with an MIC value printed on the strip (Fig. 108-6). Many investigators have analyzed the E-test's correlation with standard susceptibility methods and assessed its potential clinical use. In general, values obtained with E-test methods are comparable with or even more consistent and accurate than standard methods. In fact, the E-test method is the recommended method for susceptibility testing of *Streptococcus pneumoniae*. However, the widespread clinical use of the E-test has been limited primarily by the excessive costs of the test strips (nearly 10 times more costly than antibiotic-impregnated disks) in relation to the benefits that may be gained from their use.

AUTOMATED ANTIMICROBIAL SUSCEPTIBILITY TESTING

8 Various degrees of automation have been applied to susceptibility testing. Early advances included automated preparation of microtiter trays, instrument-assisted readers, and computer-assisted result databases.²⁹ Rapid automated susceptibility tests became available in the 1980s, and their use has increased substantially in the two subsequent decades. These systems often incorporate microprocessors, robotics, and microcomputers to rapidly identify organisms and produce susceptibility test results in as few as 3 hours.

There are two rapid automated susceptibility test systems in common use in clinical microbiology laboratories. The Vitek system (bioMérieux Vitek, Hazelwood, MO) uses small plastic reagent “cards” that contain 30 or 45 wells for the testing of various anti-

FIGURE 108-6. Photograph of E-test susceptibility strip. The minimal inhibitory concentration (MIC) is determined from the point where the zone of inhibition intersects with the numerical scale. (Photograph courtesy of the Anti-Infective Research Laboratory, Wayne State University, Detroit, Michigan.)

crobials or indicator chemicals. Bacterial test suspensions (25 mL total, providing 1×10^5 CFU/well) enter the wells by capillary diffusion, and growth is monitored automatically via photometric assessment of turbidity every hour for up to 15 hours. When the growth control reaches a specified turbidity level, growth curves for all wells are calculated and compared with the growth control curve for slope normalization. Computerized linear regression and the use of best-fit line coefficients produce an algorithm-derived MIC. The clinical laboratory can control the result output that is generated (qualitative susceptibility, quantitative susceptibility, or both).

The Microscan Walkaway system (Dade Microscan, West Sacramento, CA) is a rapid test system that uses fluorogenic substrate hydrolysis as an indicator of bacterial growth. This system uses standard microdilution test trays and a computer-controlled incubator and reader unit that can perform robotic manipulations, such as reagent addition and tray rotation, to allow for spectrophotometric or fluorometric growth assessments. Bacterial inocula (approximately 6×10^4 CFU/well for gram-negative organisms and approximately 10^5 CFU/well for gram-positive organisms are added to the wells), and growth is detected by the production of fluorophores from hydrolysis of amidomethylcoumarin or methylumbelliferyl fluorogenic substrates. Although this method is a more sensitive assessment of growth as compared with turbidity, its indirect nature allows for the possibility of bacterial growth without hydrolysis of the fluorophores; this occurrence is rare, however. As with the Vitek system, growth curves are generated, and algorithms applied for the determination of MICs; output is via computer or video display.

8 The results obtained from both systems are comparable. Both the Vitek and Walkaway systems also contain information management systems that allow for the storage and rapid retrieval of susceptibility data. Both systems are also capable of producing chartable patient data reports, antibiograms, and epidemiologic reports. Importantly, these systems can be interfaced with other clinical information systems, such as the pharmacy, infection control, or other laboratory data systems, which can help to improve clinical outcomes.³⁰

ADVANCES IN SUSCEPTIBILITY TESTING FOR MYCOBACTERIA, FUNGI, AND VIRUSES

Impressive advances have been made in the past decade in the areas of mycobacterial, fungal, and viral susceptibility testing. The use of radiometric techniques, such as the BACTEC TB460 system (Becton Dickinson Biosciences, Sparks, MD), has revolutionized the analysis of antimicrobial susceptibility for *M. tuberculosis* and other slow-growing mycobacteria.³¹ Radiometric susceptibility testing involves the incubation of *M. tuberculosis* in liquid medium containing carbon-14 (^{14}C)-labeled growth substrate. As organisms grow, respiration causes the release of ^{14}C , which is then detected. The growth indices for antimicrobial-containing bottles are compared with those of a control bottle with the calculation of an MIC. Use of this method, when coupled with the rapid processing of samples, can reduce the time to susceptibility result generation to approximately 1 week. A newer mycobacterial susceptibility testing method (the BACTEC Mycobacteria Growth Indicator Tube [MGIT 960], Becton Dickinson Diagnostic Instruments, Sparks, MD) that is fully automated and that employs detection of fluorescence related to growth also has been developed; it produces results in a similar time frame and with similar reliability as the radiometric method.³² Primary advantages of this system are its automation, the elimination of radioactivity, and the elimination of needle use. Although the slower agar proportion susceptibility method (generating results in approximately 1 month) is still considered the reference standard for mycobacterial susceptibility testing by the CLSI, the group now recommends the use of a rapid susceptibility testing method to ensure that the Centers for Disease Control and Prevention (CDC) guidelines for reporting susceptibility results for *M. tuberculosis* infections within 28 days of specimen receipt in the laboratory can be met.³³ In the future, the use of molecular probes for mycobacterial resistance genes most likely will become a more important component of mycobacterial susceptibility determinations, especially in light of the increasing problems with antimicrobial resistance.³⁴

There has been a substantial increase in the prevalence of fungal infections in the past two decades. An increase in the development and use of newer antifungal agents has followed. Historically, antifungal susceptibility testing was imprecise and fraught with many inconsistencies. However, pioneering research in the past decade has resulted in the development of CLSI guidelines for the antifungal susceptibility testing methods of both yeasts and filamentous fungi (molds).^{35,36} Use of these techniques can result in greater than 90% inter- and intralaboratory reproducibility. Although routine antifungal testing of every isolate is not generally necessary for most clinical microbiology laboratories, periodic batch testing for antibiograms and surveillance of resistance and/or antifungal testing of patients with such infections as cryptococcal meningitis or oropharyngeal candidiasis refractory to therapy are warranted.

DETECTION OF RESISTANCE FACTORS

There are a number of methods in use that directly detect the production of antimicrobial resistance in pathogens. β -Lactamase production can be detected rapidly and easily in the clinical laboratory with the use of nitrocephin disks. Nitrocephin is a chromogenic cephalosporin derivative that changes color on hydrolysis by β -lactamase. Colonies from a growing bacterial culture can be touched to a disk, with β -lactamase production noted within a few minutes. Although rapid and reliable, this method is limited to the assessment of strains of staphylococci, enterococci, *H. influenzae*, *Moraxella catarrhalis*, and *N. gonorrhoeae*. The nitrocephin disk also cannot detect β -lactam resistance caused by altered penicillin-binding proteins or by some of the newer ESBLs. The use of PCR or DNA probes for detection of β -lactamases improves sensitivity/specificity but is still limited to the research setting. In the

years to come, these molecular biologic techniques should become more refined and more prominent in the clinical microbiology laboratory.

PCR has now become a standard method to quantify the replication of the HIV and hepatitis viruses in infected patients (the *viral load*, described as copies per milliliter).³⁷ Similar methods are used to determine the presence of genetic mutations in the HIV that are associated with increased resistance to one or more of the many antiretroviral medications available for clinical use. The use of these genotyping methods as an aid to select an optimized antiretroviral regimen has been correlated with an improved clinical response to therapy, as well as with a more potent reduction in the viral load.³⁷

The detection of methicillin resistance in *Staphylococcus* (methicillin-resistant *S. aureus* [MRSA]) is crucial to ensure appropriate therapy. Methicillin resistance is the result of the *mecA* gene, which encodes for an altered penicillin-binding protein (penicillin-binding protein 2a) that has a low binding affinity for β -lactams. It is particularly difficult to detect this resistance, although, because of the heterogeneous expression of the phenotype—it is common for only 1 in 10^{4-6} tested cells to express methicillin resistance (even though all cells may have the genetic ability to do so). Screening via oxacillin disks or by oxacillin-containing agar (6 mcg/mL) was once considered the gold standard for resistance detection prior to the development of PCR and DNA probes that were specific for *mecA*. The *mecA* PCR test is available for clinical use, is 99% sensitive and specific, and allows for the rapid (within 6 hours) determination of the presence of methicillin resistance. Although the *mecA* PCR test has been available for many years, many laboratories do not use it commonly because of its high cost relative to other screening methods with acceptable sensitivity/specificity. For example, the presence of MRSA in a nasal swab or a blood culture sample can now be determined directly and rapidly within 24 hours using chromogenic technology (CHROMagar MRSA). This technology uses chromogenic substrates and a cephalosporin; MRSA strains will grow in the presence of cephalosporins such as cefoxitin and will produce mauve-colored colonies resulting from hydrolysis of the chromogenic substrates. The sensitivity and specificity for this test is as high as 97% and 99%, respectively.^{38,39} In addition, fluorescence in situ hybridization (FISH) is a novel technique that uses peptide nucleic acid probes to target ribosomal RNA (rRNA) to rapidly identify both bacteria and yeasts in culture. Peptide nucleic acid probes that specifically target 16S rRNA of *S. aureus* have now been developed for rapid and specific identification of *S. aureus* directly from blood cultures that are Gram-stain positive for gram-positive cocci. The assay has 100% sensitivity and 96% specificity.⁴⁰

The detection of decreased vancomycin susceptibility in gram-positive organisms has become more important with the increased prevalence of both vancomycin-resistant *Enterococcus* (VRE) and vancomycin-intermediate-resistant and vancomycin-resistant *S. aureus* (VISA and VRSA). The vancomycin agar screening method (Brain-Heart Infusion agar containing 6 mcg/mL of vancomycin) is an inexpensive and reliable way to detect vancomycin resistance for both of these problem pathogens.²⁴ With this test, the growth of any colonies from a sample of the test organism (10^5 – 10^6 CFU) after 24 hours of incubation indicates the presence of decreased vancomycin susceptibility (VISA) or vancomycin resistance (VRE, VRSA) within the test strain. Most MIC test methods used in the clinical laboratory that incorporate at least a 16-hour incubation period also appear to reliably detect strains of VRE, VISA, and VRSA.

SPECIAL IN-VITRO TESTS OF ANTIMICROBIAL ACTIVITY

MINIMAL BACTERICIDAL CONCENTRATION

9 In certain infections (e.g., meningitis and endocarditis), the bactericidal (killing) activity may be more predictive of a favorable

infection outcome than the MIC.⁴¹ The minimal bactericidal concentration (MBC) can be performed in conjunction with the broth microtiter MIC test by taking aliquots of broth from microtiter wells that demonstrate no visible growth and plating the samples onto antibiotic-free agar plates for subsequent incubation. The MBC is defined as the lowest concentration of drug that kills 99.9% of the total initially viable cells (representing a $3 \log_{10}$ CFU/mL or greater reduction in the starting inoculum).

For certain antibiotic classes such as the aminoglycosides and the quinolones, the MIC often approximates the MBC. However, for β -lactam antibiotics and glycopeptides, the MBC can exceed the MIC substantially, resulting in an overestimation of in-vivo bactericidal activity. When the MBC exceeds the MIC by 32-fold or more, an organism is said to be *tolerant* to the antimicrobial's killing activity. Although the phenomenon of tolerance has been documented for β -lactams and glycopeptides against certain staphylococci, streptococci, and enterococci, its impact on the outcome of infections caused by organisms other than those just mentioned appears to be limited.

TIMED-KILL CURVE TESTS

Timed-kill curve tests are not performed routinely in the clinical laboratory but can provide important additional data on the effects of an antimicrobial on bacteria. For timed-kill curve tests, a standard inoculum of bacteria (10^6 CFU/mL) is placed in a test tube containing liquid growth medium with or without desired test concentrations of antimicrobial. Samples are removed periodically to determine the number of living cells at the given time points. The viable cell counts are plotted versus time to construct the timed-kill profile of the antimicrobial. The tested concentration of antimicrobial is considered to be bactericidal if it causes at least a $3 \log_{10}$ CFU/mL reduction in viable inoculum. Comparisons of the relative rates of bacterial killing also can be performed in timed-kill curve experiments. Additionally, the presence of concentration-dependent killing activity (where killing increases with increasing drug concentrations above the MIC) versus concentration-independent killing activity can be determined from a timed-kill curve experiment. An example of results from a timed-kill curve experiment is depicted in Fig. 108-7. These data can help to predict the best way to administer an antimicrobial to maximize activity. For example, lower-dose, more frequent (or continuous) infusions would be preferable for concentration-independent antibiotics, while higher-dose intermittent administrations would maximize activity for concentration-dependent antibiotics.

FIGURE 108-7. Killing curve depicting the effect of concentration on antibiotic bactericidal activity. (CFU, colony-forming unit; MIC, minimal inhibitory concentration [0.25–64 times the MIC; the organism tested was *P. aeruginosa* ATCC 27853]). (From Pape et al.³⁹)

POSTANTIBIOTIC EFFECT

The *postantibiotic effect* (PAE) is defined as the persistent suppression of an organism's growth after a brief exposure to an antibiotic.⁴² A PAE experiment is performed by exposing a fixed inoculum of organism to a set concentration of antibiotic (typically some multiple of the MIC) (Fig. 108–8). The antibiotic is then removed either by inactivation (e.g., inactivation by a β -lactamase or binding the antibiotic to a resin) or by filtration/centrifugation of the mixture. The cells are resuspended in antibiotic-free growth medium, and samples are removed frequently (every 0.5 to 2 hours) to determine resumption of normal growth. The PAE is quantified as the difference in time that it takes the organism exposed to the antibiotic to demonstrate a 10-fold increase in viable cells per milliliter as compared with a separate culture of organism not subjected to the antibiotic. A PAE equal to or greater than 1 hour has been demonstrated for most antibiotics against gram-positive bacteria. As a general rule, antibiotics that inhibit DNA or protein synthesis (e.g., quinolones and aminoglycosides) demonstrate significant PAEs against gram-negative organisms. An exception to this rule are the carbapenem cell wall synthesis inhibitors (e.g., ertapenem, imipenem, and meropenem), which demonstrate PAEs against selected strains of gram-negative organisms. The primary clinical application of the PAE is to allow for less frequent administration of antimicrobials while still maintaining adequate antibacterial activity (e.g., extended-interval aminoglycoside administration).⁴²

ANTIMICROBIAL COMBINATION EFFECT TEST

Antimicrobial combination therapy is used frequently to treat serious infections. Combination therapy can be used prior to knowing the pathogen or antibiotic susceptibility for the treatment of infections in neutropenic patients and in patients with enterococcal endocarditis or bacteremia, sepsis, or pneumonia caused by *P. aeruginosa*. In these cases, it is important to know whether the combination will have beneficial (or detrimental) effects on the overall antibacterial activity of the regimen. For example, the combination can result in activity that is significantly greater than the sum of activity of either agent alone (i.e., synergy). Conversely,

FIGURE 108-8. Postantibiotic effect. In this experiment, fixed inocula of *Staphylococcus aureus* and *Pseudomonas aeruginosa* are exposed to ticarcillin, imipenem, and ciprofloxacin at a set concentration of four times the MIC. The organism and the antibiotic are then diluted 1,000-fold to a point where the antibiotic concentration is far below the MIC of the organism. Growth suppression of *S. aureus* following exposure to the three drugs (postantibiotic effect [PAE]) occurs for approximately 2 hours. Growth suppression of *P. aeruginosa*, however, is only demonstrated for imipenem and ciprofloxacin. The β -lactam ticarcillin has no effect on the growth of *P. aeruginosa*. (CFU, colony-forming unit; MIC, minimal inhibitory concentration.) (From Oliveria et al.⁴⁰)

the combination can result in activity that is worse than either agent alone (i.e., antagonism). Combination activity that is neither synergistic nor antagonistic is said to be *indifferent* or *additive*.⁴³

Two methods are used to determine the expected effects of combination antibiotic therapy. For the most part, both methods are not used commonly in the clinical microbiology laboratory owing to the substantial labor involved with these tests and the lack of strong correlation with clinical outcome in the majority of infections. The first method is the microtiter fractional inhibitory concentration (FIC, or “checkerboard” method). The FIC is performed in a similar manner to the microtiter broth MIC except that two antibiotics are tested in the same microtiter plate. Twofold serial dilutions of one antibiotic are made in one direction on the plate (e.g., from right to left), whereas dilutions of the second antibiotic are made from the other direction on the same plate (e.g., from top to bottom). This method produces all possible combinations of twofold concentrations for the two drugs being tested. An inoculum of test bacteria is added to all wells, and the results are read in a similar manner as the MIC test. The FIC is expressed mathematically by calculation of the FIC index. The FIC index is calculated as

$$\text{FIC index} = \frac{A}{\text{MIC}_A} + \frac{B}{\text{MIC}_B}$$

where *A* or *B* is the lowest concentration of the drug that is inhibitory in the presence of the second drug, and the MIC is the minimal inhibitory concentration of each drug tested alone. Synergism is defined as an FIC index of 0.5 or less, indifference is defined as an FIC index of between 0.6 and 4.0, and antagonism is defined as an FIC index of greater than 4.0.⁴⁴ The microtiter FIC methods have been adapted to allow the use of E-test antibiotic-susceptibility test strips.⁴⁵ In this method, two antibiotic E-test strips are crossed at the individual MIC of each antibiotic; an extension of the zone of inhibition beyond that from either antibiotic alone is considered additive or synergistic activity, and an FIC index can be calculated in a similar manner as the microtiter method.

The second most common method to determine the effects of antibiotic combinations is an adaptation of timed-kill curve tests. Two antibiotics are added to the same test tube at fixed concentration fractions of the MIC for each drug, and killing is quantified. With this method, synergism is defined as a 100-fold decrease in viable organisms at 24 hours for the combination as compared with the most potent antibiotic tested alone. Antagonism is defined as a 100-fold or greater increase in viable organism count⁴⁴ (Fig. 108–9). It is important to note that although antagonism has been demonstrated for several combinations in vitro (e.g., penicillin plus tetracycline, chloramphenicol and an aminoglycoside, fluoroquinolones and rifampin), antagonism in vivo has been demonstrated only infrequently.

FIGURE 108-9. Timed-kill curve illustrating indifference, synergy, and antagonism. (CFU, colony-forming unit.)

Although the methods for testing the effects of antimicrobial combinations are well described, the results from these tests have not been adequately studied in the context of infection outcome. There is little debate that the combination of a β -lactam antibiotic and an aminoglycoside is required for successful treatment of enterococcal endocarditis. For enterococci, susceptibility to high concentrations of aminoglycosides (e.g., gentamicin, 500 mg/mL) is evaluated in the clinical laboratory because it correlates closely with synergy when the drug is combined with β -lactam antibiotics.

The concept of combination therapy is not universally accepted for the treatment of other infections. There is ongoing debate as to whether the combination of a broad-spectrum β -lactam and an aminoglycoside is needed (versus the β -lactam alone) for the therapy of such infections as gram-negative bloodstream infections or infections in neutropenic patients.⁴⁶ In individual studies, combination therapy has resulted in improved outcomes in patients with severe illness and in patients with *P. aeruginosa* bloodstream infections, but pooled meta-analyses have disputed these results.⁴⁶

LABORATORY MONITORING OF ANTIMICROBIAL THERAPY

10 The clinician should have an understanding of in-vivo antimicrobial agent disposition to select the most appropriate therapy for a given infection and to help monitor for clinical or bacteriologic efficacy. Serum concentration monitoring is the most common method used to attempt to maximize efficacy and minimize toxicity of antimicrobials. Because most antimicrobials are well tolerated at their usual doses, only a select few agents (e.g., aminoglycosides, chloramphenicol, and vancomycin) are monitored routinely in the current clinical environment. There are a number of direct and indirect methods that are used to quantify the concentration of antimicrobial in an experimental sample.

METHODS OF ANTIMICROBIAL CONCENTRATION DETERMINATION IN CLINICAL SAMPLES

Fluorescence-Polarization Immunoassay

The fluorescence-polarization immunoassay (FPIA) technique involves the application of the principles of fluorescence when molecules are exposed to light. A fluorescein-labeled drug and antibody that is directed against the drug are added in constant amounts to samples with unknown drug concentrations and to concentration standards. When the fluorescein-labeled drug complexes with the antibody, a quantifiable change in the fluorescence polarization occurs. When a sample containing non-fluorescein-labeled drug (i.e., a patient's serum sample) is mixed with the standard mixture, competition for antibody binding occurs. Comparison of the change caused by the patient's sample to the changes caused by standard concentrations determines the specific drug concentration in the patient sample.

FPIA is the most commonly used assay method for the determination of aminoglycoside and vancomycin serum concentrations in the clinical laboratory setting. Advantages of this technique include its automation through the use of the TDx system (Abbott Laboratories, North Chicago, IL). Disadvantages include the expenses for reagents and the cost for the purchase of the automated system.

Radioimmunoassay

Radioimmunoassay (RIA) uses a radiolabeled drug and an antibody directed against the specific drug to determine the concentration contained in an unknown sample. The theory behind the assay is

similar to FPIA because radiolabeled antibiotic and unlabeled antibiotic (in the patient's serum sample) are equilibrated with the antibody. The amount of free radiolabeled drug is measured and compared with the values obtained with standard concentrations of the radiolabeled drug alone to determine the concentration in the patient sample. Although RIA has good sensitivity and specificity, its main disadvantage compared with FPIA is the expense and hassle of handling and disposal of the radioactive waste generated during the test.

High-Pressure Liquid Chromatography

High-performance liquid chromatography (HPLC) permits the separation of different molecular species by passing a mobile solvent phase over a stationary phase. Drugs with a polarity similar to that of the stationary phase are retained for a time on the chromatographic column and then released after various retention times. Detection can be accomplished via fluorescence, electrochemical, or radiometric methods. The detector signal is proportional to the amount of molecules present. Standard curves are generated from known concentrations of the drug (usually recorded as peak area or peak height). Advantages of HPLC include a rapid turnaround time, precision, and an ability to detect the test drug in the presence of its metabolites and/or other drugs. Disadvantages include the high cost of HPLC instruments and the expertise required to perform the assays. These disadvantages usually relegate HPLC drug assay to the experimental and/or research settings.

Serum Inhibitory/Bactericidal Titers

Serum inhibitory titers (SITs) and serum bactericidal titers (SBTs) sometimes are used to monitor the antimicrobial therapy of certain serious infections (e.g., osteomyelitis and endocarditis). SITs and SBTs for antimicrobials are determined in a similar standardized manner as microdilution MICs and MBCs, but dilutions of the patient's serum are used instead of known concentrations of antimicrobial.⁴⁷ Patient serum can be collected near the expected peak, midpoint, and/or trough concentration(s) of the antimicrobial dose. The SIT is the highest twofold dilution of the serum sample that inhibits the visible growth of the patient's infecting organism, whereas the SBT is defined as the highest dilution of serum that kills 99.9% of the original bacterial inoculum is the SBT. Values for the SIT and SBT are expressed as the number of twofold serial dilutions relative to the original serum sample (e.g., SIT = 1:32, SBT = 1:8). A peak SBT of greater than 1:32 predicted successful outcome for endocarditis, whereas a trough SBT of greater than 1:2 predicted success for osteomyelitis.^{48,49}

Microbiologic Assay

Microbioassay of antimicrobial agents can be performed by several methods. The most common method is a modification of the disk diffusion antimicrobial-susceptibility technique. Typically, paper disks are placed on agar that contains an inoculum of a bacterium known to be highly susceptible to the antimicrobial agent to be assayed. Fixed volumes (usually 10 mL) of a range of prepared concentration standards of the test drug are placed on the disks. The zones of growth inhibition are measured and plotted versus the drug concentration to generate a standard curve. Zone sizes from samples containing the unknown concentrations of the test drug are measured, and the concentrations are determined from the plotted curve; the drug concentration in unknown samples is determined from the standard curve generated from the known concentrations of the drug. The advantages of this method include its relative ease of performance and the minimal cost for equipment. The disadvantages of this method include interference from other antibiotics that can be present in the unknown sample, a lack of sensitivity/

specificity for certain antimicrobials, and a slow turnaround time (usually 24 to 48 hours) for generation of results.

TIMING OF COLLECTION OF SERUM SAMPLES

11 Peak and/or trough concentrations are monitored routinely for only a select few antimicrobials (e.g., aminoglycosides and vancomycin) during the contemporary management of infections. It is crucial for the healthcare team to ensure that the antimicrobial's administration time and serum sample time(s) are meticulously recorded because even small errors in recording these (e.g., 1 hour) can have a substantial impact on the calculation of pharmacokinetics for antibiotics such as the aminoglycosides, which have relatively short elimination half-lives.

Samples ideally should be obtained after steady state is achieved (usually defined as the passage of at least 3 to 4 anticipated half-lives), but in certain situations, this may not be possible (e.g., critically ill patients with fluctuations in drug elimination owing to fluctuating hemodynamics, kidney function, and/or liver function). Generally, the timing of the peak serum sample collection is usually more critical than the trough concentration because adequate time must elapse to allow for completion of the distribution phase and to avoid underestimating the drug's volume of distribution.

SPECIFIC AGENTS

The aminoglycosides (i.e., amikacin, gentamicin, and tobramycin) and vancomycin remain the most common agents for which serum concentrations are monitored. A summary of the recommendations for serum concentration monitoring of these agents is shown in Table 108–2.

Aminoglycosides

12 There are many studies that have linked serum aminoglycoside concentrations with clinical response and with the occurrence of nephrotoxicity. One of the classic investigations into the relationship between serum aminoglycoside activity and clinical outcome revealed that peak serum concentrations of at least 5 mcg/mL for gentamicin and tobramycin and at least 20 mcg/mL for amikacin were associated with a lower prevalence of clinical failure rates during the treatment of gram-negative bacteremia.⁵⁰ Although earlier studies suggested that trough concentrations exceeding 2 to 4

mcg/mL for gentamicin and tobramycin and 10 mcg/mL for amikacin predisposed patients to nephrotoxicity, more recent investigations indicate that the development of aminoglycoside-related ototoxicity and nephrotoxicity is more complex and also is associated with the total exposure to the aminoglycoside (as measured by the AUC) and/or the total duration of aminoglycoside therapy.⁵¹ The specific recommended serum peak and trough concentrations for the various aminoglycosides are described in Table 108–2.

Newer regimens of once-daily or extended-interval aminoglycoside administration have gained widespread acceptance for use in the clinical setting. These regimens exploit the pharmacodynamic properties of these agents (i.e., concentration-dependent bacterial killing and a substantial PAE) to maximize activity while also attempting to minimize drug nephrotoxicity by reducing the total aminoglycoside exposure time for the patient's kidneys. The doses employed for extended-interval treatment typically range from 5 to 7 mg/kg of lean body weight (administered every 24 to 48 hours), with the dose and/or interval adjusted based on renal function or observed mid-dose serum concentrations.⁵² Many prospective studies have been performed to evaluate the safety and efficacy of once-daily aminoglycoside dosing, and most have revealed similar rates of efficacy and toxicity, or trends toward improved efficacy and reduced toxicity for once-daily dosage regimens as compared with traditional (thrice daily) regimens.

Traditional methods of aminoglycoside serum concentration monitoring (evaluating peak and trough serum concentrations) cannot be applied to extended-interval dosing because the serum concentrations 24 hours after a dose ideally should be undetectable. A mid-interval serum sample can be taken approximately 6 to 12 hours after the dose to allow for use of first-order pharmacokinetic equations.

CLINICAL CONTROVERSY

Although some clinicians believe that the clinical data are sufficient to support widespread use of once-daily aminoglycoside dosing without determination of individualized patient pharmacokinetics, other clinicians believe that the data from investigations on once-daily aminoglycosides are incomplete and that patients still should receive individualized pharmacokinetic assessments and dosage adjustments.

TABLE 108-2 Suggested Therapeutic Serum Concentrations for Selected Antimicrobial Agents

Drug	Sample	Target Concentrations	
		(mg/L)	Comments
Gentamicin, Tobramycin (Traditional dosage regimens)	Peak (1 hour after the start of a 15- to 45-minute infusion)	<5	Urinary tract infections
		>5	Bacteremia
		>6	Bacterial pneumonia
		>12	Endocarditis caused by <i>Pseudomonas aeruginosa</i>
		<2–3	High trough concentrations are most likely a result of and not a cause of nephrotoxicity
Amikacin	Trough	>15	Urinary tract infections
		>20	Bacteremia
		>24	Bacterial pneumonia, other serious infections
		>9–10	See comments regarding trough gentamicin/ tobramycin concentrations
Single daily dosage regimens ⁴⁹ Gentamicin Netilmicin Tobramycin Vancomycin	8-hour postdose (mid-dose)	1.5–6	Concentrations above this range associated with nephrotoxicity in one study with netilmicin
		20–50	Recommendations should be considered tentative, as definitive data are not available
		15–20	Recent data suggest this higher trough range in pneumonia due to low lung penetration and increasing vancomycin MICs/MBCs ^{52,53}

MIC, minimal inhibitor concentration; MBC, minimal bactericidal concentration.

Data from Weinstein et al.,⁴⁹ Nicalau et al.,⁵² and Rybak.⁵³

Vancomycin

13 Although vancomycin appears to possess a time-dependent killing profile, the area under the concentration-time curve to MIC ratio (AUC/MIC) appears to be the most likely parameter predicting efficacy as demonstrated by animal and limited human data.⁵³ Although intravenous vancomycin has been associated with oto- and nephrotoxicity in humans, most of these reports occurred with older, impure formulations of the drug, with extremely high concentrations uncommon with contemporary dosing regimens, or when vancomycin was combined with known nephrotoxic agents. Indeed, continuous infusions of vancomycin that resulted in constant serum vancomycin concentrations of 20 to 25 mcg/mL caused no substantial nephrotoxicity when compared with intermittent regimens that targeted the “accepted” serum trough concentration range.⁵⁴

Because vancomycin appears to possess a time-dependent killing-activity profile, it has been recommended that vancomycin concentrations remain above the organism’s MIC during the entire dosing interval. Most methods of empirical vancomycin dosing result in peak concentrations of between 20 and 50 mcg/mL and trough concentrations of between 5 and 15 mcg/mL. A number of weight-based dosage regimens and/or nomogram-based dosage methods can be used to minimize monitoring of serum concentrations for the vast majority of patients. However, recent data suggest that higher vancomycin trough concentrations are now needed because of its poor penetration into the lung tissue, combined with the trend toward increased prevalence of strains of staphylococci with higher MICs and/or MBCs. Recent guidelines for the treatment of hospital- and ventilator-associated pneumonia reflect these trends, as troughs of 15 to 20 mg/L are recommended.^{55,56}

INTEGRATING ORGANISM SUSCEPTIBILITY WITH SERUM CONCENTRATION DATA TO IMPROVE ANTIMICROBIAL THERAPY

7 14 We have advanced our understanding substantially of the importance of considering both antimicrobial pharmacokinetics and organism susceptibility when selecting therapy for the treatment of infections. Antimicrobial regimens should be selected and/or designed to maximize the probability that bacterial killing is optimized and that the probability of resistance is minimized. For example, the activity of antimicrobials such as the fluoroquinolones and the aminoglycosides can be maximized if the ratio of the peak serum concentration to the organism MIC (peak-to-MIC ratio) is greater than or equal to 10.⁵⁷ Similarly, the probability of clinical and/or microbiologic infection cure can be maximized if a fluoroquinolone is chosen that achieves an area under the curve (AUC)-to-MIC ratio of 100 to 125 or greater for gram-negative bacteria (e.g., *P. aeruginosa*) and 30 to 40 or greater for gram-positive bacteria (e.g., *S. pneumoniae*).^{58,59} The clinical application of these principles to aminoglycoside dosage regimen optimization is depicted in Fig. 108–10. Although the maintenance of concentrations above the infecting organism’s MIC (the time above the MIC) best predicts the clinical efficacy of the β -lactam antimicrobials, the AUC-to-MIC ratio also appears to be a strong predictor for treatment outcome for certain organisms and in certain clinical situations (e.g., vancomycin for staphylococcal infections).^{53,60}

Most of the data on optimization of antimicrobial pharmacodynamics have been generated in in-vitro models of infection, in animal models of infection, within the context of controlled clinical trials, or through mathematical modeling of small data sets. However, research continues to emerge on the best ways to apply these valuable data to the everyday management of patients in the clinical setting. The recognition of the importance of antimicrobial pharmacodynamics already has resulted in the expansion of serum concen-

FIGURE 108-10. Illustration of the concept of peak concentration to the minimal inhibitory concentration (MIC) ratio for aminoglycosides. The MIC for the given organism to gentamicin is 2 mg/L, whereas the tobramycin MIC is 0.5 mg/L. Administration of gentamicin would result in a suboptimal peak:MIC ratio (<10), which could increase the chances for development of resistance or an inadequate response. Administration of tobramycin would result in a peak:MIC ratio of 12, which should improve efficacy. Note that modification of the gentamicin regimen to produce peak serum concentrations of 20 mg/L or more (as commonly done with once-daily administration) also would result in a peak:MIC ratio of 10 or greater.

tration monitoring for select antimicrobials (e.g., antiretroviral agents, antifungal agents), suggested revisions of breakpoint values that define antimicrobial susceptibility and/or resistance, development of nomograms or computer programs that can suggest optimal drugs and doses for a given infection, and/or the development of newer antimicrobial agents that minimize the probability of suboptimal pharmacodynamics. These developments present exciting opportunities for healthcare providers to improve the outcomes of patients with infections in a variety of different healthcare settings.

DAVID S. BURGESS

KEY CONCEPTS

- 1 Every attempt should be made to obtain specimens for culture and sensitivity testing prior to initiating antibiotics.
- 2 Empirical antibiotic therapy should be based on knowledge of likely pathogens for the site of infection, information from patient history (e.g., recent hospitalizations, work-related exposure, travel, and pets), and local susceptibility.
- 3 Patients with delayed dermatologic reactions to penicillin generally can receive cephalosporins. Patients with type I hypersensitivity reactions (anaphylaxis) to penicillins should not receive cephalosporins or carbapenems (alternatives include aztreonam, quinolones, sulfa drugs, or vancomycin based on type of coverage indicated).
- 4 Estimated renal function should be calculated for every patient who is to receive antibiotics and the antibiotic dose interval adjusted accordingly. Hepatic function should be considered for drugs eliminated through the hepatobiliary system, such as clindamycin, erythromycin, and metronidazole.
- 5 All concomitant drugs and nutritional supplements should be reviewed when an antibiotic is added to a patient's therapy.
- 6 Combination antibiotic therapy may be indicated for polymicrobial infections (abdominal, gynecologic infections), to produce synergistic killing (β -lactam plus aminoglycoside versus *Pseudomonas aeruginosa*), or to prevent the emergence of resistance.
- 7 All patients receiving antibiotics should be monitored for resolution of infectious signs and symptoms (e.g., decreasing temperature and white blood cell [WBC] count) and adverse drug events.
- 8 Antibiotic agents with the narrowest effective spectrum of activity are preferred. Antibiotic route of administration should be evaluated daily, and conversion from intravenous to oral therapy should be attempted as signs of infection improve for patients with functioning gastrointestinal tracts (general exceptions are endocarditis and central nervous system infections).
- 9 Patients not responding to an appropriate antibiotic treatment in 2 to 3 days should be reevaluated to ensure (a) the correct

diagnosis, (b) that therapeutic drug concentrations are being achieved, (c) that the patient is not immunosuppressed, (d) that the patient does not have isolated infection (i.e., abscess, foreign body), or (e) that resistance has not developed.

Choosing an antimicrobial agent to treat an infection is far more complicated than matching a drug to a known or suspected pathogen.^{1,2} Most clinicians generally follow a systematic approach to select an antimicrobial regimen (Table 109–1). Problems arise when this systematic approach is replaced by prescribing broad-spectrum therapy to cover as many organisms as possible. Consequences of not using the systematic approach include the use of more expensive and potentially more toxic agents, which can, in turn, lead to widespread resistance and difficult-to-treat superinfections. Another abuse of antimicrobial agents is administration when they are not needed. An example of this is prescribing antibacterials for self-limited clinical conditions that are most likely viral in origin (i.e., the common cold).

Initial selection of antimicrobial therapy is nearly always empirical, which is the initiation of antimicrobials sometimes prior to documentation of the presence of infection and before the offending organism is identified. Infectious diseases generally are acute, and a delay in antimicrobial therapy can result in serious morbidity or even mortality. Thus empirical antimicrobial therapy selection is based on information gathered from the patient's history and physical examination and results of Gram stains or of rapidly performed tests on specimens from the infected site. This information, combined with knowledge of the most likely offending organism(s) and an institution's local susceptibility patterns, should result in a rational selection of antibiotics to treat the patient.

This chapter introduces a systematic approach to the selection of antimicrobial therapeutic regimens.

CONFIRMING THE PRESENCE OF INFECTION

FEVER

The presence of a temperature greater than the expected 37°C (98.6°F) “normal” body temperature is considered a hallmark of infectious diseases. Body temperature is controlled by the hypothalamus. In addition, the circadian rhythm, a built-in temperature cycle, is also operational. The daily temperature rhythm can vary for each individual. In a healthy person, the internal thermostat is set between the morning low temperature and the afternoon peak as controlled by the circadian rhythm. During fever, the hypothalamus is reset at a higher temperature level.

Fever is defined as a controlled elevation of body temperature above the normal range. The average normal body temperature range taken orally is 36.7 to 37°C (98.0 to 98.6°F). Body temperatures obtained rectally generally are 0.6° (1°F) higher and axillary temperatures are 0.6°C (1°F) lower than oral temperatures, respectively. Skin temperatures are also less than the oral temperature but can vary depending on the specific measurement method. Fever can be a manifestation of disease states other than infection. Collagen-vascular (autoimmune) disorders and several malignancies can have fever as a manifestation. Fever of unknown or undetermined origin is a diagnostic dilemma and is reviewed extensively elsewhere.³

Many drugs have been identified as causes of fever.⁴ *Drug-induced fever* is defined as persistent fever in the absence of infection or other underlying condition. The fever must coincide temporally with the administration of the offending agent and disappear promptly on its withdrawal, after which the temperature remains normal. Possible mechanisms of drug-induced fever are either a hypersensitivity reaction or development of antigen-antibody complexes that result in the stimulation of macrophages and the release of interleukin 1 (IL-1). Although this is not a common drug effect (accounting for no more than 5% of all drug reactions), it should be suspected when obvious reasons for fever are not present. Almost any medication can produce fever, but β -lactam antibiotics, anticonvulsants, allopurinol, hydralazine, nitrofurantoin, sulfonamides, phenothiazines, and methyldopa appear to be responsible more often than others.⁴

Noninfectious etiologies of fever can be referred to as “false-positives.” Although these certainly can confuse the clinician, even more troublesome are false-negatives: the absence of fever in a patient with signs and symptoms consistent with an infectious disease. Careful questioning of the patient or family is vital to assess the ingestion of any medication that can mask fever (e.g., aspirin, acetaminophen, nonsteroidal antiinflammatory agents, and corticosteroids). The use of antipyretics should be discouraged during the treatment of infection unless absolutely necessary because they can mask a poor therapeutic response. Moreover, elevated body temperature, unless very high (>40.5°C [105°F]), is not harmful and may be beneficial.

SIGNS AND SYMPTOMS

White Blood Cell Count

Most infections result in elevated WBC counts (leukocytosis) because of the increased production and mobilization of granulocytes (neutrophils, basophils, and eosinophils), lymphocytes, or both to ingest and destroy invading microbes. The generally accepted range of normal values for WBC counts is between 4,000 and 10,000 cells/mm³. Values above or below this range hold important prognostic and diagnostic value.

Bacterial infections are associated with elevated granulocyte counts, often with immature forms (band neutrophils) seen in peripheral blood smears. Mature neutrophils are also referred to as

segmented neutrophils or *polymorphonuclear (PMN) leukocytes*. The presence of immature forms (left shift) is an indication of an increased bone marrow response to the infection. With infection, peripheral WBC counts can be very high, but they are rarely higher than 30,000 to 40,000 cells/mm³. Because leukocytosis indicates the normal host response to infection, low leukocyte counts after the onset of infection indicate an abnormal response and generally are associated with a poor prognosis.

The most common granulocyte defect is neutropenia, a decrease in absolute numbers of circulating neutrophils. A thorough description of the consequences of neutropenia is given in Chap. 120. Lymphocytosis, even with normal or slightly elevated total WBC counts, generally is associated with tuberculosis and viral or fungal infections. Increases in monocytes can be associated with tuberculosis or lymphoma, and increases in eosinophils can be associated with allergic reactions to drugs or infections caused by metazoa. Many types of infections can be accompanied by a completely normal WBC count and differential.

Local Signs

The classic signs of pain and inflammation can manifest as swelling, erythema, tenderness, and purulent drainage. Unfortunately, these are only visible if the infection is superficial or in a bone or joint. The manifestations of inflammation in deep-seated infections (e.g., meningitis, pneumonia, endocarditis, and urinary tract infection) must be ascertained by examining tissues or fluids. For example, the presence of neutrophils in spinal fluid, lung secretions (sputum), or urine is highly suggestive of a bacterial infection.

Symptoms referable to an organ system must be sought out carefully because not only do they help in establishing the presence of infection, but they also aid in narrowing the list of potential pathogens. For example, a febrile patient with complaints of flank pain and dysuria can well have pyelonephritis. In this situation, enteric gram-negative bacilli, especially *Escherichia coli*, are the predominant pathogens. If a febrile patient has no symptoms suggestive of an organ system but only constitutional complaints, the list of possible infectious diseases is lengthy.³ A febrile individual with cough and sputum production probably has a pulmonary infection. What is not so evident, however, is the etiologic organism in this situation, because it can be caused by bacteria, mycobacteria, viruses, chlamydia, or mycoplasmas.⁵ In this situation, attention to the patient's history and background disease states is important. Even more important is a careful examination of the infected material (in this case sputum) to ascertain the identity of the pathogen.

IDENTIFICATION OF THE PATHOGEN

MICROBIOLOGY ISSUES

1 Infected body materials must be sampled, if at all possible or practical, before institution of any antimicrobial therapy for two reasons. First, a Gram stain of the material might reveal bacteria, or an acid-fast stain might detect mycobacteria or actinomycetes. Second, a delay in obtaining infected fluids or tissues until after antimicrobial therapy is started might result in false-negative culture results or alterations in the cellular and chemical composition of infected fluids. This is particularly true in patients with urinary tract infections, meningitis, and septic arthritis.⁶

Blood cultures usually should be performed in the acutely ill febrile patient. Blood culture collection should coincide with sharp elevations in temperature, suggesting the possibility of microorganisms or microbial antigens in the bloodstream. Ideally, blood should be obtained from peripheral sites as two sets (one set consists of an aerobic bottle and one set an anaerobic bottle) from two different

sites approximately 1 hour apart. In selected infections, bacteremia is qualitatively continuous (e.g., endocarditis), so cultures can be obtained at any time.⁷

In addition to the infected materials produced by the patient (e.g., blood, sputum, urine, stool, and wound or sinus drainage), other less accessible fluids or tissues must be obtained based on localized signs or symptoms (e.g., spinal fluid in meningitis and joint fluid in arthritis). Abscesses and cellulitic areas also should be aspirated.

INTERPRETING RESULTS

After a positive Gram stain, culture results, or both are obtained, the clinician must be cautious in determining whether the organism recovered is a true pathogen, a contaminant, or a part of the normally expected flora (see Chap. 108). This latter consideration is especially problematic with cultures obtained from the skin, oropharynx, nose, ears, eyes, throat, and perineum. These surfaces are heavily colonized with a wide variety of bacteria, some of which can be pathogenic in certain settings. For example, coagulase-negative staphylococci are found in cultures of all the aforementioned sites yet are seldom regarded as pathogens unless recovered from blood, venous access catheters, or prosthetic devices.

Importantly, cultures of specimens from purportedly infected sites that are obtained by sampling from or through one of these contaminated areas might contain significant numbers of the normal flora. In the case of urine cultures, the urinalysis should be used in combination with culture results to assess the presence of WBCs, nitrite, and leukocyte esterase to help confirm infection and rule out colonization.

Particularly problematic are expectorated sputum specimens that must be evaluated carefully by determination of the presence of squamous epithelial cells and leukocytes.⁵ A predominance of epithelial cells in sputum specimens reduces the likelihood that recovered bacteria are pathogenic, especially when multiple types of organisms are seen on Gram stain. In contrast, the discovery of leukocytes in large numbers with one predominant type of organism is a more reliable indicator of a valid collection. In general, however, sputum evaluation has poor sensitivity and specificity as a diagnostic test.⁵

Caution also must be used in the evaluation of positive culture results from normally sterile sites (e.g., blood, cerebrospinal fluid, or joint fluid). The recovery of bacteria normally found on the skin in large quantities (e.g., coagulase-negative staphylococci or diphtheroids) from one of these sites can be a result of contamination of the specimen rather than a true infection. These organisms can be pathogenic in certain settings.

Gram-staining techniques, culture methods, and serologic identification, as well as susceptibility testing, are discussed in detail in Chap. 108. Emphasis must be placed on the proper collection and handling of specimens and careful assessment of Gram stain or other test results in guiding the clinician toward appropriate selection of initial antimicrobial therapy.⁸

SELECTION OF PRESUMPTIVE THERAPY

2 To select rational antimicrobial therapy for a given clinical situation, a variety of factors must be considered. These include the severity and acuity of the disease, host factors, factors related to the drugs used, and the necessity for using multiple agents. In addition, there are generally accepted drugs of choice for the treatment of most pathogens (see Appendix 109–1).

Drugs of choice are compiled from a variety of sources and are intended as guidelines rather than as specific rules for antimicrobial use. These choices are influenced by local antimicrobial susceptibility data rather than information published by other institutions or

national compilations. Each institution should publish an annual summary of antibiotic susceptibilities (antibiogram) for organisms cultured from patients. Antibiograms contain both the number of nonduplicate isolates for common species and the percentage susceptible to the antibiotics tested. To further guide empirical antibiotic therapy, some hospitals publish unit-specific antibiograms in unique patient care areas, such as intensive care units or burn units.

Susceptibility of bacteria can differ substantially among hospitals within a community. For example, the prevalence of hospital-acquired methicillin-resistant *Staphylococcus aureus* (HA-MRSA) in some centers is quite high, whereas in other centers the problem might be nonexistent. This particular situation will influence the selection of therapy for possible *S. aureus* infection, where the clinician must choose either a β -lactam or vancomycin. The problem of differing susceptibilities is limited not only to gram-positive bacteria but also to gram-negative organisms, and all drug classes are affected.

Empirical therapy is directed at organisms that are known to cause the infection in question. These organisms for different sites of infection are discussed in Chap. 110 to 129. To define the most likely infecting organisms, a careful history and physical examination must be performed. The place where the infection was acquired should be determined, for example, the home (community-acquired), nursing home environment, or hospital-acquired (nosocomial). Nursing home patients can be exposed to potentially more resistant organisms because they are often surrounded by ill patients who are receiving antibiotics. Other important questions to ask infected patients regarding the history of the present illness include the following:

1. Are any other people sick at home, especially children?
2. Are any unusual pets kept in the home such as pigeons?
3. Where are you employed (i.e., are you exposed to contaminated meat or infectious biohazards)?
4. Has there been any recent travel, for example, to endemic areas of fungal infections or developing countries?

HOST FACTORS

Several host factors should be considered when evaluating a patient for antimicrobial therapy. The most important factors are drug allergies, age, pregnancy, genetic or metabolic abnormalities, renal and hepatic function, site of infection, concomitant drug therapy, and underlying disease states.

Allergy

3 Allergy to an antimicrobial agent generally precludes its use. Careful assessment of allergy histories must be performed because many patients confuse common adverse drug effects (i.e., gastrointestinal disturbance) with true allergic reactions.⁹ Among the most commonly cited antimicrobial allergies are those to penicillin, penicillin-related compounds, or both. In the absence of complete penicillin skin testing capabilities, a rule of thumb for giving cephalosporins or carbapenems to patients allergic to penicillin is to avoid giving them to patients who give a good history for immediate or accelerated reactions (e.g., anaphylaxis, laryngospasm) and to give them under close supervision in patients with a history of delayed reactions, such as a rash.¹⁰ If gram-negative infection is suspected or documented, therapy with a monobactam may be appropriate because cross-reactivity with other β -lactams is virtually nil.

Age

The patient's age is an important factor both in trying to identify the likely etiologic agent and in assessing the patient's ability to eliminate the drug(s) to be used. The best example of an age determinant of organisms is in bacterial meningitis, where the pathogens differ

as the patient grows from the neonatal period through infancy and childhood and into adulthood.⁶

In the case of the neonate, hepatic and liver functions are not well developed. The use of chloramphenicol can lead to shock and cardiovascular collapse (gray baby syndrome) caused by the inability of the newborn's liver to metabolize and detoxify the drug.⁴ Serum concentrations of chloramphenicol must be monitored to ensure that concentrations of the drug do not exceed 20 to 25 mcg/mL. Neonates (especially when premature) can develop kernicterus when given sulfonamides. This results from displacement of bilirubin from serum albumin.⁴ Additional special drug considerations for pediatric patients include low frequency of adverse effects and compliance-enhancing features (e.g., absorption not affected by food, once- to twice-daily dosing, and good taste).¹¹

The major physiologic change in persons older than 65 years of age is a decline in the number of functioning nephrons that, in turn, results in decreased renal function.¹² This is usually manifested by an increased incidence of side effects caused by antimicrobials that are eliminated renally. For example, renal toxicity caused by aminoglycosides may be apparent much sooner during therapy than in younger patients.

Pregnancy

During pregnancy, not only is the fetus at risk for drug teratogenicity (see Chap. 81), but also the pharmacokinetic disposition of certain drugs can be altered.¹³ Penicillins, cephalosporins, and aminoglycosides are cleared from the peripheral circulation more rapidly during pregnancy. This is probably a result of marked increases in intravascular volume, glomerular filtration rate, and hepatic and metabolic activities. The net result is that maternal serum antimicrobial concentrations can be as much as 50% lower during this period than in the nonpregnant state. Increased dosages of certain compounds might be necessary to achieve therapeutic levels during late pregnancy.

Metabolic Abnormalities

Inherited or acquired metabolic abnormalities will influence the therapy of infectious diseases in a variety of ways. For example, patients with impaired peripheral vascular flow may not absorb drugs given by intramuscular injection. In addition, certain metabolic states can predispose patients to enhanced drug toxicity. For example, patients who are phenotypically slow acetylators of isoniazid are at greater risk for peripheral neuropathy.¹⁴ Patients with severe deficiency of glucose-6-phosphate dehydrogenase can develop significant hemolysis when exposed to such drugs as sulfonamides, nitrofurantoin, nalidixic acid, antimalarials, dapsone, and perhaps, chloramphenicol.⁴ Although mild deficiencies are found in African Americans, the more severe forms of the disease generally are confined to persons of eastern Mediterranean origin.

Organ Dysfunction

4 Patients with diminished renal or hepatic function or both will accumulate certain drugs unless the dosage is adjusted.^{15,16} Recommendations for dosing antibiotics in patients with liver dysfunction are not as formalized as guidelines for patients with renal dysfunction. Antibiotics that should be adjusted in severe liver disease include clindamycin, erythromycin, metronidazole, and rifampin. Significant accumulation can occur when both liver dysfunction and renal dysfunction are present for these drugs: cefotaxime, nafcillin, piperacillin, and sulfamethoxazole.

Concomitant Drugs

5 Any concomitant therapy that the patient is receiving can influence the drug selection, dose, and monitoring. For example, adminis-

tration of isoniazid to a patient who is also receiving phenytoin can result in phenytoin toxicity secondary to inhibition of phenytoin metabolism by isoniazid. Furthermore, drugs that possess similar adverse-effect profiles can increase the risk for effects, for example, two drugs that cause nephrotoxicity or neutropenia. A detailed review of drug interactions is beyond the scope of this chapter, but an excellent textbook on this subject is available.¹⁷ Lists of potentially severe drug-drug interactions are provided in Table 109–2.

Concomitant Disease States

Concomitant disease states can influence the selection of therapy. Certain diseases will predispose patients to a particular infectious disease or will alter the type of infecting organism. For example, patients with diabetes mellitus and the resulting peripheral vascular disease often develop infections of the lower extremity soft tissue. Moreover, the alterations in peripheral blood flow associated with the disease and perhaps altered immunity make such infections more difficult to treat than in nondiabetics. Patients with chronic lung disease or cystic fibrosis develop frequent pulmonary infections that can be caused by somewhat different microorganisms than are found in otherwise normal hosts.

Patients with immunosuppressive diseases, such as malignancies or acquired immunologic deficiencies, are highly predisposed to infections, and the types of organisms can be vastly different from what would be expected (see Chap. 126). For example, patients undergoing chemotherapy for acute forms of leukemia often are profoundly granulocytopenic and are predisposed to infections caused by bacteria and fungi.¹⁸ Patients with the acquired immunodeficiency syndrome (AIDS) often become infected with an enormous variety of organisms (see Chap. 129).¹⁹

Many factors predisposing to infection are related to disruption of the host's integumentary barriers. For example, trauma, burns, and iatrogenic wounds induced in surgery can lead to a substantial risk of infection depending on the severity and location of the injury or disruption. For a complete discussion of the various risks involved in surgical procedures, see Chap. 127.

DRUG FACTORS

Pharmacokinetic and Pharmacodynamic Considerations

Integration of both pharmacokinetic and pharmacodynamic properties of an agent is important when choosing antimicrobial therapy to ensure efficacy and to prevent resistance.²⁰ Early researchers relied solely on pharmacokinetic properties such as the area under the (drug concentration) curve (AUC), maximum observed concentration (peak), and drug half-life to optimize therapy. Pharmacodynamics is the study of the relationship between drug concentration and the effects on the microorganism (see Chap. 108). Researchers now realize the important relationship between both pharmacokinetic and microbiologic parameters that has resulted in new measurements such as AUC:minimal inhibitory concentration (MIC) ratio, peak:MIC ratio, and time (*T*) the concentration is above MIC (*T* > MIC).^{21,22}

Aminoglycosides exhibit concentration-dependent bactericidal effects.^{20–22} An example of the integration of pharmacokinetics and microbiological activity is the use of high-dose, once-daily aminoglycosides. For these regimens, the drug is given as a single large daily dose to maximize the peak:MIC ratio. Aminoglycosides also possess a postantibiotic effect (persistent suppression of organism growth after concentrations decrease below the MIC) that appears to contribute to the success of high-dose, once-daily administration.²⁰ Fluoroquinolones exhibit concentration-dependent killing activity, but optimal killing appears to be characterized by the AUC:MIC ratio.^{20–23}

TABLE 109-2 Major Drug Interactions with Antimicrobials

Antimicrobial	Other Agent(s)	Mechanism of Action/Effect	Clinical Management
Aminoglycosides	Neuromuscular blocking agents Nephrotoxins (N) or ototoxins (O) (e.g., amphotericin B (N) cisplatin (N/O), cyclosporine (N), furosemide (O), NSAIDs (N), radio contrast (N), vancomycin (N)	Additive adverse effects Additive adverse effects	Avoid Monitor aminoglycoside SDC and renal function
Amphotericin B	Nephrotoxins (e.g., aminoglycosides, cidofovir, cyclosporine, foscarnet, pentamidine)	Additive adverse effects	Monitor renal function
Azoles	See Chap. 125		
Chloramphenicol	Phenytoin, tolbutamide, ethanol	Decreased metabolism of other agents	Monitor phenytoin SDC, blood glucose
Foscarnet	Pentamidine IV	Increased risk of severe nephrotoxicity/hypocalcemia	Monitor renal function/serum calcium
Isoniazid	Carbamazepine, phenytoin	Decreased metabolism of other agents (nausea, vomiting, nystagmus, ataxia)	Monitor drug SDC
Macrolides/azalides	Digoxin	Decreased digoxin bioavailability and metabolism	Monitor digoxin SDC; avoid if possible
Metronidazole	Theophylline	Decreased metabolism of theophylline	Monitor theophylline SDC
Penicillins and cephalosporins	Ethanol (drugs containing ethanol) Probenecid, aspirin	Disulfiram-like reaction Blocked excretion of β -lactams	Avoid Use if prolonged high concentration of β -lactam desirable
Ciprofloxacin/norfloxacin	Theophylline	Decreased metabolism of theophylline	Monitor theophylline
Quinolones	Class Ia and III Antiarrhythmics Multivalent cations (antacids, iron, sucralfate, zinc, vitamins, dairy, citric acid) didanosine	Increased Q-T interval Decreased absorption of quinolone	Avoid Separate by 2 hours
Rifampin	Azoles, cyclosporine, methadone propranolol, PIs, oral contraceptives, tacrolimus, warfarin	Increased metabolism of other agent	Avoid if possible
Sulfonamides	Sulfonylureas, phenytoin, warfarin	Decreased metabolism of other agent	Monitor blood glucose, SDC, PT
Tetracyclines	Antacids, iron, calcium, sucralfate Digoxin	Decreased absorption of tetracycline Decreased digoxin bioavailability and metabolism	Separate by 2 hours Monitor digoxin SDC; avoid if possible

PI, protease inhibitor; PT, prothrombin time; SDC, serum drug concentrations.

Azalides: azithromycin; Azoles: fluconazole, itraconazole, ketoconazole, and voriconazole; Macrolides: erythromycin, clarithromycin; Protease inhibitors: amprenavir, indinavir, lopinavir/ritonavir, nelfinavir, ritonavir, and saquinavir; Quinolones: ciprofloxacin, gatifloxacin, levofloxacin, moxifloxacin.

β -Lactams display time-dependent bactericidal effects. Killing activity is enhanced only marginally if drug concentration exceeds the MIC. Therefore, the important pharmacodynamic relationship for these antimicrobials is the duration that drug concentrations exceed the MIC ($T > \text{MIC}$). Effective dosing regimens require serum drug concentrations to exceed the MIC for at least 40% to 50% of the dosing interval.^{20–23} Frequent small doses or a continuous infusion of β -lactams appears to be correlated with positive outcomes.

The ability of bacteriostatic antimicrobial agents to eradicate infections is reliant on host immune function and a postantibiotic effect. Examples include clindamycin, macrolides, ketolides, and tetracyclines.^{20–23}

Tissue Penetration

The importance of tissue penetration varies with site of infection. Some of the difficulties in interpreting data include a lack of correlation with clinical outcomes and poor understanding of whether the antimicrobial agents are present in a biologically active form. An example of the former problem is the recognized efficacy of drugs with low biliary fluid concentrations in the treatment of cholecystitis, cholangitis, or both and the absence of the enhanced efficacy of drugs whose primary route of elimination is biliary excretion of active drug. An example of the latter difficulty is with penetration to deep infections, such as abscesses, where various factors such as acid pH, WBC products, and various enzymes can inactivate even high concentrations of certain drugs.

The central nervous system (CNS) is one body site where antimicrobial penetration is relatively well defined, and correlations with clinical outcomes are established.^{6,24} Cerebrospinal fluid (CSF) concentrations of antimicrobial agents necessary to cure bacterial meningitis have been

defined, and drugs that do not reach significant concentrations in the CSF should either be avoided or instilled directly, if feasible.

Caution must be exercised when selecting an antimicrobial agent for clinical use on the basis of tissue or fluid penetration. Body fluids where drug concentration data are clinically relevant include CSF, urine, synovial fluid, and peritoneal fluid. Apart from these areas, more attention should be paid to clinical efficacy, antimicrobial spectrum, toxicity, and cost than to comparative data on penetration into a given body site.

The proper route of administration for an antimicrobial depends on the site of infection. Parenteral therapy is warranted when patients are being treated for febrile neutropenia or deep-seated infections such as meningitis, endocarditis, and osteomyelitis. Severe pneumonia often is treated initially with intravenous antibiotics and switched to oral therapy as clinical improvement is evident.^{5,25} Patients treated in the ambulatory setting for upper respiratory tract infections (e.g., pharyngitis, bronchitis, sinusitis, and otitis media), lower respiratory tract infections, skin and soft tissue infections, uncomplicated urinary tract infections, and selected sexually transmitted diseases can receive oral therapy.

Drug Toxicity

It is incumbent on health professionals to avoid toxic drugs whenever possible. Antibiotics associated with CNS toxicities, usually when not dose-adjusted for renal function, include penicillins, cephalosporins, quinolones, and imipenem. Hematologic toxicities generally are manifested with prolonged use of nafcillin (neutropenia), piperacillin (platelet dysfunction), cefotetan (hypoprothrombinemia), chloramphenicol (bone marrow suppression, both idiosyncratic and dose-related toxicity), and trimethoprim (megaloblastic anemia). Revers-

ible nephrotoxicity classically is associated with aminoglycosides and vancomycin. Reversible ototoxicity can occur with aminoglycosides or erythromycin. In the outpatient setting, patients must be counseled regarding photosensitivity with azithromycin, quinolones, tetracyclines, pyrazinamide, sulfamethoxazole, and trimethoprim. Lastly, all antibiotics have been implicated in causing diarrhea and colitis secondary to *Clostridium difficile*²⁶ (see Chap. 38).

Aside from consideration of drug toxicity, some antimicrobial use requires more intensive risk-benefit analysis. An example of this is the decision to use isoniazid prophylactically to prevent tuberculosis. Because the hepatotoxicity of isoniazid increases in frequency with age, older persons (>45 years of age) who are candidates for isoniazid prophylaxis (positive skin test) must have additional risk factors for tuberculosis to balance the potential toxic effects. These include evidence of recent skin-test conversion, immunosuppression, or previous gastrectomy. Older patients without additional risk factors are more likely to suffer toxicity from isoniazid than derive benefit from its use.²⁷

Cost

The costs of drug therapy are increasing dramatically, especially as new products, derived from biotechnology, are introduced. Greater attention is being paid to the pharmacoeconomics of drug therapy, where patient outcomes are valued, and the costs to arrive at those outcomes are estimated. Understanding the true cost of antimicrobial therapy is more important than ever. The total cost of antimicrobial therapy includes much more than just the acquisition cost of the drugs.²⁸

Many ancillary costs and factors affect the true cost of therapy. These include factors such as storage, preparation, distribution, and administration, as well as all the costs incurred from monitoring for adverse effects and factors such as length of hospitalization, readmissions, and all directly provided healthcare goods and services. More difficult to value but equally as important are indirect costs such as patient quality-of-life issues. Pharmacoeconomic and outcomes analyses are becoming more widely applied and used in order to derive values such as cost-benefit ratios and the cost-effectiveness of various products as compared with other products. A detailed review of pharmacoeconomic analyses is beyond the scope of this chapter, but excellent reviews of the subject are available.²⁹ A great deal more research in this area is needed, and multidisciplinary, collaborative efforts with the involvement of pharmacy, medicine, nursing, and microbiology are essential.

Many oral antimicrobials have been approved, including cephalosporins, linezolid, and fluoroquinolones, that can be used in place of more expensive parenteral therapy. These agents offer extended-spectrum killing activity, increased tissue penetration, and excellent safety and pharmacokinetic profiles. When oral therapy is being considered, the choice between convenient once-a-day expensive agents versus multiple-dose inexpensive agents arises. It is easy to calculate the difference in acquisition cost; however, the overall cost between agents is more difficult to determine. Factors to weigh include safety, effectiveness, tolerability, patient compliance, and potential drug-drug interactions. In some instances, more expensive agents can be warranted to avoid adverse outcomes.

COMBINATION ANTIMICROBIAL THERAPY

6 In selecting a drug regimen for a given patient, consideration must be given to the necessity of using more than one drug. Combinations of antimicrobials generally are used to broaden the spectrum of coverage for empirical therapy, achieve synergistic activity against the infecting organism, and prevent the emergence of resistance.

Broadening the Spectrum of Coverage

Increasing the coverage of antimicrobial therapy generally is necessary in mixed infections where multiple organisms are likely to be

present. This is the case in intraabdominal and female pelvic infections, in which a variety of aerobic and anaerobic bacteria can produce disease.³⁰ Traditionally, a combination of a drug active against aerobic gram-negative bacilli, such as an aminoglycoside, and a drug active against anaerobic bacteria, such as metronidazole or clindamycin, is selected. Newer compounds, which possess good activity against both these types of organisms, such as the β -lactam/ β -lactamase inhibitor combinations, carbapenems or glycolcyclines, might be adequate to replace the combination and thereby reduce the cost of therapy. The other clinical situation in which an increased spectrum of activity is desirable is with nosocomial infections.²⁵

Synergism

The achievement of synergistic antimicrobial activity is advantageous for infections caused by enteric gram-negative bacilli in immunosuppressed patients. Laboratory tests to identify synergy between antibiotic combinations are described in Chap. 108. Traditionally, combinations of aminoglycosides and β -lactams have been used because these drugs together generally act synergistically against a wide variety of bacteria. However, the data supporting superior efficacy of synergistic over nonsynergistic combinations are weak. At best, it would appear that synergistic combinations produce better results in certain infections caused by *P. aeruginosa* and *Enterococcus* species.^{31,32}

The most obvious example of the use of synergy is the treatment of enterococcal endocarditis. The causative organism is usually only inhibited by penicillins, but it is killed rapidly by the addition of streptomycin or gentamicin to a penicillin.³¹ The need for bactericidal activity in the treatment of endocarditis underscores the need for these synergistic combinations.

Preventing Resistance

The use of combinations to prevent the emergence of resistance is applied widely but not often realized. The only circumstance where this has been clearly effective is in the treatment of tuberculosis. The prevalence of resistance to a first-line drug such as isoniazid or rifampin in a population of organisms may be as high as 1 in 10^6 to 10^8 . Because the bacterial load in a patient with active tuberculosis often exceeds this, two drugs are given to reduce the likelihood of encountering resistance to less than 1 in 10 .²⁷ There is ample evidence from in-vitro data and experimental bacterial infections that combinations of drugs with different mechanisms are effective in the prevention of the emergence of resistance. Data from clinical trials, however, are either conflicting or do not convincingly support this concept.³³

Disadvantages of Combination Therapy

Although there are potentially beneficial effects from combining drugs, there also are potential disadvantages, including increased cost, greater risk of drug toxicity such as nephrotoxicity such as aminoglycosides, amphotericin, and possibly vancomycin, and superinfection with even more resistant bacteria.^{32,33}

The combination of two or more antibiotics can result in antagonistic effects. Clinically, the effect of antagonism may be evident when one drug induces β -lactamase production and another drug is β -lactamase unstable. Cefoxitin and imipenem are examples of drugs capable of inducing β -lactamases and may result in more rapid inactivation of penicillins when used together.

MONITORING THERAPEUTIC RESPONSE

7 After antimicrobial therapy has been instituted, the patient must be monitored carefully for a therapeutic response. Culture and sensitivity reports from specimens sent to the microbiology laboratory must be reviewed and the therapy changed accordingly. Use of agents with the narrowest spectrum of activity against identified

pathogens is recommended. If anaerobes are suspected, even if they are not identified, anaerobic therapy should be continued.

Patient monitoring should include many of the same parameters used to diagnose the infection. The WBC count and temperature should start to normalize. Physical complaints from the patient also should diminish (i.e., decreased pain, shortness of breath, cough, or sputum production). Appetite should improve. Radiologic improvement can lag behind clinical improvement. Determinations of serum (or other fluid) levels of antimicrobials can be useful in ensuring outcome, preventing toxicity, or both. There are only a few antimicrobials that require serum concentration monitoring and then only in selected situations. These include the aminoglycosides, flucytosine, and chloramphenicol. Achievement of adequate aminoglycoside concentrations within the first few days of therapy of gram-negative infection has been correlated with better therapeutic outcome.³⁴

Changes in the volume of distribution can have a significant impact on the efficacy, safety, or both of therapy. An unexpectedly low volume of distribution (such as in the dehydrated patient) will result in higher, potentially toxic drug concentrations, whereas a larger-than-expected volume of distribution (such as in patients with edema or ascites) will result in low, potentially subtherapeutic concentrations. The most effective methods use measured serum concentrations of the drugs rather than estimations from renal function tests to assess true drug clearance from the body.

8 As patients improve clinically, the route of administration should be reevaluated. Streamlining therapy from parenteral to oral (switch therapy) has become an accepted practice for many infections.⁵ Criteria that should be present to justify a switch to oral therapy include (1) overall clinical improvement, (2) lack of fever for 8 to 24 hours, (3) decreased WBC count, and (4) a functioning gastrointestinal tract. Drugs that exhibit excellent oral bioavailability when compared with intravenous formulations include ciprofloxacin, clindamycin, doxycycline, levofloxacin, metronidazole, moxifloxacin, linezolid, and trimethoprim-sulfamethoxazole.

FAILURE OF ANTIMICROBIAL THERAPY

9 A variety of factors may be responsible for an apparent lack of response to therapy. Patients who fail to respond over 2 to 3 days require a thorough reevaluation. It is possible that the disease is not infectious or is nonbacterial in origin, or there is an undetected pathogen in a polymicrobial infection. Other factors include those directly related to drug selection, the host, or the pathogen. Laboratory error in identification, susceptibility testing, or both (presence of inoculum effect or resistant subpopulations) is a rare cause of antimicrobial failure.

Failures Caused by Drug Selection

Factors related directly to the drug selection include an inappropriate drug selection or dosage or route of administration. Malabsorption of a drug product because of gastrointestinal (GI) disease, such as a short-bowel syndrome, or a drug interaction, such as complexation of fluoroquinolones with multivalent cations resulting in reduced absorption, can lead to potentially subtherapeutic serum concentrations. Accelerated drug elimination is also possible. This can occur in patients with cystic fibrosis or during pregnancy, when more rapid clearance or larger volumes of distribution can result in low serum concentrations, particularly for aminoglycosides. A common cause of failure of therapy is poor penetration into the site of infection. This is especially true for sites such as the CNS, eye, and prostate gland. Drug failure also can result from drugs that are highly protein bound or that are chemically inactivated at the site of infection.

Failures Caused by Host Factors

Host defenses must be considered when evaluating a patient who is not responding to antimicrobial therapy. Patients who are immunosuppressed (e.g., granulocytopenia from chemotherapy or AIDS) may respond poorly to therapy because their defenses are inadequate to eradicate the infection despite seemingly adequate drug regimens. A good example is the poor response of infection in granulocytopenic patients that is seen when their WBC counts remain low during therapy. This contrasts with a much better response when granulocyte counts increase during therapy.

Other host factors are related to the need for surgical drainage of abscesses or removal of foreign bodies, necrotic tissue, or both. If these situations are not corrected, they result in persistent infection and, occasionally, bacteremia despite adequate antimicrobial therapy.

Failures Caused by Microorganisms

Factors related to the pathogen include the development of drug resistance during therapy.³⁵ *Primary resistance* refers to the intrinsic resistance of the pathogens producing the infection. Several infections are more likely to result in drug resistance because of drug inaccessibility (e.g., pneumonia, endocarditis, abdominal and deep-seated skin and soft tissue infections). It has become increasingly obvious that despite the development and introduction of new antimicrobial agents, bacterial resistance has continued to increase both within and across different bacterial genera.

Organisms in which resistance has increased most dramatically include enterococci, pneumococci, and *Mycobacterium tuberculosis*. Enterococci have been isolated with multiple resistance patterns. They may be resistant to β -lactams (by virtue of β -lactamase production, altered penicillin-binding proteins [PBPs], or both), vancomycin (via alterations in peptidoglycan synthesis), and high levels of aminoglycosides (via enzymatic degradation).

Pneumococci resistant to penicillins, certain cephalosporins, and macrolides are increasingly common. These organisms generally are susceptible to vancomycin, the new fluoroquinolones, and cefotaxime or ceftriaxone. *M. tuberculosis* resistant to one or more first-line antitubercular agents (e.g., isoniazid, rifampin, ethambutol, streptomycin, and pyrazinamide) have increased in frequency as well. This has been observed principally in populations of prison inmates and patients with AIDS.

The increase in resistance among these organisms is believed to be a result of continued overuse of antimicrobials in the community, as well as in hospitals, and the increasing prevalence of immunosuppressed patients receiving long-term suppressive antimicrobials for the prevention of infections. These resistance patterns are regionally variable, and susceptibility patterns in the community (or hospital) should be monitored closely to promote rational antimicrobial selection.³⁶

Antimicrobial agents such as linezolid, daptomycin, and tigecycline have been targeted at resistant gram-positive bacteria. Several other drugs currently in development also have enhanced activity against these bacteria.

The emergence of resistance during antimicrobial therapy is reported most frequently in pulmonary or other deep-seated infections caused by *P. aeruginosa*. This occurs in 20% to 30% of cases and with all the available antibacterial agents, including imipenem. This organism and a group of enteric gram-negative bacilli (*Enterobacter aerogenes*, *Enterobacter cloacae*, *Citrobacter freundii*, *Serratia marcescens*, and a few others) can produce a β -lactamase that is capable of hydrolyzing broad-spectrum cephalosporins and, to a lesser extent, penicillins.^{35,36} These enzymes are categorized as Bush group I, and their genetic code is found on the chromosome. Resistant mutants of these aforementioned organisms that produce large quantities of these enzymes can be present within an infection and can be responsible for the emergence of resistance during therapy. The mutants

occur at a frequency of 1 in 10^6 to 1 in 10^8 bacteria, the numbers of bacteria commonly encountered in clinical infections.³⁶ Because only 10^4 to 10^5 bacteria are tested for susceptibility in the microbiology laboratory, however, this potential resistance may not be detected.

Treatment of an infection caused by *Enterobacter*, *Citrobacter*, *Serratia*, or *P. aeruginosa* with a third-generation cephalosporin or aztreonam may produce an initial clinical response by eradicating all the susceptible bacteria in the population. Within a few days, however, the highly resistant subpopulations have a selective advantage and can overgrow the infection site to produce a relapse.^{35,36} These bacteria usually retain susceptibility to aminoglycosides, carbapenems, and fluoroquinolones but are resistant to all other β -lactams. Host defenses are extremely important in this scenario. Debilitated patients with pulmonary infections, abscesses, or osteomyelitis are at high risk for drug failure. In these situations, a combination regimen to prevent the emergence of resistance or the use of carbapenem or a fluoroquinolone may be warranted for empirical therapy.

ANTIMICROBIAL USE MANAGEMENT

ANTIBIOTIC FORMULARY

Institutions must decide which antibiotics to include on their formularies. The actual decision to have a formulary remains controversial; however, restricting choices does encourage familiarity with a core of antibiotics for residents and attending physicians.³⁷ Open formularies allow the empirical use of any commercially available antibiotics, with recommended guidelines for changes when culture and sensitivity results are finalized. Many institutions have organized an antibiotic subcommittee to the pharmacy and therapeutics committee that meets to discuss trends in resistance and review new agents. The subcommittee is generally a multidisciplinary group including representation from microbiology, infection control, pharmacy, and physicians from several disciplines, including infectious disease. The actual implementation of the guidelines and restrictions recommended by such groups requires the cooperation of the entire medical staff. Education is vital to the success of the antibiotic formulary.³⁸

ANTIMICROBIAL CYCLING

An interesting topic in formulary management that continues to gain interest and scientific research is *antimicrobial cycling*. Antimicrobial cycling is a predetermined change in an antimicrobial recommendation for empirical therapy of a specific infection at a predetermined time. It also has been called *rotation of antimicrobials*. This strategy should not be confused with *antimicrobial switch therapy*, which involves changes in the route of administration of antimicrobial therapy (i.e., intravenous to oral).

Antimicrobial cycling is employed as a mechanism to reduce or prevent antimicrobial resistance. *Proactive cycling* is a planned switch to preempt resistance at a predetermined point or series of points with a predetermined schedule. *Reactive cycling* is a response to high or unacceptable resistance and is often a one-time switch. Most programs incorporate aspects of both types of cycling. Cycling implies returning to the original drug after other choices have been used. Rotation implies several planned changes.

Antimicrobial cycling is based on the assumptions that the resistance problem is (1) caused by the overuse of a particular agent or class of agents and (2) that discontinuation of the particular agent or class of agents will restore susceptibility. These assumptions correlate best with nosocomial gram-negative organisms that can rapidly develop resistance. Theoretically, antimicrobial agents should be sequenced in such an order that mechanisms of resistance

do not overlap (i.e., changing drug classes).^{39,40} However, to date there has been insufficient evidence to clearly demonstrate the usefulness of antibiotic cycling.

KEEPING CURRENT

Attention must be paid to the literature on antimicrobials to assist in the selection of therapy. The results from prospective, controlled, randomized clinical trials should be evaluated whenever possible when considering appropriate antimicrobial therapy. Results from preclicensing open trials offer only limited information that can be useful in this regard because patients in these trials generally are not seriously ill and are not infected with multiple resistant bacteria and other confounding factors found in most clinical situations are excluded by virtue of the study design. Therefore, comparative data in more seriously ill patients are essential for the appropriate application of new agents.

Postmarketing trials are also important because results can demonstrate superiority of one regimen over another, either in efficacy, safety, or cost-effectiveness. Appropriate antimicrobial therapy can change as new organisms are discovered, susceptibility patterns change, new drugs become available, and new clinical trial results are published. Classical thinking in the treatment of infectious diseases will continue to change and evolve to maintain antimicrobial efficacy. Optimal use of modern antimicrobials is just beginning to be defined.

ABBREVIATIONS

AUC: area under the curve

IL: interleukin

MIC: minimal inhibitory concentration

PBP: penicillin-binding protein

PMN: polymorphonuclear leukocytes

WBC: white blood cell

Appendix 109-1

Drugs of Choice, First Choice, Alternative(s)

GRAM-POSITIVE COCCI

- Enterococcus faecalis* (generally not as resistant to antibiotics as *Enterococcus faecium*)
 Serious infection (endocarditis, meningitis, pyelonephritis with bacteremia)
 Ampicillin (or penicillin G) + (gentamicin or streptomycin)
 Vancomycin + (gentamicin or streptomycin), linezolid, daptomycin, tigecycline
 Urinary tract infection (UTI)
 Ampicillin, amoxicillin
 Fosfomycin or nitrofurantoin
- E. faecium* (generally more resistant to antibiotics than *E. faecalis*)
 Recommend consultation with infectious disease specialist.
 Linezolid, quinupristin/dalfopristin, daptomycin, tigecycline
- Staphylococcus aureus/Staphylococcus epidermidis*
 Methicillin (oxacillin)-sensitive
 PRP^a
 FGC,^{b,c} trimethoprim-sulfamethoxazole, clindamycin,^d ampicillin-sulbactam, or amoxicillin-clavulanate
 Methicillin (oxacillin)-resistant
 Vancomycin ± (gentamicin or rifampin)
 Trimethoprim-sulfamethoxazole, doxycycline^e or clindamycin^d, Linezolid, quinupristin-dalfopristin, daptomycin, or tigecycline
- Streptococcus* (groups A, B, C, G, and *Streptococcus bovis*)
 Penicillin G^f or V^g or ampicillin
 FGC,^{b,c} erythromycin, azithromycin, clarithromycin,^h
- Streptococcus pneumoniae*
 Penicillin-sensitive (MIC <0.1 mcg/mL)
 Penicillin G or V or ampicillin
 Erythromycin, FGC,^{b,c} doxycycline, azithromycin, clarithromycin^h
 Penicillin intermediate (MIC 0.1–1.0 mcg/mL)
 High-dose penicillin (12 million units/day for adults) or ceftriaxone^e or cefotaxime^c
 Levofloxacin,ⁱ moxifloxacin,ⁱ gemifloxacin,ⁱ telithromycin, or vancomycin
 Penicillin-resistant (MIC ≥1.0 mcg/mL)
 Recommend consultation with infectious disease specialist.
 Vancomycin ± rifampin
 Per sensitivities: TGC,^{c,j} telithromycin, levofloxacin,ⁱ moxifloxacin,ⁱ or gemifloxacinⁱ
- Streptococcus, viridans* group
 Penicillin G ± gentamicin^k
 TGC,^{c,j} erythromycin, azithromycin, clarithromycin,^h or vancomycin ± gentamicin

GRAM-NEGATIVE COCCI

- Moraxella (Branhamella) catarrhalis*
 Amoxicillin-clavulanate, ampicillin-sulbactam
 Trimethoprim-sulfamethoxazole, erythromycin, azithromycin, clarithromycin,^h doxycycline,^e SGC,^l TGC,^{c,j} or TGC PO^{c,m}
- Neisseria gonorrhoeae* (also give concomitant treatment for *Chlamydia trachomatis*)
 Disseminated gonococcal infection

- Ceftriaxone^c or cefotaxime^c
 Oral followup: Cefpodoxime,^c ciprofloxacin,ⁱ or levofloxacinⁱ
 Uncomplicated infection
 Ceftriaxone^c or cefotaxime,^c or cefpodoxime^c
 Ciprofloxacinⁱ or levofloxacinⁱ
Neisseria meningitides
 Penicillin G
 TGC^{c,j}

GRAM-POSITIVE BACILLI

- Clostridium perfringens*
 Penicillin G ± clindamycin
 Metronidazole, clindamycin, doxycycline,^e cefazolin,^c imipenem,ⁿ meropenem,ⁿ or ertapenemⁿ
- Clostridium difficile*
 Oral metronidazole
 Oral vancomycin

GRAM-NEGATIVE BACILLI

- Acinetobacter* spp.
 Imipenem or meropenem ± aminoglycoside^o (amikacin usually most effective)
 Ciprofloxacin,ⁱ ampicillin-sulbactam, colistin, or tigecycline
- Bacteroides fragilis* (and others)
 Metronidazole
 BLIC,^p clindamycin, cephamycins,^{c,q} or carbapenemⁿ
- Enterobacter* spp.
 Imipenem, meropenem, ertapenem, or cefepime ± aminoglycoside^p
 Ciprofloxacin,ⁱ levofloxacin,ⁱ piperacillin-tazobactam, ticarcillin-clavulanate, or tigecycline
- Escherichia coli*
 Meningitis
 TGC^{c,j} or meropenem
 Systemic infection
 TGC^{c,j}
 Ampicillin-sulbactam, FGC,^{b,c} BL/BLI,^p fluoroquinolone,^{i,n,r} imipenem,ⁿ meropenemⁿ
 Urinary tract infection
 Most oral agents: check sensitivities
 Ampicillin, amoxicillin-clavulanate, doxycycline,^e or cephalexin^c
 Aminoglycoside,^p FGC^{b,c} nitrofurantoin, fluoroquinolone^{i,n,r}
- Gardnerella vaginalis*
 Metronidazole
 Clindamycin
- Haemophilus influenzae*
 Meningitis
 Cefotaxime^c or ceftriaxone^c
 Meropenemⁿ or chloramphenicol^l
 Other infections
 BLIC,^p or if β-lactamase-negative, ampicillin or amoxicillin
 Trimethoprim-sulfamethoxazole, cefuroxime,^c azithromycin, clarithromycin,^h or fluoroquinolone^{i,n,r}

*Klebsiella pneumoniae*TGC^{e,k} (if UTI only: aminoglycoside^p)Cefuroxime,^e fluoroquinolone,^{b,r} BLIC,^s imipenem,^o meropenem,^o or ertapenem*Legionella* spp.Erythromycin ± rifampin or fluoroquinolone^{i,r}Trimethoprim-sulfamethoxazole, clarithromycin,^h azithromycin, or doxycycline^e*Pasteurella multocida*

Penicillin G, ampicillin, amoxicillin

Doxycycline,^e BLIC,^p trimethoprim-sulfamethoxazole or ceftriaxone^{c,j}*Proteus mirabilis*

Ampicillin

Trimethoprim-sulfamethoxazole, most antibiotics except PRP^a*Proteus* (indole-positive) (including *Providencia rettgeri*, *Morganella morganii*, and *Proteus vulgaris*)TGC^{c,h} or fluoroquinolone^{f,r}BLIC,^p aztreonam,^t imipenem,ⁿ or TGC PO^{c,m}*Providencia stuartii*TGC^{c,j} or fluoroquinolone^{i,r}Trimethoprim-sulfamethoxazole, aztreonam,^t imipenem,ⁿ meropenem,ⁿ or ertapenem*Pseudomonas aeruginosa*Cefepime,^c ceftazidime,^c piperacillin-tazobactam, or ticarcillin-clavulanate plus aminoglycoside^oCiprofloxacin,ⁱ levofloxacin,ⁱ aztreonam,^t imipenem,ⁿ meropenem,ⁿ or colistinUTI only: aminoglycoside^oCiprofloxacin,ⁱ levofloxacinⁱ*Salmonella typhi*Ciprofloxacin,ⁱ levofloxacin,ⁱ ceftriaxone,^c or cefotaxime^c

Trimethoprim-sulfamethoxazole

*Serratia marcescens*Piperacillin-tazobactam, ticarcillin-clavulanate, or TGC^{c,j} ± gentamicinTrimethoprim-sulfamethoxazole, ciprofloxacin,ⁱ levofloxacin,ⁱ aztreonam,^t imipenem,ⁿ meropenem,ⁿ or ertapenem*Stenotrophomonas (Xanthomonas) maltophilia*

Trimethoprim-sulfamethoxazole

Generally very resistant to all antimicrobials; check sensitivities to ceftazidime,^e ticarcillin-clavulanate, doxycycline,^e and minocycline^e

SPIROCHETES

Treponema pallidum

Neurosyphilis

Penicillin G

Ceftriaxone^c

Primary or secondary

Benzathine penicillin G

Doxycycline^e or ceftriaxone^c*Borrelia burgdorferi* (choice depends on stage of disease)Ceftriaxone^c or cefuroxime axetil,^c doxycycline,^e amoxicillinHigh-dose penicillin, cefotaxime,^c or azithromycin

BLIC, β -lactamase inhibitor combination; BL/BLI, β -lactamase/ β -lactamase inhibitor; FGC, first-generation cephalosporin; MIC, minimal inhibitory concentration; PO, orally; PRP, penicillinase-resistant penicillin; SGC, second-generation cephalosporin; TGC, third-generation cephalosporin.

^aPenicillinase-resistant penicillin: nafcillin or oxacillin.

^bFirst-generation cephalosporins—IV: cefazolin; PO: cephalexin, cephadrine, or cefadroxil.

^cSome penicillin-allergic patients may react to cephalosporins.

^dNot reliably bactericidal; should not be used for endocarditis.

^eNot for use in pregnant patients or children younger than 8 years old.

^fEither aqueous penicillin G or benzathine penicillin G (pharyngitis only).

^gOnly for soft tissue infections or upper respiratory infections (pharyngitis, otitis media).

^hDo not use in pregnant patients.

ⁱNot for use in pregnant patients or children younger than 18 years old.

^jThird-generation cephalosporins—IV: cefotaxime, ceftriaxone.

^kGentamicin should be added if tolerance or moderately susceptible (MIC >0.1 g/mL) organisms are encountered; streptomycin is used but can be more toxic.

^lSecond-generation cephalosporins—IV: cefuroxime; PO: cefaclor, cefdinor, cefprozil, cefuroxime axetil, and loracarbef.

^mThird-generation cephalosporins—PO: cefdinor, cefixime, cefetamet, cefpodoxime proxetil, and cefibuten.

ⁿReserve for serious infection.

^oAminoglycosides: gentamicin, tobramycin, and amikacin; use per sensitivities.

^p β -Lactamase inhibitor combination—IV: ampicillin-sulbactam, piperacillin-tazobactam, ticarcillin-clavulanate; PO: amoxicillin-clavulanate.

^qCefoxitin

^rTV/PO: ciprofloxacin, levofloxacin, and moxifloxacin.

^sReserve for serious infection when less toxic drugs are not effective.

^tGenerally reserved for patients with hypersensitivity reactions to penicillin.

MISCELLANEOUS MICROORGANISMS

*Chlamydia pneumoniae*Doxycycline^eErythromycin, azithromycin, clarithromycin,^h telithromycin or fluoroquinolone^{f,r}*C. trachomatis*Doxycycline^e or azithromycinLevofloxacinⁱ or ofloxacinⁱ*Mycoplasma pneumoniae*Erythromycin, azithromycin, clarithromycin^hDoxycycline^e or fluoroquinolone^{f,r}

Central Nervous System Infections

ISAAC F. MITROPOULOS, ELIZABETH D. HERMSEN, JEREMY A. SCHAFER,
AND JOHN C. ROTSCHAFER

KEY CONCEPTS

- 1 The three most likely pathogens of bacterial meningitis in the United States are *Streptococcus pneumoniae*, *Neisseria meningitidis*, and *Haemophilus influenzae*. Routine vaccination is having a dramatic effect on the incidence of these pathogens causing infection.
- 2 In cases of meningitis, initial findings can include (a) *presenting signs and symptoms*: fever, headache, and nuchal rigidity (classic triad), Brudzinski or Kernig sign, and altered mental status, and (b) *abnormal cerebrospinal fluid (CSF) chemistries*: elevated white blood cell count (>100 cells/mm³), elevated protein (>50 mg/dL), and decreased glucose levels (<40 mg/dL).
- 3 Two main microbiologic tests that should be obtained include a Gram stain of the CSF and CSF cultures.
- 4 Three primary goals of treatment in meningitis are (a) *eradication* of infection, (b) *amelioration* of signs and symptoms, and (c) *prevention* of development of neurologic sequelae, such as seizures, deafness, coma, and death.
- 5 When selecting antibiotics, the clinician must consider the antibiotic concentration at the site of infection as well as the spectrum of antibacterial activity. Empirical choices should be based on age and predisposing conditions. (a) *Ceftriaxone* or *cefotaxime* and *vancomycin* are reasonable initial choices for empirical coverage of community-acquired meningitis in adult patients. (b) *Listeria monocytogenes* is a common pathogen in infants and elderly; therefore, *ampicillin* should be added empirically to antimicrobial coverage.
- 6 Empirical coverage with an appropriate antibiotic should be started as soon as possible when clinical suspicion of meningitis exists. If lumbar puncture is to be delayed (even by 30–60 minutes) or if the patient is to undergo neuroimaging, the first dose of an antibiotic *should not* be withheld. Changes in CSF after initiation of antibiotics usually take 12 to 24 hours.
- 7 In contrast to treatment of other infectious diseases, antibiotic dosages for treatment of meningitis should be maximized to optimize central nervous system penetration.
- 8 The duration of antibiotic treatment for meningitis is not standardized; however, the duration of antibiotic therapy generally

is based on the causative organism and the individual case and may range from 7 to 21 days.

- 9 Close contacts and relatives of the index case should be assessed for appropriate prophylaxis, particularly with *N. meningitidis* and *H. influenzae* meningitis.
- 10 Steroid treatment includes dexamethasone 0.15 mg/kg per dose given four times daily for 4 days in infants and children older than 2 months with proven or strongly suspected bacterial meningitis. Steroids should be given *prior* to antibiotics.

Central nervous system (CNS) infections are caused by various pathogens, including bacteria, viruses, fungi, and parasites. Infections are the result of hematogenous spread from a primary infection site, seeding from a parameningeal focus, reactivation from a latent site, trauma, or congenital defects in the CNS. Newer diagnostic techniques have enabled more rapid and definitive diagnoses, thus diminishing the number of unknown “aseptic meningitis” diagnoses and improving targeted therapy. Bacteria resistant to multiple antibiotics present new challenges in the management of meningitis. This chapter presents the etiologies, pathophysiology, therapy, and prophylaxis of these infections, with concentration on bacterial meningitis.

EPIDEMIOLOGY

Approximately 1.2 million cases of acute bacterial meningitis, excluding epidemics, occur every year around the world, resulting in 135,000 deaths.¹ Overall mortality rates for patients with meningitis range from 2% to 30% depending on the causative microorganism, approaching 20% in most cases of bacterial meningitis.² Neurologic sequelae frequently associated with meningitis include seizures, sensorineural hearing loss, and hydrocephalus. Risk for development of neurologic sequelae depends on the infecting organism, with pneumococcal meningitis associated with the highest risk.³ Generally, 30% to 50% of patients who survive meningitis may develop neurologic disabilities.^{4,5} Despite the availability of antimicrobial therapy against the most common CNS pathogens, CNS infections continue to have significant morbidity and mortality.

Two findings have the potential for great epidemiologic impact on bacterial meningitis. First, both passive and active exposure to cigarette smoke were shown to be risk factors for bacterial meningitis, especially meningococcal disease.⁶ Second, children with cochlear implants that include a positioner are at increased risk for bacterial meningitis, specifically pneumococcal meningitis. The incidence of meningitis due to *Streptococcus pneumoniae* in children with cochlear implants was more than 30 times the incidence in a similar cohort of the U.S. population without implants.⁷

and other resources can be found at
www.pharmacotherapyonline.com.

ETIOLOGY

1 CNS infections are caused by a variety of microorganisms. Historically, CNS infections were primarily community acquired; however, an increasing number now are nosocomial.⁸ *Haemophilus influenzae* was the most commonly identified cause of bacterial meningitis (45%), followed by *S. pneumoniae* (18%) and *Neisseria meningitidis* (14%). However, in 1995, approximately 5 years after introduction of the *H. influenzae* type b conjugate (Hib) vaccine, *S. pneumoniae* became the most commonly identified cause of bacterial meningitis (47%), followed by *N. meningitidis* (25%), *Listeria monocytogenes* (8%), and *H. influenzae* (7%).

The incidence of invasive *H. influenzae* infections has decreased by more than 90% since the introduction of the Hib vaccine.⁹ Mass immunization with the Hib vaccine also has resulted in alterations in the age distribution of bacterial meningitis. Whereas in 1986 the median age was 15 months, by 1995 that age increased to 25 years. Accordingly, the proportion of cases in those 18 years and older increased from 20.8% to 51.5%.⁹ However, many developing countries have not adopted the Hib vaccine as part of the standard vaccines offered to children because of cost. Thus, approximately 350,000 to 700,000 children die each year worldwide due to invasive *H. influenzae* infections.¹

Following the release of the heptavalent protein-polysaccharide conjugate vaccine, the rate of invasive pneumococcal disease dropped from 24.3 cases per 100,000 people in 1999 to 17.3 per 100,000 in 2001. The largest impact was in children younger than 2 years, in whom a nearly 70% decline in infection rate was reported as a result of implementation of the routine childhood vaccination schedule. Among children younger than 5 years, the rates of pneumococcal meningitis were reduced nearly 60% from 10.3 cases per 100,000 to 4.2 cases during the same time period. Interestingly, the effect carried into the adult population as well, with significant reduction in invasive pneumococcal disease across all age groups.¹⁰ Both the Hib and pneumococcal vaccines are of limited availability in developing countries, where cost often is prohibitive.

ANATOMY AND PHYSIOLOGY OF THE CENTRAL NERVOUS SYSTEM

MENINGES

The skull and vertebrae protect the CNS from blunt or penetrating trauma (Fig. 110-1). The brain is suspended in these structures by cerebrospinal fluid (CSF) and is surrounded by the meninges. The meninges are made up of three separate membranes: dura mater, arachnoid, and pia mater.¹¹ *Dura mater*, or *pachymeninges*, lies directly beneath and is adherent to the skull. The other two membranes are referred to collectively as *leptomeninges*. *Pia mater* lies directly over brain tissue. Arachnoid, the middle layer, lies between the dura mater and the pia mater. The *subarachnoid space*, located between the arachnoid and the pia mater, is the conduit for CSF. By definition, *meningitis* refers to inflammation of the subarachnoid

FIGURE 110-1. Diagram of the central nervous system.

space or spinal fluid, whereas *encephalitis* is an inflammation of the brain itself. Because infectious microorganisms frequently are an underlying cause of these inflammatory processes, the terms *meningitis* and *encephalitis* frequently are used to denote an infectious process. The decision regarding the diagnosis of meningoencephalitis depends on radiographic, laboratory, and clinical information but refers to inflammation of both tissue and fluid.

CEREBROSPINAL FLUID

Approximately 85% of the CSF is produced within the third, fourth, and lateral ventricles by the choroid plexus (Fig. 110-1). CSF volume in the CNS is related to patient age. Infants have approximately 40 to 60 mL of CSF, older children have 60 to 100 mL, and adults have 110 to 160 mL. Normally, CSF is produced at the rate of approximately 500 mL/day and flows unidirectionally downward through the spinal cord. The CSF is removed by the arachnoid villi and vertebral venous plexus located in the spinal cord and does not recommunicate with the point of production.¹¹

The CSF normally is clear, with a protein content <50 mg/dL, glucose concentration approximately 50% to 66% of the simultaneous peripheral serum glucose concentration, and pH approximately 7.4. It typically contains fewer than five white blood cells (WBCs) per cubic millimeter, all of which should be lymphocytes (Table 110-1). As meninges become inflamed, the constituency of the CSF changes, and these changes can be used diagnostically as markers of infection.

TABLE 110-1 Mean Values of Components of Normal and Abnormal Cerebrospinal Fluid

Type	Normal	Bacterial	Viral	Fungal	Tuberculosis
WBC (cells/mm ³)	<5	1,000–5,000	100–1,000	40–400	100–500
Differential (%)	>90 ^a	≥80 PMNs	50 ^{b,c}	>50 ^b	>80 ^{b,c}
Protein (mg/dL)	<50	100–500	30–150	40–150	≤40–150
Glucose (mg/dL)	50–66% simultaneous serum value	<40 (<60% simultaneous serum value)	<30–70	<30–70	<30–70

^aMonocytes.

^bLymphocytes.

^cInitial cerebrospinal fluid; while blood cell (WBC) count may reveal a predominance of polymorphonuclear neutrophils (PMNs).

BLOOD–BRAIN BARRIER/BLOOD–CEREBRAL SPINAL FLUID BARRIER

Natural barriers to the exchange of drugs and endogenous compounds among the blood, brain, and CSF are the blood–brain barrier and the blood–CSF barrier (Fig. 110–2). The blood–brain barrier consists of tightly joined capillary endothelial cells. Drug entry into brain tissue is accomplished by direct passage through the capillary endothelial cells and further penetration of the glial cells that envelop the capillary structure.¹¹

Passage of drugs into the CSF is controlled by the blood–CSF barrier. This barrier is created by ependymal cells of the choroid plexus, which function as an active transport system similar to the renal tubular epithelial cells. The inflammatory process associated with meningitis inhibits the active transport system of the choroid plexus.¹² As in the active transport system in the kidney, secretion of substances out of the choroid plexus can be inhibited by administration of probenecid.¹¹

PATHOPHYSIOLOGY OF CENTRAL NERVOUS SYSTEM INFECTION

The development of bacterial meningitis occurs following bacterial invasion of the host and CNS, bacterial multiplication with subsequent inflammation of the CNS, specifically the subarachnoid space and the ventricular space, pathophysiologic alterations owing to progressive inflammation, and the resulting neuronal damage.¹³ The critical first step in the acquisition of acute bacterial meningitis is nasopharyngeal colonization of the host. Immunoglobulins (Igs) such as secretory IgA are found in high concentrations within nasopharyngeal secretions and work to inhibit bacterial colonization. However, the mucus barrier is deteriorated by IgA proteases secreted by the bacteria, which then extend pili that allow adherence to the host cell surface receptors.¹⁴ Bacterial pathogens attach themselves to nasopharyngeal epithelial cells and are phagocytized into the host's bloodstream. After accessing the patient's bloodstream, bacteria must overcome the host's defense mechanisms.¹ Commonly, CNS bacterial pathogens produce an extensive polysaccharide capsule resistant to neutrophil phagocytosis and complement

opsonization. *H. influenzae*, *Escherichia coli*, and *N. meningitidis* strains lacking polysaccharide capsules are unable to cause meningitis. Capsular polysaccharides activate the alternate complement pathway, which promotes phagocytosis and clearance of infecting pathogens. Patients unable to activate the alternative complement pathway, such as patients with asplenic and sickle cell, are predisposed to bacterial infections caused by encapsulated microorganisms and therefore are at risk for meningitis.

Although the exact site and mechanism of bacterial invasion into the CNS are unknown, studies suggest that invasion into the subarachnoid space occurs by continuous exposure of the CNS to large bacterial inocula. Bacteremia with inoculum densities of at least 10^3 colony-forming units per milliliter appears to be essential for subarachnoid space invasion.⁵ Although several sites of bacterial invasion have been theorized, the most plausible sites are the choroid plexus and/or the cerebral microvasculature. Successful translocation of *E. coli* across the blood–brain barrier requires a high bacterial inoculum, *E. coli* binding to and invading the brain microvascular endothelial cells through specific ligand–receptor interactions, host cytoskeletal reorganization, and activation of various signaling pathways.⁵ Host defense mechanisms within the subarachnoid space are inadequate to combat bacterial pathogens; therefore, bacteria replicate freely within the CSF until either overgrowth occurs or an effective antibiotic regimen is administered that terminates the process.

The effects of meningitis, namely, inflammation within the subarachnoid space and the ensuing neurologic damage, are not a direct result of the pathogens themselves. The neurologic sequelae occur due to activation of the host's inflammatory pathways, which is induced by the pathogens or their products.² Bacterial cell death can cause the release of cell wall components, such as lipopolysaccharide, lipid A (endotoxin), lipoteichoic acid, teichoic acid, and peptidoglycan, depending on whether the pathogen is gram-positive or gram-negative (Fig. 110–3). These cell wall components cause capillary endothelial cells and CNS macrophages to release cytokines (interleukin 1 [IL-1], tumor necrosis factor [TNF]) and other inflammatory mediators

FIGURE 110-2. Schematic representation of a blood–cerebrospinal fluid barrier capillary, brain tissue capillary, and normal tissue capillary (below).

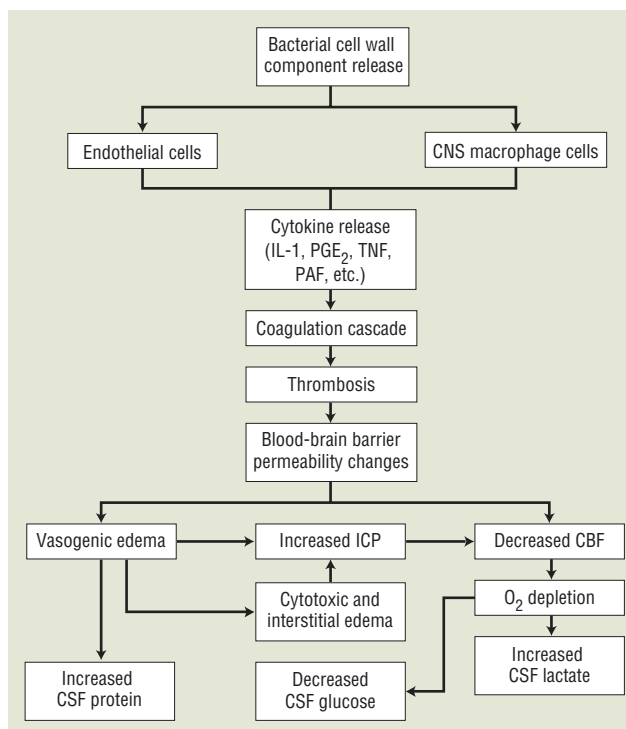

FIGURE 110-3. Hypothetical schema of pathophysiologic events that occur during bacterial meningitis. (CBF, cerebral blood flow; CSF, cerebrospinal fluid; ICP, intracranial pressure; IL-1, interleukin 1; PAF, platelet-activating factor; PGE₂, prostaglandin E₂; TNF, tumor necrosis factor.)

(IL-6, IL-8, platelet-activating factor [PAF], nitric oxide, arachidonic acid metabolites [e.g., prostaglandin and prostacyclin], macrophage-derived proteins). Proteolytic products and toxic oxygen radicals are released from the capillary endothelium, causing an alteration in the permeability of the blood–brain barrier. PAF activates the coagulation cascade, and arachidonic acid metabolites stimulate vasodilation. These events propagate other sequential events that lead to cerebral edema, elevated intracranial pressure (ICP), CSF pleocytosis, decreased cerebral blood flow, cerebral ischemia, and death.²

CLINICAL PRESENTATION AND DIAGNOSIS

CLINICAL PRESENTATION OF ACUTE MENINGITIS

General

- Clinical presentation varies with age; generally, the younger the patient, the more atypical and the less pronounced is the clinical picture.
- Up to 50% of patients may receive antibiotics before a diagnosis of meningitis is made, delaying presentation to the hospital. Prior antibiotic therapy may cause the Gram stain and CSF culture to be negative, but antibiotic therapy rarely affects CSF protein or glucose.¹⁵

Signs and Symptoms

- ② Classic signs and symptoms include fever, nuchal rigidity, and altered mental status (the classic triad), chills, vomiting, photophobia, and severe headache. Kernig and Brudzinski signs may be present but are poorly sensitive and frequently are absent in children^{15,16} (Figs. 110–4 and 110–5).
- Other signs and symptoms include irritability, delirium, drowsiness, lethargy, and coma.
- Clinical signs and symptoms in young children also may include bulging fontanelle, apnea, purpuric rash, and convulsions.¹⁵
- Seizures occur more commonly in children (20%–30%) than in adults (0%–12%).¹⁷

FIGURE 110-4. A, B. Brudzinski neck signs. Hip and knee flexion occur as a result of flexion of the neck (B). C–E. Brudzinski leg signs. C. Patient's leg is flexed by examiner (arrow). D. Contralateral leg begins to flex—identical contralateral sign (arrows). E. Contralateral leg now begins to extend spontaneously, resembling a little kick (arrows).

FIGURE 110-5. Kernig sign. A. Knees are raised to form a 90-degree angle relative to the trunk, and the examiner attempts to extend the knees. B. Once the knee angle reaches approximately 135 degrees, contracture or extensor spasm occurs.

Differential Signs and Symptoms²

- Purpuric and petechial skin lesions typically indicate meningococcal involvement, although the lesions may be present with *H. influenzae* meningitis. Rashes rarely occur with pneumococcal meningitis.
- Waterhouse-Friderichsen syndrome, a rapid eruption of multiple hemorrhagic lesions associated with a shock-like state, is associated with meningococcal meningitis.
- *H. influenza* meningitis and meningococcal meningitis both can cause involvement of the joints during the illness.
- A history of head trauma with or without skull fracture or presence of a chronically draining ear is associated with pneumococcal involvement.

Laboratory Tests

- Several tubes of CSF are collected via lumbar puncture for chemistry, microbiologic, and hematologic tests. Theoretically, the first tube has a higher likelihood of being contaminated with both blood and bacteria during the puncture, although in practice the total volume is more important than the tube cultured. CSF should not be refrigerated or stored on ice.¹⁸
- Analysis of CSF chemistries typically includes measurement of glucose and total protein concentrations. An elevated CSF protein ≥ 100 mg/dL and CSF glucose concentration $< 50\%$ of the simultaneously obtained peripheral value suggest bacterial meningitis (Table 110–1).
- The values for CSF glucose, protein, and WBC concentrations found with bacterial meningitis overlap significantly with those for viral, tuberculous, and fungal meningitis (Table 110–1). Therefore, CSF WBC counts and CSF glucose and protein concentrations cannot always distinguish the different etiologies of meningitis.

Other Diagnostic Tests¹⁸

- In patients presenting with new-onset seizures, signs of space-occupying lesions, or moderate-to-severe impairment of consciousness, cranial imaging via magnetic resonance imaging or cranial computed tomography (CT) should precede a lumbar puncture. In these instances, withdrawal of CSF fluid from a lumbar puncture reduces counterpressure that may result in compression of the brain from above with risk of brain herniation complicating the clinical course.^{19,20} However, neuroimaging should not delay initiation of antibiotic therapy, as doing so can result in a poor outcome in this disease.²¹
- Blood and other specimens should be cultured according to clinical judgment because meningitis frequently can arise via hematogenous dissemination or can be associated with infections at other sites. A minimum of 20 mL of blood in each of two to three separate cultures per each 24-hour period is necessary for detection of most bacteremias.

- **3** Gram stain and culture of the CSF are the most important laboratory tests performed for bacterial meningitis. The Gram stain continues to be the most rapid and accurate method of presumptively diagnosing acute bacterial meningitis. When performed before antibiotic therapy is initiated, Gram stain is both rapid and sensitive and can confirm the diagnosis of bacterial meningitis in 75% to 90% of cases. The sensitivity of the Gram stain decreases to 40% to 60% in patients who received prior antibiotic therapy. Culture is required to differentiate the various bacterial etiologies.
- Polymerase chain reaction (PCR) techniques can be used to diagnose meningitis caused by *N. meningitidis*, *S. pneumoniae*, and Hib. PCR is considered to be highly sensitive and specific, but use of this powerful diagnostic approach is limited because of expense and availability.
- Latex fixation, latex coagglutination, and enzyme immunoassay tests provide for rapid identification of several bacterial causes of meningitis, including *S. pneumoniae*, *N. meningitidis*, and Hib.¹³ Rapid-identification latex tests work by bringing potential capsular antigens of the pathogen causing meningitis in contact with a specific antibody, causing an antigen–antibody reaction. This capsular antigen–antibody reaction can be observed visually and quickly without waiting for culture results. The rapid antigen tests should be used in situations where in which the Gram stain is negative.¹⁷ The sensitivity and specificity of latex fixation and coagglutination tests can vary with the manufacturer of the antibody, density of the antigen present in the CSF, and pathogen being tested.
- Diagnosis of tuberculosis meningitis uses acid-fast staining, culture, and PCR of the CSF.
- PCR testing of the CSF is the preferred method for diagnosing most viral meningitis infections.
- The standard diagnostic tests for fungal meningitis include culture, direct microscopic examination of stained and unstained specimens of CSF, antigen detection of cryptococcal or histoplasma antigens, and antibody assay of serum and/or CSF.

TREATMENT

Central Nervous System Infections

■ DESIRED OUTCOME

Supportive care, particularly early in the course of treatment, is critically important. Administration of fluids, electrolytes, antipyretics, analgesics, and other supportive measures is indicated for patients presenting with acute bacterial meningitis. Although supportive care is important initially, appropriate antibiotic therapy (empirical or definitive) should be started as soon as possible. **4** Understanding antibiotic selection and the issues surrounding antibiotic penetration will assist in meeting the goals of treatment, which include eradication of infection with amelioration of signs and symptoms and prevention of neurologic sequelae, such as seizures, deafness, coma, and death.

■ APPROACH TO TREATMENT

This section discusses issues surrounding the approach to treatment, such as antibiotic penetration within the CNS, duration of antibiotic therapy, and use of adjunctive corticosteroids. Until a pathogen is identified, prompt empirical antibiotic coverage often is needed. **5** Based on the patient's profile (i.e., allergies, age, and

TABLE 110-2 Most Likely and Empirical Therapy for Bacterial Meningitis by Age Group

Age Commonly Affected	Most Likely Organisms	Empirical Therapy	Risk Factors for All Age Groups
Newborn–1 month	Group B <i>Streptococcus</i> Gram-negative enterics ^a <i>Listeria monocytogenes</i>	Ampicillin plus cefotaxime or ceftriaxone or aminoglycoside	Respiratory tract infection Otitis media Mastoiditis Head trauma Alcoholism High-dose steroids
1 month–4 years	<i>S. pneumoniae</i> <i>N. meningitidis</i> <i>H. influenzae</i>	Vancomycin ^b and cefotaxime or ceftriaxone	Splenectomy Sickle cell disease Immunoglobulin deficiency Immunosuppression
5–29 years	<i>N. meningitidis</i> <i>S. pneumoniae</i> <i>H. influenzae</i>	Vancomycin ^b and cefotaxime or ceftriaxone	
30–60 years	<i>S. pneumoniae</i> <i>N. meningitidis</i>	Vancomycin ^b and cefotaxime or ceftriaxone	
>60 years	<i>S. pneumoniae</i> Gram-negative enterics <i>L. monocytogenes</i>	Vancomycin ^b plus ampicillin plus cefotaxime or ceftriaxone	

^a*Escherichia coli*, *Klebsiella* species, *Enterobacter* species common.

^bVancomycin use should be based on local incidence of penicillin-resistant *S. pneumoniae* and until cefotaxime or ceftriaxone minimum inhibitory concentration results are available.

tion, and spectrum of activity, appropriate recommendations can be made, and therapy should last at least 48 to 72 hours or until the diagnosis of **6** bacterial meningitis can be ruled out (Tables 110–2 and 110–3). The first dose of antibiotics should not be withheld even if lumbar puncture is to be delayed or neuroimaging is to be performed. Changes in the CSF after antibiotic administration usually take 12 to 24 hours. Continued therapy should be based on the assessment of clinical improvement, cultures, and susceptibility testing results. Once a pathogen is identified, antibiotic therapy should be tailored to the specific pathogen (Tables 110–4 and 110–5). Throughout the course of treatment, efficacy parameters (e.g., signs and symptoms, microbiologic findings, and CSF examination) should be followed to evaluate the success of meeting the desired outcomes.

Several factors influence the transfer of antibiotic from capillary blood into the CNS, including inflammation of the meninges, which increases antibiotic penetration through damage to tight junctions between capillary endothelial cells and decreases the activity of an energy-dependent efflux pump in the choroid plexus responsible for movement of penicillins, and, to a much lesser extent, fluoroquinolones and aminoglycosides (Table 110–3). Antibiotics having low molecular weights are passed more easily through biologic barriers than are compounds of higher molecular weight. Only antibiotics that are nonionized at physiologic or pathologic pH are capable of diffusion. Highly lipid-soluble compounds penetrate more readily than are water-soluble compounds. Antibiotics not extensively protein bound in the serum provide a larger free fraction of drug capable of passing into the CSF. Passage of large, polar antibiotics into the CSF may be assisted, however, by a carrier transport system. **7** Unlike the treatment of many other infections, antibiotic dosages in the treatment of CNS infections must be maximized to optimize penetration to the site of infection.

Problems of CSF penetration may be overcome by direct instillation of antibiotics intrathecally, intracisternally, or intraventricularly (Table 110–6). However, advantages of direct instillation must be weighed against the risks of invasive CNS procedures. Intrathecal administration of antibiotics is unlikely to produce therapeutic

concentrations in the ventricles, possibly because of the unidirectional flow of CSF.²² Although intraventricular administration from a therapeutic standpoint may be preferred over intrathecal administration, the former requires neurosurgical placement of a subcutaneous reservoir. Intraventricular delivery may be necessary when bacteria that require treatment with aminoglycosides, such as *L. monocytogenes*, *Pseudomonas aeruginosa* or enterococci, are isolated. In a review of antibiotic-induced endotoxin release, children receiving both parenteral antibiotics and intrathecal gentamicin had higher CSF endotoxin levels, higher CSF IL-1 β levels, and higher mortality than did children receiving only parenteral antibiotics. Interestingly, the differences were attributed to direct CSF administration of gentamicin, which generally is thought to blunt the endotoxin release caused by β -lactam antibiotics.²³

8 Although the length of treatment for bacterial meningitis generally is based on the causative organism, there is no universally accepted standard (Table 110-4). Meningitis caused by *S. pneumoniae* has been treated successfully with 10 to 14 days of antibiotic therapy. Meningitis caused by *N. meningitidis* usually can be treated with a 7-day course of antibiotics. In contrast, a longer duration (≥ 21 days) has been recommended for patients infected with *L. monocytogenes* (A-III, see guidelines in Table 110-4). Therapy should be individualized, and some patients may require longer courses.

CAUSATIVE AGENTS

Neisseria meningitidis (Meningococcus)

N. meningitidis is the leading cause of bacterial meningitis in children and young adults in the United States.²⁴ The source of infection usually is an asymptomatic carrier. Most cases occur in the winter or spring when viral meningitis is relatively uncommon. Five serogroups of *N. meningitidis* (A, B, C, Y, and W-135) are primarily

TABLE 110-4 Antimicrobial Agents of First Choice and Alternative Choice for Treatment of Meningitis Caused by Gram-Positive and Gram-Negative Microorganisms

Organism	Antibiotic of First Choice	Alternative Antibiotics	Recommended Duration of Therapy
Gram-positive

<i>Enterobacteriaceae</i> ^d	Cefotaxime or ceftriaxone (A-II)	Cefepime (A-III), fluoroquinolone (A-III), meropenem (A-III), aztreonam (A-III)	21 days
<i>Pseudomonas aeruginosa</i>	Cefepime or ceftazidime (A-II) ± tobramycin ^{a,b} (A-III)	Ciprofloxacin (A-III), meropenem (A-III), piperacillin plus tobramycin ^{a,b} (A-III), colistin sulfomethate ^{a,c} (B-III), aztreonam (A-III)	21 days

Strength of recommendation: A, good evidence to support a recommendation for use; should always be offered; B, moderate evidence to support a recommendation for use; should generally be offered. Quality of evidence: I, evidence from ≥ 1 properly randomized, controlled trial; II, evidence from ≤ 1 well-designed clinical trial, without randomization; from cohort or case-controlled analytic studies (preferably from >1 center) or from multiple time-series; III, evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert committees.

^aMonitor drug levels in serum.^bDirect central nervous system administration may be added; see Table 110-6 for dosage.^cShould be reserved for multidrug-resistant *Pseudomonas* or *Acinetobacter* infections for which all other therapeutic options have been exhausted.^dIncludes *Escherichia coli* and *Klebsiella* species.^eBased on clinical experience; no clear recommendations.

TABLE 110-5 Dosing of Antimicrobial Agents by Age Group

Antimicrobial Agent	Infants and Children	Adults
Antibacterials		
Ampicillin	75 mg/kg every 6 h	2 g every 4 h
Aztreonam		2 g every 6–8 h
Cefepime	50 mg/kg every 8 h	2 g every 8 h
Cefotaxime	75 mg/kg every 6–8 h	2 g every 4–6 h
Ceftazidime	50 mg/kg every 8 h	2 g every 8 h
Ceftriaxone	100 mg/kg once daily	2 g every 12–24 h
Chloramphenicol	25 mg/kg every 6 h	1–1.5 g every 6 h
Ciprofloxacin	10 mg/kg every 8 h	400 mg every 8–12 h
Colistin ^{a,c}	5 mg/kg once daily	5 mg/kg once daily
Gentamicin ^{a,b}	2.5 mg/kg every 8 h	2 mg/kg every 8 h
Linezolid	10 mg/kg every 8 h	600 mg every 12 h
Meropenem	40 mg/kg every 8 h	2 mg every 8 h
Moxifloxacin		400 mg once daily
Oxacillin/nafcillin	50 mg/kg every 6 h	2 mg every 4 h
Penicillin G	0.05 million units/kg every 4–6 h	4 million units every 4h
Piperacillin	50 mg/kg every 4–6 h	3 g every 4–6 h
Tobramycin ^{a,b}	2.5 mg/kg every 8 h	2 mg/kg every 8 h
Trimethoprim-sulfamethoxazole ^d	5 mg/kg every 6–12 h	5 mg/kg every 6–12 h
Vancomycin ^a	15 mg/kg every 6 h	15 mg/kg every 8–12 h
Antimycobacterials		
Isoniazide	10–15 mg/kg once daily	5 mg/kg once daily
Rifampin	10–20 mg/kg once daily	600 mg once daily
Pyrazinamide	15–30 mg/kg once daily	15–30 mg/kg once daily
Ethambutol	15–25 mg/kg once daily	15–25 mg/kg once daily
Antifungals		
Amphotericin B		0.7–1 mg/kg once daily
Lipid amphotericin B		4 mg/kg once daily
Flucytosine		25 mg/kg every 6 h
Fluconazole		400–800 mg once daily
Voriconazole		6 mg/kg every 12 h × 2 doses, then 4 mg/kg every 12 h
Antivirals		
Acyclovir	20 mg/kg every 8 h	10 mg/kg every 8 h
Foscarnet		60 mg/kg every 8–12 h

^aMonitor drug levels in serum.^bDirect central nervous system administration may be added; see Table 110-6 for dosage.^cShould be reserved for multidrug-resistant pseudomonal or *Acinetobacter* infections for which all other therapeutic options have been exhausted.^dDosing based on trimethoprim component.^eSupplemental pyridoxine hydrochloride (vitamin B₆) 50 mg/day is recommended.

responsible. Clusters of meningococcal disease, defined as two or more cases of the same serogroup that are closer in time and space than expected for the population or group under observation, generally are associated with schools.²⁵ Although some of these clusters have been due to serogroup B, the majority have been due to serogroup C. Serogroup A, which is associated with meningococcal outbreaks in Africa and Asia, is a rare cause of disease in the United States.²⁶ Serogroup Y, which frequently is associated with pneumonia, is emerging as an important cause of invasive meningococcal disease in select areas.^{27,28} Overall, *N. meningitidis* accounts for 25% of all meningitis cases and 60% of cases in persons aged 2 to 18 years, and it carries a case-fatality rate of approximately 10%.^{9,27}

Initially, patients are colonized and, at some point, develop a bacteremia, which most likely occurs prior to hospital admission. Meningitis occurs after the bacteria seeds into the meninges, which can occur in 50% of cases of meningococcal disease.²⁹ After the acute phase of meningitis has resolved, a unique immune reaction occurs that distinguishes meningococcal meningitis from other bacterial causes. The patient develops a characteristic immunologic reaction of fever, arthritis (usually involving large joints), and pericarditis approximately 10 to 14 days after the onset of disease and despite

TABLE 110-6 Intraventricular and Intrathecal Antibiotic Dosage Recommendation

Antibiotic	Dose (mg)	Expected CSF Concentration ^a (mg/L)	Reference
Ampicillin	10–50	60–300	104–106
Methicillin	25–100	160–600	104–106
Nafcillin	75	500	105
Cephalothin	25–100	160–600	104–106

^aAssumes adult cerebrospinal fluid (CSF) volume = 150 mL.

successful treatment.³⁰ At this time, examination of the synovial fluid will reveal a large number of polymorphonuclear cells, elevated protein concentrations, normal glucose concentrations, and sterile cultures. The reaction may last 1 week or longer, and no additional antibiotic therapy is required. However, patients may benefit from nonsteroidal antiinflammatory drugs and supportive care.³⁰

Seizures and coma are uncommon with meningococcal meningitis. However, patients may behave aggressively and often are manic. Patients may develop deafness and transiently impaired ocular movements. Deafness unilaterally or, more commonly, bilaterally may develop early or late in the disease course.³⁰ Hearing loss secondary to sensory nerve damage (sensorineural hearing) usually is permanent, whereas conductive hearing impairment, such as damage to the tympanic membrane, often is reversible.

The presence of petechiae may be the primary clue that the underlying pathogen is *N. meningitidis*. Approximately 50% of patients with meningococcal meningitis have purpuric lesions, petechiae, or both. Patients may have an obvious or subclinical picture of disseminated intravascular coagulation, which may progress to infarction of the adrenal glands and renal cortex and cause widespread thrombosis.

Aggressive, early intervention with high-dose intravenous crystalline penicillin G (50,000 units/kg every 4 hours) usually is recommended for treatment of *N. meningitidis* meningitis. Chloramphenicol is bactericidal for *N. meningitidis* and can be used in place of penicillin G. However, chloramphenicol has unpredictable metabolism in young infants and several drug–drug interactions and is used rarely in developed countries.² Several third-generation cephalosporins (e.g., cefotaxime, ceftriaxone, ceftazidime, ceftizoxime) have indications for treatment of meningitis and are acceptable alternatives to penicillin G (Table 110-5). Meropenem and fluoroquinolones are suitable alternatives for treatment of penicillin-nonsusceptible meningococci (A–III).

Cases of meningitis caused by relatively (minimum inhibitory concentration [MIC] 0.1–1 mg/L) and highly (MIC ≥256 mg/L) penicillin-resistant meningococci have been reported. Prevalence varies geographically, ranging from 0.4% to 42.6%.³¹ Isolated cases of treatment failure with penicillin have been reported.^{32,33} Completely resistant strains produce β -lactamase, whereas relatively resistant strains have an alteration of penicillin-binding proteins. Given the emergence of β -lactamase-producing strains of meningococci, more practitioners are prescribing third-generation cephalosporins (cefotaxime or ceftriaxone) instead of penicillin, which long has been considered the drug of choice for meningococcal meningitis.³⁴

N. meningitidis is spread by direct person-to-person close contact, including respiratory droplets and pharyngeal secretions.²⁹ Close contacts of patients contracting *N. meningitidis* meningitis

are at an increased risk for developing meningitis. Close contacts include daycare center contacts, members of the household, or anyone who has been exposed to respiratory or oral secretions through activities such as coughing, sneezing, or kissing. Household contacts of people who have sporadic disease are estimated to have an incidence of meningococcal meningitis that is 500 to 800 times greater than that of the overall population.²⁹ Secondary cases of meningitis usually develop within the first week following exposure but may take up to 60 days after contact with the index case.³⁵ Young children are at the greatest risk for contracting *N. meningitidis*; however, persons of all ages are at risk, especially close contacts exposed via household, daycare, or military contact.

9 Prophylaxis of close contacts should be started only after consultation with the local health department. In general, rifampin is given as prophylaxis for 2 days.²⁶ The adult dose is 600 mg every 12 hours, whereas children 1 month and older should receive 10 mg/kg every 12 hours, and children younger than 1 month should receive 5 mg/kg every 12 hours (A-III). Intramuscular ceftriaxone (250 mg in adults, 125 mg in children younger than 12 years) and oral ciprofloxacin (500 mg in adults and children older than 12 years) are alternatives to rifampin (A-III).¹⁵ Further discussion of who should receive prophylaxis is beyond the scope of this chapter; interested readers can refer to the recommendations of the U.S. Centers for Disease Control and Prevention (CDC) for that information.³⁶

***Streptococcus pneumoniae* (Pneumococcus or Diplococcus)**

S. pneumoniae is the leading cause of meningitis in adults. Moreover, *S. pneumoniae* is the most common cause of bacterial meningitis in children younger than 2 years, accounting for four to six cases per 100,000 of this population, and is the second most common cause in children older than 2 years.³⁷ Case-fatality rates in children are highest with this organism and approach 20%. Approximately 50% of cases are secondary infections resulting from primary infections of parameningeal foci, such as the ear or paranasal sinuses. Pneumonia, endocarditis, CSF leak secondary to head trauma, splenectomy, alcoholism, sickle cell disease, and bone marrow transplantation may predispose the patient to the development of pneumococcal meningitis.

Neurologic complications, such as coma and seizures, are common with pneumococcal meningitis. Children with pneumococcal meningitis have lower mortality rates (4%–17%) compared with adults (20%–30%), but children who survive have a high rate of neurologic sequelae (29%–56%).^{38,39} Risk factors for recurrent pneumococcal meningitis include traumatic tears of the dura, fracture of the cribriform plate or paranasal sinuses, nasal meningoceles, repeated episodes of otitis media, basilar skull fractures, and CSF leaks. The prognosis of pneumococcal meningitis depends on a variety of factors, including the number of WBCs in the CSF, number of WBCs in the periphery, CSF glucose concentration, CSF protein concentration, serum sodium concentration, and presence of a comatose state and/or shock.⁴⁰

Treatment with intravenous crystalline penicillin G (50,000 units/kg every 4 hours) in adult patients with a penicillin-susceptible isolate and normal renal function usually results in a favorable outcome. However, the frequency of penicillin-resistant pneumococcal strains (MIC \geq 2 mg/L) in the United States increased from 14% in 1994 to 25% in 1997 and continues to rise.³⁴ Based on these resistance patterns and the fact that sufficient CSF concentrations of penicillin are difficult to achieve with standard intravenous doses, penicillin should not be used as empirical therapy if *S. pneumoniae* is a suspected pathogen. Furthermore, appropriate Clinical Laboratory Standards Institute (CLSI)-approved testing of

all CSF isolates for penicillin resistance is recommended. Ceftriaxone and cefotaxime have served as alternatives to penicillin in the treatment of penicillin intermediate- and high-resistant pneumococci. Of note, treatment failures with third-generation cephalosporins in the management of penicillin-resistant pneumococci have been reported.³⁴ Therapeutic approaches to cephalosporin-resistant pneumococcus include the addition of vancomycin and rifampin, which have demonstrated synergistic activity with ceftriaxone. However, no data from controlled clinical trials supporting the use of rifampin are available. Therefore, the combination of vancomycin and ceftriaxone has been suggested as empirical treatment until the results of antimicrobial susceptibility testing are available.^{2,34} Some investigators have suggested that the addition of vancomycin to the initial empirical regimen may not be necessary because the prevalence of β -lactam-resistant pneumococci has been reduced greatly as a result of the pneumococcal vaccines.²

Ceftriaxone and vancomycin are the agents of choice for treatment of presumed pneumococcal meningitis empirically until the susceptibility is known. Penicillin can be used for drug-susceptible isolates with MIC \leq 0.06 mg/L, but for intermediate isolates, ceftriaxone is used, and for highly drug resistant isolates, a combination of ceftriaxone and vancomycin should be used. Vancomycin should not be used as monotherapy.³⁴ In severe cases, therapeutic drug monitoring of the CSF and possibly even direct antibiotic instillation may be necessary.

Reports of the isolation of pneumococcal strains exhibiting tolerance to vancomycin are of great concern, but the clinical significance is unknown.^{41,42} Based on concern about the limited therapeutic options for penicillin- and cephalosporin-resistant pneumococcal meningitis, newer agents have been evaluated. Meropenem is approved by the Food and Drug Administration (FDA) for treatment of bacterial meningitis in children aged 3 months and older and has shown similar clinical and microbiologic efficacy to cefotaxime or ceftriaxone. Meropenem currently is recommended as an alternative to a third-generation cephalosporin in penicillin-nonsusceptible isolates (B-II). Some concern is warranted with use of imipenem for CNS infections because of the possibility of drug-induced seizures, especially if the dose is not adjusted for renal function. Of note, seizures may be caused by the meningitis itself or by imipenem, and the cause is difficult to differentiate. The newer fluoroquinolones are another therapeutic option as a result of favorable activity against multidrug-resistant pneumococci and good penetration into the CSF.⁴³ However, clinical data regarding fluoroquinolone treatment of pneumococcal meningitis are limited mainly to animal models. Comparative, controlled clinical efficacy trials in patients with meningitis will be necessary before routine use of the fluoroquinolones is viable. Interestingly, some of the newer fluoroquinolones act synergistically with vancomycin and β -lactam antibiotics against penicillin-resistant pneumococcal meningitis in an animal model, but this claim has not been substantiated in humans.^{34,44,45}

Linezolid and daptomycin have emerged as therapeutic options for treatment of multidrug-resistant gram-positive infections. Linezolid in combination with ceftriaxone has been used to treat a limited number of cases of pneumococcal meningitis with outcomes similar to standard treatment.⁴⁶ Penetration of daptomycin in the CSF was approximately 6% following a 15 mg/kg bolus and achieved maximum concentration approximately 4 hours after the dose in a rabbit meningitis model. The 15 mg/kg dose produces similar serum concentrations in rabbits as the 6 mg/kg dose in humans. In this study, daptomycin was able to clear both the penicillin-resistant and the quinolone-resistant pneumococci from the CSF more rapidly than the standard regimen of vancomycin and ceftriaxone.⁴⁷ However, limited data are available, and use of these agents cannot be recommended for treatment of pneumococcal meningitis.

CLINICAL CONTROVERSY

Some investigators believe that use of vancomycin for empirical treatment of pneumococcal meningitis is no longer necessary because the widespread use of pneumococcal vaccines has greatly reduced the prevalence of β -lactam-resistant pneumococci. However, because the infecting organism is rarely known initially, most clinicians still use the combination of a third-generation cephalosporin and vancomycin for empirical treatment.

Pneumococcal vaccines help reduce the risk of invasive pneumococcal disease. Virtually all serotypes of *S. pneumoniae* exhibiting intermediate or complete resistance to penicillin are found in the 23-serotype pneumococcal polysaccharide vaccine. However, in 1997, surveillance data indicated that only 30% of people 65 years and older had been immunized against pneumococcal disease.⁴⁸ Therefore, the CDC issued stronger recommendations for use of the pneumococcal polysaccharide vaccine, calling for vaccination of the following high-risk groups: persons older than 65 years; persons aged 2 to 64 years who have a chronic illness, who live in high-risk environments (e.g., Alaskan Natives and residents of long-term care facilities), and who lack a functioning spleen (e.g., sickle cell disease and splenectomy); and immunocompromised persons older than 2 years, including those with human immunodeficiency virus (HIV) infection. Additionally, the question of whether or not college students living in dormitories, a possible high-risk environment, should be vaccinated remains debatable. Unfortunately, variability in the host's ability to mount an immune response to the vaccine limits its usefulness for penicillin-resistant pneumococci in children younger than 2 years and in immunocompromised adults.

In 2000, a heptavalent pneumococcal conjugate vaccine (Prevnar) was approved for use in children aged 2 months and older. Use of the vaccine has reduced invasive pneumococcal infections, including sepsis and meningitis, by more than 90%.⁴⁹ Moreover, the vaccine is safe and effective in low-birth-weight and preterm infants.^{50,51} Widespread vaccination is expected to have a significant impact on the prevalence of pneumococcal meningitis, including infection caused by antibiotic-resistant strains. A cohort study of 3.8 million healthy infants projected that vaccination would prevent more than 12,000 cases of invasive disease for each U.S. birth cohort, resulting in substantial decreases in morbidity and mortality as well as possible cost savings.⁵² According to current recommendations, all healthy infants younger than 2 years should be immunized with the heptavalent vaccine at 2, 4, 6, and 12 to 15 months. The recommendations are extended to include Alaskan Native, Native American, and African American children between the ages of 2 and 5 years. In 2003, the CDC issued a recommendation that all persons with cochlear implants receive age-appropriate vaccination with the pneumococcal conjugate vaccine, pneumococcal polysaccharide vaccine, or both.⁵³

Haemophilus influenzae

Historically, *H. influenzae* was the most common cause of meningitis in children aged 6 months to 3 years. Since the introduction of effective vaccines, however, the incidence of *H. influenzae* type B disease in the United States has declined dramatically. Widespread vaccination of infants and children has decreased the incidence of bacterial meningitis due to *H. influenzae* in children between the ages of 1 month and 5 years by 87%, resulting in a 55% decline in all cases of bacterial meningitis.¹⁴ Worldwide, in countries that have adopted universal immunization, the incidence of bacterial meningitis caused by *H. influenzae* type b has decreased more than 99%.² In children older than 3 years and in adults, meningitis caused by *H. influenzae* may indicate a parameningeal focus of infection such as middle ear infection, paranasal sinus infection, or CSF leakage.

Spread of the organism occurs through direct spread from infected sinuses, draining of these areas via the veins, or bacteremia originating from the local focus of infection.⁵⁴

In the past, ampicillin and chloramphenicol were the drugs of choice to treat pediatric meningitis. However, because approximately 30% to 40% of *H. influenzae* now are ampicillin resistant, many clinicians prescribe a third-generation cephalosporin until sensitivities are available. If the organism is found to be sensitive to ampicillin, the patient can be switched to ampicillin and the third-generation cephalosporin discontinued. Most clinicians regard third-generation cephalosporins as the drugs of choice for meningitis caused by *H. influenzae* (A-1). Third-generation cephalosporins (cefotaxime and ceftriaxone) are active against β -lactamase-producing and non- β -lactamase-producing strains of *H. influenzae*, are relatively free of toxicity, and do not require serum concentration monitoring. Cefepime (A-I) and fluoroquinolones (A-III) are suitable alternatives regardless of β -lactamase activity.

Secondary cases resulting from close contact with an index case occur within 30 days of the onset of disease. Close contacts, which include household members, individuals sharing sleeping quarters, daycare attendees, nursing home residents, and crowded, confined populations, may be at 200 to 1,000 times the risk of the general population for acquiring *H. influenzae* meningitis. The risk of acquiring *H. influenzae* meningitis is low without intimate contact with the index patient's respiratory secretions.⁵⁵

9 The aim of prophylaxis is to protect close contacts from the index case by eliminating nasopharyngeal and oropharyngeal carriage of *H. influenzae*. Invasive disease should be reported to the local public health department and the CDC. Prophylaxis of close contacts should be started only after consultation with the local health department. In general, children should receive rifampin 20 mg/kg/day (maximum 600 mg) and adults 600 mg/day in one dose for 4 days. Any unvaccinated children between the ages of 12 and 48 months should receive one dose of the vaccine, whereas those between the ages of 2 and 11 months should be given three doses of the vaccine.¹⁵ Individuals fully vaccinated are not recommended to receive prophylaxis.²⁶ Further discussion of who should receive prophylaxis is beyond the scope of this chapter; interested readers can refer to the recommendations of the American Academy of Pediatrics for that information.⁵⁶

Vaccination includes a series of doses and usually is started in children at age 2 months. The diphtheria, tetanus toxoids, acellular pertussis–*H. influenzae* type B (DTaP–Hib) combination vaccine also is available as a booster following the Hib series. In addition to pediatric immunization, the vaccine should be considered in patients older than 5 years with the following underlying conditions: sickle cell disease, asplenia, and immunocompromising diseases (see Chap. 128 for further information on dosing and administration).

Listeria monocytogenes

L. monocytogenes is a gram-positive diphtheroid-like organism responsible for 8% of all reported cases of meningitis. This disease primarily affects neonates, alcoholics, immunocompromised adults, and the elderly. *Listeria* infections in healthy individuals are extremely rare. *L. monocytogenes* is implicated in 20% of meningitis cases in patients older than 60 years and carries a case-fatality rate of approximately 15%.⁹

Transmission usually involves colonization of the patient's gastrointestinal (GI) tract with the organisms, which then penetrate the gut lumen. Coleslaw, unpasteurized milk, Mexican-style soft cheese, ready-to-eat foods, and raw beef and poultry all have been identified as sources of this food-borne pathogen.²⁶ If a sufficient cell-mediated immune response (T lymphocytes, macrophages) is not produced, bacteremia, meningitis, meningoencephalitis, or cerebritis may develop. Infection of the CNS may be diffuse or localized,

possibly involving the cerebral hemispheres, thalamus, and brainstem. In immunocompromised hosts, approximately 75% of *L. monocytogenes* infections result in transmission into the CNS.⁵⁷

Incidence of *L. monocytogenes* meningitis tends to peak in the summer and early fall. As with gram-negative meningitis, presentation may be subtle and insidious, and clinical suspicion should prompt lumbar puncture. *L. monocytogenes* produces primarily a mononuclear CSF response.⁵⁷ One common laboratory error seen with *L. monocytogenes* is a tendency to misidentify the organism on Gram stain as a diphtheroid, streptococcus, or poorly staining gram-negative rod.

Treatment of *L. monocytogenes* meningitis with penicillin G or ampicillin may result in only a bacteriostatic effect and possible persistence of infection. Usually the combination of penicillin G or ampicillin with an aminoglycoside results in a bactericidal effect. Patients should be treated for 2 to 3 weeks after defervescence (A-III).¹⁵ Combination therapy usually is given for at least 10 days, with the remaining course of therapy completed with penicillin G or ampicillin alone. Trimethoprim-sulfamethoxazole may be an effective alternative because adequate CSF penetration is achieved (A-III). Chloramphenicol and vancomycin both possess in vitro activity against *Listeria*, but they are not recommended for use in meningitis caused by *L. monocytogenes* because of unacceptably high failure rates.³⁴

Gram-Negative Meningitis

During the last several years, the incidence of gram-negative bacillary meningitis, excluding *H. influenzae*, has been increasing in both children and adults. Enteric gram-negative organisms are the fourth leading cause of meningitis, with only *S. pneumoniae*, *H. influenzae*, and *N. meningitidis* having higher incidences.

Several factors predispose patients to the development of gram-negative meningitis: congenital defects involving the CNS, accidental cranial trauma, neurosurgery, use of antimicrobial agents with exclusive gram-positive activity preoperatively in neurosurgery, any form of communication between the skin and subarachnoid space (e.g., dermal sinus), diabetes, malignancy, urinary tract infection in neonates, cirrhosis, parameningeal infection, spinal anesthesia, advanced age, immunosuppression, and hospitalization in general.

Elderly debilitated patients are at increased risk for gram-negative meningitis but typically lack the classic signs and symptoms of the disease. Nuchal rigidity may be difficult to detect secondary to cervical arthritis. Presence of a low-grade fever and changes in mental status without other obvious cause should prompt consideration of meningitis and a lumbar puncture. Neonates also are at risk for gram-negative meningitis with *E. coli* and *Klebsiella pneumoniae*, which are responsible for 60% to 70% of cases.

Optimal antimicrobial therapies for gram-negative bacillary meningitis have not been fully defined. Therapy for gram-negative meningitis is complex because of the variety of organisms that can infect the CNS. Treatment of meningitis due to *P. aeruginosa* remains a unique problem because antibiotics showing good antibacterial activity against *P. aeruginosa*, such as antipseudomonal penicillins and aminoglycosides, penetrate the CSF poorly. Furthermore, many isolates of *P. aeruginosa* are resistant to multiple, if not all, commonly used agents, and this trend in resistance is increasing. Initially, cases of *P. aeruginosa* meningitis should be treated with an extended-spectrum β -lactam such as ceftazidime or cefepime (A-II), or alternatively piperacillin \pm tazobactam, or meropenem plus an aminoglycoside, usually tobramycin.² Because aminoglycosides penetrate the CSF poorly, they are included predominantly to aid in the treatment of extracerebral infections. If multidrug-resistant *Pseudomonas* is suspected initially, intraventricular administration of aminoglycoside should be considered along with intravenous administration. Preservative-free forms of gentamicin and tobramycin

are available and should be used for direct administration into the CSF. Intraventricular aminoglycoside dosages should be adjusted to the estimated CSF volume (0.03 mg tobramycin or gentamicin per milliliter of CSF and 0.1 mg amikacin per milliliter of CSF every 24 hours). Because CSF flows unidirectionally with gravity, intraventricular aminoglycoside administration is more likely to produce therapeutic concentrations throughout the CSF than will intrathecal administration. Although intraventricular administration of aminoglycosides is considered for treatment of *P. aeruginosa* meningitis, this method produced higher mortality in a sample of infants treated for gram-negative bacillary meningitis.²² Thus, intraventricular administration of aminoglycosides to infants is not recommended routinely. Ventricular levels of aminoglycoside should be monitored every 2 or 3 days, just prior to the next intraventricular dose, and should approximate 2 to 10 mg/L. Interpretation of drug levels may be difficult because determinations often are contaminated with residual aminoglycoside from the preceding dose.

One patient exhibited favorable effects of high-dose intravenous ciprofloxacin (400 mg every 8 hours) plus intravenous ceftazidime for treatment of pseudomonal meningitis.⁵⁸ However, this information must be evaluated in a controlled clinical trial before use of high-dose ciprofloxacin can be recommended.

Multidrug-resistant *Pseudomonas* and *Acinetobacter* infections are of concern to clinicians because of the limited therapeutic options available for treatment. This concern has led to the reemergence of the use of older antibiotics, such as colistin. Colistin can be used, both intravenously and intrathecally, for treatment of multidrug-resistant *Pseudomonas* or *Acinetobacter* CNS infections.^{59–61} Furthermore, there is synergistic activity with the combination of colistin and ceftazidime against multidrug-resistant *P. aeruginosa*.⁶² Use of colistin should be reserved for only the most severe cases.

Other gram-negative organisms causing meningitis, excluding *P. aeruginosa* and *Acinetobacter* species, most likely can be treated with a third or fourth-generation cephalosporin, such as cefotaxime, ceftriaxone, ceftazidime, or cefepime. However, ceftazidime may not be the best choice of empirical antibiotic for situations where the offending organism is not known initially because CSF antibiotic concentrations more than 10 times the minimal bactericidal concentration may not be produced reliably for gram-positive organisms. In adults, daily doses of 8 to 12 g/day of third-generation cephalosporins (ceftriaxone 2 g twice daily) should produce CSF concentrations of 5 to 20 mg/L. Ceftriaxone is not recommended for use in the neonatal period because of the potential for displacement of bilirubin from albumin-binding sites.² In this situation, cefotaxime should be used in place of ceftriaxone.

Trimethoprim-sulfamethoxazole is useful in the management of the Enterobacteriaceae family and may be useful in the management of *L. monocytogenes*.^{2,8} One advantage of trimethoprim-sulfamethoxazole is that its penetration into the CSF does not depend on meningeal inflammation. However, trimethoprim-sulfamethoxazole is not bactericidal. Trimethoprim-sulfamethoxazole produces CSF levels of 1.9 to 5.7 mg/L for the former and 20 to 63 mg/L for the latter when given parenterally in doses of trimethoprim 10 mg/kg/day and sulfamethoxazole 50 mg/kg/day.

Fluoroquinolones have good penetration into the CSF and are effective in animal models of both gram-negative and gram-positive meningitis. However, data on the efficacy of fluoroquinolones in clinical practice are limited. Ciprofloxacin is recommended as an alternative for treatment of *E. coli* and other Enterobacteriaceae as well as *Pseudomonas aeruginosa* (A-III). Cefepime and meropenem are other therapeutic options for treatment of gram-negative bacterial meningitis, as is aztreonam (A-III).^{2,34}

CSF cultures may remain positive for at least several days with a regimen that eventually will be curative. Therapeutic efficacy can be monitored through bacterial colony counts every 2 or 3 days, which

should decrease progressively over the period of therapy. Therapy for gram-negative meningitis should be continued for a minimum of 21 days from the start of treatment.¹⁵

Bacillus anthracis

B. anthracis is a large, endospore-forming, aerobic, gram-positive bacteria capable of producing infection via the cutaneous, pulmonary, or GI routes. Cases of meningitis following both cutaneous and inhalational infection have been reported. Prior to the bioterrorism-related outbreak of 11 inhalational and 12 suspected or confirmed cases of cutaneous anthrax in 2001, only 18 sporadic cases had occurred in the United States in the 20th century, with the last occurrence in 1976.⁶³ However, since the terrorist attack on the United States on September 11, 2001, heightened awareness of biologic warfare agents, including *B. anthracis*, has percolated throughout the United States.

The major neurologic complication of anthrax infection is fulminant, rapidly fatal hemorrhagic meningoencephalitis. The inhalational form of anthrax seems to be a potent inducer of neurologic symptoms, and death usually occurs within 1 week in those with neurologic complications.⁶³ Neurologic manifestations may be the initial symptoms leading to the diagnosis of anthrax. An index case of fatal inhalational anthrax from bioterrorism developed acute fever, emesis, disorientation, and confusion. A head CT scan showed no abnormalities, but spinal tap revealed cloudy CSF, low CSF glucose concentration, high CSF protein concentration, increased leukocytes in the CSF, and large gram-positive bacilli in chains. Shortly thereafter, the patient developed a generalized seizure and died on the third hospital day.⁶⁴

Consistent findings in the CSF of anthrax meningitis cases include a low CSF glucose level, marked infiltration of WBCs into the CSF, and presence of gram-positive bacilli in chains. High suspicion of anthrax meningitis is warranted in the additional presence of grossly visible blood or elevated red blood cell counts in the CSF with hemorrhagic changes on a CT scan. Molecular advances can aid in the rapid diagnosis of *B. anthracis* infections. Rapid PCR techniques, such as the Light Cycler (Roche Applied Science, Indianapolis, IN), can provide molecular confirmation of the presence of anthrax within 1 hour.⁶³ Extreme caution is warranted for diagnosis without the use of molecular techniques because *B. anthracis* can be confused easily with *B. cereus*, which is found commonly in soil and often considered a contaminant if identified.

B. anthracis typically is susceptible to penicillin, amoxicillin, erythromycin, doxycycline, ciprofloxacin, and chloramphenicol. The bioterrorism-related strain was susceptible to the fluoroquinolones, rifampin, tetracycline, vancomycin, imipenem, meropenem, chloramphenicol, clindamycin, and the aminoglycosides. However, the strain was resistant to third-generation cephalosporins and trimethoprim-sulfamethoxazole. Ciprofloxacin or doxycycline plus one or two of the aforementioned antibiotics is the currently recommended regimen for treatment of inhalational anthrax, but doxycycline is not recommended for treatment of anthrax meningitis because of poor CNS penetration and recent in vitro resistance.⁶³

Dexamethasone as Adjunctive Treatment of Meningitis

In addition to antibiotics, dexamethasone has become a commonly used therapy for treatment of meningitis. Corticosteroids inhibit the production of TNF and IL-1, which both are potent proinflammatory cytokines. A series of clinical studies assessing the efficacy of corticosteroid therapy for the initial treatment of bacterial meningitis has reported conflicting results.^{65–69} A fundamental problem with corticosteroid investigations is that the majority of patients in the trials had *H. influenzae* meningitis. Although *H. influenzae* was the most commonly identified causative pathogen responsible for bacterial meningitis in the United States in 1986, the incidence of *H.*

influenzae meningitis has decreased dramatically because of the introduction of polysaccharide conjugate vaccines. Additionally, the majority of studies examining dexamethasone use for pneumococcal meningitis were conducted before the widespread problem of penicillin-resistant pneumococcus had emerged or were conducted in parts of the world where penicillin resistance was minimal. Whether or not steroids are beneficial for treatment of meningitis caused by penicillin-resistant *S. pneumoniae*, *N. meningitidis*, and group B streptococci is unclear at this time.

The findings of several studies have shown significant improvement in markers of active infection, such as CSF levels of proinflammatory cytokines, as well as CSF protein, glucose, and lactate concentrations, after corticosteroid administration as adjunctive treatment.¹⁴ Trials consistently detected a significantly lower incidence of neurologic sequelae commonly associated with bacterial meningitis with corticosteroid use. In trials that measured inflammatory mediators, lower levels of TNF, PAF, or IL-1 were detected in patients treated with dexamethasone.^{65,66,69}

The majority of clinical trials on the use of adjunctive dexamethasone in bacterial meningitis has involved children. A retrospective analysis of pediatric patients with pneumococcal meningitis and one unblinded, noncontrolled trial suggested that adjunctive steroids may decrease the neurologic sequelae and mortality associated with *S. pneumoniae* meningitis.^{65,70} A meta-analysis suggests that, with the possible exception of hearing loss, dexamethasone does not protect against neurologic sequelae.⁷¹ The protective effect of dexamethasone was observed to be strongest in patients with meningitis due to *H. influenzae*.

10 The American Academy of Pediatrics suggests that dexamethasone be considered for infants and children aged 2 months and older with pneumococcal meningitis (C-II) and given to those with *H. influenzae* meningitis.^{56,72} The recommended intravenous dose is 0.15 mg/kg every 6 hours for 4 days. Alternatively, prospective, randomized, double-blinded studies have found dexamethasone 0.15 mg/kg every 6 hours for 2 days or dexamethasone 0.4 mg/kg every 12 hours for 2 days to be equally effective and potentially less toxic.^{69,73} Dexamethasone should be administered prior to or with the first antibiotic dose and not after antibiotics already have been started (A-I).¹⁴ Additionally, serum hemoglobin and stool guaiac should be monitored for evidence of GI bleeding.^{66,68,70,73} Dexamethasone should not be given to neonates or any infant younger than 6 weeks.^{14,22} Use of dexamethasone interferes with the interpretation of clinical response to treatment. For example, corticosteroid use interferes with resolution of fever. Thus, all infants and children are recommended to undergo a repeat lumbar puncture 24 to 48 hours after treatment to verify CSF sterilization.¹⁴

Data supporting the use of corticosteroids in adults with meningitis are scarce. A prospective, randomized, double-blinded multicenter study evaluated the use of adjuvant therapy plus dexamethasone compared with adjuvant therapy plus placebo in adults with acute bacterial meningitis.⁷⁴ Early treatment with dexamethasone improved clinical outcome in adults with bacterial meningitis, reducing the risk of both unfavorable outcome and death. However, the study did not show a beneficial effect of dexamethasone on neurologic sequelae, including hearing loss. Furthermore, a meta-analysis of five trials⁷⁵ involving 623 adults with acute bacterial meningitis described a significant reduction in mortality in patients treated with steroids and antibiotics compared to those treated with antibiotics alone. There was no significant reduction in neurologic sequelae, but this could have been limited by the sample size, as two of the five trials did not investigate neurologic complications. The safety and adverse events were similar between those who received steroids and those who did not.⁷⁵

If pneumococcal meningitis is suspected or proven, it is recommended that adults receive dexamethasone 0.15 mg/kg every 6

hours for 2 to 4 days, with the first dose administered 10 to 20 minutes prior to first dose of antibiotics. Patient outcome likely will not improve if dexamethasone is given after the first dose of antibiotic and therefore should be avoided (A-I). Because ascertaining the responsible pathogen on presentation often is difficult, some clinicians recommend initiating dexamethasone in all adult patients presenting with meningitis (B-III).

Routine use of dexamethasone in meningitis is not without controversy. A potential concern is that adjunctive dexamethasone therapy might reduce the penetration of antibiotics into the CSF by inhibiting meningeal inflammation. In experimental models of meningitis, steroids decreased the CSF concentrations of ampicillin, rifampin, vancomycin, and gentamicin.^{69,76} Ceftriaxone and vancomycin penetration into CSF was unaffected by concurrent dexamethasone administration in pediatric patients.^{77,78}

CLINICAL CONTROVERSY

Some clinicians believe that dexamethasone should be initiated in all patients older than 2 months with bacterial meningitis and continued for the recommended 2 to 4 days regardless of bacterial etiology. However, others believe corticosteroids have limited proven benefit in the treatment of nonpneumococcal meningitis and recommend stopping dexamethasone if another bacterial pathogen is identified.

Mycobacterium tuberculosis

M. tuberculosis is the primary cause of tuberculous meningitis. Tuberculous meningitis is associated with significant morbidity and mortality and is difficult to diagnose in a timely manner. The most life-threatening form of extrapulmonary tuberculosis is tuberculous meningitis.⁷⁹ The epidemiology of tuberculous meningitis as a cause of extrapulmonary tuberculosis has changed. Between 1997 and 1990, an average of 193 cases of tuberculous meningitis was reported to the CDC, representing 4.7% of extrapulmonary cases. The number of cases reported in 1990 was 284, or 6.2% of extrapulmonary cases. This change most likely is secondary to HIV/acquired immune deficiency syndrome (AIDS) and rising rates among minority adults leading to increased tuberculosis in their children.⁸⁰ The incidence of tuberculosis in general has increased 15% since 1985, and the increase is more substantial in children than in adults.⁷⁹

The most useful clue to the diagnosis of tuberculous meningitis is the presence of inflammation of the CSF in an individual who is at epidemiologic risk for tuberculosis. Although up to 40% of patients may present with evidence of pulmonary involvement with hilar adenopathy, tuberculous meningitis still may exist in the absence of disease in the lung or extrapulmonary sites. The tuberculin skin test (purified protein derivative) is negative in 5% to 50% of cases.⁸¹

On initial examination, CSF usually contains 100 to 1,000 WBCs/mm³, which may be 75% to 80% polymorphonuclear cells. Over time, the pattern of WBCs in the CSF will shift to lymphocytes and monocytes (Table 110-1). CSF glucose concentration initially may be normal but gradually decreases as the disease progresses.^{81,82} Protein concentration within the CSF may be normal or elevated, with high protein levels shown to correlate with advanced disease.⁸¹⁻⁸³ CSF cultures often are positive for *M. tuberculosis* even if the patient is asymptomatic.

One potentially useful diagnostic sign unique to tuberculous meningitis is paralysis of cranial nerve VI, which initially is unilateral and then progresses to bilateral.³⁰ Initial acid-fast bacilli smears are approximately 37% sensitive and as high as 87% sensitive following subsequent smears. Sensitivity of the acid-fast bacilli smear is enhanced by examination of multiple CSF specimens collected on consecutive days. Cultures of CSF are positive in 45% to 90% of cases

depending on the quantity of CSF used in the culture, pathogen density, and experience of the laboratory in culturing *M. tuberculosis*. Some clinicians obtain fluid from the base of the brain or the ventricles in an attempt to increase the yield. Positive culture results may take up to 8 weeks, providing little help with the initial diagnosis.^{81,82} Several systems using rapid broth culture (Organon Teknika MB/BacT, Organon Teknika, Durham, NC; ESP system, Trek Diagnostic Systems, Inc., Westlake, OH; and Bactec 9000 TB series or Bactec 460, Becton Dickinson Diagnostic Instruments, Sparks, MD) have considerably shortened the time to detection and are able to detect organisms in less than 3 weeks.¹⁸ Nucleic acid amplification products, such as Amplicor (Roche) and MTD (Gen-Probe), allow for direct identification of *M. tuberculosis* within 48 hours and yield higher sensitivity than a smear.

The incidence of multidrug-resistant strains of *M. tuberculosis* has increased, necessitating the use of at least three antitubercular agents for treatment of active pulmonary disease. The CDC recommends an initial regimen of four drugs for empirical treatment of *M. tuberculosis*.⁸⁴ This regimen consists of isoniazid, rifampin, pyrazinamide, and ethambutol 15 to 20 mg/kg/day (maximum 1.6 g/day) for the first 2 months, generally followed by isoniazid plus rifampin for the remaining duration of therapy. The recommended therapy for HIV-positive individuals is the same as for immunocompetent patients, although rifabutin may be considered in place of other rifamycins in an effort to minimize drug interactions with protease inhibitors and nonnucleoside reverse transcriptase inhibitors. Therapy in HIV-negative and HIV-positive patients should be individualized based on susceptibility patterns and guidelines from the CDC and the American Thoracic Society, which are updated frequently and available on the Internet (www.cdc.gov/nchstp/tb/pubs/mmwrhtml/maj_guide.htm). Patients with *M. tuberculosis* meningitis should be treated with multiple-drug therapy for 9 months or longer, and patients with rifampin-resistant strains should receive 18 to 24 months of therapy.

Isoniazid, the mainstay in virtually any regimen for treatment of *M. tuberculosis*, penetrates the CSF with or without meningeal inflammation and achieves concentrations more than 30 times the MIC of *M. tuberculosis* (MIC 0.05–0.2 mg/L).^{57,81,82} Rifampin's penetration of CSF approximates only 20% of serum concentrations in the presence of meningeal inflammation. *M. tuberculosis* typically is so exquisitely sensitive to rifampin that the low penetration ratio is of little clinical significance.^{81,82,85} However, the incidence of *M. tuberculosis* resistance to rifampin has increased, necessitating empirical multiple-antibiotic regimens.

Pyrazinamide is a small molecule that penetrates the CSF well in the presence or absence of meningeal inflammation. Streptomycin, an aminoglycoside, penetrates the CSF poorly, even in the presence of meningeal inflammation. The incidence of resistance to streptomycin is increasing, and this drug should not be recommended unless susceptibility is known. Ethambutol is a weak antitubercular agent that reaches the CSF in moderate concentrations. Use of ethambutol is also limited by a high incidence of dose-related optic neuritis. Ethionamide and cycloserine are two other agents that sometimes are used to treat tuberculous meningitis. Both of these agents penetrate the CSF well in the absence of meningeal inflammation.^{81,82}

The usual dose of isoniazid in children is 10 to 15 mg/kg/day (maximum 300 mg/day); adults usually receive 5 mg/kg/day or a daily dose of 300 mg.⁸⁴ Supplemental doses of pyridoxine hydrochloride (vitamin B₆) 50 mg/day are recommended to prevent the peripheral neuropathy associated with isoniazid administration.^{81,82} Concurrent administration of rifampin is recommended at doses of 10 to 20 mg/kg/day (maximum 600 mg/day) for children and 600 mg/day for adults. The addition of pyrazinamide (children and adults 15–30 mg/kg/day; maximum 2 g/day in both) to the regimen of isoniazid and rifampin is recommended.⁸⁴ Duration of concom-

itant pyrazinamide therapy generally should be limited to 2 months to avoid hepatotoxicity.

The role of steroids in the management of tuberculous meningitis remains unclear. Administration of oral prednisone 60 to 80 mg/day or 0.2 mg/kg/day of intravenous dexamethasone for adults and prednisone 1 to 2 mg/kg/day for children, tapered over 4 to 8 weeks, has been used in clinical practice. Corticosteroids improve neurologic sequelae and survival in adults and decrease mortality, long-term neurologic complications, and permanent sequelae in children. Concerns regarding the use of steroids include possible interference with CSF chemistry studies and decreased penetration of antitubercular agents because of a decrease in inflammation. Despite the controversy, the trend toward an improved outcome generally supports their use for tuberculous meningitis.^{86,87}

Tuberculous meningitis has a mortality rate of 10% to 50% despite early diagnosis and treatment.^{81,82,88} The level of patient consciousness at the start of therapy is the most useful prognostic indicator. Patients who are comatose at the beginning of therapy have a mortality rate of approximately 75%.⁸² Other negative prognostic factors include old age, poor nutrition, evidence of miliary disease, high initial CSF protein concentrations, presence of hydrocephalus, and evidence of elevated ICP.⁸² Between 10% and 30% of patients surviving the disease have physical or mental sequelae, including deafness, vertigo, and short-term memory loss.^{81,82}

Cryptococcus neoformans

Cryptococcal meningitis is the most common form of fungal CNS infection in the United States and is a major cause of morbidity and mortality in immunosuppressed patients. In the United States, 85% of cases occur in HIV-infected patients. *C. neoformans* is a soil fungus acquired by inhalation of spores from the environment leading to a pneumonia that usually is asymptomatic. Most patients present initially with disseminated disease, especially meningoencephalitis. The incubation period in AIDS patients may be very short, as opposed to a relatively normal host, in whom the incubation period may be very long.

Symptoms of cryptococcal meningitis are insidious and may be present for varying periods, depending on the host involved, before the definitive diagnosis is made. Fever and a history of headaches are the most common symptoms, although altered mentation and evidence of focal neurologic deficits may be present. Examination of the CSF usually reveals small numbers of WBCs ($<150/\text{mm}^3$), which are primarily lymphocytes (Table 110–1). Diagnosis is based on the presence of a positive CSF, blood, sputum, or urine culture for *C. neoformans*. CSF cultures are positive in more than 90% of cases. Organisms may be seen by microscope when stained with India ink and are more likely to be seen in AIDS patients compared with other hosts. An additional rapid test helpful in diagnosis is latex agglutination, which detects the presence of cryptococcal antigens.⁸⁹ Latex agglutination is positive in more than 90% of culture-positive cases. A cryptococcal antigen test can be used to follow the prognosis of non-AIDS patients, but cryptococcal antigen titers do not correlate well with treatment efficacy in AIDS patients.⁹⁰ A cryptococcal antigen detection test must be considered in any patient presenting initially with meningitis. Risk factors predictive of a poor outcome include lethargy at presentation, high CSF cryptococcal antigen titer, and low CSF WBC count.⁹¹

Despite poor penetration into the CSF, amphotericin B has long been the drug of choice for treatment of acute *C. neoformans* meningitis. Amphotericin B 0.5 to 1 mg/kg/day combined with flucytosine 100 mg/kg/day is more effective than amphotericin alone, with successful outcomes in 75% of non-AIDS patients and 50% in AIDS patients.⁹² Unfortunately, flucytosine often is poorly tolerated in the AIDS population, causing bone marrow suppression and GI distress. Amphotericin B alone, although less effective,

has been used in AIDS patients with preexisting granulocytopenia.^{92,93} Because of the high acute mortality rate of up to 40% and a relapse rate of 50% in AIDS patients receiving therapy, many new agents and regimens are being investigated in this population.⁹¹ A small, noncomparative open study evaluating the safety and efficacy of liposomal amphotericin B (AmBisome) found the product to be well tolerated and moderately effective.⁹⁴ A second study found high-dose liposomal amphotericin B (4 mg/kg) to clear CSF cultures more rapidly relative to standard amphotericin B, although clinical efficacy was not significantly different.⁹⁵

Azole therapy is the most studied alternative regimen for treatment of *C. neoformans* meningitis in AIDS patients. Fluconazole at doses of 200 mg/day was compared with amphotericin B alone (0.4 mg/kg/day), with no significant difference in overall mortality between groups. However, patients receiving fluconazole had a higher 2-week mortality rate and time to CSF conversion.⁹⁶ High-dose fluconazole therapy (800 mg/day) as salvage therapy was attempted in eight AIDS patients who had not responded to antifungal therapy, but success was limited.⁹⁷ A randomized trial in Thailand compared amphotericin B (0.7 mg/kg/day), amphotericin B plus flucytosine (100 mg/kg/day), amphotericin B plus fluconazole (400 mg/day) and triple therapy with amphotericin B, flucytosine, and fluconazole daily for treatment of HIV-associated cryptococcal meningitis. The addition of fluconazole to the standard therapy of amphotericin B plus flucytosine resulted in less fungicidal activity against *C. neoformans* than the current standard of amphotericin B plus flucytosine.⁹⁸ Itraconazole 200 mg orally twice daily was less effective than amphotericin B plus flucytosine in a small nonblinded study.⁹⁹ Voriconazole has demonstrated good in vitro activity against *C. neoformans*; however, no comparative data suggest an improvement over fluconazole.¹⁰⁰ Posaconazole has demonstrated clinical activity against cryptococcal and other fungal infections of the CNS in patients with refractory disease or who are otherwise intolerant to standard antifungal agents. Posaconazole at oral doses of 800 mg/day divided appeared well tolerated.¹⁰¹ More data are needed to determine the role new azole antifungal agents will play in treatment of cryptococcal meningitis.

Patients with AIDS often require lifelong maintenance or suppressive therapy because of high relapse rates following acute therapy for *C. neoformans*. A large multicenter, controlled trial compared fluconazole (200 mg/day) and amphotericin B (1 mg/kg/wk) in the prevention of relapse.¹⁰² Two percent of patients receiving fluconazole versus 18% of patients receiving amphotericin B relapsed. In addition, the amphotericin B group had significantly more frequent bacterial infections, bacteremias, and drug-related toxicity.¹⁰² Fluconazole is superior to itraconazole in the prevention of relapse.¹⁰³ Current guidelines for patients with AIDS-associated cryptococcal meningitis recommend 2 weeks of therapy with a combination of amphotericin B 0.7–1 mg/kg/day and flucytosine 100 mg/kg/day. This is often referred to as the *induction phase* and is followed by 8 weeks of fluconazole 400 mg/day as part of the *consolidation phase*. Therapy should be continued thereafter with fluconazole 200 mg/day until immune reconstitution occurs. Guidelines for prevention of opportunistic infections in HIV-infected persons are updated frequently and can be found at www.aidsinfo.nih.gov.

Viral Encephalitis

The epidemiology of viral encephalitis in the United States has changed dramatically since the mid-1960s because of the introduction of large-scale polio and mumps immunization programs. In the United States, the incidence of mumps decreased 98% between 1967 and 1985. Worldwide, mumps remains a causative agent of viral encephalitis in countries with low vaccination rates. Poliomyelitis, once a significant cause of encephalitis, now is confined to only a few less developed countries and soon likely will be eradicated as an infectious agent.

Nonpolio enteroviruses such as coxsackievirus A and B, echoviruses, and enterovirus 70 and 71 cause approximately 85% of all viral encephalitis cases.^{104,105} The remaining 10% to 15% of viral encephalitis cases are caused by a variety of pathogens, such as arboviruses, adenoviruses, influenzae virus A and B, rotavirus, corona virus, cytomegalovirus, varicella-zoster, herpes simplex virus, Epstein-Barr virus, and lymphocytic choriomeningitis.^{18,104} In the past, the St. Louis and LaCrosse viruses have been the most common cause of arbovirus encephalitis.¹⁸ However, in 2002, the largest arboviral meningoencephalitis epidemic in the western hemisphere was caused by the West Nile virus, accounting for 4,156 human cases of West Nile disease in 44 states and the District of Columbia.¹⁰⁶ To date, nearly 20,000 cases of West Nile disease and almost 800 deaths have been reported in the United States since surveillance began in 1999.¹⁰⁷

Viral encephalitis is acquired primarily by hematogenous spread or, alternatively, by neuronal spread of the causative pathogen. After entry into the host, viral replication occurs, resulting in dissemination through the reticuloendothelial system or vasculature. Infection of the capillary endothelial cells and choroid plexus may provide a conduit for CNS infections. Viruses such as polio, herpes, and varicella-zoster virus also may gain access to the CNS by axonal retrograde transmission from peripheral nerve endings.¹⁰⁸ Once a virus gains access to the CNS, the course of infection depends on the virulence of the particular virus and the host immune response. Host response to aseptic CNS infections is mediated by a complex cascade of inflammatory cytokines in a manner similar to purulent meningitis. In contrast with purulent meningitis, host response to viral encephalitis is mediated primarily through cytotoxic T lymphocytes. Although TNF is a prominent mediator in purulent bacterial meningitis, TNF concentrations are not increased in viral encephalitis, whereas increases in concentrations of IL-1 and interferon (INF) and INF- occur. TNF concentrations have been suggested as a diagnostic tool for differentiating between bacterial meningitis and viral encephalitis.¹⁰⁹ Although cytokine assays are available for investigational use, they are not used routinely in the clinical diagnosis of viral encephalitis.

The clinical syndrome associated with viral encephalitis generally is independent of viral etiology and may vary depending on the patient's age. Common signs in adults include headache, mild fever (<40°C), nuchal rigidity, malaise, drowsiness, nausea, vomiting, and photophobia. Only fever and irritability may be evident in the infant, and meningitis must be ruled out as a cause of fever when no other localized findings are observed in a child. Symptoms generally last 1 to 2 weeks, and specific manifestations outside the meninges can occur depending on the viral etiology.

Laboratory examination of the CSF usually reveals a pleocytosis with 100 to 1,000 WBCs/mm³, which are primarily lymphocytic; however, 20% to 75% of patients with viral encephalitis may have a predominance of polymorphonuclear cells on initial examination of the CSF, especially in enteroviral meningitis.⁹² On repeat lumbar puncture, 90% of patients initially presenting with a predominance of neutrophils experience a shift to a predominance of mononuclear cells. Other laboratory findings include normal to mildly elevated protein concentrations and normal or mildly reduced glucose concentrations (Table 110-1).¹⁰⁴

Historically, pathogens responsible for viral encephalitis were not identified.¹¹⁰ Poor laboratory recovery of viral pathogens and limited treatment options for viral encephalitis made the need for specific identification of pathogens of questionable value. Advances in diagnostic laboratory techniques and the potential for decreased costs associated with longer duration of hospitalization for patients with unconfirmed viral encephalitis have led to a reevaluation of the need for confirmatory pathogen diagnosis.¹¹¹ When clinical signs warrant pathogen identification, appropriate laboratory diagnostic tech-

niques, including PCR, should be undertaken. Molecular methods are preferred to conventional laboratory tests for diagnosis of viral encephalitis because of the ability to detect a specific virus in 30% to 70% of cases as compared with the 14% to 24% sensitivity of viral culture.¹⁸

Although there are numerous pathogenic causes of viral encephalitis, much of the clinical presentation, diagnosis, and treatment are similar. The most commonly isolated viral etiologies are described here.

Commonly, the incidence of enteroviral encephalitis peaks in late summer and continues into early fall. Enteroviruses are transmitted in the host via the fecal-oral route. Clinical presentation of enteroviral infection frequently is nonspecific and characterized by fever, nausea, vomiting, and malaise; GI symptoms may not be present. Following a prodrome of 1 to 2 days, headache, photophobia, and neck stiffness develop. Diagnosis can be confirmed by cell culture from the CSF, where the incidence of successful isolation has ranged from 40% to 80%.¹⁰⁹ In addition, enterovirus can be isolated from throat swabs (60%) and stool cultures (80%), but they are not necessarily diagnostic because the virus is shed in the stool for 1 to 2 weeks following infection.¹¹⁰ Conversely, an enterovirus-specific reverse-transcription PCR test can provide prompt results within 24 hours, with sensitivity and specificity of 100%.¹¹² Treatment of enteroviral encephalitis consists of supportive care, fluids, antipyretics, and analgesics. Generally, disease progression is self-limiting, and the patient recovers fully without long-term neurologic complications.

Both herpes simplex virus type 1 (HSV-1) and herpes simplex virus type 2 (HSV-2) have been associated with infections of the CNS. HSV-1 is associated with encephalitis in adults, whereas HSV-2 is associated predominantly with encephalitis in newborns.¹⁰⁵ An HSV infection of the CNS most likely is spread via retrograde movement from the dorsal root ganglion. Sexually active adults acquire herpes simplex meningitis during or after an attack of genital or rectal herpes. Although HSV-2 frequently can be cultured from CSF, HSV-1 cannot. As such, PCR may be more useful than culture in detecting infection with HSV; diagnosis usually is made by PCR, culture, or a fourfold rise in complement-fixing antibody to the virus. Establishing the correct diagnosis as early as possible is paramount because mortality rates range between 50% and 85% without treatment, and, unlike other viral encephalitides, specific and effective therapy is available. As a result, empirical therapy of suspected HSV encephalitis is necessary while awaiting results of laboratory tests. Additionally, a clinical decision to treat may be needed regardless of test results.

Acyclovir is the drug of choice for herpes simplex encephalitis. In patients with normal renal function, acyclovir usually is administered 10 mg/kg intravenously every 8 hours for 2 to 3 weeks.¹⁰⁵ Herpes virus resistance to acyclovir has been reported with increasing incidence, particularly from immunocompromised patients with prior or chronic exposures to acyclovir.¹¹³ The alternative treatment of acyclovir-resistant herpes simplex virus is foscarnet.¹⁰⁵ The major toxicity of foscarnet is renal impairment, and doses must be individualized for renal function.¹¹⁴ The dose for patients with normal renal function is 40 mg/kg infused over 1 hour every 8 to 12 hours for 2 to 3 weeks. Ensuring adequate hydration is imperative. Patients receiving foscarnet should be monitored for seizures related to alterations in plasma electrolyte levels.

Historically, the four most important arboviral pathogens in the United States were the St. Louis virus, the La Crosse virus, and the eastern and western equine viruses. However, West Nile virus has been recognized as an emerging pathogen and has been implicated in an epidemic occurring in the United States since 1999. Transmission occurs through the bites of mosquitoes. Typically, an incubation period of 2 to 14 days precedes the onset of clinical symptoms. Infection of the brain tissue results in fever, headache, paralysis, and

coma. Although many patients have a benign presentation, symptomatic cases are associated with a higher degree of mortality. Mortality rates of 50% to 75% have been reported for eastern equine virus, whereas mortality rates for western equine and St. Louis viruses are 3% to 4% and 10% to 20%, respectively.^{105,108} Treatment is supportive, including treatment of seizures and increased ICP. In the majority of cases, the disease is self-limiting.¹⁰⁸

Because of the recent epidemic in the United States, a separate discussion of the West Nile virus is warranted. Although West Nile virus is transmitted primarily by mosquitoes, transmission of the virus via blood products, organ transplantation, transplacental transfer, and breast milk has been documented.¹⁰⁶ Similar to the other arboviruses, the incubation period for West Nile virus ranges from 3 days to 2 weeks. West Nile virus infection is asymptomatic in most adults or causes a mild flu-like syndrome characterized by fever, malaise, myalgia, and lymphadenopathy. Typically, less than 1% of patients develop neurologic disease, and approximately two thirds have encephalitis, with the remainder having meningitis without encephalitis.¹⁴ Many patients develop a maculopapular, erythematous rash, which is more common in children than in adults and is uncommon in other forms of viral encephalitis.¹⁴ Other neurologic manifestations include fever, nausea, vomiting, headache, altered mental status, movement disorders, and/or a syndrome much like poliomyelitis.^{14,115,116} The primary risk factor for this manifestation seems to be advanced age. The poliomyelitis syndrome is characterized by an early prodromic phase of fevers and weakness followed by the sudden onset of flaccid paralysis. Among patients hospitalized with West Nile virus, the mortality rate is approximately 10% to 15%, whereas patients with encephalitis and weakness have a mortality rate of 30%.¹⁴ CSF examination of West Nile virus encephalitis typically shows pleocytosis and a slightly elevated CSF protein concentration.¹⁴ Several diagnostic methods have been developed for West Nile virus, including a PCR assay and an enzyme-linked immunosorbent assay (ELISA). However, serologic tests (ELISA) can cross-react with other flaviviruses, causing a false-positive result. Moreover, the IgM antibodies for West Nile virus can persist for up to 1 year, leading to confusion regarding whether the infection is an acute or previous infection.¹⁴ Ribavirin has shown inhibitory effects on the West Nile virus in neural tissue cultures, but this has not been studied in controlled trials.

HIV encephalitis is the most common CNS complication associated with AIDS. Patients frequently may complain of headache, photophobia, or stiff neck at the time of presumed seroconversion. As the disease progresses, however, neurologic symptoms are reported frequently secondary to other opportunistic infections. Diagnosis of viral encephalitis is difficult because mental status and neurologic examinations are not sensitive enough to detect early changes. Direct evidence of HIV encephalitis can be obtained through CSF culture, p24 antigen testing, or qualitative or quantitative PCR for HIV RNA. Diagnostic workup of other potential copathogens, such as HSV, *Toxoplasma gondii*, *M. tuberculosis*, *Aspergillus* species, and *Cryptococcus*, also should be performed (see Chap. 126 for a complete discussion of infectious complications in HIV-positive individuals.)

EVALUATION OF THERAPEUTIC OUTCOMES

SIGNS AND SYMPTOMS

Because of the potential for rapid deterioration associated with meningitis, signs and symptoms of fever, headache, meningismus (e.g., nuchal rigidity, Brudzinski sign, Kernig sign), vital signs, and signs of cerebral dysfunction should be evaluated every 4 hours for the initial 3 days and daily thereafter. The Glasgow Coma Scale

should be used in severely ill patients. Trends in improvement and resolution rather than single evaluations in time are more important in monitoring the signs and symptoms of meningitis.

MICROBIOLOGIC FINDINGS

CSF and blood samples for Gram stain, cultures, and sensitivity testing should be taken prior to starting antibiotic therapy. If lumbar puncture is delayed, however, antibiotics should be started. Although the CSF cultures may be negative, antibiotic therapy rarely interferes with the protein and/or glucose concentrations in the CSF.¹⁵ Furthermore, if the laboratory is made aware of the antibiotic therapy, steps can be taken to diminish the effects of the antibiotic during the detection process.¹⁸ Gram stain results can be obtained immediately and can guide empirical antibiotic treatment. Identification of the organism can be made within 24 hours, and sensitivities should be available within 48 hours. Repeat cultures should be performed to help determine if sterilization is achieved. A second tube of blood should be taken to allow for latex agglutination tests of antigens to common meningeal pathogens (*H. influenzae*, *S. pneumoniae*, *N. meningitidis*, *E. coli*, group B streptococcus) if the Gram stain has not been helpful.

CEREBRAL SPINAL FLUID EXAMINATION

In bacterial meningitis, the CSF WBC count usually is >1,000 cells/mm³, CSF protein concentration is elevated, and CSF glucose concentration (hypoglycorrhachia) often is low (<50 mg/dL or 50%–60% of a simultaneous blood glucose value). In contrast, viral encephalitis results in relatively normal CSF protein and glucose levels and typically does not result in >90% polymorphonuclear neutrophils in the CSF (Table 110–1).

Lower Respiratory Tract Infections

MARK L. GLOVER AND MICHAEL D. REED

KEY CONCEPTS

- 1 Respiratory infections remain the major cause of morbidity from acute illness in the United States and likely represent the most common reasons why patients seek medical attention.
- 2 The majority of pulmonary infections follow colonization of the upper respiratory tract with potential pathogens, whereas microbes less commonly gain access to the lungs via the blood from an extrapulmonary source or by inhalation of infected aerosol particles. The competency of a patient's immune status is an important factor influencing the susceptibility to infection, etiologic cause, and disease severity.
- 3 An appropriate treatment regimen for the patient with uncomplicated lower respiratory tract infection usually can be established by patient history, physical examination, chest radiograph, and properly collected sputum for culture interpreted in light of current knowledge of the most common lung pathogens and their antibiotic susceptibility patterns within the community.
- 4 Acute bronchitis is caused most commonly by respiratory viruses and almost always is self-limiting. Therapy targets associated symptoms, such as lethargy, malaise, or fever (ibuprofen or acetaminophen), and fluids for rehydration. Routine use of antibiotics should be avoided.
- 5 Chronic bronchitis is caused by several interacting factors, including inhalation of noxious agents (most prominent are cigarette smoke and exposure to occupational dusts, fumes, and environmental pollution) and host factors including genetic factors and bacterial (and possibly viral) infections. The hallmark of this disease is a chronic cough, excessive sputum production, and expectoration with persistent presence of microorganisms in the patient's sputum.
- 6 Treatment of acute exacerbations of chronic bronchitis includes attempts to mobilize and enhance sputum expectoration (chest physiotherapy, humidification of inspired air), oxygen if needed, aerosolized bronchodilators (albuterol) in select patients with demonstrated benefit, and antibiotics.
- 7 Respiratory syncytial virus is the most common cause of acute bronchiolitis, an infection that mostly affects infants during their first year of life. In the well infant, bronchiolitis usually is a self-limiting viral illness, whereas in the child with underlying respiratory disease, cardiac disease, or both, the child may develop severe respiratory compromise (failure) necessitating in-hospital treatment, such as rehydration, oxygen, and, in select patients, bronchodilators, ribavirin aerosol, or both.
- 8 The most prominent pathogen causing community-acquired pneumonia in otherwise healthy adults is *Streptococcus pneumoniae*, whereas the most common pathogens causing hospital-acquired pneumonia (including nursing home residents) are *Staphylococcus aureus* and gram-negative aerobic bacilli. Anaerobic bacteria are the most common etiologic agents in pneumonia that follows aspiration of gastric or oropharyngeal contents.
- 9 Treatment of community-acquired pneumonia may consist of humidified oxygen for hypoxemia, bronchodilators (albuterol) when bronchospasm is present, rehydration fluids, and chest physiotherapy for marked accumulation of retained respiratory secretions. Antibiotic regimens should be selected based on presumed causative pathogens and pulmonary distribution characteristics and should be adjusted to provide optimal activity against pathogens identified by culture (sputum or blood).
- 10 Treatment of nosocomial pneumonia requires aggressive therapy with careful consideration of the dominance and susceptibility patterns of the pathogens present within the institution. The epidemiology of these common pathogens should be evaluated on a regular basis in order to identify changing resistance patterns and subsequent alternation of treatment guidelines.

1 Respiratory tract infections remain the major cause of morbidity from acute illness in the United States and most likely represent the single most common reason patients seek medical attention. This chapter focuses on bacterial and viral infections involving the lower respiratory tract, which includes the tracheobronchial tree and lung parenchyma.

2 The respiratory tract has an elaborate system of host defenses, including humoral immunity, cellular immunity, and anatomic mechanisms.¹ When functioning properly, the host defenses of the respiratory tract are markedly effective in protecting against pathogen invasion and removing potentially infectious agents from the lungs. For the most part, infections in the lower respiratory tract occur only when these defense mechanisms are impaired, as in cases of dysgammaglobulinemia or compromised ciliary function, such as that caused by the chronic inflammation accompanying cigarette smoking. In addition, local defenses may be overwhelmed when a particularly virulent microorganism or excessive inoculum invades lung parenchyma. The majority of pulmonary infections follow colonization of the upper respiratory tract with potential pathogens, which, after achieving sufficiently high concentrations, gain access to the lung via aspiration of oropharyngeal secretions. Less commonly, microbes enter the lung via the blood from an extrapulmonary source or by

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

inhalation of infected aerosolized particles. The specific type of pulmonary infection caused by an invading microorganism is determined by a variety of host factors, including age, anatomic features of the airway, and specific characteristics of the infecting agent.

The most common infections involving the lower respiratory tract are bronchitis, bronchiolitis, and pneumonia. Lower respiratory tract infections in children and adults most commonly result from either viral or bacterial invasion of lung parenchyma. The diagnosis of viral infections rests primarily on the recognition of a characteristic constellation of clinical signs and symptoms. Because treatment is largely supportive, only occasionally does the diagnosis require laboratory confirmation; this is achieved through serologic tests or identification of the organism by culture or antigen detection in respiratory secretions.² New laboratory techniques using polymerase chain reaction and genetic “fingerprinting” technology have emerged as a means to identify specific pathogens rapidly and accurately.³

In contrast, because bacterial pneumonia usually necessitates expedient, effective, and specific antibiotic therapy, its management depends, in large part, on isolation of the etiologic agent by culture from lung tissue or secretions.^{4,5} The pharynx is colonized with many organisms that can cause pneumonia; therefore, culture of expectorated sputum can be misleading unless the specimen is examined to ensure that it has originated from the lower respiratory tract. The Gram stain provides the easiest method for distinguishing lower from upper respiratory tract secretions; moreover, through determination of the shape and color of the bacteria, the Gram stain frequently narrows the microbiologic differential diagnosis sufficiently to allow accurate initial therapy. Scanned under low-power microscopy, Gram-stained expectorated upper respiratory tract secretions contain many irregularly shaped epithelial cells with little evidence of inflammation. In contrast, a lower-tract specimen from a patient with bacterial pneumonia usually contains multiple neutrophils per high-powered field and a single or predominant bacterial species. Culture of specimens confirmed to originate from the lower tract by Gram stain provides valuable diagnostic information in the majority of patients with bacterial pneumonia. In addition, pneumonia promotes the release of inflammatory mediators and acute phase proteins such as C-reactive protein, which is significantly elevated in serum in the presence of respiratory tract infections.⁶

③ An appropriate treatment regimen for the patient with an uncomplicated lower respiratory tract infection usually can be established by history, physical examination, chest radiograph, and properly collected sputum cultures interpreted in light of the most common lung pathogens and their antibiotic susceptibility patterns within the community.^{2,4,5,7,8} More sophisticated or invasive diagnostic methods (e.g., computed tomography, bronchoscopy, and lung biopsy)^{9,10} should be reserved for very ill patients who are unable to expectorate sputum or who are not responding to empirical therapy or for pulmonary infections occurring in immunocompromised patients.

BRONCHITIS

Bronchitis and bronchiolitis are inflammatory conditions of the large and small elements, respectively, of the tracheobronchial tree. The inflammatory process does not extend to the alveoli. Bronchitis frequently is classified as acute or chronic. Acute bronchitis occurs in individuals of all ages, whereas chronic bronchitis primarily affects adults. Bronchiolitis is a disease of infancy.

ACUTE BRONCHITIS

Epidemiology and Etiology

Acute bronchitis occurs most commonly during the winter months, following a pattern similar to those of other acute respiratory tract

infections. Cold, damp climates and the presence of high concentrations of irritating substances (e.g., air pollution, cigarette smoke) may precipitate attacks.

④ Respiratory viruses are by far the most common infectious agents associated with acute bronchitis.¹¹ The common cold viruses (rhinovirus and coronavirus) and lower respiratory tract pathogens (influenza virus and adenovirus) account for the majority of cases. In children, similar pathogens are observed, with the addition of the parainfluenza viruses. Although the true incidence remains to be defined, *Mycoplasma pneumoniae* appears to be a frequent cause of acute bronchitis. Additionally, *Chlamydia pneumoniae*¹² and *Bordetella pertussis*¹³ (agent responsible for whooping cough) have been associated with acute respiratory tract infections. Although a variety of bacteria, including *Streptococcus pneumoniae*, *Streptococcus* species, *Staphylococcus* species, and *Haemophilus* species, may be isolated from throat or sputum culture, these organisms probably represent contamination by normal flora of the upper respiratory tract rather than true pathogens. Although a primary bacterial etiology for acute bronchitis appears rare, secondary bacterial infection may be involved.

Pathogenesis

④ Because acute bronchitis is primarily a self-limiting illness and rarely a cause of death, few data describing the pathology are available. In general, infection of the trachea and bronchi yields hyperemic and edematous mucous membranes with an increase in bronchial secretions. Destruction of respiratory epithelium can range from mild to extensive and may affect bronchial mucociliary function. In addition, the increase in bronchial secretions, which can become thick and tenacious, further impairs mucociliary activity. The probability of permanent damage to the airways as a result of acute bronchitis remains unclear; however, epidemiologic evaluations support the belief that recurrent acute respiratory infections may be associated with increased airway hyperreactivity and possibly the pathogenesis of asthma or chronic obstructive pulmonary disease (COPD).

Clinical Presentation

Acute bronchitis usually begins as an upper respiratory infection with nonspecific complaints (Table 111-1).^{11,14} Cough is the hallmark of acute bronchitis and occurs early. The onset of cough may be insidious or abrupt, and the symptoms persist despite resolution of nasal or nasopharyngeal complaints. Frequently, the cough initially is nonproductive but then progresses, yielding mucopurulent sputum. In older children and adults, the sputum is raised and expectorated; in the young child, sputum often is swallowed and can result in gagging and vomiting. Substantial discomfort may result from the coughing. Dyspnea, cyanosis, or signs of airway obstruction are observed rarely unless the patient has underlying pulmonary disease, such as emphysema or COPD. Fever, when present, rarely exceeds 39°C (102.2°F) and appears most commonly with adenovirus, influenza virus, and *M. pneumoniae* infections. The diagnosis

TABLE 111-1 Clinical Presentation of Acute Bronchitis

Signs and symptoms
Cough persisting >5 days to weeks
Coryza, sore throat, malaise, headache
Fever rarely >39°C
Physical examination
Rhonchi or coarse, moist, bilateral rales
Purulent sputum in ~50% of patients
Chest radiograph
Normal

typically is made on the basis of a characteristic history and physical examination. Bacterial cultures of expectorated sputum generally are of limited use because of the inability to avoid normal nasopharyngeal flora by the sampling technique. In routine cases, viral cultures are unnecessary and frequently unavailable. Viral antigen detection tests, developed to identify respiratory viral antigens from nasal secretions rapidly, can be obtained in many hospital laboratories and in some practice settings when a specific diagnosis is necessary for clinical or epidemiologic reasons. Cultures or serologic diagnosis of *M. pneumoniae* and culture or direct fluorescent antibody detection for *B. pertussis* should be obtained in prolonged or severe cases when epidemiologic considerations would suggest their involvement.

TREATMENT

Acute Bronchitis

■ DESIRED OUTCOME

In the absence of a complicating bacterial superinfection, acute bronchitis almost always is self-limiting. The goals of therapy are to provide comfort to the patient and, in the unusually severe case, to treat associated dehydration and respiratory compromise.¹¹

■ GENERAL APPROACH TO TREATMENT

④ Treatment of acute bronchitis is symptomatic and supportive in nature. Reassurance and antipyretics frequently are all that are needed. Bed rest for comfort may be instituted as desired. Patients should be encouraged to drink fluids to prevent dehydration and possibly to decrease the viscosity of respiratory secretions. Mist therapy (use of a vaporizer) may promote the thinning and loosening of respiratory secretions.

■ PHARMACOLOGIC THERAPY

Mild analgesic–antipyretic therapy often is helpful in relieving the associated lethargy, malaise, and fever. Aspirin or acetaminophen (650 mg in adults or 10–15 mg/kg per dose in children; maximum daily pediatric dose 60 mg/kg; maximum daily adult dose 4 g) or ibuprofen (200–800 mg in adults or 10 mg/kg per dose in children; maximum daily pediatric dose 40 mg/kg; maximum daily adult dose 3.2 g) should be administered every 4 to 6 hours. In children, aspirin should be avoided and acetaminophen used as the preferred agent because of the possible association between aspirin use and the development of Reye syndrome.¹⁵

Use of ibuprofen as an antipyretic has increased. The drug's antipyretic efficacy appears identical to that of aspirin or acetaminophen, although its duration of antipyretic effect may be slightly longer (e.g., 3–4 hours for aspirin and acetaminophen versus 5–6 hours for ibuprofen). Caution should be exercised in the administration of ibuprofen in patients younger than 3 months, elderly patients, and individuals with poor renal function. Aspirin and ibuprofen inhibit prostaglandin synthesis and may adversely influence renal function in these predisposed patient populations.

Patients suffering from acute bronchitis frequently medicate themselves with nonprescription cough and cold remedies containing various combinations of antihistamines, sympathomimetics, and antitussives despite the lack of definitive evidence supporting their effectiveness. In fact, the tendency of these agents to dehydrate bronchial secretions could aggravate and prolong the recovery process. Although not recommended for routine use, persistent, mild cough, which may be bothersome, can be treated with dextromethorphan; more severe coughs may require intermittent codeine or other similar agents.¹⁴ In severe cases, the cough may be persistent enough to disrupt sleep, and use of a mild sedative–hypnotic, con-

comitantly with a cough suppressant, may be desirable. However, antitussives should be used cautiously when the cough is productive. The primary or supplemental use of expectorants is questionable because their clinical effectiveness has not been well established.

Routine use of antibiotics for treatment of acute bronchitis should be discouraged.¹¹ In previously healthy patients who exhibit persistent fever or respiratory symptoms for more than 4 to 6 days or in predisposed patients (e.g., elderly, immunocompromised), the possibility of a concurrent bacterial infection should be suspected. When possible, antibiotic therapy should be directed toward anticipated respiratory pathogen(s) (i.e., *S. pneumoniae*). *M. pneumoniae*, if suspected by history, by finding of cold hemagglutinins in serum (immunoglobulin M antibodies) with titers >1:32, or if confirmed by culture or serology, can be treated with azithromycin. Alternatively and empirically, a fluoroquinolone antibiotic with activity against these suspected pathogens (e.g., levofloxacin) can be used. During known epidemics involving the influenza A virus, amantadine or rimantadine may be effective in minimizing associated symptoms if administered early in the course of the disease.¹⁶ Also, the neuraminidase inhibitors (e.g., zanamivir and oseltamivir) are active against both influenza A and B viral infections and may reduce the severity and duration of the influenza episode if administered promptly during the onset of the viral infection (see Chap. 114).^{17,18} Unfortunately, the incidence of influenzae virus resistance to available antiviral drugs is increasing.¹⁹

CHRONIC BRONCHITIS

Epidemiology and Etiology

Chronic bronchitis is a nonspecific disease that primarily affects adults. Between 10% and 25% of the adult population 40 years of age and older suffer from chronic bronchitis, resulting in substantial healthcare dollar expenditures and lost wages. This disease is so common that acute bronchitis and acute exacerbations of chronic bronchitis result in approximately 16 million physician visits per year in the United States. Similar to acute bronchitis, cold, damp climates and elevated airborne concentrations of irritating substances may favor this disease. Chronic bronchitis occurs more commonly in men than in women.^{20,21}

⑤ Chronic bronchitis is a result of several contributing factors; the most prominent include cigarette smoking, exposure to occupational dusts, fumes, and environmental pollution; and host factors (e.g., genetic factors and bacterial [and possibly viral] infections). The contribution of each of these factors and of others (either alone or in combination) to chronic bronchitis is unknown. Cigarette smoke is a well-known airway irritant and is believed to be the predominant factor in the etiology of chronic bronchitis. Studies of lungs from smoking and nonsmoking individuals clearly have demonstrated a substantial increase in the number of alveolar macrophages, as well as the presence of bronchial inflammation, in individuals who smoke cigarettes. Although the majority of patients who suffer from chronic bronchitis have a positive smoking history, no history of smoking can be identified in as many as 10% of patients. These findings suggest that additional airway irritants, either alone or more probably in combination, are responsible for the pathogenesis of chronic bronchitis. It appears from candidate gene association studies that a genetic basis for some COPD phenotypes will be described in the near future.²² In addition, the influence of recurrent respiratory tract infections during childhood or young adult life on the later development of chronic bronchitis remains obscure. Recurrent respiratory infections may predispose individuals to the development of chronic bronchitis²³; however, whether these recurrent respiratory tract infections are a result of unrecognized anatomic abnormalities of the airways or impaired pulmonary defense mechanisms is unclear.

Chronic bronchitis is a disease of the bronchi that is manifested by cough and excessive sputum expectoration that occurs on most

days of the week for a minimum of 3 consecutive months per year for at least 2 consecutive years that is unrelated to other pulmonary or cardiac disease. Numerous consensus statements and published authoritative guidelines define chronic bronchitis and emphysema as the two main components of chronic obstructive pulmonary (lung) disease (COPD/COLD).^{20,21,24} The NHLBI/WHO Global Initiative for Chronic Obstruction Lung Disease (GOLD)²¹ guidelines document does not distinguish these two diagnosis (e.g., emphysema or chronic bronchitis) in the definition of COPD, but it does define COPD as a disease characterized by airflow obstruction that is not fully reversible and progressive.²⁰ The GOLD guidelines provide a COPD classification scoring system according to severity that can be very helpful in staging patients for intensity of therapy and prognosis.²¹ Unfortunately, differences in definitions between authoritative organizations^{20,21,24} may cause confusion in the assignment of patients in clinical trials and thus to assessment and applications of study results to clinical care.

Pathogenesis

Chronic inhalation of an irritating noxious substance compromises the normal secretory and mucociliary function of bronchial mucosa. Bronchial biopsy specimens in bronchitic patients underscore the importance of proinflammatory cytokines (e.g., interleukins 1, 6, and 8, and tumor necrosis factor- α) in the pathogenesis and propagation of the observed inflammatory changes. In chronic bronchitis, the bronchial wall is thickened, and the number of mucus-secreting goblet cells on the surface epithelium of both larger and smaller bronchi is increased markedly. In contrast, goblet cells generally are absent from the smaller bronchi of normal individuals. In addition to the increased number of goblet cells, hypertrophy of the mucous glands and dilation of the mucous gland ducts are observed. As a result of these changes, chronic bronchitics have substantially more mucus in their peripheral airways, further impairing normal lung defenses. This increased quantity of tenacious secretions within the bronchial tree frequently causes mucous plugging of the smaller airways. Accompanying these changes are squamous cell metaplasia of the surface epithelium, edema, and increased vascularity of the basement membrane of larger airways and variable chronic inflammatory cell infiltration. Continued progression of this pathology can result in residual scarring of small bronchi and peribronchial fibrosis augmenting airway obstruction and weakening of bronchial walls.

Clinical Presentation

5 The hallmark of chronic bronchitis is a cough that may range from a mild “smoker’s cough” to severe, incessant coughing productive of purulent sputum. Coughing may be precipitated by multiple stimuli, including simple, normal conversation. Expectoration of the largest quantity of sputum usually occurs on arising in the morning, although many patients expectorate sputum throughout the day. The expectorated sputum usually is tenacious and can vary in color from white to yellow–green. Patients with chronic bronchitis often expectorate as much as 100 mL/day more than normal. As a result, many patients complain of a frequent bad taste in their mouth and of halitosis.

The diagnosis of chronic bronchitis is based primarily on clinical assessment and history. Any patient who reports coughing sputum on most days for at least 3 consecutive months each year for 2 consecutive years presumptively has chronic bronchitis.²⁰ The diagnosis of chronic bronchitis is made only when the possibilities of bronchiectasis, cardiac failure, cystic fibrosis, and lung carcinoma have been effectively excluded. In an attempt to be more specific in the diagnosis, some investigators have added the criteria of lost wages for 3 or more weeks. In addition, many clinicians attempt to subdivide their patients based on severity of disease to guide therapeutic interventions. As noted earlier, GOLD has published a COPD classification system that many clinicians find useful (Table 111–2). The importance of accurate classification for grouping patients of similar disease involvement cannot be overemphasized with respect to assessing publications outlining treatment strategies for these patients.²⁵ The typical clinical presentation of chronic bronchitis is listed in Table 111–3.

In more advanced stages of chronic bronchitis, physical findings associated with cor pulmonale, including cardiac enlargement, hepatomegaly, and edema of the lower extremities, are observed. In general, chronic bronchitics tend to maintain at least normal body weight and commonly are obese. Radiographic studies are of limited value either in the diagnosis or followup of a patient. The microscopic and laboratory assessments of sputum are considered important components in the overall evaluation of patients with chronic bronchitis. A fresh sputum specimen obtained as an early-morning sample is preferred. Comparison of the cellular constituents of chronic bronchitic sputum with those of normal sputum can provide insight into the degree of activity of the disease processes. An increased number of polymorphonuclear granulocytes often suggests continual

TABLE 111-2 Useful Clinical Classification System for Patients with Chronic Bronchitis and Initial Treatment Options

Baseline Status	Criteria or Risk Factors	Usual Pathogens	Initial Treatment Options
Class I Acute tracheobronchitis	No underlying structural disease	Usually a virus	1. None unless symptoms persist 2. Amoxicillin; amoxicillin–clavulanate; a macrolide/azalide if bacterial infection is suspected/documented
Class II Chronic bronchitis	FEV ₁ >50% predicted value, increased sputum volume and purulence	<i>Haemophilus influenzae</i> (usually nontypeable), <i>Haemophilus</i> species, <i>Moraxella catarrhalis</i> , <i>Streptococcus pneumoniae</i> (β -lactam resistance possible)	1. Same as Class I, no. 2, or a fluoroquinolone if prevalence of <i>H. influenzae</i> resistance to amoxicillin is >20% 2. Fluoroquinolone, amoxicillin–clavulanate, azithromycin, tetracycline, or trimethoprim–sulfamethoxazole
Class III Chronic bronchitis with complications	FEV ₁ <50% predicted value, increased sputum volume and purulence, advanced age, at least four flares per year, or significant comorbidity	Same as class II; also <i>E. coli</i> , <i>Klebsiella</i> , <i>Enterobacter</i> species, <i>Pseudomonas aeruginosa</i> (β -lactam resistance common)	1. Fluoroquinolone 2. Extended spectrum cephalosporin, amoxicillin–clavulanate, or azithromycin
Class IV Chronic bronchial infection	Same as for class III plus yearlong production of purulent sputum	Same as class III	1. Oral or parenteral fluoroquinolone, carbapenem, or extended spectrum cephalosporin

Carbapenem: imipenem–cilastatin; meropenem; extended-spectrum cephalosporin; ceftazidime, cefepime; fluoroquinolone: ciprofloxacin, levofloxacin, moxifloxacin; tetracycline, tetracycline HCl, doxycycline; 1, preferred therapy; 2, alternative treatment options.

TABLE 111-3 Clinical Presentation of Chronic Bronchitis

Signs and symptoms
Cyanosis (advanced disease)
Obesity
Physical examination
Chest auscultation usually reveals inspiratory and expiratory rales, rhonchi, and mild wheezing with an expiratory phase that is frequently prolonged; hyperresonance on percussion with obliteration of the area of cardiac dullness
Normal vesicular breathing sounds are diminished
Clubbing of digits (advanced disease)
Chest radiograph
Increase in anteroposterior diameter of the thoracic cage (observed as a barrel chest)
Depressed diaphragm with limited mobility
Laboratory tests
Erythrocytosis (advanced disease)
Pulmonary function tests
Decreased vital capacity
Prolonged expiratory flow

bronchial irritation, whereas an increased number of eosinophils suggests an allergic component that should be further investigated. Gram staining of the sputum often reveals a mixture of both gram-positive and gram-negative bacteria, reflecting normal oropharyngeal flora and chronic tracheal colonization (in order of frequency) by nontypeable *Haemophilus influenzae*, *S. pneumoniae*, and *Moraxella catarrhalis*. Table 111-4 lists the most common bacterial isolates identified from sputum culture in patients experiencing an acute exacerbation of chronic bronchitis. In patients with more severe airflow disease (e.g., forced expiratory volume in the first second of expiration [FEV₁] <40%), enteric gram-negative bacilli, *Escherichia coli*, *Klebsiella*, *Enterobacter*, and *Pseudomonas aeruginosa* may be significant pathogens during acute exacerbations.²⁶

TREATMENT

Chronic Bronchitis

■ DESIRED OUTCOME

The goals of therapy for chronic bronchitis are twofold: to reduce the severity of chronic symptoms and to ameliorate acute exacerbations and achieve prolonged infection-free intervals.

■ GENERAL APPROACH TO TREATMENT

The approach to treatment of chronic bronchitis is multifactorial. First and foremost, attempts must be made to reduce the patient's exposure to known bronchial irritants (e.g., smoking, workplace pollution). A complete occupational and environmental history for determination of exposure to noxious, irritating gases, as well as preference toward cigarette smoking, must be assessed. Often easier discussed than accomplished, honest, yet reasonable attempts should be made with the patient to reduce or eliminate completely the number of cigarettes smoked daily and to reduce exposure to secondhand smoke. In an organized, coordinated, smoking cessation program, including counseling and hypnotherapy, the adjunctive use of nicotine substitutes (e.g., nicotine gum or patch) may promote the reduction or complete withdrawal from cigarette smoking. Often just as difficult is modification of exposure to irritating substances within the home and workplace.

6 Measures to provide pulmonary toilet can be instituted. During acute pulmonary exacerbations of the disease, the patient's ability to mobilize and expectorate sputum may be reduced dramatically. In these instances, attempts at postural drainage techniques, with instruction, active participation, or both from a respiratory therapist, may assist in promoting clearance of pulmonary secretions. In

TABLE 111-4 Common Bacterial Pathogens Isolated from Sputum of Patients with Acute Exacerbation of Chronic Bronchitis

Pathogen	Percent of Cultures
<i>Haemophilus influenzae</i> ^a	45

<i>Streptococcus pneumoniae</i> ^b	20
<i>Escherichia coli</i> , <i>Enterobacter</i> species, <i>Klebsiella</i> , <i>Pseudomonas aeruginosa</i>	5

^aOften β -lactamase positive; vast majority are nontypeable strains.

^bAs many as 25% of strains may have intermediate or high resistance to penicillin.

addition, humidification of inspired air may promote the hydration (liquefaction) of tenacious secretions, allowing for more productive removal. Use of mucolytic aerosols, such as *N*-acetylcysteine and DNase, is of questionable therapeutic value, particularly considering their propensity to induce bronchospasm (*N*-acetylcysteine) and their excessive cost. A Cochrane meta-analysis of mucolytic therapy in subjects with chronic bronchitis or COPD found that treatment with mucolytics was associated with a small reduction in acute exacerbations and a reduction in total number of days of disability. The clinical benefit may be greater in chronic bronchitis/COPD patients who have frequent or prolonged exacerbations or in those who are repeatedly admitted to hospitals with acute exacerbations. Mucolytics may have the greatest benefit in patients with moderate or severe COPD who are not receiving inhaled corticosteroids.²⁷ Although limited data are available, chronic use of oral or aerosolized bronchodilators may be of benefit by increasing mucociliary and cough clearance. In patients with moderate-to-severe COPD, twice-daily inhaled salmeterol/fluticasone propionate 50/250 or 50/500 micrograms for 24–52 weeks improves FEV₁ significantly more than does salmeterol or fluticasone monotherapy and results in clinically significant improvements in health-related quality of life.²⁸ Furthermore, patients may benefit from inhaled corticosteroids; patients with severe disease (FEV₁ <50%) with a history of frequent exacerbations should receive chronic inhaled corticosteroid therapy. Use of systemic corticosteroid therapy (oral or IV) in patients with an acute exacerbation significantly reduces treatment failures and the need for additional medical treatment.²⁹ Finally, in the face of an acute exacerbation, a trial of antibiotics directed against the most likely underlying pathogens should be initiated.

■ PHARMACOLOGIC THERAPY

For patients who consistently demonstrate clinical limitation in airflow, a therapeutic challenge of β_2 -agonist bronchodilators (e.g., as albuterol aerosol) should be considered. Pulmonary function tests can be performed before and after β_2 -agonist aerosol administration for more objective determination of a patient's propensity to benefit from supplemental aerosol therapy. However, this laboratory assessment, often performed at times of better health, may not accurately predict a patient's potential benefit from β_2 -agonists during acute exacerbations of chronic bronchitis. Nevertheless, sufficient published experience supports the use of inhalation therapy with short-acting β_2 -agonist in patients with chronic bronchitis to improve pulmonary function and exercise tolerance and to reduce the sense of breathlessness.²⁰ As noted earlier, chronic inhalation of the salmeterol/fluticasone combination has been associated with improved pulmonary function and quality of life.

Published experience with inhaled anticholinergic drugs, including ipratropium and tiotropium, is limited. In stable patients, long-term inhalation of ipratropium has been associated with a decreased frequency of cough, less severe coughing, and a decrease in the volume of expectorated sputum. Once-daily tiotropium inhalation

was associated with significant bronchodilation and dyspnea relief compared to placebo but had no significant effect on the incidence or severity of cough.²⁰ Although chronic theophylline administration has been used extensively in the past, this therapy is being used with decreasing frequency in favor of aerosolized β_2 -receptor agonists.

Use of antimicrobials for treatment of chronic bronchitis is controversial. Numerous comparative evaluations, including placebo-controlled studies of antibiotic administration with acute and chronic treatment of chronic bronchitics, have suggested definite clinical benefit, whereas other similar studies have not.²⁶ The antibiotics selected most frequently possess variable in-vitro activity against the common sputum isolates *H. influenzae*, *S. pneumoniae*, *M. catarrhalis*, and *M. pneumoniae*. In general, these conflicting results appear independent of the antibiotic used or the regimen compared. The wide disparity that exists in the results from these studies, combined with the difficulties in recognition and lack of standardized diagnostic criteria for acute exacerbations of chronic bronchitis, serves as the basis for the enormous controversy surrounding the use of antibiotics in this condition.³⁰ A review of 14 double-blinded randomized clinical trials compared fluoroquinolones to more standard antibiotic regimens (e.g., macrolides, azalides, oral cephalosporins, and the combination drug amoxicillin–clavulanate).²⁶ As expected, no statistically significant differences were observed between treatment arms. However, in a small subset of studies ($n = 4$), the sputum culture became negative in a significantly higher number of fluoroquinolone-treated patients. Other studies showed an increase in the interval between acute exacerbations in patients who received fluoroquinolone therapy. An additional advantage of fluoroquinolone therapy is the short course (e.g., 5 days) and once-daily dosing compared to other antibiotic regimens.

The increasing resistance of the common bacterial pathogens to first-line agents further complicates antibiotic selection. As many as 30% to 40% of *H. influenzae* and 95% of *M. catarrhalis* isolates produce β -lactamases. Moreover, up to 30% of *S. pneumoniae* isolates demonstrate resistance to penicillin (minimum inhibitory concentration [MIC] = 0.1–2 mg/L), with approximately 14% of isolates being highly resistant (MIC >2 mg/L). In addition, concern regarding *S. pneumoniae* resistance is increasing, given the incidence of macrolide resistance approximating 20%. Despite these changes in bacterial susceptibility, the current recommendation is to initiate therapy with first-line agents in less severely affected patients.

Regardless of the antibiotic selected, careful attention to predetermined outcome measures should be monitored closely in each patient to determine the success or failure of the therapeutic intervention. Oral antibiotics with broader antibacterial spectra (e.g., amoxicillin–clavulanate, fluoroquinolones, or azalides) that possess more potent in-vitro activity against sputum isolates are increasingly becoming first-line antibiotics as initial therapy for treatment of acute exacerbations of chronic bronchitis.²⁶

An important clinical outcome variable directing drug selection and criteria for beginning antibiotics in individual patients is the infection-free period when chronic bronchitics are off antibiotics. The actual length of the infection-free time period and the change in the number of physician office visits and hospital admissions with a particular antibiotic regimen are extremely important to identify, whenever possible, for each patient. The antibiotic regimen that results in the longest infection-free period defines the “regimen of choice” for specific patients for future acute exacerbations of their disease.

Antibiotics should be selected that are effective against responsible pathogens, demonstrate the least risk of drug interactions, and can be administered in a manner that promotes compliance. Antibiotics commonly used for treatment of these patients and their respective adult starting doses are listed in Table 111–5. Doses of antibiotics should be adjusted as needed to the desired clinical effect

TABLE 111-5 Oral Antibiotics Commonly Used for the Treatment of Acute Respiratory Exacerbations in Chronic Bronchitis

Antibiotic	Usual Adult Dose (g)	Dose Schedule (doses/day)
Preferred drugs		
Ampicillin	0.25–0.5	4
Amoxicillin	0.5–0.875	3–2
Amoxicillin–clavulanate	0.5–0.875	3–2
Ciprofloxacin	0.5–0.75	2

and the lowest incidence of acceptable side effects. A frequently used clinical strategy to enhance the duration of symptom-free periods incorporates higher-dose antibiotic regimens using the upper limit of the recommended daily antibiotic dose for a period of 5 to 7 days.

In the patient whose history suggests recurrent exacerbations of disease that might be attributable to specific events (e.g., seasonal or related to the winter months), a trial of prophylactic antibiotics might be beneficial. If no clinical improvement is noted over an appropriate time period (2–3 months per year for 2–3 years), further attempts at prophylactic therapy can be discontinued. Similarly, patient-specific antibiotic trials can be performed in individuals experiencing acute exacerbations, focusing on attaining the maximum infection-free period. Although less than desirable, this method of clinical assessment may distinguish patients who will benefit from prophylactic antibiotic therapy from those who will not.

BRONCHIOLITIS

EPIDEMIOLOGY AND ETIOLOGY

7 Bronchiolitis is an acute viral infection of the lower respiratory tract that affects approximately 50% of children during the first year of life and 100% by age 3 years. The occurrence of bronchiolitis peaks during the winter months and persists through early spring. Bronchiolitis remains the major reason for hospital admission during the first year of life. The incidence of bronchiolitis appears to be more common in males than in females.^{31,32}

Respiratory syncytial virus (RSV) is the most common cause of bronchiolitis, accounting for up to 70% of all cases. During epidemic periods, the incidence of RSV-induced bronchiolitis can exceed 80% of cases. Parainfluenza viruses type 3 (10%–15%), type 1 (5%–10%), and type 2 (1%–5%) are the second most common pathogens, constituting as a group nearly 25% of cases. Bacteria serve as secondary pathogens in a minority of cases.^{31,33}

CLINICAL PRESENTATION

A prodrome suggesting an upper respiratory tract infection, usually lasting from 2 to 8 days, precedes the onset of clinical symptoms (Table 111–6). As a result of limited oral intake because of coughing combined with fever, vomiting, and diarrhea, infants frequently are dehydrated. The increased work of breathing and tachypnea most

TABLE 111-6 Clinical Presentation of Bronchiolitis

Signs and symptoms
Prodrome with irritability, restlessness, and mild fever
Cough and coryza
Vomiting, diarrhea, noisy breathing, and increased respiratory rate as symptoms progress
Labored breathing with retractions of the chest wall, nasal flaring, and grunting
Physical examination
Tachycardia and respiratory rate of 40–80 per minute in hospitalized infants
Wheezing and inspiratory rales
Mild conjunctivitis in one third of patients
Otitis media in 5%–10% of patients
Laboratory tests
Peripheral white blood cell count normal or slightly elevated
Abnormal arterial blood gases (hypoxemia and, rarely, hypercarbia)

likely further increases fluid loss. In most cases, this clinical picture persists between 3 and 7 days. Although the hospital course of bronchiolitic children often is variable, substantial clinical improvement usually is observed within the first 2 days, with gradual improvement and complete resolution requiring 4 to 8 weeks.

The diagnosis of bronchiolitis is based primarily on history and clinical findings. It is important for the clinician to attempt to differentiate between bronchiolitis and a host of other clinical entities affecting infants, which may produce a similar picture of dyspnea and wheezing. Asthma, congestive heart failure, anatomic airway abnormalities, cystic fibrosis, foreign bodies, and gastroesophageal reflux are the primary disease entities that may present with wheezing on physical examination in children. Isolation of a viral pathogen in the respiratory secretions of a wheezing child establishes a presumptive diagnosis of infectious bronchiolitis. However, the ability to identify specific viral pathogens often is hindered by the limited availability of special virology laboratories. In addition, in the elderly and in immunocompromised patients, antigen detection lacks adequate sensitivity, and patients frequently seek medical care after the acute stage of the infection, thus compromising the ability of the available tests to diagnose RSV. However, the proliferation of commercial enzyme-linked immunosorbent assays and fluorescent antibody staining techniques of nasopharyngeal secretions has increased the ability to identify viral antigens within several hours.³¹ Identification of RSV by polymerase chain reaction should be available routinely from most clinical laboratories, but its relevance to the clinical management of bronchiolitis remains obscure.

Multiple clinical laboratory determinations have been used to assist in the management of cases of bronchiolitis. Roentgenographic evaluation of the chest in children with bronchiolitis yields variable findings but may help to distinguish this illness from other entities characterized by wheezing. In children requiring hospitalization, abnormalities in blood gas tensions are frequent and appear to relate to disease severity. Hypoxemia is common and increases the respiratory drive, whereas hypercarbia is seen in only the most severe cases. Despite the presence of moderate degrees of hypoxemia, clinical cyanosis is unusual.

TREATMENT

Bronchiolitis

■ DESIRED OUTCOME

7 In the well infant, bronchiolitis usually is a self-limiting illness, and reassurance and antipyretics usually are all that are necessary while waiting for resolution of the underlying viral infection. In-hospital support is necessary for the child suffering from respiratory

failure or dehydration; underlying cardiac and pulmonary diseases potentiate these conditions.

■ GENERAL APPROACH TO TREATMENT

7 Almost all otherwise healthy babies with bronchiolitis can be followed as outpatients. Such infants are treated for fever, provided generous amounts of oral fluids, and observed closely for evidence of respiratory deterioration.³⁴ In severely affected children, the mainstays of therapy for bronchiolitis are oxygen therapy and intravenous fluids. In a subset of patients, aerosolized bronchodilators may have a role. In selected infants, particularly those with underlying pulmonary disease, cardiac disease, or both, therapy with the antiviral agent ribavirin can be considered.³⁵

■ PHARMACOLOGIC THERAPY

7 Aerosolized β_2 -adrenergic therapy appears to offer little benefit for the majority of patients and may even be detrimental.³³ However, this therapy may offer some benefit to the child with a predisposition toward bronchospasm. In addition, although clinical trials have demonstrated varied results, nebulized epinephrine seems to be more efficacious than salbutamol in hospitalized patients with bronchiolitis.^{36,37} In such patients, bronchodilator therapy may be offered initially but should not be pursued in the absence of a clear-cut clinical benefit. Similarly, controlled trials of corticosteroids have failed to reveal any therapeutic benefit (or harmful effect) when administered to bronchiolitic infants.³³ As a result, the routine use of systemically administered corticosteroids is discouraged. Although placing children with bronchiolitis in mist tents has been common practice, no data have documented the effectiveness of this practice.

CLINICAL CONTROVERSY

Because bacteria are not primary pathogens in the etiology of bronchiolitis, antibiotics should not be administered routinely. Despite this, many clinicians frequently administer antibiotics while awaiting culture results because the clinical and radiographic findings in bronchiolitis often are suggestive of possible bacterial pneumonia.

Ribavirin may offer benefit to a subset of infants with bronchiolitis. Although ribavirin, a synthetic nucleoside, possesses in-vitro antiviral properties against a variety of RNA and DNA viruses, including influenza A, influenza B, parainfluenza, and adenovirus,³³ it is approved only in aerosolized form against RSV. Use of the drug requires special equipment (small-particle aerosol generator) and specially trained personnel for administration via oxygen hood or mist tent. Special care must be taken to avoid drug particle deposition and the resulting clogging of respiratory tubing and valves in mechanical ventilators.

Among hospital admissions for RSV infection, ribavirin therapy failed to decrease length of hospital stay, number of days in the intensive care unit, or number of days receiving mechanical ventilation. Consequently, the American Academy of Pediatrics has modified its recommendation for the use of ribavirin from “should be used” to “may be considered.”³³ In light of this and because of the requirement for special aerosolization equipment and the cost of the drug itself, most experts recommend reserving use of ribavirin for severely ill patients, especially those with chronic lung disease (particularly bronchopulmonary dysplasia), congenital heart disease, prematurity, and immunodeficiency (especially severe combined immunodeficiency and human immunodeficiency virus [HIV] infection). Ribavirin also can be considered in otherwise healthy patients with severe distress because of RSV infection.

In infants with underlying pulmonary or cardiovascular disease, prophylaxis against RSV may be warranted. When administered monthly during the RSV season, both RSV immune globulin³⁸ and palivizumab^{39,40} (a monoclonal antibody for RSV) may decrease the number of RSV episodes and the need for hospitalization. Between the two, palivizumab appears to be preferred, given its ease of administration, lack of administration-related adverse effects, and noninterference with select immunizations.

PNEUMONIA

EPIDEMIOLOGY

Pneumonia is the most common infectious cause of death in the United States, where approximately three million cases are diagnosed annually at a cost of more than \$20 billion to the healthcare system.^{41,42} Pneumonia occurs throughout the year, with the relative prevalence of disease resulting from different etiologic agents varying with the seasons. It occurs in persons of all ages, although the clinical manifestations are most severe in the very young, the elderly, and the chronically ill.

PATHOGENESIS

Microorganisms gain access to the lower respiratory tract by three routes. They may be inhaled as aerosolized particles, or they may enter the lung via the bloodstream from an extrapulmonary site of infection; however, aspiration of oropharyngeal contents, a common occurrence in both healthy and ill persons during sleep, is the major mechanism by which pulmonary pathogens gain access to the normally sterile lower airways and alveoli. When pulmonary defense mechanisms are functioning optimally, aspirated microorganisms are cleared from the region before infection can become established; however, aspiration of potential pathogens from the oropharynx can result in pneumonia if lung defenses are impaired.¹ Factors that promote aspiration, such as altered sensorium and neuromuscular disease, may result in an increase in the size of the inoculum delivered to the lower respiratory tract, thereby overwhelming local defense mechanisms. Lung infections with viruses suppress the antibacterial activity of the lung by impairing alveolar macrophage function and mucociliary clearance, thus setting the stage for secondary bacterial pneumonia. Mucociliary transport is also depressed by ethanol and narcotics and by obstruction of a bronchus by mucus, tumor, or extrinsic compression. All these factors can severely impair pulmonary clearance of aspirated bacteria.

8 The most prominent pathogen causing community-acquired pneumonia in otherwise healthy adults is *S. pneumoniae* (pneumococcus) and accounts for up to 75% of all acute cases. Other common pathogens include *M. pneumoniae*, *Legionella*, *C. pneumoniae*, *H. influenzae*, and a variety of viruses including influenza.^{41,42} Community-acquired pneumonias caused by *Staphylococcus aureus* and gram-negative rods are observed primarily in the elderly, especially those residing in nursing homes, and in association with alcoholism and other debilitating conditions. The term *atypical* may be applied to pneumonia to indicate that the pneumonia may be caused by an atypical pathogen. Although this older terminology is slowly fading, atypical pneumonia or atypical pathogens refers to pneumonia (e.g., bilateral lobar pneumonia with a negative Gram stain of sputum) caused by *M. pneumoniae*, *C. pneumoniae*, or *Legionella*.⁴³

Gram-negative aerobic bacilli and *S. aureus* are the leading causative agents in hospital-acquired pneumonia.⁴⁴ Anaerobic bacteria are the most common etiologic agents in pneumonia that follows the gross aspiration of gastric or oropharyngeal contents.⁴⁵

Pneumonia in infants and children is caused by a wider range of microorganisms, and, unlike the situation in adults, nonbacterial

pathogens predominate. Most pneumonias occurring in the pediatric age group are caused by viruses, especially RSV, parainfluenza, and adenovirus.³³ *M. pneumoniae* is an important pathogen in older children. Beyond the neonatal period, pneumococcus is the major bacterial pathogen in childhood pneumonia, followed by group A *Streptococcus* and *S. aureus*. *H. influenzae* type b, once a major childhood pathogen, has become an infrequent cause of pneumonia since the introduction of active vaccination against this organism in the late 1980s.

CLINICAL PRESENTATION

Bacterial Pneumonia

Bacterial pneumonia is caused most commonly by gram-positive streptococci and staphylococci and gram-negative organisms that normally inhabit the gastrointestinal tract (enterics) and soil and water (nonenterics). In addition, *Legionella*, itself a weakly staining gram-negative nonenteric organism, accounts for a small percentage of community- and hospital-acquired bacterial pneumonia, although the true incidence may be underreported.⁴⁶ Finally, *Mycobacterium tuberculosis*, an acid-fast staining bacillus, has reemerged as an important cause of pneumonia in urban centers throughout the United States.⁴⁷

A wide array of gram-positive and gram-negative organisms can cause pneumonia, but they usually present a similar clinical appearance (Table 111-7). Pneumococcus, *Staphylococcus*, the enteric gram-negative rods, and occasionally other organisms may produce local irritation or destruction of blood vessels leading to rust-colored sputum or hemoptysis. Pleural effusions, both sterile and empyematous, may be associated with many of these entities, as evidenced by distant breath sounds and a wide area of dulled percussion. The chest radiograph and sputum examination and culture are the most useful diagnostic tests for gram-positive and gram-negative bacterial pneumonia. Typically, the chest radiograph reveals a dense lobar or segmental infiltrate. However, patchy consolidation may be seen occasionally with virtually all these pathogens. Occasionally, pneumonia resulting from hematogenous spread of the organisms results in a diffuse, alveolar pattern on chest radiograph. Gram stain of the expectorated sputum demonstrates many polymorphonuclear cells per high-powered field in the presence of a predominant organism, which is reflected as heavy growth of a single species on culture. Other laboratory tests are less sensitive or specific. Blood cultures may be helpful in identifying the offending organism but are positive in only a minority of patients. The complete blood count usually reflects a leukocytosis with a predominance of polymorphonuclear cells; in some instances, particularly with pneumococcus, elevation of the white blood cell (WBC) count may be pronounced. Normal or

TABLE 111-7 Clinical Presentation of Pneumonia

Signs and symptoms
Abrupt onset of fever, chills, dyspnea, and productive cough
Rust-colored sputum or hemoptysis
Pleuritic chest pain
Physical examination
Tachypnea and tachycardia
Dullness to percussion
Increased tactile fremitus, whisper pectoriloquy, and egophony
Chest wall retractions and grunting respirations
Diminished breath sounds over affected area
Inspiratory crackles during lung expansion
Chest radiograph
Dense lobar or segmental infiltrate
Laboratory tests
Leukocytosis with predominance of polymorphonuclear cells
Low oxygen saturation on arterial blood gas or pulse oximetry

mildly elevated WBC counts, however, do not exclude bacterial pneumonic disease. The patient also may be hypoxic, as reflected by low oxygen saturation on arterial blood gas or pulse oximetry.

Although the clinical appearance of gram-positive and gram-negative pneumonias is similar, epidemiologic and clinical clues render one more likely than the other.

Gram-Positive Bacteria

8 *Pneumococcus* is the most common community-acquired bacterial pneumonia, accounting for up to 76% of cases.⁴² It is particularly prevalent and severe in patients with splenic dysfunction, diabetes mellitus, chronic cardiopulmonary or renal disease, or HIV infection. *S. aureus* pneumonia occurs in both the community and hospital settings.⁴⁸ Community-acquired disease with *S. aureus* is identified most frequently in young infants, patients with early cystic fibrosis, and those recovering from an antecedent respiratory viral infection. *S. aureus* is a prominent cause of nosocomial pneumonia and may result from hematogenous spread from a distant source. In both settings, it is characteristically severe and accompanied by the formation of pneumatoceles (air-containing cavities within the lung). Group B *Streptococcus*, although rare in adults, is the most common cause of bacterial pneumonia among neonates, in whom it typically causes a clinical and radiographic picture nearly indistinguishable from hyaline membrane disease.⁴⁹ Group A *Streptococcus* is an uncommon cause of community-acquired pneumonia and frequently occurs after a viral respiratory tract infection. Only occasionally is it associated with streptococcal pharyngitis. The organism is pyogenic, and the presentation can be severe.

Enteric Gram-Negative Bacteria

Community-acquired enteric gram-negative pneumonia is identified most frequently among patients with chronic illness, especially alcoholism and diabetes mellitus. The enteric gram-negative bacteria are leading causes of nosocomial pneumonia because the upper respiratory tract becomes rapidly colonized with gram-negative organisms after hospitalization, particularly among critically ill patients and those receiving antibiotics.⁵⁰ Outbreaks of nosocomial disease may be caused occasionally by contaminated respiratory therapy equipment. *Klebsiella pneumoniae* is the most frequently encountered pathogen among the gram-negative enteric bacteria, although the relative prominence of these organisms varies among hospitals. The gram-negative bacilli are associated with high mortality, sometimes exceeding 50%; their potential to produce significant morbidity and mortality has been enhanced by the emergence of highly antibiotic-resistant organisms in some hospital settings.⁵¹

Nonenteric Gram-Negative Bacteria

The most prominent nonenteric gram-negative rods associated with pneumonia include *Pseudomonas*, *Haemophilus*, and *Moraxella*. Like the enteric gram-negative organisms, *P. aeruginosa* is a frequent cause of hospital-acquired pneumonia and is particularly prominent among neutropenic and burn patients.⁵¹ In addition, cystic fibrosis patients suffer from chronic, multilobar infections with *P. aeruginosa* as well as other *Pseudomonas* species; these infections are punctuated with acute exacerbations.⁵² *H. influenzae* type b historically has been a prominent pathogen in childhood pneumonia. However, the incidence of all invasive disease due to this organism in the pediatric age group has dropped dramatically since the introduction of the conjugated *Haemophilus* vaccines in the late 1980s. However, two different clinical presentations of *H. influenzae* pneumonia still are seen in adults. The most common by far is the bronchopneumonia form, which develops most frequently in patients with underlying chronic lung disease and is believed to

represent, in most patients, an exacerbation of chronic bronchitis. In the second form of *H. influenzae* pneumonia, segmental or lobar involvement predominates. The course of this illness is more acute, with sudden onset of cough, fever, and pleuritic chest pain. Finally, *M. catarrhalis*, an important cause of otitis media and sinusitis, is an increasingly important cause of lower respiratory tract infections in immunoincompetent and hospitalized patients.

Legionella pneumophila

Of the several *Legionella* species known to cause pneumonia in humans, *Legionella pneumophila* is by far the most important, accounting for 2% to 15% of all community-acquired pneumonias in North America and Europe.⁴⁶ *Legionella* is a water and soil organism and most probably is transmitted by inhalation of aerosols containing the organism or by microaspiration of contaminated water. Outbreaks of illness caused by *L. pneumophila* have been linked to excavation sites and to contaminated water from air conditioners and showers. Person-to-person transmission has not been demonstrated. In addition to epidemics, *L. pneumophila* causes sporadic illness that peaks in summer and fall. Individuals who are male, middle-aged or older, immunocompromised, chronic bronchitics, or cigarette smokers are at increased risk.

Infection with *L. pneumophila* is characterized by multisystem involvement, including rapidly progressive pneumonia. It has a gradual onset, with prominent constitutional symptoms (e.g., malaise, lethargy, weakness, anorexia) occurring early in the course of the illness. A dry, nonproductive cough is present initially and becomes productive of mucoid or purulent sputum over several days. Fevers exceeding 40°C (104°F) develop in more than half of patients, typically are unremitting, and are associated with a relative bradycardia. Pleuritic chest pain and progressive dyspnea may be seen. Extrapulmonary symptoms, particularly diarrhea, nausea, and vomiting, remain evident throughout the course of the illness. Myalgias and arthralgias also occur. Substantial changes in the patient's mental status, often out of proportion to the degree of fever, are seen in approximately one fourth of patients. Obtundation, hallucinations, grand mal seizures, and focal neurologic findings are also associated with this illness. Chest roentgenograms initially reveal patchy alveolar infiltrates that may be bilateral. Progression to lobar or multilobar consolidation is frequent, as are small pleural effusions.

Laboratory findings include leukocytosis with a predominance of mature and immature granulocytes in 50% to 75% of patients. Urinalysis may reveal proteinuria, hematuria, and casts; liver function tests may be abnormal. Hyponatremia and hypophosphatemia have been reported frequently. Because *L. pneumophila* stains poorly with commonly used stains, routine microscopic examination of sputum is of little diagnostic value. Although it exhibits slow growth and has highly selective growth requirements, *L. pneumophila* has been isolated successfully from tissue using a specialized medium. Direct fluorescent antibody examination of respiratory tract secretions, lung tissue, or pleural fluid is the most rapid means of establishing the diagnosis. The sensitivity of this method approaches 70% for sputum and 90% for lung tissue, and diagnostic specificity is high for both. Commercially available urine antigen tests have been developed for *L. pneumophila*. These tests are 70% sensitive and remain positive for weeks, even after effective antibiotics have been started. Because these diagnostic tests are unavailable in many clinical laboratories, the diagnosis of Legionnaires' disease often is presumptive and based on a suggestive clinical presentation.

Anaerobic Pneumonia

8 Anaerobic pneumonitis is most likely to occur in individuals predisposed to aspiration by impaired consciousness and may be

more prevalent in those with periodontal disease or dysphagia. Bronchogenic carcinoma is an associated underlying condition. A variety of gram-positive and gram-negative anaerobic bacteria indigenous to the upper airway may cause pneumonitis when large quantities of oropharyngeal secretions are aspirated into the lower airways. The organisms most frequently implicated are *Peptostreptococcus* species, *Fusobacteria*, *Bacteroides melaninogenicus*, *Bacteroides fragilis*, and *Peptococcus* species; polymicrobial infections with anaerobes and aerobes, such as *S. aureus*, *S. pneumoniae*, and gram-negative bacilli, are common.⁴⁵

The course of illness typically is indolent, with cough, low-grade fever, and weight loss, although an acute presentation may occur. Rigors are notably absent, and bacteremia is rare. Putrid sputum, when present, is highly suggestive of the diagnosis. Chest radiographs reveal infiltrates typically located in dependent lung segments, and lung abscesses develop in 20% of patients 1 to 2 weeks into the course of the illness.

Tuberculosis

The acid-fast bacillus *M. tuberculosis* causes tuberculosis. After years of steady decline, the number of cases of pneumonia caused by *M. tuberculosis* in the United States began to increase in the middle to late 1980s. The new epidemic was a consequence of an increased incidence among prison inmates, intravenous drug abusers, immigrants, and, most prominently, HIV-infected patients.⁵³ It is most prominent in urban neighborhoods afflicted with crowded conditions and poor access to healthcare. Unlike previous eras in which tuberculosis was seen most frequently in elderly men, infection currently is identified in increasing numbers of young minority adults. As mentioned, the resurgence of tuberculosis is at least partially related to coinfection with HIV; HIV-infected patients are more likely to develop symptomatic disease with its associated fits of coughing than are their immunocompetent counterparts, and this enables further spread of infection. Other groups prone to tuberculosis include the homeless and patients in chronic care facilities and homes for the elderly. Fortunately, since 1992, the incidence of tuberculosis in the United States has declined, reaching a record low. However, the incidence of tuberculosis worldwide continues to increase. Both the sustained worldwide increase in tuberculosis and the reemergence of tuberculosis in the United States are important reasons for the development of multiple-drug resistance, that is, mycobacteria that are resistant to two or more of the first-line antituberculosis drugs. Infection caused by these organisms is poorly responsive to alternative therapy and is associated with mortality rates exceeding 50% (see Chap. 116).

Tuberculosis is spread from person to person by inhalation of droplet nuclei generated by vigorous coughing. Most patients who become infected with *M. tuberculosis* remain asymptomatic despite lifelong infection and have a normal chest radiograph. Infection in these patients is detected only through routine skin testing. Less frequently, particularly in those with poor immunity, the infection cannot be contained by local macrophages, and the tuberculous burden grows sufficiently to cause clinical manifestations.

Adult disease (from adolescence onward) begins with constitutional complaints, followed by a prominent chronic, troublesome cough productive of mucopurulent material. The infection initially appears in the lung apices with little or no hilar adenopathy and, in advanced disease, results in lung necrosis, producing a cavity containing enormous numbers of organisms. With sufficient cough, the cavity contents are mobilized and aspirated into other areas of the lung, where additional cavities may be formed.

In contrast, pediatric tuberculosis commonly is associated with little cough even in the presence of extensive pulmonary infection. Instead, the child presents with a subacute course of poor appetite, weight loss, lethargy, fever, and sweats. Chest radiograph reveals a

widened mediastinum representing enlarged hilar lymph nodes reacting to the tuberculin inoculum. In progressive cases, the nodes impinge on or erode through a large bronchus, resulting in a dense consolidation of the segment distal to the lesion. Cavitary disease is uncommon.

Nonbacterial Pneumonia

Viruses, *Mycoplasma* species, *Chlamydia* species, and fungi are recognized causes of pneumonia syndromes in all age groups. The designation *atypical pneumonia*, distinct from the typical bacterial pneumonia seen most commonly in adults, has been used to describe the illness caused by many of these agents.⁵⁴

Mycoplasma Pneumonia

Taxonomically, the mycoplasmas are included in their own class labeled Mollicutes. Although their small size and filterability are similar to viruses, the structure of their ribosomal RNA indicates that they have evolved from bacteria, and, unlike any virus, they contain cytoplasm and can replicate in an extracellular environment. They are distinguished from eubacteria by their low genetic content. In addition, the mycoplasmas lack a cell wall and are surrounded instead by a lipid membrane.⁵⁵

M. pneumoniae causes human disease throughout the year, with a slightly increased incidence in fall and early winter. During the summer months when other causes of pneumonia are less common, *M. pneumoniae* is responsible for a greater proportion of cases. Both infection and disease from *M. pneumoniae* are common, with two thirds of children ages 2 to 5 years and 97% of persons older than 17 years having detectable serum antibody to the organism. Overall, *M. pneumoniae* is responsible for approximately 20% of pneumonia cases, although in enclosed populations, such as military recruits and college dormitory residents, it may cause more than 50%. Infection is spread by close person-to-person contact, and the incubation period is 2 to 3 weeks. *M. pneumoniae* infections are unusual in children younger than 5 years and show a peak incidence in older children and young adults. Only 3% to 10% of persons infected with *M. pneumoniae* develop pneumonia, with the majority of respiratory tract involvement manifested as pharyngitis and tracheobronchitis. Asymptomatic infection is common.

M. pneumoniae presents with a gradual onset of fever, headache, and malaise, with the appearance 3 to 5 days after the onset of illness of a persistent, hacking cough that initially is nonproductive. Sore throat, ear pain, and rhinorrhea often are present. Chills are seen only occasionally, and pleuritic pain is uncommon. Lung findings generally are limited to rales and rhonchi; findings of consolidation are rare. Nonpulmonary manifestations are extremely common and include nausea, vomiting, diarrhea, myalgias, arthralgias, polyarticular arthritis, skin rashes, myocarditis and pericarditis, hemolytic anemia, meningoencephalitis, cranial neuropathies, and Guillain-Barré syndrome. Systemic symptoms generally clear in 1 to 2 weeks, whereas respiratory symptoms may persist for up to 4 weeks. Although the course of mycoplasmal pneumonia usually is benign and self-limited, severe respiratory disease may develop in patients with sickle cell disease, agammaglobulinemia, and COPD.⁵⁵

Radiographic findings generally are more impressive than the patient's physical findings and include patchy or interstitial infiltrates, which are seen most commonly in the lower lobes. Small unilateral, transient pleural effusions are common, but large effusions and empyema are rare. Roentgenographic abnormalities resolve slowly, and 4 to 6 weeks may be required for complete resolution.

Sputum Gram stain may reveal mononuclear or polymorphonuclear leukocytes, with no predominant organism. Although *M. pneumoniae* can be cultured from respiratory secretions using specialized medium, its growth is slow, and 2 to 3 weeks may be

necessary for culture identification. Indirect evidence of infection by *M. pneumoniae* is the presence of elevated levels of serum cold hemagglutinins. These immunoglobulin M antibodies develop in approximately half of patients with mycoplasmal pneumonia and can be elevated in other illnesses, especially viral infection. A definitive diagnosis also can be made by demonstrating a fourfold or greater rise in serum antibodies to *M. pneumoniae*. However, because this test also requires 2 to 4 weeks for results, the diagnosis of mycoplasmal pneumonia during the acute phase of the illness must be based on the characteristic history, appropriate clinical setting, and typical physical findings.

Chlamydia Pneumonia

C. pneumoniae, formally designated the TWAR agent, after the laboratory designations for the first two isolates, is a relatively recently identified pathogen antigenically similar to *Chlamydia psittaci*. *C. pneumoniae* infection is ubiquitous worldwide, but only a small percentage of infections result in clinically apparent pneumonia. Conversely, approximately 5% to 15% of pneumonia is associated with this pathogen.⁵⁶ Primary-infection *Chlamydia* pneumonia typically occurs in young adults and is characterized by mild respiratory symptoms with a gradual onset. Constitutional manifestations, particularly fever and headache, are common. The radiographic findings are nonspecific and usually consist of multilobular interstitial infiltrates. Immunity is incomplete, and reinfection with *C. pneumoniae* is common, particularly among the elderly. Definitive diagnosis of *C. pneumoniae*-associated pneumonia depends on identification of the organism in sputum. Culture of this organism is difficult, and commercially available antigen detection systems are insensitive.

Viral Pneumonia

Viruses are an uncommon cause of pneumonia in adults, except in the immunosuppressed.³ Influenza virus, usually type A, is the most common cause of pneumonia in the adult civilian population⁵⁶; adenoviruses cause most cases in military trainees. In contrast, viruses are by far the most common agents producing pneumonia in infants and young children, with RSV, parainfluenza, and adenovirus producing most cases.³¹

All viral respiratory tract infections occur more commonly in the winter, and rapid person-to-person spread through susceptible populations is typical. Underlying cardiac or pulmonary disease predisposes to an increased incidence and severity of viral lower respiratory tract infection, especially with influenza virus in adults and RSV in children. Radiographic findings are nonspecific and include bronchial wall thickening and perihilar and diffuse interstitial infiltrates. Pleural effusions may be seen, especially in adenovirus and parainfluenza pneumonia.

The clinical pictures produced by respiratory viruses are sufficiently variable and overlap to such a degree that an etiologic diagnosis cannot be made confidently based on clinical grounds alone. Although virus isolation in tissue culture is possible, a period of 7 or more days often is required for virus identification; thus, this method usually cannot be used for definitive diagnosis during the acute phase of illness. Serologic tests for virus-specific antibodies are used often in the diagnosis of viral infections. The diagnostic fourfold rise in titer between acute and convalescent phase sera may require 2 to 3 weeks to develop. Same-day diagnosis of viral infections now is possible through the use of indirect immunofluorescence tests on exfoliated cells from the respiratory tract. The immunofluorescence technique frequently uses a battery of monoclonal antibodies, including those against influenza A and B, RSV, parainfluenza, and adenovirus, to provide rapid diagnosis of a range of viral infections.³

PNEUMONIA IN SPECIAL CLINICAL CIRCUMSTANCES

Pneumonia in the HIV-Infected Patient

HIV infects and destroys helper T lymphocytes bearing the CD4 surface molecule; these cells are critical for orchestrating a wide variety of immunologic responses. Their depletion consequently results in dysfunction of both cell-mediated and humoral immunity. As a result, a broad range of pathogens can cause pneumonia in HIV infection (Table 111-8).⁵⁷⁻⁵⁹ The HIV-infected patient may be afflicted with pneumonia multiple times in his or her lifetime, particularly in the advanced stages of the disease, and a given episode may be caused by more than one species.

The clinical presentation of pneumonia in HIV-infected persons frequently is not helpful in distinguishing one pathogen from another. The pneumonia usually is subacute in onset and consists of fever, nonproductive cough, and dyspnea. Radiographically, most of these entities produce a multilobular or diffuse pattern. Some practitioners initially treat the HIV-infected patient with pneumonia empirically, covering the most common entities (bacteria and *Pneumocystis carinii*). However, given the wide array of possible pathogens, more frequently a specific microbiologic diagnosis is aggressively pursued early in the patient's course through sputum induction or bronchoalveolar lavage to allow a rational choice of an antimicrobial regimen. The diagnosis and treatment of HIV-infected patients with pulmonary disease is discussed in detail in Chap. 129.

Pneumonia in the Neutropenic Host

Neutropenia in the cancer patient is a common complication of aggressive chemotherapy but occasionally results from the cancer itself. The risk of infection in the cytopenic patient is increased significantly

when the absolute neutrophil count falls below 500 cells/mm³ and the neutropenia persists for more than 7 days.^{60–62} In many patients, the duration of chemotherapy-induced cytopenia can be reduced by judicious application of colony-stimulating factors.^{63,64}

The organisms that cause pneumonia in the cytopenic cancer patient include a broad range of bacteria and fungi.⁶⁰ The most prominent among these are gram-positive bacteria (staphylococci and streptococci); others include enteric and nonenteric (particularly *Pseudomonas*) gram-negative rods as well as the fungi (*Candida*, *Aspergillus*). The chest radiograph may reveal the lobar pattern typical of bacterial infection in the normal host, or it may exhibit a diffuse pattern. Sometimes the pneumonia remains invisible by chest radiograph until the neutropenia resolves. Noninfectious entities that may cause pulmonary symptoms include toxicity from radiation or chemotherapy or infiltration of the lung parenchyma by the tumor itself.

Nosocomial Pneumonia

After the urinary tract and the bloodstream, the lungs are the most frequent site of infection acquired in the hospital. Nosocomial pneumonia is seen most commonly in critically ill patients.^{65,66} Factors that predispose patients to the development of nosocomial pneumonia include the severity of illness, duration of hospitalization, supine positioning, witnessed aspiration, coma, acute respiratory distress syndrome, patient transport, and prior antibiotic exposure.⁶⁷ The strongest predisposing factor, however, is mechanical ventilation (intubation), which bypasses the natural airway defenses against the migration of upper respiratory tract organisms into the lower tract. This situation is exacerbated by the wide use of H₂-receptor blocking agents in the intensive care unit, which increases the pH of gastric secretions and may promote the proliferation of microorganisms in the upper gastrointestinal tract. Subclinical microaspirations are events that occur routinely in intubated patients and result in the inoculation of bacteria-contaminated gastric contents into the lung and a higher incidence of nosocomial pneumonia. Ventilator-associated pneumonia can be diagnosed accurately by any one of multiple standard criteria, including histopathologic examination of lung tissue obtained by open-lung biopsy, rapid cavitation of a pulmonary infiltrate in the absence of cancer or tuberculosis, positive pleural fluid culture, and same species with an identical antibiogram for a pathogen(s) isolated from blood and respiratory secretions without another identifiable source of bacteremia.⁸

The organisms most commonly associated with nosocomial pneumonia are *S. aureus* and enteric (e.g., *Klebsiella* or *E. coli*) and nonenteric (e.g., *Pseudomonas*) gram-negative bacilli, organisms that colonize the pharynx of the hospitalized, critically ill patient. The diagnosis of nosocomial pneumonia usually is established by the presence of a new infiltrate on chest radiograph, fever, worsening respiratory status, and the appearance of thick, neutrophil-laden respiratory secretions. In actuality, the diagnosis often is difficult to make in the intensively ill patient with underlying lung pathology that itself can be associated with an abnormal changing radiograph, as occurs with congestive heart failure or chronic lung disease. Broad-spectrum antibiotics frequently are started empirically even in equivocal circumstances, with bronchoscopy reserved for poorly responsive patients.⁵¹

Severe Acute Respiratory Syndrome

In November 2002, an extremely contagious atypical pneumonia manifested in China that since has been termed *severe acute respiratory syndrome* (SARS).⁶⁸ The etiology of SARS is an enveloped RNA virus, a coronavirus, referred to as SARS-CoV. The virus is transmitted primarily via large-droplet spread; however, surface contamination and airborne and fecal spread are possible. Signs and symptoms associated with SARS include high fever, myalgias, headache, diarrhea, and a dry nonproductive cough. Respiratory symp-

toms may progress to shortness of breath and hypoxemia, necessitating the need for intubation and mechanical ventilation. Diagnostic tests for patients suspected of contracting SARS should include chest x-ray film, blood cultures, sputum cultures and Gram stain, pulse oximetry, and identification of other potential pathogens, including influenza A and B, *Legionella*, and RSV. For unclear reasons, SARS appears to be less severe in pediatric patients.

Avian Influenza (Bird Flu)

All influenza viruses may be present in aquatic birds, with the H5N1 subtype being extremely pathogenic and fatal to fowl.^{69,70} The first known cases of humans infected with this subtype occurred in Hong Kong in 1997, with six deaths among 18 infected patients. Signs and symptoms typical of the H5N1 virus are those common to other subtypes and include conjunctivitis, fever, rhinitis, and pharyngitis. However, pneumonia, respiratory distress syndrome, lymphopenia, and clotting abnormalities tend to occur rapidly in patients infected with this highly virulent subtype. Laboratory tests used to detect the H5N1 virus include immunoassays and reverse-transcription polymerase chain reactions.

TREATMENT

Pneumonia

■ DESIRED OUTCOME

Eradication of the offending organism through selection of the appropriate antibiotic and complete clinical cure are the goals of therapy for bacterial pneumonia. Therapy should minimize associated morbidity, including one or both of the following: reversible or irreversible disease and drug-induced organ toxicity (e.g., renal, lung, or hepatic dysfunction). Most cases of viral pneumonia are self-limiting, although therapy of influenza pneumonia with specific antiviral agents (amantadine or rimantadine) may hasten recovery. All efforts should focus on the design of the most cost-effective approach to therapy. Whenever possible, the oral (versus parenteral) route for drug administration should be selected, encouraging outpatient management rather than hospitalization.

■ GENERAL APPROACH TO TREATMENT

9 The first priority in assessing the patient with pneumonia is to evaluate the adequacy of respiratory function and to determine the presence of signs of systemic illness, specifically dehydration or sepsis with resulting circulatory collapse. Oxygen or, in severe cases, mechanical ventilation and fluid resuscitation should be provided as necessary. Further supportive care of the patient with pneumonia includes humidified oxygen for hypoxemia, administration of bronchodilators (albuterol) when bronchospasm is present, and chest physiotherapy with postural drainage if evidence of retained secretions is seen. Additional therapeutic adjuncts include adequate hydration (intravenously if necessary), optimal nutritional support, and control of fever. Appropriate sputum samples may be obtained to determine the microbiologic etiology. Rehydration should be provided to replace losses that may have occurred as a result of fever, poor intake, and/or associated vomiting. Selection of an appropriate antimicrobial must be made based on the patient's probable or documented microbiology, distribution in the respiratory tract, side effects, and cost.

■ PHARMACOLOGIC THERAPY

Antibiotic Concentrations

Antibiotic concentrations in respiratory secretions in excess of the pathogen MIC are necessary for successful treatment of pulmonary

infections.⁷¹ The concept of a blood-bronchus barrier, analogous but dissimilar to the blood-brain barrier, has been used to assess the characteristics of drug penetration into pulmonary secretions. The ability of a drug to penetrate respiratory secretions depends on multiple physicochemical factors, including molecular size, lipid solubility, and degree of ionization at serum and biologic fluid pH and extent of protein binding. Studies performed in animals and cystic fibrosis patients suggest that larger molecular size favors the accumulation of drugs in bronchial secretions. This finding contrasts with data on drug penetration of other physiologic compartments, such as the cerebrospinal fluid, and may be a result of the trapping of lower-molecular-weight compounds in mucin pores. Nevertheless, the rate at which a drug may accumulate in certain respiratory secretions appears to remain an important factor relative to the drug's clinical efficacy in treating pulmonary infections. The un-ionized form of a drug and lipid solubility also appear to favor drug penetration. Of note, the pH of the infected bronchi often is more acidic than that of normal tissue and blood.

Fewer data are available for assessing the influence of drug protein binding on the rate and amount of respiratory secretion penetration. Clearly, it is the free antibiotic fraction reaching the infected site capable of binding to the bacterial cell target that is responsible for antibacterial activity. Given that the degree of protein binding influences a drug's ability to traverse membranes, a similar relationship would be expected within the lung. However, focusing on the absolute amount of an antibiotic bound to plasma/tissue proteins without accounting for the drug's overall antibacterial potency is errant. To completely assess an antibiotic's therapeutic potential in the treatment of pneumonia or any infectious process, it is prudent to assess the antibiotic's integrated pharmacokinetic-pharmacodynamic characteristics (e.g., bacterial killing may be concentration dependent or time dependent) that account for the drug's degree of binding to serum proteins, tissue distribution, and in-vitro potency. Thus, simply focusing on a drug's degree of protein binding is an errant, overly simplistic approach that does not account for the drug's inherent antibacterial activity or distribution characteristics.

These concepts relating to antibiotic activity and overall drug penetration of respiratory secretions have supported the clinical practice of administering certain antibiotics (aminoglycosides) to achieve high peak serum concentrations on the assumption that higher (and possibly more effective) biologic fluid concentrations of the drug will be achieved. The aminoglycosides are large polar molecules that diffuse poorly into tissue and respiratory secretions; however, with increasing concentrations obtained with once-daily dosing, increased target-tissue concentrations would be expected with increasing individual doses. Substantial clinical experience supports this practice for treating pulmonary infections with certain antibiotics (e.g., concentration-dependent antimicrobials), although more data are needed to describe the relationships between these variables and clinical response.

CLINICAL CONTROVERSY

Prior to the availability of newer β -lactam and fluoroquinolone antibiotics possessing consistently potent activity against multiple gram-negative pathogens, some investigators promoted the administration of antibiotics by direct endotracheal instillation. This method of drug administration attempts to provide increased topical concentrations of antibiotics that do not appear to penetrate respiratory secretions effectively while reducing the likelihood of systemic toxicity. In addition, greater local concentrations of antibiotics, particularly of the polymyxins and aminoglycosides, are believed to overcome partially the substantial decrease in antibiotic bioactivity observed when these agents interact with the purulent material present in infectious foci. Despite these potential theoretical advantages, the role of antibiotic aerosols or direct endotracheal instillation in clinical practice remains controversial.⁷¹

Sputum is frequently assessed as possibly representing the pharmacodynamic interface for pulmonary infections. Sputum is only one of many pulmonary fluids and secretions, and it may serve as a reservoir for pathogen growth. These beliefs have led many investigators to assess antibiotic concentrations in sputum, frequently describing sputum drug concentrations as a ratio of serum to sputum drug concentration. Although sputum drug concentrations provide some insight into the characteristics of drug penetration of respiratory secretions, caution should be exercised in the interpretation of these data. Data describing sputum drug concentrations often are difficult to interpret because of differences in analytic techniques, method of sputum sampling, and random nature of sampling times relative to drug dose. Moreover, representation of sputum drug concentrations as a ratio of serum drug concentration can be misleading and most probably should be described relative to absolute drug concentration or apparent area under the drug concentration versus time curve in sputum. To more accurately describe the distribution characteristics of antimicrobial agents in sputum, research studies should be designed to allow sequential repeated sputum sampling over a dosage interval under both first-dose and steady-state conditions. Thus, until greater sophistication is achieved in our understanding of the relationships between antibiotic concentrations in specific anatomic sites, plasma (blood)-based integrated pharmacokinetic-pharmacodynamic correlates should be used for antibiotic and dose selection.

Selection of Antimicrobial Agents

Treatment of bacterial pneumonia, like the treatment of most infectious diseases, initially involves the empirical use of a relatively broad-spectrum antibiotic that is effective against probable pathogens after appropriate cultures and specimens for laboratory evaluation have been obtained.⁵⁶ Therapy should be narrowed to cover specific pathogens after the results of cultures are known. Multiple factors that help to define the potential pathogens involved include patient age, previous and current medication history, underlying disease(s), major organ function, and present clinical status. These factors must be evaluated to select an appropriate and effective empirical antibiotic regimen as well as the most appropriate route for drug administration (oral or parenteral). For a more detailed discussion on the principles of antibiotic selection, see Chap. 109.

Numerous antibiotics are available, and the majority are effective in the treatment of bacterial pneumonia. Superiority of one antibiotic over another when both demonstrate similar in-vitro activity and tissue distribution characteristics is difficult to define. Our opinions on appropriate empirical choices for the treatment of bacterial pneumonias relative to a patient's underlying disease are listed in Table 111-9 for adults and Table 111-10 for children. A complete listing of antimicrobial agents for specific pathogens is beyond the scope of this chapter and is presented in Chap. 108.

Table 111-11 lists dosages for the treatment of bacterial pneumonia. The list of commercially available antimicrobial agents with documented bacterial and clinical effectiveness in the treatment of pneumonia appears endless. The large number of expensive drugs mandates critical evaluation for formulary selection and clinical use. Similarities of in-vitro activity, resistance to bacterial-inactivating enzymes, and overall effectiveness often make rational therapeutic decisions difficult and even appear random. However, some general principles can be applied to guide rational antibiotic choice, including direct comparison of the antibiotic's likely attainment of the defined pharmacokinetic-pharmacodynamic target correlate for specific bacterial species within the infected site. For treatment of bacterial pneumonia with concentration-independent antimicrobials (e.g., β -lactams and carbapenems), a plasma drug concentration exceeding the pathogen MIC for more than 50% of the dosing interval correlates with bacteriologic cure. For concentration-depen-

TABLE 111-9 Empirical Antimicrobial Therapy for Pneumonia in Adults^a

Clinical Setting	Usual Pathogen(s)	Presumptive Therapy
Previously healthy, ambulatory patient	Pneumococcus, <i>Mycoplasma pneumoniae</i>	Macrolide/azalide, ^b tetracycline ^c
Elderly	Pneumococcus, gram-negative bacilli (e.g., <i>Klebsiella pneumoniae</i>); <i>Staphylococcus aureus</i> , <i>Haemophilus influenzae</i>	Piperacillin-tazobactam, cephalosporin, ^d carbapenem ^e
Chronic bronchitis	Pneumococcus, <i>H. influenzae</i> , <i>M. catarrhalis</i>	Amoxicillin, tetracycline, ^c trimethoprim-sulfamethoxazole, cefuroxime, amoxicillin-clavulanate, macrolide/azalide, ^b fluoroquinolone
Alcoholism	Pneumococcus, <i>K. pneumoniae</i> , <i>S. aureus</i> , <i>H. influenzae</i> , possibly mouth anaerobes	Ticarcillin-clavulanate, piperacillin-tazobactam, plus aminoglycoside; carbapenem, ^e fluoroquinolone ^f
Aspiration		
Community	Mouth anaerobes	Penicillin or clindamycin
Hospital/residential care	Mouth anaerobes, <i>S. aureus</i> , gram-negative enterics	Clindamycin, ticarcillin-clavulanate, piperacillin-tazobactam, plus aminoglycoside
Nosocomial pneumonia	Gram-negative bacilli (e.g., <i>K. pneumoniae</i> , <i>Enterobacter</i> species, <i>Pseudomonas aeruginosa</i>), <i>S. aureus</i>	Piperacillin-tazobactam, carbapenem, ^e or extended spectrum cephalosporin ^g plus aminoglycoside; fluoroquinolone ^f

^aSee section on treatment of bacterial pneumonia.^bMacrolide/azalide: erythromycin, clarithromycin, azithromycin.^cTetracycline: tetracycline HCl, doxycycline.^dCephalosporin: cefuroxime, ceftriaxone, cefotaxime.^eCarbapenem: imipenem-cilastatin, meropenem.^fFluoroquinolone: ciprofloxacin, gatifloxacin, or levofloxacin.^gExtended-spectrum cephalosporin: ceftazidime, cefepime.

dent antimicrobials (e.g., aminoglycosides and fluoroquinolones), a peak drug concentration to pathogen MIC ratio >8 to 10 or ratio of pathogen MIC to antibiotic area under the curve >25 to 40 for gram-positive pathogens and >100 for gram-negative pathogens correlates with bacteriologic cure. An understanding and application of these inherent drug characteristics appears to be of the utmost importance for the selection of an optimal therapeutic regimen. Thus, whenever possible, identification of the causative pathogen and expected/defined antibiotic activity (e.g., MIC) is of paramount importance to the selection/design of the optimal antibiotic regimen.

Community-Acquired Pneumonia

Tables 111-12 and 111-13 provide evidence-based guidelines for the treatment of community-acquired pneumonia.⁷² The bacterial

causes are relatively constant, even across geographic areas and patient populations. Unfortunately, pathogen resistance to standard antimicrobials is increasing (e.g., penicillin-resistant pneumococci), necessitating careful attention by the clinician to local and regional bacterial susceptibility patterns.⁷³ Thus, whenever possible, initial therapy should be based on presumed antibacterial susceptibility and consist of older, less-expensive agents, with newer and more

TABLE 111-11 Antibiotic Doses for Treatment of Bacterial Pneumonia

Antibiotic Class	Antibiotic	Daily Antibiotic Dose	
		Pediatric (mg/kg/day)	Adult (total dose/day)
Macrolide	Clarithromycin	15	0.5–1 g
	Erythromycin	30–50	1–2 g
Azalide	Azithromycin	10 mg/kg × 1 day, then 5 mg/kg/day × 4 days	500 mg day 1, then 250 mg/day × 4 days
Tetracycline ^a	Tetracycline HCl	25–50	1–2 g
		Oxytetracycline	15–25
Penicillin	Ampicillin	100–200	2–6 g
		Amoxicillin/ amoxicillin-clavulanate ^b	40–90
	Piperacillin-tazobactam	200–300	12 g
		Ampicillin-sulbactam	100–200
Extended-spectrum cephalosporins	Ceftriaxone	50–75	1–2 g
		Ceftazidime	150
Fluoroquinolones	Gatifloxacin ^c	10–20	0.4 g
		Levofloxacin	10–15
Aminoglycosides	Ciprofloxacin	20–30	0.5–1.5 g
		Gentamicin	7.5
	Tobramycin	7.5	3–6 mg/kg

Doses can be increased for more severe disease and may require modification in patients with organ dysfunction.

^aTetracyclines are rarely used in pediatric patients, particularly in those younger than 8 years because of tetracycline-induced permanent tooth discoloration.

^bHigher-dose amoxicillin, amoxicillin-clavulanate (e.g., 90 mg/kg/day) is used for penicillin-resistant *S. pneumoniae*.

^cFluoroquinolones are avoided in pediatric patients because of the potential for cartilage damage; however, their use in pediatrics is emerging. Doses shown are extrapolated from adults and require further study.

TABLE 111-10 Empirical Antimicrobial Therapy for Pneumonia in Pediatric Patients^a

Age	Usual Pathogen(s)	Presumptive Therapy
1 month	Group B streptococcus, <i>Haemophilus influenzae</i> (nontypeable), <i>Escherichia coli</i> , <i>Staphylococcus aureus</i> , <i>Listeria</i> , CMV, RSV, adenovirus	Ampicillin-sulbactam, cephalosporin ^b carbapenem ^c Ribavirin for RSV
1–3 months	<i>Chlamydia</i> , possibly <i>Ureaplasma</i> , CMV, <i>Pneumocystis carinii</i> (atypical pneumonia syndrome) RSV Pneumococcus, <i>S. aureus</i>	Macrolide/azalide, ^d trimethoprim-sulfamethoxazole Ribavirin Semisynthetic penicillin ^e or cephalosporin ^f
3 months–6 years	Pneumococcus, <i>H. influenzae</i> , RSV, adenovirus, parainfluenza	Amoxicillin or cephalosporin ^f Ampicillin-sulbactam, amoxicillin-clavulanate Ribavirin for RSV
>6 years	Pneumococcus, <i>Mycoplasma pneumoniae</i> , adenovirus	Macrolide/azalide ^d cephalosporin, ^f amoxicillin-clavulanate

CMV, cytomegalovirus; RSV, respiratory syncytial virus.

^aSee section on treatment of bacterial pneumonia.^bThird-generation cephalosporin: ceftriaxone, cefotaxime, cefepime. Note that cephalosporins are not active against *Listeria*.^cCarbapenem: imipenem-cilastatin, meropenem.^dMacrolide/azalide: erythromycin, clarithromycin/azithromycin.^eSemisynthetic penicillin: nafcillin, oxacillin.^fSecond-generation cephalosporin: cefuroxime, cefprozil.

See text for details regarding ribavirin treatment for RSV infection.

TABLE 111-12 Evidence-Based Guidelines for Management of Community-Acquired Pneumonia in Immunocompetent Adults

Recommendation	Recommendation Grade ^a
Preferred parenteral agents for treatment of pneumococcal pneumonia for strains with reduced susceptibility to penicillin are cefotaxime or ceftriaxone.	B-III
For susceptible strains, amoxicillin is the preferred antibiotic for oral treatment of pneumococcal pneumonia.	B-II
Recommended initial therapy for a hospitalized patient consists of a β -lactam plus macrolide combination or a respiratory fluoroquinolone alone.	A-I
For an intensive care patient and in the absence of a <i>Pseudomonas</i> infection, a combination of a β -lactam plus either a macrolide or a respiratory fluoroquinolone should be prescribed.	B-III
For an intensive care patient and in the presence of a penicillin-resistant isolate, cefotaxime, ceftriaxone, or a respiratory fluoroquinolone or other agent indicated by in-vitro testing may be prescribed.	A-III
For hospitalized patients, the preferred treatment for Legionnaires' disease is azithromycin or a fluoroquinolone.	B-II
For nonhospitalized patients, Legionnaires' disease may be treated with erythromycin, doxycycline, azithromycin, clarithromycin, or a fluoroquinolone.	A-II
Amantadine, rimantadine, oseltamivir, or zanamivir is effective for early (within 48 hours of appearance of symptoms) treatment of influenza A and oseltamivir and zanamivir for influenza B.	B-I

^aQuality of evidence: I, evidence from at least one properly randomized, controlled trial; II, evidence from at least one well-designed clinical trial without randomization, from cohort or case-controlled analytic studies (preferably from more than one center), or from multiple time-series studies or dramatic results from uncontrolled experiments; III, evidence from opinions of respected authorities based on clinical experience, descriptive studies, or reports of expert committees. Strength of recommendation: A, good evidence to support a recommendation for use; B, moderate evidence to support a recommendation for use.

expensive antibiotics reserved for unresponsive illness or special circumstances. Indiscriminate use of recently introduced agents increases healthcare costs and, in some instances (e.g., widespread use of fluoroquinolones), induces resistance among a significant percentage of community-acquired organisms.^{74,75} It must be emphasized, however, that the rapidly evolving epidemiology of bacterial resistance, including the increasing emergence of penicillin-resistant pneumococcus in many areas of the United States and Europe,⁷⁶ forces the clinician to be vigilant and knowledgeable about antibiotic sensitivity patterns in each community. Indiscriminate use of antimicrobials for treatment of pneumonia has contributed to the problem of antimicrobial resistance, underscoring the need for defining the optimal antibiotic regimen for each patient.⁷⁴

9 Evidence-based empirical therapy differs among outpatients, hospitalized patients, and hospitalized patients admitted to an intensive care unit (Table 111-13).^{72,77,78} Antimicrobial therapy should be initiated in hospitalized patients with acute pneumonia within 8 hours of admission because an increase in mortality has been demonstrated when therapy was delayed beyond 8 hours of admission.

Nosocomial Pneumonia

10 Antibiotic selection within the hospital environment demands greater care because of constant changes in antibiotic resistance patterns in-vitro and in-vivo. Ironically, some β -lactam antibiotics, which were developed to treat multiple-antibiotic-resistant hospital-acquired organisms, can themselves induce broad-spectrum bacterial β -lactamases and thereby lead to even greater problems with resistance.⁷⁹ These facts underscore the importance of regularly documenting the epidemiology of pathogens and infectious diseases within a specific

TABLE 111-13 Initial Evidence-Based Empirical Therapy for Suspected Bacterial Community-Acquired Pneumonia

Clinical Setting	Empirical Therapy
Outpatient	
Previously healthy	A macrolide ^a or doxycycline
No recent antibiotic therapy	A respiratory fluoroquinolone ^c alone, an advanced macrolide ^d plus high-dose amoxicillin, or an advanced macrolide plus high-dose amoxicillin-clavulanate
Recent antibiotic therapy ^b	
Comorbidities (chronic obstructive pulmonary disease, diabetes, renal or congestive heart failure, malignancy)	
No recent antibiotic therapy	An advanced macrolide ^d or a respiratory fluoroquinolone
Recent antibiotic therapy ^b	A respiratory fluoroquinolone ^c alone or an advanced macrolide plus a β -lactam ^e
Suspected aspiration with infection	Amoxicillin-clavulanate or clindamycin
Influenza with bacterial superinfection	A β -lactam ^e or a respiratory fluoroquinolone
Inpatient	
Medical ward	
No recent antibiotic therapy ^b	A respiratory fluoroquinolone alone or an advanced macrolide plus a β -lactam ^f
Recent antibiotic therapy ^b	An advanced macrolide plus a β -lactam or a respiratory fluoroquinolone alone (regimen selected will depend on nature of recent antibiotic therapy)
Intensive Care Unit (ICU)	
<i>Pseudomonas</i> infection is not an issue	A β -lactam ^f plus either an advanced macrolide or a respiratory fluoroquinolone
<i>Pseudomonas</i> infection is not an issue but patient has a β -lactam allergy	A respiratory fluoroquinolone, with or without clindamycin
<i>Pseudomonas</i> infection is an issue ^g	Either (a) an antipseudomonal agent ^h plus ciprofloxacin, or (b) an antipseudomonal agent plus an aminoglycoside plus a respiratory fluoroquinolone or a macrolide
<i>Pseudomonas</i> infection is an issue but the patient has a β -lactam allergy	Either (a) aztreonam plus levofloxacin or (b) aztreonam plus moxifloxacin or gatifloxacin, with or without an aminoglycoside

^aErythromycin, azithromycin, or clarithromycin.

^bThe patient was given a course of antibiotic(s) for treatment of any infection within the past 3 months, excluding the current episode of infection. Such treatment is a risk factor for drug-resistant *Streptococcus pneumoniae* and possibly for infection with gram-negative bacilli. Depending on the class of antibiotics recently given, one or another of the suggested options may be selected. Recent use of a fluoroquinolone should dictate selection of a nonfluoroquinolone regimen, and vice versa.

^cMoxifloxacin, gatifloxacin, levofloxacin, or gemifloxacin (oral).

^dAzithromycin or clarithromycin.

^eHigh-dose amoxicillin, high-dose amoxicillin-clavulanate, cefpodoxime, cefprozil, or cefuroxime.

^fCefotaxime, ceftriaxone, ampicillin-sulbactam, or ertapenem; ertapenem was recently approved for such use (in once-daily parenteral treatment) but little experience is available.

^gThe antipseudomonal agents chosen reflect this concern. Risk factors for *Pseudomonas* infection include severe structural lung disease (e.g., bronchiectasis), and recent antibiotic therapy or stay in hospital (especially in the ICU). For patients with CAP in the ICU, coverage for *S. pneumoniae* and *Legionella* species must always be assured. Piperacillin-tazobactam, imipenem, meropenem, and cefepime are excellent β -lactams and are adequate for most *S. pneumoniae* and *Haemophilus influenzae* infections. They may be preferred when there is concern for relatively unusual CAP pathogens, such as *Pseudomonas aeruginosa*, *Klebsiella* species, and other gram-negative bacteria.

^hPiperacillin, piperacillin-tazobactam, imipenem, meropenem, or cefepime.

Data from Mandell LA, Wunderink RG, Anzueto A, et al. Infectious Diseases Society of America/American Thoracic Society consensus guidelines on the management of community-acquired pneumonia in adults. *Clin Infect Dis* 2007;44:S27-S72.

practice or institution. As a result, an antimicrobial agent for a specific infectious disease favored in one practice site may not be the most desirable selection in another site despite similarities in size and patient profile. Strict and careful control and, possibly, rotation of empirical antibiotics in the hospital environment may help to limit the emergence of resistant organisms. Newer antibiotics developed for treatment of

resistant, hospital-acquired pathogens are costly, so their use must be moderated to some extent in an era where capitated hospital costs and mandated budget cuts will not tolerate careless antibiotic use.

Severe Acute Respiratory Syndrome

Treatment of SARS involves primarily supportive care and procedures to prevent transmission to others.⁶⁸ Owing to the uncertainty associated with the diagnosis of SARS, empirical therapy with broad-spectrum antibiotics should be used. To date, fluoroquinolones (e.g., moxifloxacin, levofloxacin) or macrolides/azalides (e.g., erythromycin, clarithromycin, azithromycin) typically have been used. Although its efficacy is unproven, ribavirin also has been used to treat patients. Owing to the potential benefit of corticosteroids in the presence of progressive pulmonary disease, methylprednisolone has been used in doses ranging from 80 to 500 mg/day.

Avian Influenza

Treatment of avian influenza is primarily supportive, with the majority of patients requiring aggressive oxygen therapy and intensive care monitoring.^{69,70} Due to observed resistance with amantadine, the neuraminidase inhibitors are the recommended treatment of avian influenza, with oseltamivir being the preferred agent. For optimal efficacy, treatment should be initiated within 48 hours of the first sign of infection. Of note, there is concern regarding oseltamivir, with a resistant A/H5N1 isolate identified in Vietnam.⁷⁰

FLUOROQUINOLONE ANTIBIOTICS

The in-vitro spectrum of antibacterial activity of systemically absorbed fluoroquinolone antibiotics (e.g., ciprofloxacin, levofloxacin, moxifloxacin, gatifloxacin) suggests that these drugs have an important role in the treatment of bacterial infections of the lower respiratory tract. Numerous clinical studies describe the efficacy of these drugs for treatment of purulent bronchitis, acute exacerbations of chronic bronchitis, pneumonia, and cystic fibrosis.⁸⁰ However, the widespread use of earlier analogs (ciprofloxacin) by primary care physicians has led to pathogen resistance and treatment failures, including, perhaps most important, isolates of *S. pneumoniae*. Although newer fluoroquinolones are more active than older agents against common respiratory tract pathogens, this experience renders difficult the recommendation of their indiscriminate use for routine community-acquired pneumonia. Nevertheless, these drugs may be effective alternative agents for treatment of community-acquired pneumonia or for the initial treatment of nosocomial pneumonia in hospitalized patients and patients residing in extended-care facilities. The availability of newer analogs with broad spectra of antibacterial activity, including *S. pneumoniae* (e.g., gatifloxacin), further enhances the desirability of a fluoroquinolone as a first-line agent, expanding the therapeutic armamentarium for both community-acquired and nosocomially acquired pneumonia.

At present, fluoroquinolone use in pediatric patients remains restricted and limited because of possible fluoroquinolone-induced destructive lesions of growing cartilage, primarily of the weight-bearing joints. These fluoroquinolone-associated arthritic lesions were determined in animals following large doses but have not been reflected in the human experience. The need for fluoroquinolones for treatment of selected infections arising in pediatric patients continues, and their continued safety in these patients has served as the foundation for ongoing controlled clinical efficacy and safety trials in pediatric patients.

MACROLIDE/AZALIDE ANTIBIOTICS

Among the more recently introduced classes of oral antibiotics, the newer macrolide/azalide antibiotics (clarithromycin–azithromycin)

possess excellent activity against most *S. pneumoniae* and *Mycoplasma* organisms. They appear to offer viable alternatives to erythromycin, particularly in patients who are intolerant of erythromycin analogs (e.g., patients with gastrointestinal upset) and, with azithromycin, in patients who are taking medications that may result in a clinically significant drug–drug interaction (e.g., erythromycin with carbamazepine or theophylline). Azithromycin offers the added advantage of once-daily dosing and short-course therapy because of the drug’s extensive tissue distribution characteristics and prolonged elimination half-life.

PREVENTION

Prevention of some cases of pneumonia is possible through the use of vaccines and medications against selected infectious agents. Polyvalent polysaccharide vaccines are available for two of the leading causes of bacterial pneumonia, pneumococcus and *H. influenzae* type b. In addition, evidence-based guidelines for preventing health-care-associated pneumonia have been published (Table 111–14)⁸¹ (see Chap. 114 for a full discussion of prevention of influenza and Chap. 128).

EVALUATION OF THERAPEUTIC OUTCOMES

After therapy has been instituted, appropriate clinical parameters should be monitored to ensure the efficacy and safety of the therapeutic regimen. In patients with bacterial infections of the upper or lower respiratory tract, the time to resolution of initial presenting symptoms and the lack of appearance of new associated symptomatology are important to determine. In patients with community-acquired pneumonia or pneumonia from any source of mild-to-moderate clinical severity, the time to resolution of cough, decreasing sputum production, and fever, as well as other constitutional symptoms of malaise, nausea, vomiting, and lethargy, should be noted. If the patient requires supplemental oxygen therapy, the amount and need should be assessed regularly. A gradual and persistent improvement in the resolution of these symptoms and

TABLE 111-14 Evidenced-Based Guidelines for Preventing Health-Care Associated Pneumonia

Recommendation	Recommendation Grade ^a
For nebulizers, use aerosolized medications in single-dose vials. If multidose medication vials are used, follow manufacturers’ instructions for handling, storing, and dispensing the medications.	1B
Pneumococcal vaccination is recommended for patients at high risk for severe pneumococcal infections.	1A
Unless contraindicated, administer a macrolide to any person who has had close contact with persons having pertussis.	1B
In acute-care settings, offer vaccine to inpatients and outpatients at high risk for complications from influenza beginning in September and throughout the influenza season.	1A
Unless contraindicated, provide prophylactic treatment to all patients without influenza illness in the involved unit with amantadine, rimantadine, or oseltamivir for a minimum of 2 weeks or until approximately 1 week after the end of the outbreak.	1A
Unless contraindicated, patients with influenza should receive amantadine, rimantadine, oseltamivir, or zanamivir within 48 hours of the onset of symptoms.	1A

^aCategory 1A, strongly recommended for implementation and strongly supported by well-designed experimental, clinical, or epidemiologic studies; category 1B, strongly recommended for implementation and supported by certain clinical or epidemiologic studies and by strong theoretical rationale.

therapies should be observed. Initial resolution should be observed within the first 2 days and progression to complete resolution within 5 to 7 days but usually no more than 10 days. In patients with nosocomial pneumonia, substantial underlying diseases, or both, additional parameters can be followed, including the magnitude and character of the peripheral blood WBC count, chest radiograph, and blood gas determinations. Similar to patients with less severe disease, some resolution of symptoms should be observed within 2 days of instituting antibiotic therapy. If no resolution of symptoms is observed within 2 days of starting seemingly appropriate antibiotic therapy or if the patient's clinical status is deteriorating, the appropriateness of initial antibiotic therapy should be critically reassessed. The patient should be evaluated carefully for deterioration of underlying concurrent disease(s). Additionally, the caregiver should consider the possibility of changing the initial antibiotic therapy to expand antimicrobial coverage not included in the original regimen (e.g., *Mycoplasma*, *Legionella*, and anaerobes). Furthermore, the need for antifungal therapy (amphotericin B) should be considered. Some resolution of symptoms should be observed within 2 days of starting proper antibiotic therapy, with complete resolution expected within 10 to 14 days.

YASMIN KHALIQ, SARAH FORGIE, AND GEORGE ZHANEL

KEY CONCEPTS

- 1 Most nonspecific upper respiratory tract infections have a viral, not bacterial, etiology and tend to resolve spontaneously.
- 2 Each time antibiotics are administered for an upper respiratory tract infection, the recipient is at increased risk of selection and carriage of resistant organisms that can be passed to others. This can lead to future antibiotic failure.
- 3 Amoxicillin is the drug of choice for acute otitis media. High-dose amoxicillin (80 to 90 mg/kg/day) is recommended as it is not always known if the patient is at high risk for a penicillin-resistant pneumococcal infection.
- 4 Vaccination against influenza and pneumococcus may decrease the risk of acute otitis media, especially in those with recurrent episodes.
- 5 Viral and bacterial sinusitis are difficult to differentiate because their clinical presentations are similar. Viral infections, however, tend to resolve by 7 to 10 days. Persistence of symptoms beyond this time or worsening of symptoms likely indicates a bacterial infection.
- 6 Amoxicillin is first-line treatment for acute bacterial sinusitis. As there is no difference in clinical outcome among antibiotics, the advantages of amoxicillin include proven efficacy and safety, a relatively narrow antibacterial spectrum that minimizes emergence of resistance, good tolerability, and low cost.
- 7 Viruses cause the majority of acute pharyngitis cases. Of all the bacterial causes, group A β -hemolytic *Streptococcus* (*S. pyogenes*) is the most common and it is the only commonly occurring form of acute pharyngitis for which antimicrobial therapy is indicated.
- 8 Antimicrobial treatment of pharyngitis should be limited to those who have clinical and epidemiologic features of group A streptococcal pharyngitis with a positive laboratory test. Penicillin is the drug of choice; amoxicillin can be used for children because of its better taste.

Upper respiratory tract infections include otitis media, sinusitis, pharyngitis, laryngitis (croup), rhinitis, and epiglottitis. These infections are responsible for the majority of antibiotics prescribed in

ambulatory practice and the cost is significant.¹ In 1998, for example, the estimated cost of otitis media was \$3 to \$4 billion in the United States, and \$600 million in Canada.²

1 Most nonspecific upper respiratory tract infections have a viral, not bacterial, etiology and tend to resolve spontaneously.^{3,4} Strategies for limiting unnecessary antibiotic use have been developed^{1,3,5} in an effort to address the problem of increased bacterial resistance that is associated with antibiotic use. This is particularly important for *Streptococcus pneumoniae*, the leading bacterial cause of meningitis, pneumonia, otitis media, and sinusitis.¹ In Canada, an average of 15 deaths per year caused by *S. pneumoniae* are reported in children younger than 5 years of age.⁶

This chapter focuses primarily on otitis media, sinusitis, and pharyngitis because these infectious entities are frequently bacterial in origin, and appropriate antibiotic treatment can minimize morbidity and potentially prevent complications.

OTITIS MEDIA

Otitis media is an inflammation of the middle ear. The diagnosis of acute otitis media includes signs and symptoms of infection of the middle ear, such as otalgia, fever, and irritability, as well as the presence of fluid in the middle ear.^{7–11} In otitis media with effusion, middle ear fluid is present, but signs and symptoms of infection are absent. Otitis media is most common in infants and children, 75% of whom have had at least one episode by the age of 1 year.¹² Table 112–1 lists the risk factors for otitis media. Risk factors for bacterial otitis media caused by resistant pathogens include (a) day-care attendance, (b) recent antibiotic exposure, (c) age younger than 2 years, and (d) frequent bouts of otitis media.¹³

PATHOPHYSIOLOGY

Acute bacterial otitis media usually follows a viral upper respiratory tract infection that causes eustachian tube dysfunction and mucosal swelling in the middle ear.^{12,13} Bacteria that colonize the nasopharynx thus enter the middle ear and are not cleared properly by the mucociliary system.⁷ In the presence of effusion, the bacteria proliferate and cause infection.^{7,13} Children tend to be more susceptible to otitis media than adults because the anatomy of their eustachian tube is shorter and more horizontal, facilitating bacterial entry into the middle ear.¹³

MICROBIOLOGY

S. pneumoniae is the most common bacterial cause of acute otitis media, with an incidence of 20% to 35%.^{6,8,14} Nontypeable *Haemophilus influenzae* and *Moraxella catarrhalis* are each responsible for 20% to 30% and 20% of cases, respectively. Bacterial organisms that have been associated less frequently with otitis media include *Staphy-*

lococcus aureus, *Streptococcus pyogenes*, and gram-negative bacilli such as *Pseudomonas aeruginosa*.¹³ In 20% to 30% of cases, no bacterial pathogen is found, and in up to 44%, a viral etiology is found with or without concomitant bacteria.⁷

Bacterial Resistance

Bacterial resistance to antimicrobial therapy for acute otitis media is of growing concern, particularly in view of the increasing levels of drug-resistant *S. pneumoniae*. Data from the United States (1999–2000) indicate that 8.3% to 34.2% of all *S. pneumoniae* isolates are penicillin-nonsusceptible (minimum inhibitory concentration [MIC] = 0.12 to 1 mcg/mL), that 12.2% to 21.5% are highly penicillin-resistant (MIC ≥2 mcg/mL), and that these rates are highly variable depending on the region of the country.^{15,16} International data collected from Europe, Latin America, and North America between 1999 and 2003 indicate penicillin nonsusceptibility rates of 28.6, 28.7, and 33%, respectively. High-level resistance was reported as 14.7, 12.7, and 15.9% respectively.¹⁷ Canadian data from isolates collected between 1997 and 2005 indicate that 16.1% to 25.3% of *S. pneumoniae* isolates are penicillin-nonsusceptible.¹⁷ High-level penicillin resistance fluctuated between 2.3% and 9.7% over this time period, with a rate of 7.4% in 2006. Macrolide and fluoroquinolone resistance have been steadily increasing over 1997 to 2006, from 7.5% to 17.2%, and 0.6% to 7.3%, respectively.¹⁸ Multidrug resistance in the United States is reported as 12.2% to 22.4% of *S. pneumoniae* isolates.^{15,16} Multidrug resistance is defined as concomitant resistance to at least three different antibiotic classes. Therefore, antibiotic resistance rates with other β-lactams (penicillins other than penicillin, as well as cephalosporins), macrolides (azithromycin and clarithromycin), clindamycin, trimethoprim-sulfamethoxazole, tetracyclines, and fluoroquinolones also must be considered. In otitis media, non-β-lactam antibiotic treatment is mostly considered when penicillin-allergic patients are treated or when treatment failure occurs.

S. pneumoniae resistance to amoxicillin with clavulanate is reported to range from 0.3% to 1% in Canada, and up to 14% in the United States.^{16,17} The second-generation cephalosporins that have been found most active are cefuroxime and cefprozil, followed by cefixime and cefaclor, with resistance rates of 6% to 12% in Canada and approximately 25% to 30% in the United States.^{15,16,18} The approximate rates of resistance for individual agents are clarithromycin (8% to 26%), trimethoprim-sulfamethoxazole (16% to 30%), doxycycline (3% to 8%), and levofloxacin (0.5% to 2.5%).^{16,17}

β-Lactamase-producing *H. influenzae* and *M. catarrhalis* are found in 23% to 35% and up to 100% of infected patients, respectively.^{16,19,20} Susceptibilities, however, vary by geographic region. Although these organisms tend to cause infection that is more likely to resolve spontaneously as compared with *S. pneumoniae*, they are still pathogens that must be accounted for, particularly in treatment failures.

TABLE 112-2 Clinical Presentation of Acute Bacterial Otitis Media

General
The acute onset of signs and symptoms of middle ear infection following cold symptoms of runny nose, nasal congestion, or cough
Signs and symptoms
Pain that can be severe (more than 75% of patients)
Children may be irritable, tug on the involved ear, and have difficulty sleeping
Fever is present in less than 25% of patients and, when present, occurs more often in younger children
Examination shows a discolored (gray), thickened, bulging eardrum
Pneumatic otoscopy or tympanometry demonstrates an immobile eardrum; 50% of cases are bilateral
Draining middle ear fluid occurs (less than 3% of patients) that usually reveals a bacterial etiology
Laboratory tests
Gram stain, culture, and sensitivities of draining fluid or aspirated fluid if tympanocentesis is performed

Data from Hendley JO: Otitis media. *N Engl J Med* 2002; 347:1169–1174.

2 Each time antibiotics are administered for an upper respiratory tract infection, the recipient is at increased risk of selection and carriage of resistant organisms that can be passed to others. This can lead to future antibiotic failure. Without antibiotic therapy, however, acute otitis media secondary to *S. pneumoniae* is less likely to resolve spontaneously than that from other causes. *S. pneumoniae* is increasingly resistant to penicillin, and penicillin-resistant *S. pneumoniae* is more likely to be resistant to multiple antibiotics.^{14,15,18}

CLINICAL PRESENTATION AND DIAGNOSIS

Acute otitis media presents as an acute onset of symptoms such as fever, otalgia, irritability, and tugging on the ear, accompanied by signs such as a gray, bulging, nonmotile tympanic membrane. Bacterial otitis media often follows a viral upper respiratory tract infection, and the child will experience symptoms of runny nose, nasal congestion, or cough (Table 112–2).

Resolution of the symptoms of acute otitis media occurs over 1 week. Pain and fever tend to resolve after 2 to 3 days, with most children becoming asymptomatic at 7 days. Over a period of 1 week, changes in the eardrum normalize, and the pus becomes serous fluid. Air–fluid levels are apparent behind the eardrum, at which point the stage is now referred to as *otitis media with effusion*. This does not represent ongoing infection, nor are additional antibiotics required.¹² Otitis media with effusion also can occur de novo and is thought to be a result of respiratory viruses. The diagnosis of acute otitis media and otitis media with effusion are easily confused, and careful attention to history, signs, and symptoms as well as results from pneumatic otoscopy are important. Otitis media with effusion usually occurs in spring or autumn, not winter, and may be a result of allergens or viruses common at these times. It also differs from acute otitis media in that pain is not present, nor a bulging eardrum. Effusions resolve slowly. At 3 months, 90% have disappeared.^{10,12} Younger children and those with a history of recurrent infections have a further delay in resolution.^{7,12} Complications of otitis media are infrequent but include mastoiditis, bacteremia, meningitis, and auditory sequelae with potential for speech and language impairment.^{21,22}

TREATMENT

Acute Otitis Media

■ DESIRED OUTCOME

The goals of treatment of acute otitis media are the reduction in signs and symptoms, eradication of the infection, and prevention of com-

cephalosporins do not achieve adequate middle ear fluid concentrations against drug-resistant *S. pneumoniae* for the desired duration over the dosing interval. Use of trimethoprim-sulfamethoxazole and erythromycin-sulfisoxazole are discouraged because of high rates of resistance.^{9,11} Intramuscular ceftriaxone is the only agent other than amoxicillin that achieves middle ear fluid concentrations above the MIC for more than 40% of the dosing interval.²⁰ Although single doses have been used, daily doses for 3 days are recommended to optimize clinical outcomes.^{11,13,14} Ceftriaxone should be reserved for severe and unresponsive infections or for patients in whom oral medication is inappropriate because of vomiting, diarrhea, or possible nonadherence. Ceftriaxone is an expensive agent, and the intramuscular injections are painful. The drug can be given intravenously, but the risk-to-benefit ratio of starting an intravenous line must also be examined. Tympanocentesis also can be considered for treatment failure or persistent acute otitis media. It has a therapeutic effect of relieving pain and pressure and can be used to collect fluid to identify the causative agent. This procedure, however, is not frequently performed in practice in Canada.¹³ Clindamycin may also be considered at this point for coverage of documented penicillin-resistant *S. pneumoniae*.^{9,11,14} Patients with penicillin allergy can be treated with several alternative antibiotics. If the reaction is not type I hypersensitivity, cefdinir, cefpodoxime, or cefuroxime can be used.¹¹ If the reaction is type I, a macrolide such as azithromycin or clarithromycin may be used. If *S. pneumoniae* is documented, clindamycin is an alternative. However, the incidence of resistance is much higher with these agents,^{9,13} and of these agents, only clindamycin is recommended by the Centers for Disease Control and Prevention (CDC) and American Academy of Pediatrics guidelines.^{11,14} Table 112-4 lists evidence-based principles guiding management of otitis media.

Short Courses of Therapy

A meta-analysis of 32 trials³² reported no difference in effect (cure rates) after short (<7 days) and usual durations (≥7 days) of antibiotic therapy in children. The advantages of short-term therapy are an increased likelihood the patient will adhere to the full course of treatment, decreased side effects and cost, and decreased bacterial-selective pressure for both the individual and the community. How-

ever, the data has limitations, including inadequate study sample sizes, lack of use of standardized diagnostic criteria, and subtherapeutic doses. Short treatment courses in children younger than 2 years of age are not recommended.³³ In children at least 6 years old who have mild to moderate acute otitis media, a 5- to 7-day course may be used.¹¹

CLINICAL CONTROVERSY

Some guidelines suggest that children between 2 and 5 years of age should not receive short-course therapy for acute otitis media. Others suggest there is adequate data unless it is a case of recurrent otitis media or the otitis media is accompanied by a perforated tympanic membrane.^{9,11}

EVALUATION OF THERAPEUTIC OUTCOMES

Treatment failure is a lack of clinical improvement after 3 days in the signs and symptoms of infection, including pain, fever, and redness/bulging of the tympanic membrane. Early reevaluation of the eardrum when signs and symptoms are improving can be misleading because effusions persist. Immediate reevaluation is appropriate if hearing loss results from persistent middle ear effusions following infection.¹⁰

Antibiotic Prophylaxis of Recurrent Infections

Recurrent otitis media is defined as at least three episodes in 6 months or at least four episodes in 12 months. Recurrent infections are of concern because patients younger than 3 years of age are at high risk for hearing loss and language and learning disabilities.²¹ Data from studies generally do not favor prophylaxis. A meta-analysis demonstrated that prophylaxis prevents one infection each time one child is treated for 9 months.³⁵ Of further concern is antibiotic resistance. Treatment can be delayed until the onset of symptoms of an upper respiratory tract infection (viral symptoms), or antibiotic prophylaxis can be limited to 6 months duration during the winter months. T-tube placement, adenoidectomy, and tonsillectomy may be of value in children with recurrent treatment failure.

Vaccination

④ Vaccination against influenza and pneumococcus may decrease the risk of acute otitis media, especially in individuals with recurrent episodes. Immunization with the influenza vaccine is associated with up to a 36% reduction in the incidence of acute otitis media infection.³⁶ Others have described a benefit during the influenza season.^{12,37} The influenza vaccine can be administered to any healthy person without contraindications, especially individuals with chronic disease who are at least 6 months of age.^{6,14,25}

A conjugate pneumococcal vaccine that is indicated in infants and children provides a 6% reduction in the frequency of acute otitis media and a 20% reduction in the need for placement of T tubes.³⁸ Also, vaccine use has demonstrated an 8% decrease in office visits, as well as a 10% to 26% decrease in otitis media episodes in children who experienced 3 to 10 infections per year.³⁹ Pneumococcal conjugate vaccine is recommended for all children ages 2 to 23 months; it is also recommended for those 24 to 59 months of age who are at high risk of invasive disease.^{6,40} Previously unvaccinated children who are older than 1 year of age and who have had recurrent otitis media infections do not benefit from later vaccination.⁴¹

TABLE 112-4 Evidence-Based Principles for the Treatment of Acute Otitis Media

Recommendations	Rating
Properly diagnosed acute otitis media should be treated with antibiotics.	AI
Delayed therapy (observation) may be an option in nonsevere cases.	BI
Antimicrobial resistance should be considered before choosing an antibiotic.	AII-1
High-dose amoxicillin (80–90 mg/kg/day) is first line for uncomplicated infection.	AI-II-2
Short-course therapy may be considered in some instances.	AI
Ten-day courses are recommended for children older than age 2 years and in recurrent otitis media, or otitis media with perforated tympanic membrane.	AI-AIII
When episodes of acute otitis media are frequent, preventive measures are recommended, including handwashing, and limiting exposure to daycare, pacifiers, and second-hand smoke.	BII-III
Influenza vaccine is recommended in children with chronic medical conditions.	AII
Pneumococcal conjugate vaccine is recommended for children ages 2 months to 2 years, and in those with high-risk conditions and older than age 2.	AI

Rating system:

Strength: A, good evidence; B, fair evidence; C, conflicting evidence; D, evidence against; I, insufficient evidence.

Level of evidence: I, randomized controlled trials; II-1, controlled trials not randomized; II-2, cohort or case control studies; II-3, dramatic results from uncontrolled experiments; III, expert opinion.

From Forgie et al.⁹

SINUSITIS

Sinusitis is an inflammation and/or infection of the paranasal sinus mucosa.^{42–44} The term *rhinosinusitis* is used by some specialists because

sinusitis typically also involves the nasal mucosa.^{42,44} Even though the majority of these infections are viral in origin, antimicrobials are prescribed frequently. It is thus important to differentiate between viral and bacterial sinusitis to aid in optimizing treatment decisions.

5 Viral sinusitis and bacterial sinusitis are difficult to differentiate because their clinical presentations are similar. Viral infections, however, tend to resolve by 7 to 10 days. Persistence of symptoms beyond this time or worsening of symptoms likely indicates a bacterial infection.⁴³ Acute bacterial sinusitis lasts less than 30 days with complete resolution of symptoms, whereas chronic sinusitis is defined as episodes of inflammation lasting more than 3 months with persistence of respiratory symptoms.^{42,47}

Bacterial sinusitis is overdiagnosed by family physicians and thus antibiotics are overprescribed.^{42,46} No one clinical finding can accurately diagnose this disease as compared to the gold standard, sinus aspiration ($>10^5$ organisms/mL).⁴² Table 112–5 illustrates the signs and symptoms that best predict a diagnosis of bacterial sinusitis. Between 5% and 13% of viral upper respiratory tract infections in children are complicated by bacterial sinusitis, whereas only 0.5% to 2% of viral upper respiratory tract infections in adults are complicated by sinusitis.^{42–44,47} Other factors that can be associated with sinus disease include allergic inflammation, systemic diseases, trauma, environmental exposures, and anatomic abnormalities.^{44,46,47} Complications include osteitis, orbital cellulitis, meningitis, and brain abscess, but are extremely rare.⁴³

PATHOPHYSIOLOGY

Similar to acute otitis media, acute bacterial sinusitis usually is preceded by a viral respiratory tract infection that causes mucosal inflammation.^{42,43,47} This can lead to obstruction of the sinus ostia—the pathways that drain the sinuses. Mucosal secretions become trapped, local defenses are impaired, and bacteria from adjacent surfaces begin to proliferate. The pathogenesis of chronic sinusitis has not been well studied. Whether it is caused by more persistent pathogens or there is a subtle defect in the host's immune function, some patients develop chronic symptoms after their acute infection.^{44,48,49}

MICROBIOLOGY

Viruses are responsible for most cases of acute sinusitis; however, when symptoms are persistent (≥ 7 days) or severe, bacteria may be a primary cause or the cause of secondary infection.⁴² Acute sinusi-

tis that is bacterial in origin is caused most often by the same bacteria implicated in acute otitis media: *S. pneumoniae* and *H. influenzae*.^{1,44,45,50} These organisms are responsible for approximately 70% of bacterial causes of acute sinusitis in both adults and children.⁴⁵ *M. catarrhalis* is also frequently implicated in children (approximately 25%).^{45,47} *S. pyogenes*, *S. aureus*, fungi, and anaerobes are associated less frequently with acute sinusitis.^{42,45} Issues of bacterial resistance are similar to those found with otitis media and are further addressed in that section of this chapter.

TREATMENT

Sinusitis

■ DESIRED OUTCOME

The goals of treatment of acute sinusitis are the reduction in signs and symptoms, achieving and maintaining patency of the ostia, limiting antimicrobial treatment to those who may benefit, eradicating bacterial infection with appropriate antimicrobial therapy, minimizing the duration of illness, preventing complications, and preventing progression from acute disease to chronic disease.^{45,47,48}

■ GENERAL APPROACH TO TREATMENT

Approximately 65% of patients with acute sinusitis will recover spontaneously (these are likely patients with viral sinusitis).^{44,45} When the decision to treat with antimicrobials thus is made, the choice must be effective and safe, and cost must be considered. Tables 112–6 and 112–7 provide the evidence-based principles for acute bacterial sinusitis in children and adults.

CLINICAL CONTROVERSY

Is antimicrobial treatment warranted in bacterial sinusitis? Because most studies have not used sinus aspiration to diagnose bacterial sinusitis, it is likely that patients with viral infections have diluted the results of studies of antimicrobial therapy. It is recommended that patients with mild acute sinusitis be given decongestants and reassurance, whereas those with moderate disease for 7 days or more, and those with severe disease, be given antimicrobial therapy.

■ PHARMACOLOGIC THERAPY

Data regarding supportive therapy are limited, but such therapy may be useful in reducing symptoms in some patients.⁴⁶ Nasal deconges-

TABLE 112-5 Clinical Presentation and Diagnosis of Bacterial Sinusitis

General
A nonspecific upper respiratory tract infection that persists beyond 7 to 14 days
Signs and symptoms
Acute
Adults
Nasal discharge/congestion
Maxillary tooth pain, facial or sinus pain that may radiate (unilateral in particular) as well as deterioration after initial improvement
Severe or persistent (beyond 7 days) signs and symptoms are most likely bacterial and should be treated with antimicrobials
Children
Nasal discharge and cough for greater than 10 to 14 days or severe signs and symptoms such as temperature above 39°C (102.2°F) or facial swelling or pain are indications for antimicrobial therapy
Chronic
Symptoms are similar to acute sinusitis but more nonspecific
Rhinorrhea is associated with acute exacerbations
Chronic unproductive cough, laryngitis, and headache may occur
Chronic/recurrent infections occur three to four times a year and are unresponsive to steam and decongestants

Compiled from Hickner et al,⁴² Piccirillo,⁴³ ref. 44, Scheid et al,⁴⁶ and ref. 47.

TABLE 112-6 Evidence-Based Principles for Acute Bacterial Sinusitis in Children

Recommendation	Rating
The diagnosis of acute bacterial sinusitis is based on clinical criteria in children who present with upper respiratory symptoms that are either persistent or severe.	Strong—limited scientific data
Imaging studies are not necessary to confirm a diagnosis of clinical sinusitis in children ≤ 6 years of age.	Strong—limited scientific data
Antibiotics are recommended for the management of acute bacterial sinusitis to achieve more rapid clinical cure.	Strong—good evidence
No recommendations are made for adjuvant therapies or antibiotic prophylaxis.	Controversial and limited data

Rating: Strong recommendations are based on high-quality scientific evidence or when such was unavailable, strong expert panel consensus from a subcommittee of the American Academy of Pediatrics, the Agency for Healthcare Research and Quality, the New England Medical Center for Evidence Based Practice, and colleagues from family practice and otolaryngology organizations. Data from American Academy of Pediatrics. *Pediatrics* 2001;108:798–808.

TABLE 112-7 Evidence-Based Principles on Acute Bacterial Sinusitis in Adults

Recommendations	Rating
Most cases of acute rhinosinusitis diagnosed in ambulatory care are caused by uncomplicated viral upper respiratory tract infections.	A
Bacterial and viral rhinosinusitis are difficult to differentiate on clinical grounds.	B
Sinus radiography is not recommended for diagnosis in routine cases.	B
Acute rhinosinusitis resolves without antibiotic therapy in most cases.	A

Rating: A indicates randomized controlled trials with little or no heterogeneity; B indicates randomized controlled trials with some heterogeneity or a well-designed cohort study; C indicates case series or poor cohort studies; D indicates expert opinion.

Data from Hickner JM, Bartlett JG, Besser RE, et al. *Ann Intern Med* 2001;134:498–505.

tant sprays that reduce inflammation by vasoconstriction, such as phenylephrine and oxymetazoline, are used often in sinusitis.^{42,44} Use should be limited to the recommended duration of the product to prevent rebound congestion. Oral decongestants also may aid in nasal/sinus patency. Irrigation of the nasal cavity with saline and steam inhalation may be used to increase mucosal moisture, and mucolytics (e.g., guaifenesin) may be used to decrease the viscosity of nasal secretions.^{42,44}

Antihistamines should not be used for acute bacterial sinusitis in view of their anticholinergic effects that can dry mucosa and disturb clearance of mucosal secretions.⁴⁶ Second-generation antihistamines may play a role in chronic sinusitis where allergy is a component. Glucocorticoids intranasally may decrease inflammation causing headache, nasal congestion, and facial pain;⁵¹ however, there is little data in acute sinusitis.

Antimicrobial Therapy

Two meta-analyses^{44,52} have demonstrated that antimicrobial therapy is superior to placebo in reducing or eliminating symptoms in acute sinusitis, with a reduction in clinical failure of 25% to 30% reported. Results from individual randomized controlled trials are conflicting, and are confounded by flaws in methodology. Of two randomized, controlled, double-blind studies,^{50,53} one demonstrated that amoxicillin provided no benefit over placebo, while the other demonstrated that amoxicillin or penicillin were more effective than placebo. Although neither study used sinus aspiration for diagnosis, the study that showed no benefit with antibiotic treatment used radiography for diagnosis of sinusitis, and duration of illness was not specified. Viral infection thus was likely present in a number of patients, underestimating the value of antimicrobial therapy. The second study⁵⁰ demonstrated the effectiveness of penicillin and amoxicillin in patients with at least 7 days of illness and findings of sinusitis on computed tomography (CT). CT is considered more specific for diagnosis than radiography.⁴⁶ With more rigorous inclusion criteria and better diagnostic tools, more patients with bacterial sinusitis were likely included.

No difference between cure rates, clinical improvement, or relapse rates was noted between different antibiotics according to one meta-analysis.⁵² Another report suggests that amoxicillin-clavulanate was 41% more effective in reducing clinical failure than cephalosporins when used within 10 to 25 days; however, by 45 days, the difference disappeared.⁴⁴ There was no difference noted when other antibiotic classes were compared, but there is a lack of studies comparing older, less expensive antibiotics with newer, more costly agents.

6 Amoxicillin is first-line treatment for acute bacterial sinusitis. Because there is no difference in clinical outcome among antibiotics, the advantages of amoxicillin include proven efficacy and safety, a relatively narrow antibacterial spectrum that minimizes emergence of resistance, good tolerability, and low cost. Most consensus reports and reviews consider amoxicillin as first-line treatment for acute

TABLE 112-8 Approach to Treatment of Acute Bacterial Sinusitis

Uncomplicated Sinusitis	Amoxicillin
Uncomplicated sinusitis, penicillin-allergic patient	<i>Non-immediate-type hypersensitivity:</i> β -lactamase-stable cephalosporin <i>Immediate-type hypersensitivity:</i> Clarithromycin or azithromycin or trimethoprim-sulfamethoxazole or doxycycline or respiratory fluoroquinolone
Treatment failure or prior antibiotic therapy in past 4 to 6 weeks	High-dose amoxicillin with clavulanate or β -lactamase-stable cephalosporin Second choice: respiratory fluoroquinolone
High suspicion of penicillin-resistant <i>Streptococcus pneumoniae</i>	High-dose amoxicillin or clindamycin Second choice: respiratory fluoroquinolone

Compiled from ref. 44, ref. 45, and ref. 47.

bacterial sinusitis (Table 112–8). It is cost-effective in acute uncomplicated disease, and initial use of newer broad-spectrum agents is not justified.^{44,47,54,55} If a patient is penicillin-allergic, trimethoprim-sulfamethoxazole, doxycycline, azithromycin, or clarithromycin may be used. There is concern, however, regarding increasing resistance to trimethoprim-sulfamethoxazole and macrolides,⁴⁵ as well as the high failure rate of all these agents. In adults, a respiratory fluoroquinolone such as levofloxacin or gatifloxacin is an alternative in the penicillin-allergic patient. Use of fluoroquinolones also should be restricted, if possible, to those who have recently received antibiotics, those with severe disease, and those with drug-resistant *S. pneumoniae*.^{45,56} Furthermore, gatifloxacin should no longer be used because of well-documented hypoglycemia and hyperglycemia. If the penicillin allergy is not a true immunoglobulin (Ig) E-mediated reaction (e.g., hives or anaphylaxis), a second-generation cephalosporin is initially recommended (e.g., cefprozil, cefuroxime, or cefpodoxime).^{47,57}

If drug-resistant *S. pneumoniae* is highly suspected (daycare attendance, recent antibiotic use, age younger than 2 years), high-dose amoxicillin should be given. Some recommend clindamycin, but it is important to note that this drug is not active against *H. influenzae* and *M. catarrhalis*.⁴⁷

In the case of treatment failure with amoxicillin (i.e., no improvement in symptoms 72 hours after starting therapy) or in patients who have received antimicrobial therapy in the prior 4 to 6 weeks, limitations of initial treatment coverage must be considered.⁴⁵ Improved coverage of *H. influenzae* and *M. catarrhalis* with either high-dose amoxicillin plus clavulanate or a β -lactamase-stable cephalosporin that covers *S. pneumoniae* (e.g., cefprozil, cefuroxime, or cefpodoxime) is an option.^{45,47} Other alternatives include cefdinir, azithromycin, clarithromycin, and trimethoprim-sulfamethoxazole.^{46,47} Clinical cure rates are similar among antimicrobial agents,^{54,55} although local-area resistance rates also must be considered, as well as increasing resistance of *S. pneumoniae*, *H. influenzae*, and *M. catarrhalis* to trimethoprim-sulfamethoxazole, and of *S. pneumoniae* to macrolides. Respiratory fluoroquinolones have also been recommended, as well as ceftriaxone and telithromycin. Combination therapy is recommended in the otolaryngology guidelines in cases of treatment failure.⁴⁵ Examples include high-dose amoxicillin or clindamycin with cefixime or rifampin. However, there is no clinical evidence of the safety and efficacy of these combinations at this time. Table 112–9 lists dosing guidelines for these drugs.

Duration of therapy for treatment of sinusitis is not well established. Most trials have used 10- to 14-day antimicrobial courses, although some trials also have investigated courses as short as 3 days.⁵⁸ In one placebo-controlled comparison of 3- versus 10-day treatment with trimethoprim-sulfamethoxazole and a decongestant, a similar number in each group were cured or improved at 14 days. Since the publication of this study, however, rates of *S. pneumoniae* resistant to trimethoprim-sulfamethoxazole have increased dramatically. Furthermore, extrapolation of these results to other antimicro-

TABLE 112-9 Dosing Guidelines for Acute Bacterial Sinusitis

Drug	Adult Dosage	Pediatric Dosage
Amoxicillin	500 mg three times daily	Low dose: 40–50 mg/kg/day divided in three doses High dose: 80–100 mg/kg/day divided in three doses
Amoxicillin-clavulanate	500/125 mg three times daily High dose: 2 g/125 mg twice daily	40–50 mg/kg/day divided in three doses High dose: can add 40–50 mg/kg/day amoxicillin
Cefuroxime	250–500 mg twice daily	15 mg/kg/day divided in two doses
Cefaclor	250–500 mg three times daily	20 mg/kg/day divided in three doses
Cefixime	200–400 mg twice daily	8 mg/kg/day in one dose or divided in two doses
Cefdinir	600 mg daily or divided in two doses	14 mg/kg/day in one dose or divided in two doses
Cefpodoxime	200 mg twice daily	10 mg/kg/day in two divided doses (max: 400 mg daily)
Cefprozil	250–500 mg twice daily	15–30 mg/kg/day divided in two doses
Doxycycline	100 mg every 12 hours	—
Trimethoprim-sulfamethoxazole	160/800 mg every 12 hours	6–8 mg/kg/day trimethoprim, 30–40 mg/kg/day sulfamethoxazole divided in two doses
Clindamycin	150–450 mg every 6 hours	30–40 mg/kg/day divided in three doses
Clarithromycin	250–500 mg twice daily	15 mg/kg/day divided in two doses
Azithromycin	500 mg day 1, then 250 mg/day x days 2–5	10 mg/kg day 1, then 5 mg/kg/day x days 2–5
Levofloxacin	500 mg daily	—
Telithromycin	800 mg daily for 5 days	—
Ceftriaxone	1 g daily	50–75 mg/kg/day divided every 12–24 hours

Compiled from Piccirillo,⁴⁵ Scheid and Hamm,⁴⁶ and ref. 47.

bials is inappropriate. Recently, a 3-day course of azithromycin was approved for use in sinusitis in both Canada and the United States. A randomized double-blind study demonstrated that azithromycin 500 mg daily for 3 or 5 days was as effective as amoxicillin-clavulanate over 10 days.⁵⁷ Furthermore, a new extended-release single-dose preparation of azithromycin was recently approved in the United States. However, data supporting these short regimens are limited and new guidelines express concern over macrolide-resistant *S. pneumoniae*.⁴⁵ The current recommendations are 10 to 14 days of antimicrobial therapy or at least 7 days after signs and symptoms are under control.^{43,45}

EVALUATION OF THERAPEUTIC OUTCOMES

Antimicrobial therapy reduces the median duration of illness from 17 to 9 days (amoxicillin) or 11 days (penicillin).⁵⁰ A patient with persistence or worsening of symptoms 72 hours after initiating antimicrobial therapy may be considered a treatment failure.⁴⁵ Referral to a specialist should be considered for patients who have not responded to first- or second-line therapy; for those with severe, recurrent, and chronic disease; and for patients who are at risk for complications. Surgery may be considered in more complicated patients.

PHARYNGITIS

Pharyngitis is an acute infection of the oropharynx or nasopharynx.⁵⁹ It is the reason for 1% to 2% of all outpatient visits.⁶⁰ While viral causes are most common, group A β -hemolytic *Streptococcus*, or *S. pyogenes*, is the primary bacterial cause and is the focus of this section.^{59,61} In the pediatric population, group A *Streptococcus*, or “strep throat,” causes

15% to 30% of cases of pharyngitis. In adults, it is the cause of 5% to 15% of all symptomatic episodes of pharyngitis.^{59–62}

MICROBIOLOGY

7 Viruses cause the majority of acute pharyngitis cases. Specific etiologic agents include rhinovirus (20%), coronavirus ($\geq 5\%$), adenovirus (5%), herpes simplex (4%), influenza virus (2%), parainfluenza virus (2%), and Epstein-Barr virus ($<1\%$).^{49,59,61} A bacterial etiology for acute pharyngitis is far less likely. Of all the bacterial causes, group A *Streptococcus* is the most common (10% to 30% of persons of all ages with pharyngitis⁴⁹), and it is the only commonly occurring form of acute pharyngitis for which antimicrobial therapy is indicated.⁵⁹

Other, less-common causes of acute pharyngitis include groups C and G *Streptococcus*, *Corynebacterium diphtheriae*, *Neisseria gonorrhoeae*, *Mycoplasma pneumoniae*, *Arcanobacterium haemolyticum*, *Yersinia enterocolitica*, and *Chlamydia pneumoniae*. Treatment options for these organisms are not addressed in this chapter.^{59,61}

PATHOPHYSIOLOGY

The mechanism by which group A *Streptococcus* causes pharyngitis is not well defined.⁴⁹ Asymptomatic pharyngeal carriers of the organism may have an alteration in host immunity (e.g., a breach in the pharyngeal mucosa) and the bacteria of the oropharynx, allowing colonization to become infection. Pathogenic factors associated with the organism itself also may play a role. These include pyrogenic toxins, hemolysins, streptokinase, and proteinase.

CLINICAL PRESENTATION

Group A streptococcal pharyngitis is difficult to differentiate from viral pharyngitis based on history and clinical findings. However, although all age groups are susceptible, epidemiologic data show that certain groups are at higher risk. Children ages 5 to 15 years old are most susceptible; parents of school-age children and those who work with children are also at increased risk. Pharyngitis in a child younger than 3 years of age is rarely caused by group A *Streptococcus*.^{59,61}

Seasonal outbreaks occur, and the occurrence of group A streptococcal pharyngitis is highest in winter and early spring.^{59,63} The incubation period is 2 to 5 days, and the illness often occurs in clusters.^{60,63} Spread occurs via direct contact (usually from hands) with droplets of saliva or nasal secretions, and transmission is thus worse in institutions, schools, families, and areas of crowding.^{62,64} Untreated, patients with streptococcal pharyngitis are infectious during the acute illness and for another week thereafter.⁶⁵ Effective antimicrobial therapy reduces the infectious period to about 24 hours. Table 112–10 gives clinical presentation and diagnosis of pharyngitis.

Nonsuppurative complications such as acute rheumatic fever, acute glomerulonephritis, and reactive arthritis may occur, as well as suppurative complications, such as peritonsillar abscess, retropharyngeal abscess, cervical lymphadenitis, mastoiditis, otitis media, sinusitis, and necrotizing fasciitis.

Acute rheumatic fever is rarely seen in developed countries. Acute rheumatic fever secondary to group A streptococcal infection was a cause of concern in the 1950s and was the major reason for penicillin therapy, but the annual incidence of this disease today is extremely rare (≤ 1 case, per 1 million population). Some risk however, does remain; outbreaks have been reported in the United States as recently as the late 1980s and early 1990s. Furthermore, acute rheumatic fever is widespread in developing countries (e.g., it is estimated that there are 50,000 cases of acute rheumatic fever per year in India).

TABLE 112-10 Clinical Presentation and Diagnosis of Group A Streptococcal Pharyngitis

General
A sore throat of sudden onset that is mostly self-limited
Fever and constitutional symptoms resolving in about 3 to 5 days
Clinical signs and symptoms are similar for viral causes as well as nonstreptococcal bacterial causes
Signs and symptoms
Sore throat
Pain on swallowing
Fever
Headache, nausea, vomiting, and abdominal pain (especially children)
Erythema/inflammation of the tonsils and pharynx with or without patchy exudates
Enlarged, tender lymph nodes
Red swollen uvula, petechiae on the soft palate, and a scarlatiniform rash
Several symptoms that are not suggestive of group A <i>Streptococcus</i> are cough, conjunctivitis, coryza, and diarrhea
Laboratory tests
Throat swab and culture or rapid antigen detection testing

Compiled from Mandell et al.,⁴⁹ Bisno et al.,⁵⁹ Snow et al.,⁶⁰ Bisno,⁶¹ Cooper et al.,⁶² American Academy of Pediatrics,⁶³ Schwartz et al.,⁶⁶ and Hayes and Williamson.⁶⁷

DIAGNOSIS

For a patient presenting with pharyngitis, the most important clinical decision that needs to be made is whether or not the pharyngitis is caused by group A *Streptococcus*. Diagnosis is essential because it directs management.

Clinical scoring systems such as the Centor criteria⁶⁷ or modifications⁶⁸ have been advocated for diagnosis in adults as a way to overcome the lack of sensitivity and specificity of clinician judgment and to avoid laboratory testing of all patients.^{60,62} Table 112-11 lists the modified Centor criteria. However, concern exists that use of these criteria alone leads to overprescribing.^{59,61,70} Guidelines from the Infectious Disease Society of America, the American Academy of Pediatrics, and the American Heart Association suggest that testing be done in all patients with signs and symptoms of pharyngitis. Only those with a positive test for group A *Streptococcus* require antibiotic treatment.^{59,63,70} Recent studies suggest that limiting testing to patients who meet two or more Centor criteria will minimize overtesting.^{68,70} The simplest approach is likely bedside testing with culture confirmation in cases of negative results. This ensures those with disease are not missed.

It is important to note that laboratory testing should not be used without consideration of clinical criteria. This is because a positive test does not necessarily indicate disease. A positive test may indicate carriage (not active infection) with group A *Streptococcus*.

TABLE 112-11 Modified Centor Criteria for Clinical Prediction of Group A Streptococcal Pharyngitis

Criteria	Points
Temperature $\geq 38^{\circ}\text{C}$ (100.4°F)	1
Absence of cough	1
Swollen tender anterior cervical nodes	1
Tonsillar swelling or exudate	1
Age	
3–14 years	1
15–44 years	0
45 years or older	-1
Score	Risk of streptococcal infection
≤ 0	1%–2.5%
1	5%–10%
2	11%–17%
3	28%–35%
≥ 4	51%–53%

The original Centor score applies to adults only. This modified version allows for age.

TABLE 112-12 Evidence-Based Principles for Diagnosis of Group A *Streptococcus*

Recommendations	Level
Selective use of diagnostic testing in only those with clinical features suggestive of group A <i>Streptococcus</i> will increase the proportion of positive tests as well as results of those truly infected, not carriers.	A-II
Clinical diagnosis cannot be made with certainty even by the most experienced clinician; bacteriologic confirmation is required.	A-II
Throat culture remains the diagnostic standard with a sensitivity of 90%–95% for detection of group A <i>Streptococcus</i> if done correctly.	A-II
Rapid identification and treatment of patients with disease can reduce transmission, allow patients to return to work or school earlier, and reduce the acute morbidity of the disease.	A-II
The majority of rapid antigen-detection tests available have a specificity $>95\%$ (minimizes overprescription to those without disease), and a sensitivity of 80%–90%, compared to culture.	A-II
Early initiation of antimicrobial therapy results in faster resolution of signs and symptoms. Delays in therapy (if awaiting cultures) can be made safely for up to 9 days after symptom onset and still prevent major complications such as rheumatic fever.	A-I

Rating:

Strength of recommendation—A to E

Evidence to support use: A, good; B, moderate; C, poor

Evidence against use: D, moderate; E, good

Quality of evidence—I, II, or III

I: at least 1 randomized controlled trial

II: at least 1 well-designed clinical trial, not randomized, or a cohort or case-controlled analytical study, or from multiple time series, or from dramatic results of an uncontrolled trial

III: opinions of respected authorities

Data from Bisno AL, Gerber MA, Gwaltney JM, et al. *Clin Infect Dis* 2002;35:113–125.

The incidence of carriage in children is 5% to 20%; it is considerably lower in adults.⁶³ Table 112-12 lists the evidence-based principles for diagnosis of group A *Streptococcus*. There are several options to test for group A streptococcal pharyngitis. A throat swab can be sent for culture or used for the rapid antigen-detection test (RADT). Cultures are the “gold standard” but require 24 to 48 hours for results.⁶¹ The RADT is more practical in that it provides results quickly, it can be performed at the bedside, and it is less expensive than culture. Cultures are recommended for children, adolescents, parents, and schoolteachers with negative RADTs, as well as in situations of outbreak or to monitor resistance.^{62,63,66} Delaying therapy while awaiting culture results does not affect the risk of complications (although some argue that symptomatic benefit is postponed, and contagion remains), and patients must be educated as to the value of waiting given the low false-negative rate of RADT.

TREATMENT

Pharyngitis

■ DESIRED OUTCOME

The goals of treatment of pharyngitis are to improve clinical signs and symptoms, minimize adverse drug reactions, prevent transmission to close contacts, and prevent acute rheumatic fever and suppurative complications, such as peritonsillar abscess, cervical lymphadenitis, and mastoiditis.^{59,60}

■ GENERAL APPROACH TO TREATMENT

Antimicrobial therapy should be limited to those who have clinical and epidemiologic features of group A streptococcal pharyngitis with a positive laboratory test. Empiric therapy is not recommended. Antimicrobial overuse in those without disease and underuse in those with disease is well documented.^{59,70}

TABLE 112-13 Dosing Guidelines for Pharyngitis

Drug	Adult Dosage	Pediatric Dosage	Duration
Penicillin VK	250 mg three or four times daily or 500 mg twice daily	50 mg/kg/day divided in three doses	10 days
Penicillin benzathine	1.2 million units intramuscularly	0.6 million units for weight <27 kg (50,000 units/kg)	One dose
Penicillin G procaine and benzathine mixture	Not recommended in adolescents and adults	1.2 million units (benzathine 0.9 million units, procaine 0.3 million units)	One dose
Amoxicillin	500 mg three times daily	40–50 mg/kg/day divided in three doses	10 days
Erythromycin			10 days
Estate	20–40 mg/kg/day divided two to four times daily (max: 1 g/day)	Same as adults	
Stearate	1 g daily divided two to four times daily (adolescents, adults)	—	
Ethylsuccinate	40 mg/kg/day divided two to four times daily (max: 1 g/day)	Same as adults	
Cephalexin	250–500 mg orally four times daily	25–50 mg/kg/day divided in four doses	10 days

Compiled from Bisno et al.,⁵⁹ Bisno,⁶¹ and American Academy of Pediatrics.⁶³

■ PHARMACOLOGIC THERAPY

Because pain is often the primary reason for visiting a physician, emphasis on analgesics such as acetaminophen and NSAIDs to aid in pain relief is strongly recommended.⁷¹ However, acetaminophen is a better option because there is some concern that NSAIDs may increase the risk for necrotizing fasciitis/toxic shock syndrome. Toxic shock syndrome has been linked to group A streptococcal pharyngitis. Either systemic or topical analgesics can be used, as well as antipyretics and other supportive care, including rest, fluids, lozenges, and saltwater gargles. Symptoms may resolve 1 to 2 days sooner with such interventions.^{60–62}

Antimicrobial Therapy

Antimicrobial therapy decreases the duration of signs and symptoms by 1 to 2 days.^{60,72} Therapy also decreases the severity of symptoms when initiated within 2 to 3 days of onset in patients with proven group A *Streptococcus*. Microbiologic eradication will occur in 48 to 72 hours, which aids in decreasing transmission.⁶⁰

8 Antimicrobial treatment of pharyngitis should be limited to those who have clinical and epidemiologic features of group A streptococcal pharyngitis with a positive laboratory test. Penicillin is the drug of choice (Table 112–13).^{59,60} It has the narrowest spectrum of activity, and it is effective, safe, and inexpensive.

The only controlled studies that have demonstrated that antimicrobial therapy prevents rheumatic fever following group A streptococcal pharyngitis were done with procaine penicillin, which was later replaced with benzathine penicillin.^{73,74} Penicillin given by other routes is assumed to be equally efficacious. The ability of other antibiotics to eradicate group A *Streptococcus* has led to extrapolation that these agents also will prevent rheumatic fever.⁶² Amoxicillin can be used in children because the suspension has a better taste than that of penicillin.^{59,64} Gastrointestinal side effects and rash, however, are more common.

In patients who are allergic to penicillin, a macrolide such as erythromycin or a first-generation cephalosporin such as cephalexin (if the reaction is non-IgE-mediated hypersensitivity) can be used.⁵⁹ Newer macrolides such as azithromycin and clarithromycin are equally effective as erythromycin and cause fewer gastrointestinal adverse effects. Second-generation cephalosporins, such as cefuroxime and cefprozil, or third-generation cephalosporins, such as cefpodoxime and cefdinir, which are β -lactamase-stable, have been advocated for clinical failures with penicillin. In cases of documented macrolide resistance (owing to low-level macrolide resistance—erythromycin MIC 1 to 8 mcg/mL—because of expression of the *mefA/E* gene leading to efflux of macrolide out of the bacterial cell), clindamycin is an alternative. The new ketolides, such as telithromycin, may also have a role to play, especially in regions with a high prevalence of macrolide-resistant strains. If patients are unable to take oral medications, intramuscular benzathine penicillin can be given, although it is painful and is no longer available in Canada.⁵⁹ Amoxicillin-clavulanate or clindamycin may be considered for recurrent

episodes of pharyngitis to maximize bacterial eradication in potential carriers and to counter copathogens that produce β -lactamases.^{59,63,66} Tables 112–13 and 112–14 outline dosing for acute and recurrent episodes of pharyngitis.

To date, no resistance of group A *Streptococcus* to penicillin has been reported in clinical isolates.^{59,60,63,75,80} Macrolide resistance is low (>5%) and is not widespread.^{75–81} There has been a report of an outbreak of macrolide-resistant group A streptococcal pharyngitis in the United States and increasing rates in New York City.⁸⁰ Internationally, higher rates have also been reported,⁸¹ and as usage of macrolides increases, these rates will continue to rise. There is concern that if macrolide use continues to increase, macrolide resistance rates also will increase.^{77,78} Consequently, use of newer macrolides as first-line therapy is discouraged in febrile patients with upper respiratory tract infections. Group A *Streptococcus* resistance rates to tetracyclines and sulfonamides are high; consequently, use of these agents is no longer recommended.⁵⁹

The duration of therapy for group A streptococcal pharyngitis is 10 days to maximize bacterial eradication.⁵⁹ Short-course therapy has been advocated to help overcome compliance issues that lead to bacteriologic failure.⁸² A 6-day course of amoxicillin shows promising results; in addition, recent studies with newer broad-spectrum agents (e.g., azithromycin, cefuroxime, cefprozil, cefdinir, cefixime, cefpodoxime, and telithromycin) have demonstrated durations of 5 days to be effective.

CLINICAL CONTROVERSY

Although some clinicians propose short courses of treatment for pharyngitis, confounding factors from these studies, such as lack of strict entry criteria or differentiation between new or failed infections, limit the widespread application of short antibiotic courses at this time.⁵⁹ As well, newer agents that have been studied in this fashion are more expensive and may be more likely to lead to resistance in light of their broad spectra of activity.⁶¹

TABLE 112-14 Antibiotics and Dosing for Recurrent Episodes of Pharyngitis

Drug	Adult Dosage	Pediatric Dosage
Clindamycin	600 mg orally divided in two to four doses	20 mg/kg/day in three divided doses (max: 1.8 g/day)
Amoxicillin-clavulanate	500 mg twice daily	40 mg/kg/day in three divided doses
Penicillin benzathine	1.2 million units intramuscularly for one dose	0.6 million units for weight <27 kg (50,000 units/kg)
Penicillin benzathine with rifampin	As above Rifampin 20 mg/kg/day orally in two divided doses during last 4 days of treatment with penicillin	As above Rifampin dose same as adults

CLINICAL CONTROVERSY

Once-daily amoxicillin given at a dose of 750 mg is as effective as penicillin 250 mg three times daily (duration 10 days each) in children ages 4 to 18 years with group A streptococcal pharyngitis.⁸³ This dosing regimen has not yet been endorsed by expert panels but may gain support in the future if the results are reproducible.^{59,60,62}

Overprescribing is a large concern that requires consideration. Antibiotics are prescribed in 73% of patients who visit their physician with a complaint of sore throat.⁸⁴ This is well above the incidence of group A *Streptococcus*. For those who receive antibiotics, 68% of prescriptions are described as being nonrecommended treatments, for example, extended-spectrum macrolides (e.g., azithromycin and clarithromycin) or fluoroquinolones (e.g., ciprofloxacin, gatifloxacin, levofloxacin, and moxifloxacin). Cost and resistance are factors that should discourage this practice.

EVALUATION OF THERAPEUTIC OUTCOMES/CONTACT CASES

Most cases of pharyngitis are self-limited; however, antimicrobial therapy will hasten resolution when given early to proven cases of group A *Streptococcus*.⁵⁹ Symptoms generally resolve by 3 to 4 days even without therapy.⁶¹ Children should be kept home from daycare or school until afebrile and for the first 24 hours after antimicrobial treatment is initiated, after which time transmission is unlikely.^{62–64}

Followup testing generally is not necessary for index cases or in asymptomatic contacts of the index patient.^{59,61,63} Symptomatic contacts may be treated without cultures.⁶⁴ In epidemics or in cases of severe infection, followup testing may be prudent. The incidence of invasive group A streptococcal infection in household contacts is rare, and routine chemoprophylaxis is not recommended by the CDC,⁸⁶ although testing is advocated and guides management.^{59,63} Twenty-five percent of household contacts are carriers, but treatment would only be required in persons with signs and symptoms of disease or contacts of severe or resistant disease.⁵⁹

ABBREVIATIONS

MIC: minimal inhibitory concentration

MIC₉₀: minimal inhibitory concentration for 90% of isolates

NSAID: nonsteroidal antiinflammatory drug

RADT: rapid antigen-detection test

ELIZABETH D. HERMSEN AND MARK E. RUPP

KEY CONCEPTS

- 1 Influenza is a viral illness associated with high mortality and high hospitalization rates among persons younger than age 65 years. The aging of the population is contributing to an increased disease burden in the United States.
- 2 Seasonal influenza epidemics are the result of viral antigenic drift, which is why the influenza vaccine is changed on a yearly basis. Antigenic drift forms the foundation of the recommendation for annual influenza vaccination.
- 3 The acquisition of a new hemagglutinin and/or neuraminidase by the influenza virus is called *antigenic shift*, which results in a novel influenza virus that has the potential to cause a pandemic.
- 4 The primary route of influenza transmission is person-to-person via inhalation of respiratory droplets, and transmission can occur for as long as the infected person is shedding virus from the respiratory tract.
- 5 Clinical diagnosis of influenza is difficult. Classic signs and symptoms include abrupt onset of fever, muscle pain, headache, malaise, nonproductive cough, sore throat, and rhinitis. These signs and symptoms usually resolve within 1 week of presentation.
- 6 In the United States, the primary mechanism of influenza prevention is annual vaccination. Vaccination not only prevents influenza illness and influenza-related hospitalizations and deaths, but also may decrease healthcare resource use and the overall cost to society.
- 7 The trivalent influenza vaccine (TIV) and the live-attenuated influenza vaccine (LAIV) are the two commercially available vaccines for prevention of influenza. Both vaccines contain an influenza A (H3N2), influenza A (H1N1), and influenza B virus, which are initially grown in hens' eggs.
- 8 Antiviral drugs for prophylaxis of influenza should be considered adjuncts to vaccine and are not replacements for annual vaccination.
- 9 The sooner the antivirals are started after the onset of illness, the more effective they are.

- 10 Oseltamivir and zanamivir, neuraminidase inhibitors that have activity against both influenza A and influenza B viruses, are the agents of choice for treatment of influenza. They are most effective if started within 48 hours of the onset of illness.

Influenza causes significant morbidity and mortality, particularly among young children and the elderly. Seasonal influenza epidemics result in 25 to 50 million influenza cases, approximately 200,000 hospitalizations, and more than 30,000 deaths each year in the United States. Globally, influenza causes nearly 500,000 deaths each year. Overall, more people die of influenza than of any other vaccine-preventable illness. Significant societal consequences associated with influenza include visits to physicians' offices and emergency departments and days lost from school and/or work. The societal costs associated with influenza are more than \$37 billion in the United States alone.¹

Vaccination is the primary mechanism of prevention of influenza in the United States. The antiviral armamentarium for treatment and prophylaxis of influenza is limited, which further emphasizes the importance of prevention with vaccination and appropriate use of infection control measures during outbreaks. Research toward the development of novel antivirals and vaccines is needed for effective control of seasonal epidemics and for pandemic preparedness.

ETIOLOGY AND EPIDEMIOLOGY

Influenza infection can occur at any time during the year with the highest rates of influenza-associated illness during the winter months. The highest rate of infection occurs in children, but the highest rates of severe illness, hospitalization, and death occur among those older than age 65 years, young children (younger than 2 years old), and those who have underlying medical conditions, including pregnancy and cardiopulmonary disorders, that increase their risk of complications from influenza. 1 The seasonal influenza epidemics from 1979 through 2000 resulted in an average of 226,000 hospitalizations per year with more than 63% of the hospitalizations occurring in those older than age 65 years.² More than 90% of influenza-related deaths occur in those older than age 65 years.^{3,4} Thus the aging of the population is contributing to an increased disease burden. Deaths associated with influenza often result from secondary bacterial pneumonia, primary viral pneumonia, and/or exacerbation of underlying comorbidities.

INFLUENZA VIRUSES A, B, AND C

Influenza virus types A, B, and C are members of the Orthomyxoviridae family and affect many species, including humans, pigs, horses, and birds. Influenza A and B viruses are the two types that cause disease in humans. Influenza A viruses are responsible for the

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

regular, seasonal epidemics of the flu, whereas influenza B viruses are typically associated with sporadic outbreaks, particularly among residents of long-term care facilities. Influenza A viruses are further categorized into different subtypes based on changes in two surface antigens—hemagglutinin and neuraminidase. Influenza B viruses are not categorized into subtypes.

Hemagglutinin and Neuraminidase

Hemagglutinin allows the influenza virus to enter host cells by attaching to sialic acid receptors and is the major antigen to which antibodies are directed upon exposure.⁵ Neuraminidase allows the release of new viral particles from host cells by catalyzing the cleavage of linkages to sialic acid.⁵

Sixteen hemagglutinin subtypes (H1 to H16) and nine neuraminidase subtypes (N1 to N9) of influenza A have been isolated from birds. However, the only influenza A subtypes that have circulated among humans since the 1918 pandemic (see Pandemics and Antigenic Shift below) are H1 to H3 and N1 and N2.⁵ The primary subtypes of influenza A that have been circulating among humans for the last three decades are H3N2 and H1N1.

EPIDEMICS AND ANTIGENIC DRIFT

② Immunity to influenza virus occurs as a result of the development of antibody directed at the surface antigens, particularly hemagglutinin. However, immunity to one influenza subtype does not offer protection against other subtypes or types of influenza. Moreover, immunity to one antigenic variant of a subtype of influenza may not confer protection against other antigenic variants. Antigenic variants are created by point mutations in the surface antigens of a particular subtype, resulting in small changes in the hemagglutinin and/or neuraminidase molecules, which is called *antigenic drift*. Antigenic drift is the basis for seasonal epidemics of influenza, the reason for changes in the annual influenza vaccine, and the rationale behind the recommendation for annual vaccination.

PANDEMICS AND ANTIGENIC SHIFT

Immunity to one subtype of influenza does not confer protection against other subtypes or types. ③ Antigenic shift occurs when the influenza virus acquires a new hemagglutinin and/or neuraminidase via genetic reassortment rather than point mutations.⁵ Most likely, the genetic reassortment occurs when an animal that supports the growth of multiple subtypes of influenza, such as a pig, is concurrently infected with two subtypes of the influenza virus. Conversely, antigenic shift may occur directly from avian strains that have gained competency in the human host. Antigenic shift results in the emergence of a novel influenza virus and carries the potential of causing a pandemic. However, novelty alone is insufficient cause for an influenza pandemic; the virus must be able to replicate in humans, spread person-to-person, and affect a susceptible population.⁵

Spanish Flu of 1918

The influenza pandemic of 1918 was the most significant infectious disease outbreak known to man, causing approximately 40 to 50 million deaths in a year, with more than 500,000 deaths occurring in the United States.^{5–8} Although the reports of the first illnesses associated with this pandemic occurred in Spain, there is no evidence that the virus associated with this pandemic actually originated there, indicating a misnomer. The pandemic occurred almost concurrently in Europe, Asia, and North America.⁷

The 1918 pandemic was caused by a particularly virulent influenza A H1N1 virus, which was entirely of avian origin.^{9–11} In contrast to the other pandemics of the 20th century, the 1918 pandemic resulted

in an unusual mortality pattern. The mortality peaked for those younger than age 4 years, those between the ages of 25 and 35 years, and those older than 65 years of age, which resulted in a W-shaped mortality curve, as opposed to the U- or J-shaped curve typically associated with influenza.^{3,8} Over half of the deaths occurred in persons ages 20 to 40 years. The death toll associated with this pandemic culminated in an almost 10-year drop in the life expectancy of the population at the time.⁸

Asian Flu of 1957

The Asian flu pandemic began when a new H2 subtype of influenza A surfaced in Hunan province in China in 1957.¹² The virus appears to have formed from coinfection with an avian H2N2 virus and a human H1N1 virus in a common host, possibly a pig or a human.¹³ The H2N2 virus quickly spread to Japan, South America, the United States, New Zealand, and Europe, resulting in approximately 4 million deaths worldwide, with 70,000 deaths occurring in the United States.^{7,8,12} Unlike the Spanish flu of 1918, the mortality curve for the Asian flu pandemic was U- or J-shaped, with infants and elderly being most affected.⁷

Hong Kong Flu of 1968

The H2N2 virus of the Asian flu circulated in the human population until 1968, when a new H3 subtype emerged in China and Hong Kong¹² following genetic reassortment with the H2N2 virus.^{7,12} The H3N2 virus quickly spread to the United States and later to Europe. This pandemic caused more than 30,000 deaths in the United States and approximately 2 million deaths worldwide.^{7,8,12} The lower morbidity and mortality associated with the Hong Kong flu may be explained by previous exposure of the population to the N2 subtype.¹⁴ Similar to the Asian flu of 1957, the mortality curve for the Hong Kong flu pandemic was U- or J-shaped, primarily affecting infants and elderly.

Avian Influenza

Influenza viruses are in circulation in southern China during all months of the year.⁵ Given this fact and the close proximity of dense populations of people, pigs, and wild and domestic birds, this area proves ideal for the development of new influenza viruses via genetic reassortment (antigenic shift), as demonstrated by the pandemics of 1957 and 1968 and, most recently, the emergence of what is known as avian influenza.⁵

The first report of human infection with the avian H5N1 virus occurred in 1997 in Hong Kong in a 3-year-old who had a direct link with chickens and later died.¹⁵ This was followed by 18 confirmed cases and 6 deaths.¹⁶ The virus reemerged in 2003 as an antigenically and genetically different virus that has spread widely through wild and domestic bird populations in Asia, Africa, and Europe as well as infecting humans in 10 countries: China, Vietnam, Thailand, Indonesia, Cambodia, Turkey, Iraq, Azerbaijan, Djibouti, and Egypt.⁷ As of November 13, 2006, 258 cases and 153 deaths caused by H5N1 infection have been reported.¹⁷ The current overall case fatality is 59.3%, with 20 years being the median age at death for the first 152 cases.

In contrast to the animal-to-human transmission of the 1997 epidemic, occasional human-to-human transmission has been suggested during the recent outbreaks associated with the H5N1 virus,^{18,19} although no cases of transmission via aerosolization have been identified.²⁰ Clinical presentation includes high fever and influenza-like illness, and watery diarrhea without blood may occur up to 1 week prior to respiratory symptoms.²⁰ Almost all patients have clinically apparent pneumonia. Progression to death, most commonly as a consequence of respiratory failure, occurs a mean of 9 to 10 days after the onset of illness.²⁰ The neuraminidase inhibitors,

oseltamivir and zanamivir, have activity against the H5N1 virus, although higher doses may be needed. Oseltamivir resistance has been detected in several patients infected with the H5N1 virus who were treated with oseltamivir.²⁰ Amantadine and rimantadine are ineffective against H5N1, and no H5N1 vaccines are currently licensed, although several are under investigation.

The potential for H5N1 to cause a pandemic is of concern as it could spread more quickly than pandemics of the past because of the mobility of people in today's world. International travel has increased 73% since 1990, with 763 million people crossing international borders in 2004.²¹ A severe pandemic, like that of 1918, could cause more than 9 million hospitalizations and more than 1.9 million deaths, whereas a moderate pandemic, like those of 1957 and 1968, could result in more than 800,000 hospitalizations and more than 200,000 deaths in the United States alone.⁷

Pandemic Preparedness

This chapter is not meant to provide an exhaustive review of the biology of influenza or pandemic preparedness. This topic is rapidly changing and interested readers are referred to the following websites: www.pandemicflu.gov and www.who.int/csr/disease/avian_influenza/en/.

The United States Department of Health and Human Services released a *Pandemic Influenza Plan* focusing on surveillance, vaccine development and production, antivirals, communications, and preparedness on the state and local levels.²² The current goal for the national antiviral drug stockpile is 81 million courses of therapy, with 6 million to contain the initial outbreak and 75 million to treat 25% of the population in the United States.^{23–25} The estimated illness attack rate during a pandemic in the United States is 30%, which means that the planned antiviral drug stockpile would not be enough to treat all those infected.⁷ The current goal for the national vaccine stockpile is 20 million courses of prepandemic vaccine with the ability to dramatically increase vaccine production during a pandemic resulting in 300 million doses within 4 to 6 months.²³ Furthermore, a population previously unexposed to the pandemic subtype would likely require at least two doses of an inactivated vaccine to induce immunity, which presents challenges in prevention and control during a pandemic.²⁵ A vital component of pandemic preparedness is forethought—plans must be established for how to effectively triage large numbers of ill patients, prioritize and/or ration vaccine and antivirals, and communicate with the public through mass media during a period of severe labor shortage (a result of stress and illness amongst healthcare workers) and supply shortfall (a result of societal and economic disruption).

PATHOGENESIS

4 The route of influenza transmission is person-to-person via inhalation of respiratory droplets, which can occur when an infected person coughs or sneezes.^{26,27} Transmission may also occur if a person touches an object contaminated with respiratory secretions and then touches their mucus membranes. The incubation period for influenza ranges between 1 and 4 days, with an average incubation of 2 days.²⁸ Transmission can occur for as long as the infected person is shedding virus from the respiratory tract. Adults are considered infectious from the day before their symptoms begin through the fifth day after the onset of illness, while children can be infectious for longer than 10 days after the onset of illness.²⁹ Viral shedding can persist for weeks to months in severely immunocompromised people.³⁰

The pathogenesis of influenza in humans is not well understood. The severity of the infection is determined by the balance between viral replication and the host immune response.⁵ Severe illness is

likely a result of both a lack of ability of host defense mechanisms to inhibit viral replication and an overproduction of cytokines leading to tissue damage in the host.³¹

CLINICAL PRESENTATION AND DIAGNOSIS OF INFLUENZA

General

- The clinical diagnosis of influenza can be difficult because the presentation is similar to a number of other respiratory illnesses. The sensitivity of clinical diagnosis ranges from 38% for children to 77% for adults and largely depends on the relative prevalence of influenza and other respiratory viruses circulating in a community.³²
- The clinical course and outcome are affected by age, immunocompetence, viral characteristics, smoking, comorbidities, pregnancy, and the degree of preexisting immunity.
- Complications of influenza may include exacerbation of underlying comorbidities, primary viral pneumonia, secondary bacterial pneumonia or other respiratory illnesses (e.g., sinusitis, bronchitis, otitis), encephalopathy, transverse myelitis, myositis, myocarditis, pericarditis, and Reye syndrome.

Signs and Symptoms

- 5 Classic signs and symptoms of influenza include rapid onset of fever, myalgia, headache, malaise, nonproductive cough, sore throat, and rhinitis.
- Nausea, vomiting, and otitis media are also commonly reported in children.³³
- Signs and symptoms typically resolve in approximately 3 to 7 days, although cough and malaise may persist for more than 2 weeks.
- Primary viral pneumonia, occurring predominantly in pregnant women and in those with underlying cardiovascular disease, usually begins with fever and dry cough, which changes to a productive cough of bloody sputum. This rapidly progresses to dyspnea, hypoxemia, and cyanosis with radiologic evidence of bilateral interstitial infiltrates.³⁴
- Secondary bacterial pneumonia is usually seen in individuals with underlying pulmonary disorders and presents during the early stages of defervescence from the influenza infection. These patients usually present with fever, productive cough, and radiologic evidence of consolidation.³⁴

Laboratory Tests

- Complete blood count and chemistry panels should be obtained to assess the overall status of the patient.
- The gold standard for diagnosis of influenza is viral culture, which can provide information on the specific strain and subtype. Viral culture has a high sensitivity but can take as long as a week to develop, limiting the clinical relevancy of the results.
- Tests such as the rapid antigen and point-of-care (POC) tests, direct fluorescence antibody (DFA) test, and the reverse-transcription polymerase chain reaction (RT-PCR) assay may be used for rapid detection of virus.

Other Diagnostic Tests

- Cultures of potential sites of infection should be obtained if coinfection, superinfection, or secondary infection is suspected.
- Chest radiograph should be obtained if pneumonia is suspected.

Rapid Tests

- Rapid tests have allowed for prompt diagnosis and initiation of antiviral therapy and decreased inappropriate use of antibiotics. Rapid antigen or POC tests use enzyme immunoassay technology to provide results within 1 hour of specimen collection. Appropriate specimens for collection, in decreasing order of sensitivity, are nasopharyngeal aspirates, nasopharyngeal swabs/washes, and throat swabs.³² POC tests allow for differentiation of influenza viruses A and B, with sensitivity and specificity ranging from 57% to 90% and 65% to 99%, respectively.³² In general, use of POC tests is contraindicated in those who have had symptoms for longer than 3 days, and results may be confounded following recent immunization with live-attenuated influenza vaccine.³²
- DFA testing requires more technical expertise and infrastructure than POC tests. The advantages of DFA are increased sensitivity over POC tests and simultaneous detection of other respiratory viruses, such as respiratory syncytial virus and adenovirus.³² DFA provides results between 1 and 4 hours after specimen collection and may serve as a confirmatory assay for a POC test.
- RT-PCR assay is a nucleic acid amplification test and is the most sensitive, specific, and versatile diagnostic test for influenza.³² RT-PCR is replacing viral isolation as the reference standard and can determine the type, subtype, and strain of influenza. Results are provided within 4 to 6 hours of specimen collection.

PREVENTION

The best means to decrease the morbidity and mortality associated with influenza is to prevent infection through vaccination. Appropriate infection control measures, such as hand hygiene, basic respiratory etiquette (cover your cough, throw tissues away), and contact avoidance, are also important in preventing the spread of influenza. Additionally, chemoprophylaxis is useful in certain situations.

VACCINATION

6 The primary means of influenza prevention employed in the United States is annual vaccination. Vaccination can help prevent hospitalization and death among those at high risk, decrease influenza-like illness, decrease visits to physicians' offices and emergency rooms, decrease otitis media in children, and prevent school and/or work absenteeism. Annual vaccination is recommended for those at high risk for complications and severe disease, such as²⁹

- Children between 6 and 59 months old.
- Pregnant women.
- People older than age 50 years.
- Children between 6 months and 18 years old who are receiving long-term aspirin therapy, placing them at risk for Reye syndrome following influenza.
- People of any age with chronic pulmonary or cardiovascular disorders, including asthma but not including hypertension.
- People of any age who have required regular medical followup or hospitalization in the prior year because of chronic metabolic diseases, including diabetes, renal dysfunction, hemoglobinopathies, or immunodeficiency, including medication-induced immunosuppression and human immunodeficiency virus (HIV).

TABLE 113-1 Influenza Vaccination Rates and Goals by Patient Population

Patient Population	Vaccination Coverage	Vaccination Coverage National Goal (2000/2010)
Children ages 6–23 months	18% ^a	N/A
Persons ages 18–49 years with high-risk conditions	26% ^a	60%/60%
Persons ages 50–64 years	36% ^a	60%/60%
Persons ages 50–64 years with high-risk conditions	46% ^a	60%/60%
Persons ages >65 years	65% ^a	60%/90%
Nursing home residents	83% ^b	80%/90%
Pregnant women without other high-risk conditions	13% ^a	N/A
Healthcare workers	42% ^a	N/A

N/A, not applicable; no goals established.

^a2004 data.

^b1998 data.

From Smith et al.²⁹

- People of any age who have any condition that may compromise respiratory function or increase the risk of aspiration (e.g., cognitive dysfunction, spinal cord injuries, or epilepsy).
- Residents of long-term care facilities.

Vaccination is also recommended for those who live with and/or care for people who are at high risk, including household contacts and healthcare workers.

The ideal time for vaccination is during October or November to allow for the development and maintenance of immunity during the peak of the influenza season. Table 113–1 lists the vaccination coverage rates and goals for various patient populations.

7 The two vaccines currently available for prevention of influenza are the trivalent influenza vaccine (TIV) and the live-attenuated influenza vaccine (LAIV). Both vaccines contain an influenza A (H3N2), influenza A (H1N1), and influenza B virus; the specific strains included in the vaccine each year change based on antigenic drift. The viruses used for both vaccines are initially grown in embryonated hens' eggs, which explains the contraindication for vaccination of persons with a severe allergic reaction to eggs.

Trivalent Influenza Vaccine

7 TIV is FDA-approved for use in people over 6 months of age, regardless of their immune status. Of note, several commercial products are available and are approved for different age groups (Table 113–2). TIV is administered intramuscularly and is made with killed viruses, meaning it cannot cause signs and symptoms of influenza-like illness (Table 113–3). Age and immune status can affect the efficacy of TIV as can the similarity of the vaccine to the viruses in circulation.

In children between 6 and 24 months of age, a 2-year randomized study of TIV exhibited 89% seroconversion and efficacy of 66% in year 1 and 7% in year 2 versus culture-confirmed influenza.³⁵ In children between 1 and 15 years of age, the efficacy of TIV was 91.4% and 77.3% against culture-confirmed influenza A H1N1 and H3N2, respectively. Two doses of TIV are important for children under the age of 9 years, supporting the rationale for the recommendation of a booster dose of TIV at least 1 month after the initial dose in children between 6 months and 9 years of age (see Table 113–2).²⁹

TIV is also effective in adult populations under and older than the age of 65 years. A double-blind, randomized, controlled trial evaluating TIV in healthy adults younger than the age of 65 years demonstrated an efficacy of 50% against serologically confirmed influenza during a season in which the vaccine and the circulating viruses were not well-matched and an efficacy of 86% during a season in which the

TABLE 113-2 Approved Influenza Vaccines for Different Age Groups—United States, 2006–2007 Season

Vaccine	Trade Name	Manufacturer	Dose/Presentation	Thimerosal Mercury Content (mcg Hg/0.5 mL dose)	Age Group	Number of Doses
TIV	Fluzone	Sanofi Pasteur	0.25 mL prefilled syringe	0	6–35 mo	1 or 2 ^a
			0.5 mL prefilled syringe	0	≥36 mo	1 or 2 ^a
			0.5 mL vial	0	≥36 mo	1 or 2 ^a
			5 mL multidose vial	25	≥6 mo	1 or 2 ^a
TIV	Fluvirin	Novartis Vaccine	0.5 mL prefilled syringe	<1	≥4 y	1 or 2 ^a
			5 mL multidose vial	24.5	≥4 y	1 or 2 ^a
TIV	Fluarix	GlaxoSmithKline	0.5 mL prefilled syringe	<1.25	≥18 y	1
LAIV	FluMist	MedImmune	0.5 mL sprayer	0	5–49 y	1 or 2 ^b

LAIV, live-attenuated influenza vaccine; TIV, trivalent influenza vaccine.

^aTwo doses administered at least 1 month apart are recommended for children ages 6 months to less than 9 years who are receiving influenza vaccine for the first time.

^bTwo doses administered at least 6 weeks apart are recommended for children ages 5 to 9 years who are receiving influenza vaccine for the first time.

From Smith *et al.*²⁹

vaccine and the circulating viruses were well-matched.³⁶ These findings were corroborated by a large Cochrane Database System review, which found that TIV had an efficacy of 70% in healthy adults younger than 65 years of age, regardless of virus and vaccine concordance.³⁷ Vaccination of those younger than 65 years old during seasons when the virus and vaccine are well-matched results in decreased work absenteeism and healthcare resource use.^{36,37}

Adults older than the age of 65 years benefit from influenza vaccination, including prevention of complications and decreased risk of influenza-related hospitalization and death. However, people in this population may not generate a strong antibody response to the vaccine and may remain susceptible to infection. In patients older than the age of 60 years who do not reside in a long-term care facility, TIV efficacy was 58% against influenza illness.²⁹ Although the efficacy against influenza illness for those living in long-term care facilities is between 30% and 40%, the vaccine is 50% to 60% effective in preventing influenza-related hospitalization or pneumonia and 80% effective in preventing influenza-related death.²⁹

The most frequent adverse effect associated with TIV is soreness at the injection site that lasts for less than 48 hours. TIV may cause fever and malaise in those who have not previously been exposed to the viral antigens in the vaccine.²⁹ Allergic-type reactions (hives, systemic anaphylaxis) rarely occur after influenza vaccination and are likely a result of a reaction to residual egg protein in the vaccine.

The 1976 swine influenza vaccine was linked to a rise in the incidence of Guillain-Barré syndrome (GBS), and this has propagated the belief that TIV may cause GBS.²⁹ However, there is insufficient evidence to establish causality. Although several studies have failed to establish a relationship between influenza vaccination and increased frequency of GBS, two studies have demonstrated a small but significant increase in GBS following influenza vaccination.^{38,39} Therefore, vaccination should be avoided in persons who are not at high risk for influenza complications and who have experienced GBS within 6 weeks of receiving a previous influenza vaccine.²⁹ The potential benefits of influenza vaccination in terms of prevention of severe illness, hospitalization, and mortality significantly outweigh the risks of GBS, and vaccination is recommended for all groups previously discussed.

The multidose vials and a few of the single-dose preparations of TIV contain trace to small amounts of a preservative, thimerosal, which is a mercury-containing compound (see Table 113–2). Some individuals are concerned about thimerosal exposure, particularly among children, because of the unfounded belief that thimerosal exposure is linked to the development of autism. No scientifically persuasive evidence exists to suggest harm from thimerosal exposure from a vaccine. Conversely, accumulating evidence reports the lack of harm from such exposure.^{40–42} Thus, similar to GBS, the potential benefits of influenza vaccination in terms of prevention of severe illness, hospitalization, and mortality significantly outweigh the theoretical risk associated with thimerosal exposure, and vacci-

nation is recommended for all groups previously discussed. However, to maximize the public health benefit and placate concerned individuals, thimerosal-free vaccine is available (see Table 113–2).

Live-Attenuated Influenza Vaccine

7 LAIV is made with live, attenuated viruses and is approved for intranasal administration in healthy people between 5 and 49 years of age (see Table 113–3). Advantages of LAIV include its ease of administration, intranasal rather than intramuscular administration, and the potential induction of broad mucosal and systemic immune response.²⁹ The mucosal response occurs at the site of viral entry and may prevent infection before viral replication occurs.⁴³ LAIV is more expensive than TIV and is approved for use in a more limited population.

Controlled studies support the use of LAIV in healthy people between the ages of 5 and 49 years. Although LAIV is FDA-approved for children who are at least 5 years old, a double-blind, placebo-controlled trial demonstrated efficacy of 93% against culture-confirmed influenza in children as young as 15 months (range: 15 to 71 months).⁴⁴ Moreover, those receiving vaccine had 30% fewer episodes of acute otitis media, suggesting a decrease in healthcare resource use.⁴⁴ LAIV is only approved for children over the age of 5 years in part because of data showing an increase in asthma or reactive airway disease in those younger than 5 years old.^{45,46} However, in children ages 6 to 71 months there was a 52.7% reduction in culture-confirmed influenza in those who received LAIV compared to those who received TIV, and there was no difference between groups in the incidence of wheezing after vaccination.⁴⁷

Although LAIV is FDA approved for adults younger than the age of 49 years, LAIV is effective in healthy adults between 18 and 64 years old.^{48,49} Vaccination reduced the number of severe febrile illnesses by 18.8% and febrile upper respiratory tract illnesses by 23.6%.⁴⁸ Additionally, vaccination led to fewer days of illness, fewer days lost from

TABLE 113-3 Comparison of Trivalent (TIV) and Live-Attenuated Influenza Vaccine (LAIV)

Characteristic	TIV	LAIV
Age groups approved for use	>6 months	5 to 49 years
Immune status requirements	Immunocompetent or immunocompromised	Immunocompetent
Viral properties	Inactivated (killed) influenza A (H3N2), A (H1N1), and B viruses	Live-attenuated influenza A (H3N2), A (H1N1), and B viruses
Route of administration	Intramuscular	Intranasal
Immune system response	High serum IgG antibody response	Lower IgG response and high serum IgA mucosal response

TABLE 113-4 Recommended Daily Dosage of Influenza Antiviral Medications for Treatment and Prophylaxis—United States

Antiviral Agent	Age Group (y)				
	1–6	7–9	10–12	13–64	At Least 65
Zanamivir					
Treatment	N/A	10 mg twice daily	10 mg twice daily	10 mg twice daily	10 mg twice daily
Prophylaxis	Ages 1–4, N/A	Ages 5–9, 10 mg once daily	10 mg once daily	10 mg once daily	10 mg once daily
Oseltamivir					
Treatment ^a	According to weight ^b	According to weight ^b	According to weight ^b	75 mg twice daily	75 mg twice daily
Prophylaxis ^c	According to weight ^c	According to weight ^c	According to weight ^c	75 mg once daily	75 mg once daily

N/A, not applicable.
^aDose reduction recommended in those with creatinine clearance less than 30 mL/min.
^bTreatment dosing of oseltamivir for children weighing ≤15 kg is 30 mg twice daily; for those >15 kg to 23 kg, the dose is 45 mg twice daily; for those weighing >23 kg to 40 kg, the dose is 60 mg twice daily; and for those >40 kg, the dose is 75 mg twice daily.
^cThe prophylactic dosing of oseltamivir for children weighing ≤15 kg is 30 mg once daily; for those >15 kg to 23 kg, the dose is 45 mg once daily; for those weighing >23 kg up to 40 kg, the dose is 60 mg once daily; and for those >40 kg, the dose is 75 mg once daily.
From Smith et al.²⁹

work, fewer visits to healthcare providers, and decreased use of prescription antibiotics and nonprescription medications.⁴⁸

The adverse effects typically associated with LAIV administration include runny nose, congestion, sore throat, and headache. Because LAIV contains live, attenuated viruses, viral shedding may occur for several days following vaccination with LAIV, although this should not be equated with person-to-person transmission.²⁹ Additionally, because LAIV contains live-attenuated viruses, which carry a theoretical infection risk, LAIV should not be given to immunosuppressed patients or given by healthcare workers who are severely immunocompromised. Moreover, for the reasons discussed in the TIV section, LAIV should not be administered to persons with a history of GBS or hypersensitivity to eggs.

CLINICAL CONTROVERSY

LAIV is not recommended in several populations, including people younger than 5 or older than 50 years and pregnant women, largely because the vaccine has not been studied extensively in these populations. However, many clinicians believe the use of LAIV in these populations is acceptable.

POSTEXPOSURE PROPHYLAXIS

8 Antiviral drugs available for prophylaxis of influenza should be considered adjuncts but are not replacements for annual vaccination. The two classes of antiviral drugs available for influenza prophylaxis are the adamantanes and the neuraminidase inhibitors. The adamantanes, amantadine and rimantadine, are currently not recommended for prophylaxis or treatment in the United States because 92% of the circulating influenza A viruses are resistant to these agents.²⁹ Both of the neuraminidase inhibitors, oseltamivir and zanamivir, are effective prophylactic agents against influenza in terms of preventing laboratory-confirmed influenza when used for seasonal prophylaxis (67% and 85% effective for zanamivir and oseltamivir, respectively) and preventing influenza illness among persons exposed to a household contact who was diagnosed with influenza (79% to 81% and 68% to 89% effective for zanamivir and oseltamivir, respectively).^{50–52} Additionally, oseltamivir was 92% effective against influenza and also reduced associated complications when used as seasonal prophylaxis among immunized, institutionalized, elderly patients.⁵³ Oseltamivir is approved for prophylaxis in those older than the age of 1 year, and zanamivir is approved for prophylaxis in those older than the age of 5 years. Table 113–4 gives dosing recommendations.

In those patients who did not receive the influenza vaccination and are receiving an antiviral drug for prevention of disease during the influenza season, the medication should optimally be taken for the entire duration of influenza activity in the community. The use

of prophylaxis requires clinical judgment and depends on a variety of factors, but prophylaxis should be considered during influenza season for the following groups of patients:

- Persons at high risk of serious illness and/or complications who cannot be vaccinated.
- Persons at high risk of serious illness and/or complications who are vaccinated after influenza activity has begun in their community since the development of sufficient antibody titers after vaccination takes approximately 2 weeks.
- Unvaccinated persons who have frequent contact with those at high risk.
- Persons who may have an inadequate response to vaccination (e.g., advanced HIV disease).
- Long-term care facility residents, regardless of vaccination status, when an outbreak has occurred in the institution.
- Unvaccinated household contacts of someone who was diagnosed with influenza.

LAIV should not be administered until 48 hours after influenza antiviral therapy has stopped, and influenza antiviral drugs should not be administered for 2 weeks after the administration of LAIV because the antiviral drugs inhibit influenza virus replication.²⁹ No contraindication exists for concomitant use of TIV and influenza antiviral drugs.

SPECIAL POPULATIONS

Pregnant women and immunocompromised hosts are special populations at increased risk of influenza complications and are also populations in whom careful consideration must be given in regard to prevention strategies.

Pregnant Women

Pregnant women, regardless of trimester, should receive annual influenza vaccination with TIV but not with LAIV. No studies have demonstrated an increased incidence of adverse effects in mothers or their infants related or potentially related to TIV, but no such data exist for LAIV.⁵⁴ TIV is also safe for breast-feeding mothers. No data exist for LAIV and breast-feeding, but caution is warranted because of the potential for viral shedding.²⁹ In those who are not vaccinated or those who develop disease, limited treatment options exist. The adamantanes and neuraminidase inhibitors are not recommended during pregnancy because of concerns regarding the effects of the drugs on the fetus.

Immunocompromised Hosts

Immunocompromised hosts should receive annual influenza vaccination with TIV but not LAIV. TIV was 100% effective against

laboratory-confirmed influenza in HIV-positive patients with no significant effect on viral load or CD4 cell count.⁵⁵ However, antibody titers may not be as high as in immunocompetent individuals and are not improved with a second dose of vaccine.⁵⁶ Similarly, antibody titers may not be as high in solid-organ transplant patients as in immunocompetent persons, but conversely, antibody titers were increased significantly after a second dose of TIV in adult liver transplant patients.⁵⁷ Although this suggests a potential benefit from a two-dose regimen, such a regimen is not currently recommended for solid-organ transplant recipients.

Large, clinical trials evaluating the use of influenza antivirals for prophylaxis are lacking in immunocompromised hosts. Viral shedding occurs for prolonged periods in this population and may promote the development of antiviral resistance, which has already been documented with oseltamivir in HIV-positive patients.^{58,59}

TREATMENT

Influenza

When prevention efforts fail or are not used, clinicians must turn to the agents available for treatment of influenza. Currently, the antiviral treatment options are limited, particularly in the face of high resistance to the adamantanes.

GOALS OF THERAPY

The four primary goals of therapy of influenza are as follows:

1. Control symptoms;
2. Prevent complications;
3. Decrease work and/or school absenteeism;
4. Prevent the spread of infection.

GENERAL APPROACH TO TREATMENT

In the era of pandemic preparedness and increasing resistance, early and definitive diagnosis of influenza is crucial. ⁹ The currently available antiviral drugs are most effective if started within 48 hours of the onset of illness. Moreover, the sooner the antiviral drugs are started after the onset of illness, the more effective they are. Antiviral drugs shorten the duration of illness and provide symptom control. Adjunct agents, such as acetaminophen for fever or an antihistamine for rhinitis, may be used concomitantly with the antiviral drugs.

NONPHARMACOLOGIC THERAPY

Patients suffering from influenza should get adequate sleep and maintain a low level of activity. They should stay home from work and/or school in order to rest and prevent the spread of infection. Appropriate fluid intake should be maintained. Cough/throat lozenges, warm tea, or soup may help with symptom control (cough, sore throat).

PHARMACOLOGIC THERAPY

The two classes of antiviral drugs available for treatment of influenza are the same as those available for prophylaxis and include the adamantanes, amantadine and rimantadine, and the neuraminidase inhibitors, oseltamivir and zanamivir. Because of widespread resistance to the adamantanes among influenza A viruses in the United States, amantadine and rimantadine are not recommended for treatment of influenza until susceptibility can be reestablished. A limited discussion of these two agents can be found below, but the focus will be on the two available agents of choice, oseltamivir and zanamivir.

Amantadine/Rimantadine

Amantadine and rimantadine are adamantanes that have activity against influenza A only. The adamantanes block the M2 ion channel, which is specific to influenza A viruses, and inhibit viral uncoating. Rapid emergence of resistance is a problem with these agents because cross-resistance is conferred by a single point mutation.²⁹ Ninety-two percent of the circulating influenza A viruses are resistant to the adamantanes, which is why these agents are not currently recommended for treatment or prophylaxis of influenza in the United States.²⁹

Oseltamivir/Zanamivir

¹⁰ Oseltamivir and zanamivir are neuraminidase inhibitors that have activity against both influenza A and influenza B viruses. Without neuraminidase, release of the virus from infected cells is impaired, and thus, viral replication is decreased. When administered within 48 hours of the onset of illness, oseltamivir and zanamivir may reduce the duration of illness by approximately one day versus placebo.²⁹ In a pivotal trial, oseltamivir reduced the time to return to normal health in adults by 1.9 days and the time to return to normal activity by 2.8 days.⁶⁰ These reductions have a significant effect on not only the quality of life for the patient but also the societal costs associated with influenza. ⁹ Of note, the benefits of treatment are highly dependent on the timing of the initiation of treatment, with the ideal initiation period being within 12 hours of illness onset.⁶¹

Oseltamivir treatment in adults and adolescents with documented influenza illness resulted in a 26.7% reduction in overall antibiotic use, a 55% reduction in lower respiratory tract complications (bronchitis, pneumonia), and a 59% reduction in hospitalizations.⁶² Zanamivir treatment in adults and adolescents with influenza-like illness resulted in a 28% reduction in antibiotic use and a 40% reduction in lower respiratory tract complications.⁶³ The data in these studies largely come from healthy individuals rather than those at highest risk for complications associated with influenza. The impact of appropriate treatment in high-risk populations may be even greater than that which has been documented to date.

Oseltamivir is approved for treatment in those older than the age of 1 year, while zanamivir is approved for treatment in those older than the age of 7 years. The recommended dosages vary by agent and age (see Table 113-4), and the recommended duration of treatment for both agents is 5 days.

Resistance to the neuraminidase inhibitors has been documented but remains rare, and transmission of resistant viruses has not been documented to date.²⁹ Moreover, cross-resistance between the neuraminidase inhibitors has not been reported. A small study of oseltamivir treatment in Japanese children demonstrated a high frequency of resistant viruses (18%),⁶⁴ but this was likely caused by suboptimal dosing of oseltamivir in these children.⁵¹

The FDA has received 103 reports, occurring between August 29, 2005 and July 6, 2006, of delirium, hallucinations, and self-injury in pediatric patients (mostly from Japan) following treatment with oseltamivir.⁶⁵ Although a causal relationship has not been established, the label for oseltamivir has been updated to include neuro-psychiatric events as a precaution.⁶⁶

CLINICAL CONTROVERSY

Some clinicians debate the cost-benefit of the use of diagnostic tests for influenza as well as treatment of influenza in otherwise healthy individuals who are likely to experience resolution without treatment. This controversy is compounded by the fact that the diagnostic tests and the benefits associated with treatment of influenza are highest early in the disease process, and many patients present after this time period.

SPECIAL POPULATIONS

Inadequate data exist regarding the use of antiinfluenza medications in special populations, such as immunocompromised hosts. Furthermore, no clinical studies have been conducted evaluating the safety and efficacy of the adamantanes or the neuraminidase inhibitors during pregnancy, and all of the drugs are Pregnancy Category C. The adamantanes are embryotoxic and teratogenic in rats, and limited case reports of adverse fetal outcomes following amantadine use in humans have been published. No such data exist for the neuraminidase inhibitors. Both the adamantanes and the neuraminidase inhibitors are excreted in breast milk and should be avoided by mothers who are breast-feeding their infants. More studies are needed in these populations who are at high risk for serious disease and complications from influenza.

EVALUATION OF THERAPEUTIC OUTCOMES

Patients should be monitored daily for resolution of signs and symptoms associated with influenza, such as fever, myalgia, headache, malaise, nonproductive cough, sore throat, and rhinitis. These signs and symptoms will typically resolve within approximately 1 week. If the patient continues to exhibit signs and symptoms of illness beyond 10 days or a worsening of symptoms after 7 days, a physician visit is warranted as this may be an indication of a secondary bacterial infection. Ideally, antiviral therapy should not be started until influenza is confirmed via the laboratory. However, therapy should be initiated within 48 hours of illness onset, emphasizing the need for rapid diagnosis. Repeat diagnostic tests to demonstrate clearance of the virus are not necessary.

CONCLUSIONS

Influenza is associated with significant morbidity and mortality and substantial burden to society in terms of both direct and indirect costs. Prevention of influenza by vaccination may yield significant benefit to society in terms of reductions in influenza-related complications, decreased work/school absenteeism, reductions in hospitalizations and deaths, and general cost savings. Two highly effective influenza vaccines are currently available in the United States, yet influenza remains the leading cause of vaccine-preventable mortality. This underscores the need for targeted efforts toward populations at high risk for serious disease and complications as well as the need for more vaccines, particularly for certain populations (e.g., those younger than 6 months old, those with hypersensitivity to eggs).

Four antiviral drugs are available for treatment and prophylaxis of influenza. Thus, the antiinfluenza antiviral armamentarium is limited and has been further reduced by the significant resistance to the adamantanes in recent years. Importantly, these agents are not a replacement for vaccination but rather an adjunct. Although the neuraminidase inhibitors remain useful as agents for treatment and prophylaxis of influenza, information on the use of these agents in special populations, such as immunocompromised hosts and pregnant women, is limited. The best mechanism to decrease the morbidity, mortality, and societal burden associated with influenza remains prevention of the disease through annual vaccination.

ABBREVIATIONS

DFA: direct fluorescent antibody
 FDA: Food and Drug Administration
 GBS: Guillain-Barré syndrome
 HIV: human immunodeficiency virus

LAIV: live-attenuated influenza vaccine

POC: point of care

RT-PCR: reverse-transcription polymerase chain reaction

TIV: trivalent influenza vaccine

KEY CONCEPTS

- 1 Folliculitis, furuncles (boils), and carbuncles begin around hair follicles and are caused most often by *Staphylococcus aureus*. Folliculitis and small furuncles are generally treated with warm, moist heat to promote drainage; large furuncles and carbuncles require incision and drainage. A penicillinase-resistant penicillin such as dicloxacillin is commonly used for extensive or serious infections (e.g., fever).
- 2 Erysipelas, a superficial skin infection with extensive lymphatic involvement, is caused by *Streptococcus pyogenes*. The treatment of choice is penicillin, administered orally or parenterally, depending on the severity of the infection.
- 3 Impetigo is a superficial skin infection that occurs most commonly in children. It is characterized by fluid-filled vesicles that develop rapidly into pus-filled blisters that rupture to form golden-yellow crusts. Effective therapy includes penicillinase-resistant penicillins (dicloxacillin), first-generation cephalosporins (cephalexin), and topical mupirocin. *S. aureus* is the primary cause of impetigo, with infections caused by community-associated methicillin-resistant *S. aureus* (CA-MRSA) emerging in recent years.
- 4 Lymphangitis, an infection of the subcutaneous lymphatic channels, is generally caused by *S. pyogenes*. Acute lymphangitis is characterized by the rapid development of fine, red, linear streaks extending from the initial infection site toward the regional lymph nodes, which are usually enlarged and tender. Penicillin is the drug of choice.
- 5 Cellulitis is an infection of the epidermis, dermis, and superficial fascia most commonly caused by *S. pyogenes* and *S. aureus*. Lesions generally are hot, painful, and erythematous, with non-elevated, poorly defined margins. Treatment generally consists of a penicillinase-resistant penicillin (dicloxacillin) or first-generation cephalosporin (cephalexin) for 5 to 10 days. Trimethoprim-sulfamethoxazole should be considered for treatment of suspected staphylococcal infections in areas with a high prevalence of CA-MRSA.
- 6 Necrotizing fasciitis is a rare but life-threatening infection of subcutaneous tissue that results in progressive destruction of superficial fascia and subcutaneous fat. Early and aggressive surgical debridement is an essential part of therapy for treatment of necrotizing fasciitis. Infections caused by *S. pyogenes* or *Clostridium* species should be treated with the combination of penicillin and clindamycin.
- 7 Diabetic foot infections are managed with a comprehensive treatment approach that includes both proper wound care and antimicrobial therapy. Antimicrobial regimens for diabetic foot infections should include broad-spectrum coverage of staphylococci, streptococci, enteric gram-negative bacilli, and anaerobes. Outpatient therapy with oral antimicrobials should be used whenever possible.
- 8 Prevention is the single most important aspect in the management of pressure sores. After a sore develops, successful local care includes a comprehensive approach consisting of relief of pressure, proper cleaning (debridement), disinfection, and appropriate antimicrobial therapy if an infection is present. Good wound care is crucial to successful management.
- 9 All bite wounds (either animal or human) should be irrigated thoroughly with large volumes of sterile normal saline, and the injured area should be immobilized and elevated. Depending on the severity of the bite wound, amoxicillin-clavulanic acid or ampicillin-sulbactam are often used for treatment of animal bites because of their coverage of *Pasteurella multocida*, *S. aureus*, and anaerobes typically present in the oral flora of dogs and cats.
- 10 Although antimicrobial prophylaxis of dog or cat bites is not recommended routinely, patients with human bite injuries should be given prophylactic antimicrobial therapy for 3 to 5 days. Infected wounds, particularly clenched-fist injuries, should be treated for 7 to 14 days with ampicillin-sulbactam, cefoxitin, or other combination that has activity against *Eikenella corrodens*, *S. aureus*, and β -lactamase-producing anaerobes.

The skin serves as a barrier between humans and their environment and therefore functions as a primary defense mechanism against infections. The skin consists of the epidermis, the dermis, and subcutaneous fat. The epidermis is the outermost, nonvascular layer of the skin. It varies in thickness from approximately 0.1 mm on most areas of the body to a maximum of 1.5 mm on the soles of the feet. Although extremely thin, the epidermis is composed of several layers. The innermost layer consists of continuously dividing cells. The outer layers are renewed as cells are gradually pushed outward. As the cells approach the surface, they become flattened, lose their nuclei, and are filled with keratin. The outermost layer, the stratum corneum, is composed of flattened, cornified, nonnucleated cells. The dermis is the layer of skin directly beneath the epidermis. It consists of connective tissue and contains blood vessels and lymphatics, sensory nerve endings, sweat and sebaceous glands, hair follicles, and smooth muscle fibers. Beneath the dermis is a layer of loose connective tissue containing primarily fat cells. This subcuta-

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

neous fat layer is of variable thickness over the body. Beneath the subcutaneous fat lies the fascia, which separates the skin from underlying muscle. It is generally divided into superficial fascia, which is located immediately beneath the skin, and deep fascia, which forms sheaths for muscles.

Skin and soft-tissue infections (SSTIs) may involve any or all layers of the skin, fascia, and muscle. They also may spread far from the initial site of infection and lead to more severe complications, such as endocarditis, gram-negative sepsis, or streptococcal glomerulonephritis. Sometimes the treatment of SSTIs may necessitate both medical and surgical management. This chapter presents details of the pathogenesis and management of some of the most common infections involving the skin and soft tissues. The first part of the chapter discusses a variety of SSTIs that range in severity from superficial to life-threatening. The remainder of the chapter discusses diabetic foot infections, pressure sores, and human and animal bites.

EPIDEMIOLOGY

A number of classification schemes have been developed to describe SSTIs. Bacterial infections of the skin can be classified as primary or secondary (Table 114–1). Primary bacterial infections usually involve areas of previously healthy skin and typically are caused by a single pathogen. In contrast, secondary infections occur in areas of previously damaged skin and are frequently polymicrobial. SSTIs are also classified as complicated or uncomplicated. Infections are considered complicated when they involve deeper skin structures (e.g., fascia, muscle layers), require significant surgical intervention, or occur in patients with compromised immune function (e.g., diabetes mellitus, human immunodeficiency virus [HIV] infection).¹

The classification system developed by Eron divides SSTIs into four classes based on severity of signs and symptoms, as well as the presence and stability of any comorbidities.² The classification was used to develop an algorithm to help with admission and treatment decisions. Class 1 includes patients who are afebrile and otherwise healthy. These patients generally can be managed on an outpatient

basis with topical or oral antimicrobials. Class 2 includes patients who are febrile and ill-appearing but who have no unstable comorbid conditions. Some class 2 patients may be treated with oral antimicrobials, but most are likely to require some parenteral therapy, either as an outpatient or with short-term hospitalization. Patients having a toxic appearance, unstable comorbidity, or a limb-threatening infection are grouped into class 3. Class 4 includes patients with sepsis syndrome or another life-threatening infection, such as necrotizing fasciitis. Patients in classes 3 and 4 require hospitalization and parenteral antimicrobial therapy initially but may be candidates for oral or outpatient parenteral therapy once their condition has stabilized. Patients in class 4 also generally require some type of surgical intervention.

SSTIs are among the most common infections seen in both community and hospital settings.³ However, data on the exact incidence of SSTIs are lacking. Most infections are believed to be mild and therefore are treated in an outpatient setting, making it difficult to quantify community-acquired SSTIs. One description of office visits among health plan members listed cellulitis and impetigo as the primary diagnosis for 2.2% and 0.3% of patients, respectively.⁴ According to the most recent Healthcare Cost and Utilization Project Nationwide Inpatient Sample, SSTIs are the 28th most common diagnosis of patients in community hospitals.⁵ Soft-tissue infections were the leading cause of admissions for medical or surgical treatment in a large academic medical center.³ Approximately 0.1% of the adult population in the United States required hospitalization for SSTIs in 1995.²

Although the exact incidence of SSTIs is unknown, the frequency of infections caused by invasive group A streptococci and drug-resistant gram-positive cocci has been increasing.¹ Group A streptococci (*Streptococcus pyogenes*) are among the most common etiologic agents of SSTIs. Although they may be found in many mild, superficial skin infections, they are also responsible for life-threatening cases of necrotizing fasciitis.¹ A dramatic increase in necrotizing fasciitis caused by *S. pyogenes* is a major concern because of the high morbidity and mortality associated with these infections.

Another worrisome trend is the increased in vitro resistance reported for many gram-positive bacteria.¹ While the high incidence of nosocomial methicillin-resistant *Staphylococcus aureus* (MRSA) has been a major concern for the past decade,^{6–8} the recent emergence of community-associated MRSA (CA-MRSA) is even more problematic.^{9–16} CA-MRSA strains have been isolated from patients lacking typical risk factors (e.g., prior hospitalization, long-term care facility) and are generally susceptible to non- β -lactam antibiotics (trimethoprim-sulfamethoxazole, doxycycline, clindamycin).^{9,11,13} They also differ genetically from nosocomial strains of MRSA with methicillin resistance carried on the type IV staphylococcal chromosomal cassette *mec* (SCC*mec*) element of the *mecA* gene. CA-MRSA strains often harbor genes for Panton-Valentine leukocidin, a cytotoxin responsible for leukocyte destruction and tissue necrosis. In contrast, nosocomial strains usually lack genes for Panton-Valentine leukocidin and are associated with SCC*mec* alleles I to III.^{10,11,16} Clinicians should suspect CA-MRSA in geographic areas with a high prevalence of these strains, or in recurrent or persistent infections that are not responding to appropriate β -lactam therapy. In addition to the emergence of CA-MRSA, treatment choices for SSTIs have been further complicated by the increased incidence of macrolide-resistant strains of *Staphylococcus aureus* and *S. pyogenes*.^{1,8,11}

ETIOLOGY

The majority of SSTIs are caused by gram-positive organisms present on the skin surface.¹ Gram-positive bacteria (coagulase-negative staphylococci, diphtheroids) are the predominant flora of the skin, with gram-negative organisms (*Escherichia coli* and other

TABLE 114-1 Bacterial Classification of Important Skin and Soft-Tissue Infections

Primary infections	
Erysipelas	Group A streptococci
Impetigo	<i>Staphylococcus aureus</i> , group A streptococci
Lymphangitis	Group A streptococci; occasionally <i>S. aureus</i>
Cellulitis	Group A streptococci, <i>S. aureus</i> ; occasionally other gram-positive cocci, gram-negative bacilli, and/or anaerobes
Necrotizing fasciitis	
Type I	Anaerobes (<i>Bacteroides</i> spp., <i>Peptostreptococcus</i> spp.) and facultative bacteria (streptococci, Enterobacteriaceae)
Type II	Group A streptococci
Secondary infections	
Diabetic foot infections	<i>S. aureus</i> , streptococci, Enterobacteriaceae, <i>Bacteroides</i> spp., <i>Peptostreptococcus</i> spp., <i>Pseudomonas aeruginosa</i>
Pressure sores	<i>S. aureus</i> , streptococci, Enterobacteriaceae, <i>Bacteroides</i> spp., <i>Peptostreptococcus</i> spp., <i>Pseudomonas aeruginosa</i>
Bite wounds	
Animal	<i>Pasteurella multocida</i> , <i>S. aureus</i> , streptococci, <i>Bacteroides</i> spp.
Human	<i>Eikenella corrodens</i> , <i>S. aureus</i> , streptococci, <i>Corynebacterium</i> spp., <i>Bacteroides</i> spp., <i>Peptostreptococcus</i> spp.
Burn wounds	<i>Pseudomonas aeruginosa</i> , Enterobacteriaceae, <i>S. aureus</i> , streptococci

Enterobacteriaceae) being relatively uncommon¹⁷ (Table 114–2). *S. aureus*, as well as a variety of gram-negative bacteria, can be found in moist intertriginous areas (e.g., axilla, groin, and toe webs) of the body. *Acinetobacter* species have been cultured from these moister areas in 25% of the population.¹⁷ *S. aureus* also inhabits the anterior nares of approximately 30% of healthy individuals.¹⁷ Colonization, whether transient or permanent, provides a nidus for infection should the integrity of the epidermis be compromised.

S. aureus and *S. pyogenes* account for the majority of community-acquired SSTIs.¹ Data from the most recent SENTRY Antimicrobial Surveillance Program showed *S. aureus* to be the most common cause (45%) of SSTIs in hospitalized patients.^{6,7} Also of note in this study was the 36% incidence of methicillin resistance among strains of *S. aureus*. Other common nosocomial pathogens included *Pseudomonas aeruginosa* (11%), enterococci (9%), and *E. coli* (7%).^{6,7}

PATHOPHYSIOLOGY

The skin and subcutaneous tissues normally are extremely resistant to infection but may become susceptible under certain conditions. Even when high concentrations of bacteria are applied topically or injected into the soft tissue, resulting infections are rare.¹⁷ Several host factors act together to confer protection against skin infections. Because the surface of the skin is relatively dry and has a pH of approximately 5.6, it is not conducive to bacterial growth.¹⁷ Continuous renewal of the epidermal layer results in the shedding of keratocytes, as well as skin bacteria. In addition, sebaceous secretions are hydrolyzed to form free fatty acids that strongly inhibit the growth of many bacteria and fungi.⁴ The conditions that may predispose a patient to the development of skin infections include (a) a high concentration of bacteria ($>10^5$ microorganisms), (b) excessive moisture of the skin, (c) inadequate blood supply, (d) availability of bacterial nutrients, and (e) damage to the corneal layer allowing for bacterial penetration.^{4,17}

The majority of SSTIs result from the disruption of normal host defenses by processes such as skin puncture, abrasion, or underlying diseases (e.g., diabetes). The nature and severity of the infection depend on both the type of microorganism present and the site of inoculation.

FOLLICULITIS, FURUNCLES, AND CARBUNCLES

1 Folliculitis is inflammation of the hair follicle and can be caused by physical injury, chemical irritation, or infection.⁴ Infection occurring at the base of the eyelid is referred to as a sty. While folliculitis is a superficial infection with pus present only in the dermis, furuncles and carbuncles occur when a follicular infection extends from around the hair shaft to involve the deeper areas of the skin. A furuncle, commonly known as an *abscess* or *boil*, is a walled-off mass of purulent material arising from a hair follicle.⁴ The lesions are called *carbuncles* when they coalesce and extend to the

subcutaneous tissue. This aggregate of infected hair follicles forms deep masses that generally open and drain through multiple sinus tracts.⁴ *S. aureus* is the most common cause of folliculitis, furuncles, and carbuncles. Inadequate chlorine levels in whirlpools, hot tubs, and swimming pools have been responsible for outbreaks of folliculitis caused by *P. aeruginosa*.¹⁸ Outbreaks of furunculosis caused by *S. aureus* and CA-MRSA have been reported in settings involving close contact (such as with families, prisons), especially when skin injury was common (such as with sports). In addition, some individuals experience repeated attacks of furunculosis. The major predisposing factor in this population is the presence of *S. aureus* in the anterior nares.¹¹

CLINICAL PRESENTATION**Folliculitis**

- Pruritic, erythematous papules typically appear within 48 hours (range: 6 to 72 hours) of exposure to large numbers of organisms.
- Papules evolve into pustules that generally heal in several days.
- Systemic signs such as fever and malaise are uncommon, although they have been reported in cases caused by *P. aeruginosa*.

Furuncles

- Furuncles can occur anywhere on hairy skin but generally develop in areas subject to friction and perspiration.
- Furuncles are discrete lesions, whether occurring as singular or multiple nodules.
- The lesion starts as a firm, tender, red nodule that becomes painful and fluctuant.
- Lesions often drain spontaneously.
- Lesions caused by CA-MRSA often have necrotic centers characteristic of “spider bites.”

Carbuncles

- Carbuncles are broad, swollen, erythematous, deep, and painful follicular masses.
- Carbuncles commonly develop on the back of the neck and are more likely to occur in patients with diabetes.
- Unlike folliculitis and furuncles, carbuncles are commonly associated with fever, chills, and malaise.
- Bacteremia with secondary spread to other tissues is common.

TREATMENT**Folliculitis, Furuncles, and Carbuncles**

Table 114–3 summarizes evidence-based treatment recommendations from recently published clinical guidelines for SSTIs.^{11,19} Treatment of folliculitis generally requires only local measures, such as warm moist compresses or topical therapy (e.g., clindamycin, erythromycin, mupirocin, or benzoyl peroxide).²⁰ Topical agents generally are applied two to four times daily for 7 days. Small furuncles generally can be treated with moist heat, which promotes localization and drainage of pus.²⁰ Large and/or multiple furuncles and carbuncles require incision and drainage.²⁰ Systemic antibiotics are generally not necessary unless accompanied by fever or extensive cellulitis.¹¹ For more severe infections, treatment generally consists of a penicillinase-resistant penicillin or a first-generation cephalosporin for 5 to 10 days (refer to Table 114–4 for adult and pediatric doses). An alternative agent for penicillin-allergic patients is clindamycin. For individuals with nasal

TABLE 114-3 Evidence-Based Recommendations for Treatment of Skin and Soft-Tissue Infections

Recommendations	Recommendation Grade
Folliculitis, furuncles, carbuncles Folliculitis and small furuncles can be treated with moist heat; large furuncles and carbuncles require incision and drainage. Antimicrobial therapy is unnecessary unless extensive lesions or fever are present.	E-III
Erysipelas Most infections are caused by <i>Streptococcus pyogenes</i> . Penicillin (oral or intravenous depending on clinical severity) is the drug of choice. If <i>Staphylococcus aureus</i> is suspected, a penicillinase-resistant penicillin or first-generation cephalosporin should be used.	A-I A-I
Impetigo <i>S. aureus</i> accounts for the majority of infections; consequently, a penicillin-resistant penicillin or first-generation cephalosporin is recommended. Topical therapy with mupirocin is equivalent to oral therapy.	A-I A-I
Cellulitis Mild-moderate infections can generally be treated with oral agents (dicloxacillin, cephalexin, clindamycin) unless resistance is high in the community. Serious infections should be treated intravenously with a penicillinase-resistant penicillin (nafcillin) or first-generation cephalosporin (cefazolin). Patients with penicillin allergies should be treated with vancomycin or clindamycin. Vancomycin, linezolid, and daptomycin should be used to treat serious infections caused by methicillin-resistant <i>S. aureus</i> .	A-I A-I A-I
Necrotizing fasciitis Early and aggressive surgical debridement of all necrotic tissue is essential. Necrotizing fasciitis caused by <i>S. pyogenes</i> should be treated with the combination of clindamycin and penicillin. Clostridial gas gangrene (myonecrosis) should be treated with clindamycin and penicillin.	A-III A-II B-III
Diabetic foot infections Many mild to moderate infections can be treated with oral agents that possess high bioavailability. All severe infections should be treated with intravenous therapy. After initial response, step-down therapy to oral agents can be used. Broad-spectrum antimicrobial therapy is not generally required, except for some severe cases. Definitive therapy should be based on results of appropriately collected cultures and sensitivities, as well as clinical response to empiric antimicrobial agents. Optimal wound care, in addition to appropriate antimicrobial therapy, is essential for wound healing.	A-II C-III B-III C-III A-I
Animal bites Many bite wounds can be treated on an outpatient basis with amoxicillin-clavulanic acid. Serious infections requiring intravenous antimicrobial therapy can be treated with a β -lactam/ β -lactamase inhibitor combination or second-generation cephalosporin with activity against anaerobes (cefoxitin). Penicillinase-resistant penicillins, first-generation cephalosporins, macrolides, and clindamycin should not be used for treatment because of their poor activity against <i>Pasteurella multocida</i> .	B-II B-II D-III
Human bites Antimicrobial therapy should provide coverage against <i>Eikenella corrodens</i> , <i>S. aureus</i> , and β -lactamase producing anaerobes.	B-III

Strength of recommendation: A, good evidence for use; B, moderate evidence for use; C, poor evidence for use, optional; D, moderate evidence to support not using; E, good evidence to support not using.

Quality of evidence: I, evidence from ≥ 1 properly randomized, controlled trials; II, evidence from ≥ 1 well-designed clinical trials without randomization, case-controlled analytic studies, multiple time series, or dramatic results from uncontrolled experiments; III, evidence from expert opinion, clinical experience, descriptive studies, or reports of expert committees.

colonization, application of mupirocin ointment twice daily in the anterior nares for the first 5 days of each month decreases recurrent furunculosis by almost half.¹¹ In addition, a single oral daily dose of clindamycin 150 mg for 3 months reduced recurrent infections caused by susceptible strains of *S. aureus* by approximately 80%.¹¹

EVALUATION OF THERAPEUTIC OUTCOMES

Many follicular infections resolve spontaneously without medical or surgical intervention. Lesions should be incised if they do not respond to a few days of moist heat and nonprescription topical agents. Following drainage, most lesions begin to heal within several days without antimicrobial therapy. Any patient who is unresponsive to several days of therapy with a penicillinase-resistant penicillin or first-generation cephalosporin should have a culture and sensitivity performed because of the increasing frequency of CA-MRSA.

ERYSIPELAS

② Erysipelas is an infection of the more superficial layers of the skin and cutaneous lymphatics.²¹ The intense red color and burning pain associated with this skin infection led to the common name of St. Anthony's fire. The infection is almost always caused by β -

hemolytic streptococci, with the organisms gaining access via small breaks in the skin. Group A streptococci (*S. pyogenes*) are responsible for most infections.^{11,22} Infections are more common in infants, young children, the elderly, and patients with nephrotic syndrome.²⁰ Erysipelas also commonly occurs in areas of preexisting lymphatic obstruction or edema.²⁰ Diagnosis is made on the basis of the characteristic lesion.

CLINICAL PRESENTATION

General

- The lower extremities are the most common sites for erysipelas.

Symptoms

- Patients often experience flu-like symptoms (fever, malaise) prior to the appearance of the lesion.
- The infected area is described as painful or as a burning pain.

Signs

- The lesion is bright red and edematous, often with lymphatic streaking.
- Temperature is often mildly elevated.
- The clinical presentation differs from cellulitis in that the lesion has clearly demarcated raised margins.

TABLE 114-4 Recommended Drugs and Dosing Regimens for Outpatient Treatment of Mild–Moderate Skin and Soft-Tissue Infections

Infection	Oral Adult Dose	Oral Pediatric Dose
Folliculitis	None; warm saline compresses usually sufficient	
Furuncles and carbuncles	Dicloxacillin 250–500 mg every 6 h Cephalexin 250–500 mg every 6 h Clindamycin 300–600 mg every 6–8 h ^a	Dicloxacillin 25–50 mg/kg in four divided doses Cephalexin 25–50 mg/kg in four divided doses Clindamycin 10–30 mg/kg/day in three to four divided doses ^a
Erysipelas	Procaine penicillin G 600,000 units intramuscularly every 12 h Penicillin VK 250–500 mg every 6 h Clindamycin 150–300 mg every 6–8 h ^a Erythromycin 250–500 mg every 6 h ^a	Penicillin VK 25,000–90,000 units/kg in four divided doses Clindamycin 10–30 mg/kg in three to four doses ^a Erythromycin 30–50 mg/kg in four divided doses ^a
Impetigo	Dicloxacillin 250–500 mg every 6 h Cephalexin 250–500 mg every 6 h Cefadroxil 500 mg every 12 h Clindamycin 150–300 mg every 6–8 h ^a Mupirocin ointment every 8 h ^a	Dicloxacillin 25–50 mg/kg in four divided doses Cephalexin 25–50 mg/kg in two to four divided doses Cefadroxil 30 mg/kg in two divided doses Clindamycin 10–30 mg/kg/day in three to four divided doses ^a Mupirocin ointment every 8 h ^a
Lymphangitis	Initial intravenous therapy, followed by penicillin VK 250–500 mg every 6 h Clindamycin 150–300 mg every 6–8 h ^a	Initial intravenous therapy, followed by penicillin VK 25,000–90,000 units/kg in four divided doses Clindamycin 10–30 mg/kg/day in three to four divided doses ^a
Diabetic foot infections	Amoxicillin-clavulanic acid 875 mg/125 mg every 12 h Fluoroquinolone (levofloxacin 750 mg every 24 h or moxifloxacin 400 mg every 24 h) + metronidazole 250–500 mg every 8 h or clindamycin 300–600 mg every 6–8 h ^a	
Animal bite	Amoxicillin-clavulanic acid 875 mg/125 mg every 12 h Doxycycline 100–200 mg every 12 h ^a Dicloxacillin 250–500 mg every 6 h + penicillin VK 250–500 mg every 6 h Cefuroxime axetil 500 mg every 12 h + metronidazole 250–500 mg every 8 h or clindamycin 300–600 mg every 6–8 h Fluoroquinolone (levofloxacin 500–750 mg every 24 h or moxifloxacin 400 mg every 24 h) or clindamycin 300–600 mg every 6–8 h ^a Erythromycin 500 mg every 6 h + metronidazole 250–500 mg every 8 h or clindamycin 300–600 mg every 6–8 h ^a	Amoxicillin-clavulanic acid 40 mg/kg (of the amoxicillin component) in two divided doses Dicloxacillin 25–50 mg/kg in four divided doses + penicillin VK 40,000–90,000 units/kg in four divided doses Cefuroxime axetil 20–30 mg/kg in two divided doses + metronidazole 30 mg/kg in three to four divided doses or clindamycin 10–30 mg/kg/day in three to four divided doses Trimethoprim-sulfamethoxazole 4–6 mg/kg (of the trimethoprim component) every 12 h + metronidazole 30 mg/kg in three to four divided doses or clindamycin 10–30 mg/kg/day in three to four divided doses ^a Erythromycin 30–50 mg/kg in four divided doses + every 12 h + metronidazole 30 mg/kg in three to four divided doses or clindamycin 10–30 mg/kg/day in three to four divided doses ^a
Human bite	Amoxicillin-clavulanic acid 875 mg/125 mg every 12 h Doxycycline 100–200 mg every 12 h ^a Dicloxacillin 250–500 mg every 6 h + penicillin VK 250–500 mg every 6 h Cefuroxime axetil 500 mg every 12 h + metronidazole 250–500 mg every 8 h or clindamycin 300–600 mg every 6–8 h Fluoroquinolone (levofloxacin 500–750 mg every 24 h or moxifloxacin 400 mg every 24 h) + metronidazole 250–500 mg every 8 h or clindamycin 300–600 mg every 6–8 h ^a	Amoxicillin-clavulanic acid 40 mg/kg (of the amoxicillin component) in two divided doses Dicloxacillin 25–50 mg/kg in four divided doses + penicillin VK 40,000–90,000 units/kg in four divided doses Cefuroxime axetil 20–30 mg/kg in two divided doses + metronidazole 30 mg/kg in three to four divided doses or clindamycin 10–30 mg/kg/day in three to four divided doses Trimethoprim-sulfamethoxazole 4–6 mg/kg (of the trimethoprim component) every 12 h + metronidazole 30 mg/kg in three to four divided doses or clindamycin 10–30 mg/kg/day in 3–4 divided doses ^a

^aRecommended for patients with penicillin allergy.**Laboratory Tests**

- The causative organism usually cannot be cultured from the surface skin but sometimes may be aspirated from the edge of the advancing lesion.
- Cultures may be considered in more severe cases or those with atypical clinical findings such as fluid-filled blisters.

Other Diagnostic Tests

- A complete blood count is often performed because leukocytosis is common.
- C-reactive protein is also generally elevated.

TREATMENT**Erysipelas**

The goal of treatment of erysipelas is rapid eradication of the infection. Mild to moderate cases of erysipelas are treated with

intramuscular procaine penicillin G or penicillin VK for 7 to 10 days (see Table 114-4).^{20,23} Penicillin-allergic patients can be treated with clindamycin or erythromycin. For more serious infections, the patient should be hospitalized and aqueous penicillin G 2 to 8 million units daily administered intravenously.^{20,21} Marked improvement usually is seen within 48 hours, and the patient often may be switched to oral penicillin to complete the course of therapy. One randomized, double-blind, placebo-controlled study showed that the median time for cure, intravenous antibiotics, and hospital stay was reduced in patients receiving prednisolone in addition to antibiotics.²² Further studies are needed, however, before corticosteroids can be recommended for routine use.¹¹

EVALUATION OF THERAPEUTIC OUTCOMES

Erysipelas generally responds quickly to appropriate antimicrobial therapy. Temperature and white blood count should return to normal within 48 to 72 hours. Erythema, edema, and pain also should resolve gradually.

IMPETIGO

3 Impetigo is a superficial skin infection that is seen most commonly in children.²⁴ The infection is generally classified as bullous or nonbullous based on clinical presentation.⁴ Impetigo is most common during hot, humid weather, which facilitates microbial colonization of the skin.²⁰ Minor trauma, such as scratches or insect bites, allows entry of organisms into the superficial layers of skin, and infection ensues.²⁰ Impetigo is highly communicable and readily spreads through close contact, especially among siblings and children in daycare centers and schools.^{20,21}

Most cases of impetigo were caused by *S. pyogenes*, but recently *S. aureus*, either alone or in combination with *S. pyogenes*, has emerged as the principal cause of impetigo.²⁴ The bullous form is caused by strains of *S. aureus* capable of producing exfoliative toxins.²⁴ The bullous form most frequently affects neonates and accounts for approximately 10% of all cases of impetigo.^{20,24}

CLINICAL PRESENTATION

General

- Exposed skin, especially the face, is the most common site for impetigo.

Symptoms

- Pruritus is common, and scratching of the lesions may further spread infection through excoriation of the skin.
- Other systemic signs of infection are minimal.
- Weakness, fever, and diarrhea sometimes are seen with bullous impetigo.

Signs

- Nonbullous impetigo manifests initially as small, fluid-filled vesicles.
- These lesions rapidly develop into pus-filled blisters that rupture readily.
- Purulent discharge from the lesions dries to form golden-yellow crusts that are characteristic of impetigo.
- In the bullous form of impetigo, the lesions begin as vesicles and turn into bullae containing clear yellow fluid.
- Bullae soon rupture, forming thin, light brown crusts.
- Regional lymph nodes may be enlarged.

Laboratory Tests

- Cultures should be collected.
- Crusted tops of lesions should be raised so that purulent material at the base of the lesion can be cultured.
- Cultures should not be collected from open, draining skin pustules because they may be colonized with staphylococci and other normal skin flora.

Other Diagnostic Tests

- A complete blood count is often performed because leukocytosis is common.

TREATMENT

Impetigo

Although impetigo may resolve spontaneously, antimicrobial treatment is indicated to relieve symptoms, prevent formation of new lesions, and prevent complications, such as cellulitis. Penicillinase-resistant penicillins are preferred for treatment because of the

increased incidence of infections caused by *S. aureus*.¹¹ First-generation cephalosporins are also commonly used. Penicillin, administered as a single intramuscular dose of benzathine penicillin G (300,000 to 600,000 units in children, 1.2 million units in adults) or as oral penicillin VK, is effective for infections known to be caused by *S. pyogenes*. Penicillin-allergic patients can be treated with clindamycin. The duration of therapy is 7 to 10 days. Topical therapy with mupirocin ointment (applied three times daily for 7 days) is as effective as erythromycin.¹¹ Although erythromycin has long been a mainstay of therapy for impetigo and other SSTIs, increased macrolide resistance in both *S. aureus* and *S. pyogenes* may limit its future usefulness.¹¹ With proper treatment, healing of skin lesions generally is rapid and occurs without residual scarring. Removal of crusts by soaking in soap and warm water also may be helpful in providing symptomatic relief.^{20,23}

EVALUATION OF THERAPEUTIC OUTCOMES

Clinical response should be seen within 7 days of initiating antimicrobial therapy for impetigo. Treatment failures could be a result of noncompliance or antimicrobial resistance. A followup culture of exudates should be collected for culture and sensitivity, with treatment modified accordingly.²⁴

LYMPHANGITIS

4 Acute lymphangitis is an inflammation involving the subcutaneous lymphatic channels. Lymphangitis usually occurs secondary to puncture wounds, infected blisters, or other skin lesions. Most infections are caused by *S. pyogenes*.^{23,25}

CLINICAL PRESENTATION

General

- Lymphadenitis (acute or chronic inflammation of the lymph nodes) also may occur when microorganisms reach the lymph nodes and elicit an inflammatory response.

Symptoms

- Systemic manifestations of infection (i.e., fever, chills, malaise, and headache) often develop rapidly before any sign of infection is evident at the initial site of inoculation or even after the initial lesion has subsided.
- Systemic symptoms often are more profound than would be expected based on examination of the cutaneous lesion.

Signs

- Identification of a peripheral lesion associated with proximal red linear streaks directed toward the regional lymph nodes is diagnostic of acute lymphangitis.
- Lymph nodes usually are enlarged and tender.
- Peripheral edema of the involved extremity often is present.
- Thrombophlebitis and acute lymphangitis in the lower extremities may be confused because both are associated with red linear streaking and tender areas; however, in thrombophlebitis, no portal of entry is identifiable.

Laboratory Tests

- Cultures of the affected lesions often yield negative results because the infection resides within the lymphatic channels.
- Offending pathogens often can be identified by Gram stain of the initial lesion if done early in the course of the disease.

Other Diagnostic Tests

- A complete blood count frequently is performed because leukocytosis is common.

TREATMENT

Lymphangitis

The goal of therapy for lymphangitis is rapid eradication of infection and prevention of further systemic complications. Penicillin is the antibiotic of choice. Because these infections are potentially serious and rapidly progressive, initial treatment should be with intravenous penicillin G 1 to 2 million units every 4 to 6 hours. Parenteral treatment should be continued for 48 to 72 hours, followed by oral penicillin VK for a total of 10 days.^{23,25} Nondrug therapy includes immobilization and elevation of the affected extremity and warm-water soaks every 2 to 4 hours.²³ For penicillin-allergic patients, clindamycin may be used.

EVALUATION OF THERAPEUTIC OUTCOMES

Lymphangitis usually responds rapidly to appropriate therapy; signs and symptoms often are decreased markedly or absent within 24 hours of starting antibiotics.

CELLULITIS

5 Cellulitis is an acute, infectious process that represents a serious type of SSTI. Cellulitis initially affects the epidermis and dermis and may spread subsequently within the superficial fascia. Cellulitis is considered a serious disease because of the propensity of the infection to spread through lymphatic tissue and to the bloodstream. *S. pyogenes* and *S. aureus* are the most frequent etiologic agents. However, many bacteria have been implicated in various types of cellulitis (see Table 114–1). The rising incidence of infections caused by MRSA is a major concern in both the community and hospital settings.^{6,7,9–16}

Injection-drug users are predisposed to a number of infectious complications, including abscess formation and cellulitis at the site of injection.²⁶ These SSTIs are located most frequently on the upper extremities and often are polymicrobial in nature.²⁷ Infecting organisms are believed to originate from the skin and/or oropharynx, as well as from contaminated needles, syringes, and diluents.²⁷ *S. aureus* is the most common pathogen isolated from these infections. The incidence of MRSA is also rising in SSTIs in injection-drug users.²⁸ Anaerobic bacteria, especially oropharyngeal anaerobes, are also found commonly, particularly in polymicrobial infections.²⁷ Outbreaks caused by *Clostridium* species have been reported recently in injection-drug users, particularly as a consequence of injection of contaminated black-tar heroin.^{29,30}

Acute cellulitis with mixed aerobic and anaerobic flora generally occurs in diabetics, where the skin is adjacent to some site of trauma, at sites of surgical incisions to the abdomen or perineum, or where host defenses have been otherwise compromised (vascular insufficiency). In older patients, cellulitis of the lower extremities also may be complicated by thrombophlebitis. Other complications of cellulitis include local abscess, osteomyelitis, and septic arthritis.^{11,23}

CLINICAL PRESENTATION

General

- There is usually a history of an antecedent wound from a minor trauma, abrasion, ulcer, or surgery.
- Because these infections occur often in patients with alterations in host defense mechanisms, poor nutrition, or both, systemic findings such as hypotension, dehydration, and altered mental status are common.

Symptoms

- Patients often experience fever, chills, or malaise and complain that the affected area feels hot and painful.

Signs

- Cellulitis is characterized by erythema and edema of the skin.
- Lesions, which may be extensive, are nonelevated and have poorly defined margins.
- Affected areas generally are warm to touch.
- Inflammation generally is present with little or no necrosis or suppuration of soft tissue.
- Tender lymphadenopathy associated with lymphatic involvement is common.

Laboratory Tests

- Cultures should be collected when possible.
- A Gram stain of fluid obtained by injection and aspiration of 0.5 mL of saline (using a small 22-gauge needle) into the advancing edge of the lesion may aid the microbiologic diagnosis but often yields negative results.
- Diagnosis usually is made on clinical grounds, that is, the appearance of the lesion.

Other Diagnostic Tests

- A complete blood count frequently is performed because leukocytosis is common.
- Because bacteremia may be present in as many as 30% of cases of cellulitis, blood cultures may be useful for diagnosis in some patients.

TREATMENT

Cellulitis

The goal of therapy of acute bacterial cellulitis is rapid eradication of the infection and prevention of further complications. Antimicrobial therapy of bacterial cellulitis is directed against the type of bacteria either documented or suspected to be present based on the clinical presentation. Local care of cellulitis includes elevation and immobilization of the involved area to decrease swelling. Cool sterile saline dressings may decrease pain and can be followed later with moist heat to aid in localization of the cellulitis. Surgical intervention (incision and drainage) as a mode of therapy is rarely indicated in the treatment of uncomplicated cellulitis. The use of inappropriate antibiotic therapy for cellulitis is associated with significantly higher risk of clinical treatment failures.³¹ Therefore, in the selection of antibiotics for treatment of cellulitis, particular attention must be paid to patients with risk factors for more atypical or resistant bacterial pathogens (e.g., gram-negative bacteria, anaerobes, MRSA).

Because staphylococcal and streptococcal cellulitis are indistinguishable clinically,²¹ administration of a penicillinase-resistant penicillin (nafcillin or oxacillin) or first-generation cephalosporin (cefazolin) is recommended until a definitive diagnosis, by skin or blood cultures, can be made (Table 114–5).^{2,11,20,23} Mild to moderate infections not associated with systemic symptoms may be treated orally with dicloxacillin or cephalexin. Other oral cephalosporins, such as cefadroxil, cefaclor, cefprozil, cefpodoxime proxetil, and cefdinir, are also effective in the treatment of cellulitis but are considerably more expensive.^{23,32} If documented to be a mild cellulitis secondary to streptococci, oral penicillin VK or intramuscular procaine penicillin may be administered. More severe infections, either staphylococcal or streptococcal, should be treated initially with intravenous antibiotic regimens. Ceftriaxone 50 to

TABLE 114-5 Initial Treatment Regimens for Cellulitis Caused by Various Pathogens

Antibiotic	Adult Dose and Route	Pediatric Dose and Route
Staphylococcal or unknown gram-positive infection		
Mild infection	Dicloxacillin 0.25–0.5 g orally every 6 h ^{a,b}	Dicloxacillin 25–50 mg/kg/day orally in four divided doses ^{a,b}
Moderate–severe infection	Nafcillin or oxacillin 1–2 g IV every 4–6 h ^{a,b}	Nafcillin or oxacillin 150–200 mg/kg/day (not to exceed 12 g/24 h) IV in four to six equally divided doses ^{a,b}
Streptococcal (documented)		
Mild infection	Penicillin VK 0.5 g orally every 6 h ^d or procaine penicillin G 600,000 units IM every 8–12 h ^d	Penicillin VK 125–250 mg orally every 6–8 h, or procaine penicillin G 25,000–50,000 units/kg (not to exceed 600,000 units) IM every 8–12 h ^d
Moderate–severe infection	Aqueous penicillin G 1–2 million units IV every 4–6 h ^{a,c}	Aqueous penicillin G 100,000–200,000 units/kg/day IV in four divided doses ^a
Gram-negative bacilli		
Mild infection	Cefaclor 0.5 g orally every 8 h ^d or cefuroxime axetil 0.5 g orally every 12 h ^d	Cefaclor 20–40 mg/kg/day (not to exceed 1 g) orally in three divided doses or cefuroxime axetil 0.125–0.25 g (tablets) orally every 12 h
Moderate–severe infection	Aminoglycoside ^e or IV cephalosporin (first- or second-generation depending on severity of infection or susceptibility pattern) ^d	Aminoglycoside ^e or intravenous cephalosporin (first- or second-generation depending on severity of infection or susceptibility pattern)
Polymicrobial infection without anaerobes		
	Aminoglycoside ^e + penicillin G 1–2 million units every 4–6 h or a semisynthetic penicillin (nafcillin 1–2 g every 4–6 h) depending on isolation of staphylococci or streptococci ^b	Aminoglycoside ^e + penicillin G 100,000–200,000 units/kg/day IV in four divided doses or a semisynthetic penicillin (nafcillin 150–200 mg/kg/day [not to exceed 12 g/24 h] IV in four to six equally divided doses) depending on isolation of staphylococci or streptococci ^b
Polymicrobial infection with anaerobes		
Mild infection	Amoxicillin/clavulanate 0.875 g orally every 12 h or A fluoroquinolone (ciprofloxacin 0.4 g orally every 12 h or levofloxacin 0.5–0.75 g orally every 24 h) plus clindamycin 0.3–0.6 g orally every 8 h or metronidazole 0.5 g orally every 8 h	Amoxicillin/clavulanic acid 20 mg/kg/day orally in three divided doses
Moderate–severe infection	Aminoglycoside ^{e,f} + clindamycin 0.6–0.9 g IV every 8 h or metronidazole 0.5 g IV every 8 h or Monotherapy with second- or third-generation cephalosporin (cefoxitin 1–2 g IV every 6 h or ceftizoxime 1–2 g IV every 8 h) or Monotherapy with imipenem 0.5 g IV every 6–8 h, meropenem 1 g IV every 8 h, ertapenem 1 g IV every 24 h, extended-spectrum penicillins with a β -lactamase inhibitor (piperacillin/tazobactam 4.5 g IV every 6 h), or tigecycline 100 mg IV as loading dose, then 50 mg IV every 12 h	Aminoglycoside ^e plus clindamycin 15 mg/kg/day IV in three divided doses or metronidazole 30–50 mg/kg/day IV in three divided doses

IM, intramuscularly; IV, intravenous.

^aFor penicillin-allergic patients, use clindamycin 150–300 mg orally every 6–8 h (pediatric dosing: 10–30 mg/kg/day in three to four divided doses).

^bFor methicillin-resistant staphylococci, use vancomycin 0.5–1 g every 6–12 h (pediatric dosing 40 mg/kg/day in divided doses) with dosage adjustments made for renal dysfunction.

^cFor type II necrotizing fasciitis, use clindamycin 0.6–0.9 g IV every 8 h (in children, clindamycin 15 mg/kg/day IV in 3 divided doses).

^dFor penicillin-allergic adults, use a fluoroquinolone (ciprofloxacin 0.5–0.75 g orally every 12 h or 0.4 g IV every 12 h; levofloxacin 0.5–0.75 g orally or IV every 24 h; or moxifloxacin 0.4 g orally or IV every 24 h).

^eGentamicin or tobramycin, 2 mg/kg loading dose, then maintenance dose as determined by serum concentrations.

^fA fluoroquinolone or aztreonam 1 g IV every 6 h may be used in place of the aminoglycoside in patients with severe renal dysfunction or other relative contraindications to aminoglycoside use.

100 mg/kg as a single daily dose is efficacious in the treatment of cellulitis in pediatric patients.³³ The usual duration of therapy for cellulitis is 5 to 10 days.^{11,20,23}

In penicillin-allergic patients, oral or parenteral clindamycin may be used.^{1,2} Alternatively, a first-generation cephalosporin may be used cautiously for patients who have not experienced immediate or anaphylactic penicillin reactions and are negative for a penicillin skin test. In severe cases in which cephalosporins cannot be used because of suspected and/or documented methicillin-resistant staphylococci or severe β -lactam allergies, vancomycin should be administered.^{2,11}

Although the most optimal treatment for CA-MRSA infections is not known, initial therapy with trimethoprim-sulfamethoxazole appears to be effective in most cases and should be considered in geographic areas in which CA-MRSA infections are commonly encountered.^{9,13,14} Hospital-acquired strains of MRSA tend to be more antibiotic resistant and vancomycin is a more appropriate

choice for initial treatment of patients in whom hospital-acquired MRSA is a suspected or documented pathogen. Alternative agents for infections with resistant gram-positive bacteria such as MRSA and vancomycin-resistant enterococci include linezolid, quinupristin-dalfopristin, daptomycin, and tigecycline.^{1,2,34–40} The excellent activity of these drugs against resistant gram-positive pathogens and significantly higher cost make them most appropriate for treatment of complicated or refractory infections, or those caused by multidrug-resistant pathogens, rather than as initial therapy. The availability of orally administered linezolid may provide a cost-effective “step-down” option for many patients with more complicated infections and/or those patients who require initial hospitalization as an alternative to prolonged treatment with parenteral agents.⁴¹ Tigecycline may be considered in complicated infections, particularly those in which the presence of mixed gram-negative and/or anaerobic pathogens is suspected or documented alongside resistant gram-positive bacteria.^{39,40}

CLINICAL CONTROVERSY

Because of the recent emergence and increasing prevalence of CA-MRSA, clinicians are now debating whether current treatment guidelines for empiric antimicrobial therapy of SSTIs should change.^{42,43} Although numerous studies have documented the rise in infections caused by CA-MRSA,^{9–16} none have reported poor clinical outcomes even though the majority of patients were treated with β -lactam antibiotics.⁴² Trimethoprim-sulfamethoxazole has excellent in vitro activity against CA-MRSA, but no clinical trials have been published that correlate susceptibility data with clinical outcomes. Another concern is the lack of activity of trimethoprim-sulfamethoxazole against *S. pyogenes*, another organism commonly isolated in SSTIs. The combination of trimethoprim-sulfamethoxazole and a β -lactam antibiotic has been suggested when empiric therapy is needed for coverage of both organisms.^{42,43} Clindamycin has activity against both organisms, but with the high incidence of macrolide resistance, there is concern of inducible clindamycin resistance during therapy.¹³ Of note, most skin abscesses, even those caused by MRSA, can be cured with adequate drainage without the need for antimicrobials.^{42,43}

The carbapenems (i.e., imipenem, meropenem, and ertapenem) and the β -lactam- β -lactamase inhibitor combination antibiotics (ampicillin-sulbactam, ticarcillin-clavulanic acid, and piperacillin-tazobactam) also appear to be equivalent to standard therapies in adults.^{1,44–47} The greater cost of these newer agents without increased efficacy compared with other reliable regimens, however, makes them less desirable.

For cellulitis caused by gram-negative bacilli or a mixture of microorganisms, immediate antimicrobial chemotherapy, as determined by Gram stain, is essential (see Table 114–5). Surgical excision of necrotic tissue and drainage also may be appropriate. Gram-negative cellulitis may be treated appropriately with an aminoglycoside or first- or second-generation cephalosporin. If gram-positive aerobic bacteria are also present, penicillin G or a penicillinase-resistant penicillin should be added to the regimen. Ceftazidime and the fluoroquinolones are effective in the treatment of cellulitis caused by both gram-negative and gram-positive bacteria.^{1,48}

Because some infections may be polymicrobial in nature, antibiotic therapy may need to be broadened to include agents with good activity against anaerobic bacteria. Many different treatment regimens are possible depending on the bacteriology of the lesion (see Table 114–5). Usually an aminoglycoside combined with an anti-anaerobic cephalosporin, extended-spectrum penicillin, or clindamycin is used. Second- or third-generation cephalosporins have been suggested as single-agent therapy in certain instances.^{1,2,11} Monotherapy with a β -lactam plus β -lactamase inhibitor combination antibiotic or a carbapenem also may be appropriate in seriously ill patients.^{1,44–47} Therapy should be 10 to 14 days in duration.

CLINICAL CONTROVERSY

Oral fluoroquinolones have demonstrated efficacy similar to parenteral cephalosporins in the treatment of soft-tissue infections caused by gram-positive organisms.^{1,48–50} Caution is warranted when treating SSTIs with ciprofloxacin owing to the unreliable activity of this agent against streptococci.¹ Lower eradication rates of streptococci also have been reported with moxifloxacin when compared with cephalexin in the treatment of uncomplicated SSTIs.⁴⁹ Levofloxacin and moxifloxacin are effective for both uncomplicated and complicated SSTIs.^{1,46,49–51} The use of fluoroquinolones is of concern, however, because of increasing reports of resistance among both gram-positive and

gram-negative bacteria.^{52,53} Sensitivity testing is recommended when a fluoroquinolone is to be used. Also, fluoroquinolones are not approved for use in children because of toxicity concerns.

Because gram-negative and mixed aerobic-anaerobic cellulitis can progress quickly to serious tissue invasion, therapeutic intervention should be immediate. If treated early, a rapid response can be seen. Unfortunately, because these infections often occur in patients with compromised immune defenses, they may still progress, even with therapeutic intervention. If the infectious process is secondary to a systemic cause (e.g., diabetes), the treatment course often is prolonged and may be associated with high morbidity and mortality.

Infections in injection-drug users generally are treated similarly to those in other types of patients.²⁷ It is important that blood cultures be obtained because 25% to 35% of patients may be bacteremic.^{27,54} Also, patients should be assessed for the presence of abscesses; incision, drainage, and culture of these lesions are of extreme importance.²⁰ Initial antimicrobial therapy while awaiting culture results of abscesses should include coverage for anaerobic organisms, in addition to *S. aureus* and streptococci.²⁷ In areas where MRSA is prevalent, treatment with vancomycin plus metronidazole is preferred.²⁷

EVALUATION OF THERAPEUTIC OUTCOMES

If treated promptly with appropriate antibiotics, the majority of patients with cellulitis are cured rapidly. Culture and sensitivity results should be evaluated carefully both for the adequacy of culture material and the presence of resistant organisms. Additional high-quality samples for culture may be needed for microbiologic analysis. Failure to respond to therapy also may be indicative of an underlying local or systemic problem or a misdiagnosis.

NECROTIZING SOFT-TISSUE INFECTIONS

Necrotizing soft-tissue infections consist of a group of highly lethal infections that require early and aggressive surgical debridement in addition to appropriate antibiotics and intensive supportive care.^{55,56} A number of different descriptive terms have been used to classify necrotizing infections. These have been based on factors such as predisposing conditions, onset of symptoms, pain, skin appearance, etiologic agent, gas production, muscle involvement, and systemic toxicity. While many of the necrotizing soft-tissue infections have been designated as unique infectious processes, they all share similar pathophysiologies, clinical features, and treatment approaches.^{55,56} The major clinical entities of necrotizing infections are *necrotizing fasciitis* and *clostridial myonecrosis* (gas gangrene).⁵⁵

6 Necrotizing fasciitis is a rare but very severe infection of the subcutaneous tissue that may be caused by aerobic and/or anaerobic bacteria and results in progressive destruction of the superficial fascia and subcutaneous fat. It is generally characterized as one of two different types based on bacterial etiology. Type I necrotizing fasciitis generally occurs after trauma and surgery and involves a mixture of anaerobes (*Bacteroides*, *Peptostreptococcus*) and facultative bacteria (streptococci and members of Enterobacteriaceae) that act synergistically to cause destruction of fat and fascia. Type I necrotizing fasciitis is also being reported more commonly among injection-drug users.^{56,57} In type I infections, the skin may be spared, and the speed at which the infection spreads is somewhat slower than type II. Necrotizing fasciitis affecting the male genitalia has been termed *Fournier gangrene*. Type II necrotizing fasciitis is caused by virulent strains of *S. pyogenes* and is more commonly referred to as *streptococcal gangrene*. This type of infection has received considerable attention in recent years because of reports of

“flesh-eating bacteria” by the lay press. Unlike previous reports of streptococcal gangrene that affected older individuals with underlying diseases, recent reports have occurred primarily in young, previously healthy adults following some type of minor trauma. It differs from the polymicrobial type I infections in its clinical presentation. Type II infections have rapidly extending necrosis of subcutaneous tissues and skin, gangrene, severe local pain, and systemic toxicity.²¹ Type II infections are also highly associated with an early onset of shock and organ failure and are present in approximately half the cases of streptococcal toxic shock-like syndrome.²¹

Clostridial myonecrosis is a necrotizing infection that involves the skeletal muscle. Gas production and muscle necrosis are prominent features of this infection, which readily explains why this infection is commonly referred to as *gas gangrene*.^{55,56} The infection advances rapidly, often over a matter of a few hours.⁵⁵ Most infections occur after surgery or trauma, with *Clostridium perfringens* identified as the most common etiologic agent. Recently, outbreaks have been reported in injection-drug users who injected contaminated coal-tar heroin.^{30,33}

CLINICAL PRESENTATION

General

- These infections may occur in almost any anatomic location but most frequently involve the abdomen, the perineum, and the lower extremities.
- Patients often have predisposing factors such as diabetes mellitus, local trauma or infection, or recent surgery.

Symptoms

- Systemic symptoms generally are marked (e.g., fever, chills, and leukocytosis) and may include shock and organ failure, especially in patients with type II infections.
- In general, pain in the affected area and systemic toxicity are more pronounced than would be expected with cellulitis.

Signs

- At the beginning of an infection, it may be difficult to differentiate between necrotizing fasciitis and cellulitis.
- Like cellulitis, the affected area is initially hot, swollen, and erythematous without sharp margins.
- The affected area is often shiny, exquisitely tender, and painful.
- Diffuse swelling of the area is followed by the appearance of bullae filled with clear fluid.
- The infectious process progresses rapidly, with the skin taking on a maroon or violaceous color after several days.
- Without appropriate intervention, the infection will evolve rapidly into a frank cutaneous gangrene, sometimes with myonecrosis (involvement of skin and muscle).
- Because of the aggressive nature and high mortality (20% to 50%) associated with these infections, a rapid diagnosis is critical.

Laboratory Tests

- Although computed tomography and magnetic resonance imaging studies can distinguish these infections, the best and most rapid diagnosis of necrotizing infections is obtained via surgical exploration.
- Intraoperative samples should be collected for culture and sensitivity, as well as for histologic examination.
- Unlike necrotizing fasciitis, clostridial myonecrosis shows little inflammation on histologic examination.

Other Diagnostic Tests

- Because marked systemic symptoms are seen commonly in necrotizing infections, blood samples should be collected for complete blood count and chemistry profile, as well as for bacterial culture.

TREATMENT

Necrotizing Soft-Tissue Infections

After the diagnosis is made, immediate and aggressive surgical debridement of all necrotic tissue is essential.^{55,56} Patients often require further surgical intervention following initial debridement to ensure that all necrotic tissue has been removed.^{2,11} Broad-spectrum antibiotics should be administered, with coverage against streptococci, Enterobacteriaceae, and anaerobes. A number of antibiotic regimens have been used successfully to treat necrotizing soft-tissue infections; these are generally similar to those used for severe polymicrobial cellulitis involving anaerobes (see Table 114–5). Other combination antibiotic regimens that may be used prior to obtaining bacteriologic data include ampicillin with gentamicin and clindamycin (or metronidazole); ampicillin-sulbactam with gentamicin; and imipenem with metronidazole.²⁰

Antibiotic therapy can be modified after Gram stain and culture reports are available. If a diagnosis of type II necrotizing fasciitis is established, the broad-spectrum empirical therapy should be replaced with the combination of penicillin and clindamycin.²¹ Although *S. pyogenes* remains susceptible to penicillin, clindamycin is more effective.²¹ A number of factors have been postulated to explain the higher efficacy of clindamycin, including the mechanism of action (inhibition of protein synthesis), which is not affected by the size of the inoculum or the stage of bacterial growth.²¹ In addition, clindamycin has immunomodulatory properties that may account for the higher efficacy.²¹ The combination of penicillin and clindamycin is also recommended for treatment of clostridial myonecrosis.^{11,55,56} Hyperbaric oxygen also may be of some benefit for clostridial myonecrosis.^{55,58}

EVALUATION OF THERAPEUTIC OUTCOMES

Because of the high mortality associated with necrotizing infections, rapid and complete debridement of all devitalized and necrotic tissue is essential. Surgical debridement, coupled with appropriate antimicrobial therapy and typical supportive measures for management of shock and organ failure, should stabilize the patient. Vital signs and laboratory tests should be monitored carefully for signs of resolution of the infection. Change in antimicrobial therapy or additional surgical debridement may be needed in patients who do not show signs of improvement.

DIABETIC FOOT INFECTIONS

Three major types of foot infections are seen in diabetic patients: deep abscesses, cellulitis of the dorsum, and mal perforans ulcers.⁵⁹ Most deep abscesses involve the central plantar space (arch) and are caused by minor penetrating trauma or by an extension of infection of a nail or web space of the toes. Skin infections of the dorsal area generally arise from infections in the toes that are related to routine care of the nails, nail beds, and calluses of the toes. Mal perforans ulcer is a chronic ulcer of the sole of the foot. The ulcer develops on thickened, hardened calluses over the first or fifth metatarsal. Mal perforans

ulcers are associated with neuropathy, which is responsible for the misalignment of the weight-bearing bones of the foot.⁵⁹ Osteomyelitis is one of the most serious complications of foot problems in diabetic patients and may occur in 30% to 40% of infections.^{19,59,60}

EPIDEMIOLOGY

Disorders of the foot are among the most common complications of diabetes, accounting for as many as 20% of all hospitalizations in diabetic patients at an annual cost of \$200 to \$350 million.⁶¹ The cost of treating a patient with a diabetic foot ulcer has been estimated at \$14,000 to \$18,000 each year.^{62,63} Approximately 25% of diabetic patients experience significant soft-tissue infection at some time during the course of their lifetime. Approximately 55,000 lower-extremity amputations, often sequelae of uncontrolled infection, are performed each year on diabetic patients; this represents 50% of all nontraumatic amputations in the United States.⁶¹ Between 10% and 20% of diabetics will undergo additional surgery or amputation of a second limb within 12 months of the initial amputation.⁶⁴ By 5 years, this increases to 25% to 50%, with death reported in as much as two-thirds of patients.⁶⁴

ETIOLOGY

Diabetic foot infections begin with local bacterial invasion and typically involve a number of different bacterial pathogens.⁶⁴ The infections are polymicrobial in nature, with an average of 2.3 to 5.8 isolates per culture (Table 114-6).^{19,64-66} Staphylococci (especially *S. aureus*) and streptococci are the most common pathogens, although gram-negative bacilli and/or anaerobes occur in approximately 50% of cases.^{19,64-66} Common gram-negative bacilli isolated include *E. coli*, *Klebsiella* spp., *Proteus* spp., and *P. aeruginosa*. *Bacteroides fragilis* and *Peptostreptococcus* spp. are among the most common anaerobes isolated.

The optimum technique for obtaining culture material from ulcerated lesions is still debated.⁵⁹ Routine swab cultures of ulcerative lesions are difficult to interpret because of organisms that colonize the surface of the wounds. Cultures of material from sinus tracts are also unreliable. The correlation between these superficial cultures and true deep cultures (via biopsy or needle aspiration of drainage or abscess fluid) is often poor, particularly in chronic lesions.^{19,65} Therefore, cultures and sensitivity tests should be done

with specimens obtained from a deep culture whenever possible. Before the wound is cultured, it should be scrubbed vigorously with saline-moistened sterile gauze to remove any overlying necrotic debris.⁶⁷ Cultures then can be obtained from the wound base, preferably from expressed pus.⁶⁷ Specimens obtained from curettage of the base of the ulcer correlate best with results from deep-tissue or bone biopsies.⁶⁷

PATHOPHYSIOLOGY

Three key factors are involved in the development of diabetic foot problems: (a) neuropathy, (b) angiopathy and ischemia, and (c) immunologic defects. Any of these disorders can occur in isolation; however, they frequently occur together.

Neuropathic changes to the autonomic nervous system as a consequence of diabetes may affect the motor nerve supply of small intrinsic muscles of the foot, resulting in muscular imbalance, abnormal stresses on tissues and bone, and repetitive injuries.⁶⁸ Diminished sensory perception causes an absence of pain and unawareness of minor injuries and ulceration. Also, the sympathetic nerve supply may be damaged and can result in an absence of sweating; this leads to dry cracked skin, which can become secondarily infected.^{19,64}

Atherosclerosis is more common, appears at a younger age, and progresses more rapidly in the diabetic than in the nondiabetic. Diabetics may have problems with both small vessels (microangiopathy) and large vessels (macroangiopathy) that can result in varying degrees of ischemia, ultimately leading to skin breakdown and infection.

Diabetic patients typically have normal humoral immunity, normal levels of immunoglobulins, and normal antibody responses. Patients with diabetes, however, have impaired phagocytosis and intracellular microbicidal function as compared with nondiabetics; this may be related to angiopathy and low tissue levels of oxygen.^{19,64,68} These defects in cell-mediated immunity make patients with diabetes more susceptible to certain types of infection and impair the patients' ability to heal wounds adequately.⁶⁸

CLINICAL PRESENTATION

General

- Infections are often much more extensive than they appear initially.

Symptoms

- Patients with peripheral neuropathy often do not experience pain but seek medical care for swelling or erythema in the foot.

Signs

- Clinical signs of infection in the diabetic foot may not be present secondary to the angiopathy and neuropathy.
- When present, lesions vary in size and clinical features (e.g., erythema, edema, warmth, presence of pus, draining sinuses, pain, and tenderness).
- A foul-smelling odor suggests the presence of anaerobic organisms.
- Temperature may be mildly elevated or normal.

Laboratory Tests

- Specimens for culture and sensitivities should be collected.
- If possible, deep intraoperative samples should be obtained during surgical debridement.
- Because of the complex microbiology of these infections, wounds must be cultured for both aerobic and anaerobic organisms.

TABLE 114-6 Bacterial Isolates from Foot Infections in Diabetic Patients

Organisms	Percentage of Isolates
Aerobes	63%–75%
Gram-positive	42%–64%
<i>Staphylococcus aureus</i>	15%–20%
<i>Streptococcus</i> spp.	6%–12%
<i>Enterococcus</i> spp.	7%–20%
Coagulase-negative staphylococci	6%–10%
Other gram-positive aerobes	0%–12%
Gram-negative	16%–18%
<i>Proteus</i> spp.	5%–6%
<i>Enterobacter</i> spp.	1%–2%
<i>Escherichia coli</i>	3%–5%
<i>Klebsiella</i> spp.	1%–2%
<i>Pseudomonas aeruginosa</i>	1%–3%
Other gram-negative bacilli	3%–8%
Anaerobes	25%–40%
<i>Peptostreptococcus</i> spp.	8%–12%
<i>Bacteroides fragilis</i> group	4%–7%
Other <i>Bacteroides</i> spp.	3%–6%
<i>Clostridium</i> spp.	0%–2%
Other anaerobes	7%–10%

Compiled from Pellizzer et al,⁶⁵ and Lipsky et al.⁶⁶

Other Diagnostic Tests

- The presence of osteomyelitis also must be assessed via radiograph, bone scan, or both, as appropriate.

TREATMENT

Diabetic Foot Infections

7 The goal of therapy of diabetic foot infections is preservation of as much normal limb function as possible while preventing additional infectious complications. Up to 90% of these infections can be treated successfully with a comprehensive treatment approach that includes both wound care and antimicrobial therapy.¹⁹ After carefully assessing the extent of the lesion and obtaining necessary cultures, necrotic tissue must be thoroughly debrided, with wound drainage and amputation as required. Wounds must be kept clean and dressings changed frequently (two to three times daily). Because of the relationship between hyperglycemia and immune system defects, glycemic control must be maximized to ensure optimal wound healing. In addition, the patient’s activities should be restricted initially to bedrest for leg elevation and control of edema, if present. Adequate pressure relief from a foot wound (i.e., off-loading) is crucial to the healing process.^{19,69} Finally, appropriate antimicrobials must be initiated.^{19,60,61,67,68} However, the optimal antimicrobial therapy for diabetic foot infections has yet to be defined.

The majority of mild, uncomplicated infections can be managed successfully on an outpatient basis with oral antimicrobials and good wound care. Many different agents have been studied, including cefaclor, cephalexin, fluoroquinolones, clindamycin, and amoxicillin-clavulanic acid, and provide clinical cure rates of 60% to 85%.^{19,60,68} However, significant failure rates and/or relapse rates have been reported with the use of oral agents. In addition, the development of resistance was problematic in some infections involving *P. aeruginosa* and staphylococci.⁷⁰ Many clinicians consider amoxicillin-clavulanic acid to be the preferred agent because of its broad spectrum of activity, which includes staphylococci, streptococci, enterococci, and many Enterobacteriaceae and anaerobes.^{19,67,68} However, this agent does not have activity against *P. aeruginosa*. Fluoroquinolones, which provide coverage against *P. aeruginosa*, have been studied extensively as monotherapy, but they, perhaps, are most appropriately used in combination with metronidazole or clindamycin to provide anaerobic activity.^{2,19} Oral antimicrobials should be used cautiously in serious infections, especially those complicated by osteomyelitis, extensive ulceration, areas of necrosis, or a combination of these.

Initial therapy for patients requiring hospitalization for moderate to severe infections is similar to that for polymicrobial cellulitis with anaerobes (see Table 114–5). Monotherapy with broad-spectrum parenteral antimicrobials, along with appropriate medical or surgical management, or both, is often effective in treating these infections, including those in which osteomyelitis is present.^{66,71,72} Monotherapy is particularly attractive because of the potential advantages of convenience, cost, and avoidance of toxicities. Microbiologic and clinical cure rates ranging from 60% to 90% may be expected from any of these agents; selection of a specific regimen is determined primarily by cost. In penicillin-allergic patients, metronidazole or clindamycin plus either a fluoroquinolone, aztreonam, or possibly a third-generation cephalosporin is appropriate.^{2,19,60,68} Vancomycin also is used frequently in severe infections because of its excellent activity against gram-positive pathogens. With the increased incidence of MRSA, linezolid, quinupristin-dalfopristin, daptomycin, and tigecycline are alternatives for treatment of these resistant organisms.^{1,2,34–40} Tigecycline may be particularly useful in this setting because of its activity against gram-negative aerobes and anaerobic bacteria, thus allowing it to be used as monotherapy for the treatment of mixed infections.

Because these patients already may have some degree of diabetic nephropathy that may place them at higher risk of nephrotoxicity, strong recommendations have been made for the avoidance of aminoglycoside antibiotics unless no alternative agents are available.¹⁹ When an aminoglycoside is used, care must be taken to avoid further compromising renal function. All antibiotic regimes should be adjusted as necessary for renal dysfunction.

Empirical therapy that is totally comprehensive in its coverage of all possible pathogens is not necessary unless the infection is life-threatening.^{19,66,71,72} No differences have been reported in the efficacy of ampicillin-sulbactam versus imipenem-cilastatin for treatment of limb-threatening diabetic foot infections despite the higher incidence of potential pathogens resistant to the ampicillin-sulbactam regimen.⁷¹ Other studies demonstrate good clinical efficacy despite the presence of pathogens such as MRSA and *Pseudomonas*, which were resistant to the antibiotics used.^{47,66} These studies highlight the importance of good wound care as part of a comprehensive treatment approach.

Mild to moderate infections can be treated with oral agents that are highly bioavailable. Duration of therapy is usually 7 to 14 days, although some infections may require an additional 1 to 2 weeks of therapy. More severe infections require initial parenteral therapy. Duration of therapy for most moderate to severe infections ranges from 2 to 4 weeks.¹⁹ In cases of underlying osteomyelitis, treatment should continue for 6 to 12 weeks.^{19,60,68} After healing of the infection has occurred, a well-designed program for prevention of further infections should be instituted.

EVALUATION OF THERAPEUTIC OUTCOMES

Therapy should be reevaluated carefully after 48 to 72 hours to assess favorable response. Change in therapy (or route of administration, if oral) should be considered if clinical improvement is not observed at this time. For optimal results, drug therapy should be appropriately modified according to information from deep-tissue culture and the clinical condition of the patient. Infections in diabetic patients often require extended courses of therapy because of impaired host immunity and poor wound healing.

PRESSURE SORES

The terms *decubitus ulcer*, *bed sore*, and *pressure sore* are used interchangeably. The decubitus ulcer and the bed sore are types of pressure sores. The term *decubitus ulcer* is derived from the Latin word *decumbere*, meaning “lying down.” Pressure sores, however, can develop regardless of a patient’s position.

Numerous systems for classification of pressure sores have been described. The two most frequently used systems are those of Shea⁷³ and the 1989 National Pressure Ulcer Advisory Panel.⁷⁴ These classification systems define the various stages of progression through which a pressure sore may pass (Table 114–7).

TABLE 114-7 Pressure Sore Classification

Stage 1	Pressure sore is generally reversible, is limited to the epidermis, and resembles an abrasion. It is best described as an irregularly shaped area of soft-tissue swelling with induration and heat.
Stage 2	A stage 2 sore also may be reversible; it extends through the dermis to the subcutaneous fat along with extensive undermining.
Stage 3 ^a	In this instance, the sore or ulcer extends further into subcutaneous fat along with extensive undermining.
Stage 4 ^a	The sore or ulcer is characterized by penetration into deep fascia involving both muscle and bone.

^aStages 3 and 4 lesions are unlikely to resolve on their own and often require surgical intervention. From Shea⁷³ and National Pressure Ulcer Advisory Panel.⁷⁴

FIGURE 114-1. Distribution of forces involved with sore formation in a conical fashion.

Complications of pressure sores are not uncommon and may be life-threatening. Infection is one of the most serious and most frequently encountered complications of pressure ulcers. Bacterial colonization must be differentiated from true bacterial infection. Although most pressure sore wounds are colonized, the majority of these eventually heal.⁷⁵ When the tissue is infected, there is bacterial invasion of previously healthy tissue. Without treatment, an initial small, localized area of ulceration can progress rapidly to 5 to 6 cm within days. The visible ulcer is just a small portion of the actual wound; up to 70% of the total wound is below the skin. A pressure-gradient phenomenon is created by which the wound takes on a conical nature; the smallest point is at the skin surface, and the largest portion of the defect is at the base of the ulcer (Fig. 114-1).

EPIDEMIOLOGY

Pressure sores are seen most frequently in chronically debilitated persons, the elderly, and persons with serious spinal cord injury. Generally, patients who are at risk for pressure sores are elderly or chronically ill young patients who are immobilized, either in bed or a wheelchair, and who may have altered mental status and/or incontinence.

ETIOLOGY

Similar to diabetic foot infections, a large variety of aerobic gram-positive and gram-negative organisms, as well as anaerobes, frequently are isolated from wound cultures.⁷⁶ Curettage of the ulcer base after debridement provides more reliable culture information than does needle aspiration.⁷⁵ Biopsy specimens give the most reliable data but may not be practical to obtain. Deep-tissue cultures from different sites may give different results. Cultures collected from pressure ulcers reveal polymicrobial growth. A culture collected by swab is likely to identify surface bacteria colonizing the wound rather than to diagnose the infection.^{75,76}

PATHOPHYSIOLOGY

Many factors are thought to predispose patients to the formation of pressure sores: paralysis, paresis, immobilization, malnutrition, anemia, infection, and advanced age. Four factors thought to be most critical to their formation are pressure, shearing forces, friction, and moisture; however, there is still debate as to the exact pathophysiology of pressure sore formation.

Pressure is the essential element in the formation of pressure sores. The areas of highest pressure are generated most often over the bony prominences. Studies show that when the pressure is relieved intermittently within a 2-hour period, only minimal

FIGURE 114-2. Supine view of areas where pressure sore formation tends to occur.

changes occur in soft-tissue and skin structures.⁷⁵ Therefore, both the degree of pressure and the length of time that the pressure is applied are important.

Shearing forces are caused by the sliding of adjacent parallel surfaces of soft tissues in an unequal fashion. This situation can occur when the head of a bed is raised, causing the upper torso to slide downward, transmitting pressure to the sacrum and other areas. This effect results in occlusion or distortion of vessels, leading to compromise of the dermis. At the same time, sitting and gravity create shearing forces; the posterior sacral skin area can become fixed secondary to friction with the bed. The effects of friction and shearing forces combine, resulting in transmission of force to the deep portion of the superficial fascia and leading to further damage of soft tissue structures.

Compounding the problems of shearing and friction forces are the macerating effects of excessive moisture in the local environment, resulting from incontinence and perspiration. This factor is of critical importance because when combined with the other forces, it increases the risk of pressure sore formation fivefold.⁷⁵

CLINICAL PRESENTATION

General

- Pressure sores can occur anywhere on the body.
- However, more than 95% of all pressure sores are located on the lower part of the body (65% in the region of the pelvis and 3.4% on the lower extremities; Fig. 114-2).
- The most common sites on the lower portion of the body are the sacral and coccygeal areas, ischial tuberosities, and greater trochanter.

Symptoms

- Patients with pressure sores commonly have other medical problems that may mask the typical signs and symptoms of infection.

Signs

- Clinical infection is recognized by the presence of surrounding redness, heat, and pain.
- Purulent discharge, foul odor, and systemic signs (e.g., fever and leukocytosis) of infection may be present.

Laboratory Tests

- Cultures should be collected from either a biopsy or fluid obtained by needle aspiration.

Other Diagnostic Tests

- Because clinicians also must be aware of the possibility of underlying osteomyelitis, magnetic resonance imaging or other radiographic procedures should be considered.

TREATMENT**Pressure Sores**

8 Prevention is the single most important aspect in the management of pressure sores. Prevention is far easier and less costly than the intensive care necessary for the healing and eventual closure of pressure sores. Of primary importance, then, is the ability to identify patients who are at high risk so that preventive measures may be instituted.

The medical approach to the treatment of pressure sores depends on the stage of the disease. Medical management generally is indicated for lesions that are of moderate size and relatively shallow depth (stage 1 or 2 lesions) and are not located over a bony prominence. Depending on their location and severity, from 30% to 80% of these ulcers will heal without an operation. Surgical intervention is almost always necessary for ulcers that extend through superficial fascia or into bone (stage 3 and 4 lesions).

The goal of therapy is to clean and decontaminate the ulcer to promote wound healing by permitting the formation of healthy granulation tissue or to prepare the wound for an operative procedure. The main factors to be considered for successful topical therapy (local care) are (a) relief of pressure, (b) debridement of necrotic tissue as needed, (c) wound cleansing, (d) dressing selection, and (e) prevention, diagnosis, and treatment of infection.⁷⁷

Friction and shearing forces can be minimized with proper positioning. Skin care and prevention of soiling are important, with the intent being to keep the surface relatively free of moisture. Patients with problems of incontinence should be cleaned frequently, and efforts should be made to keep the involved areas dry. Natural sheepskin is believed to be useful in minimizing the effects of moisture, shearing forces, and friction. Relief of pressure is probably the single most important factor in preventing pressure sore formation. Relief for a period of only 5 minutes once every 2 hours is believed to give protection against pressure sore formation.^{74,76,77}

The goals of debridement and cleansing measures are removal of devitalized tissue and reduction of bacterial contamination, which can slow granulation time and, therefore, impede healing. Debridement can be accomplished by surgical, mechanical, or chemical means. Surgical debridement rapidly removes necrotic material from the wound and is recommended for urgent situations (e.g., cellulitis and sepsis).⁷⁷ Mechanical debridement generally involves wet-to-dry dressing changes. Saline-soaked gauze is applied to the wound; after drying, the gauze is removed and with it any adherent necrotic tissue. Other effective mechanical therapies include hydrotherapy (use of the whirlpool [Hubbard tank] to remove necrotic tissue and debris), wound irrigation, and dextranomers (beads placed in the wound to absorb exudate and bacteria). Chemical

debridement includes enzymatic and autolytic agents. Enzymatic debridement involves application of topical debriding agents to remove devitalized tissue. This method is recommended for patients who cannot tolerate surgery or are in a long-term care or home setting. Autolytic debridement involves the use of synthetic dressings that allow devitalized tissue to self-digest via enzymes present in wound fluids. Autolytic debridement is contraindicated in the treatment of infected pressure sores.

Pressure sore wounds should be cleaned with normal saline. Cleansing agents that are cytotoxic, such as povidone-iodine, iodophor, sodium hypochlorite solution, hydrogen peroxide, and acetic acid, should be avoided.⁷⁷ Many of these agents impair healing. Many different types of dressings are available for pressure sores. Wound dressing materials should keep the wound moist, allow free exchange of air, act as a physical barrier to bacteria, and prevent physical damage. Controlled studies of the various types of wound dressings have shown no significant differences in healing outcomes.⁷⁷ Occlusive dressings should be avoided if infection is present.^{74–77} If occlusive dressings are used, any infection should be controlled or the dressing frequency increased.

Systemic treatment (see Table 114–5) of an infected pressure ulcer should be guided by results from appropriately collected cultures. Systemic antibiotics generally are reserved for treatment of bacteremia, sepsis, cellulitis, or osteomyelitis.^{74–77} However, a 2-week trial of topical antibiotics (silver sulfadiazine or triple antibiotic) is recommended for a clean ulcer that is not healing or is producing a moderate amount of exudate despite appropriate care.⁷⁴

Other nonpharmacologic approaches to shortening the healing time have included the use of hyperbaric oxygenation, hydrotherapy, high-frequency/high-intensity sound waves, and electrotherapy.^{75,78} Electrical stimulation is the only adjunctive therapy that is effective.^{75,78}

EVALUATION OF THERAPEUTIC OUTCOMES

With appropriate wound care and antimicrobial therapy, infected pressure sores can heal. A reduction in erythema, warmth, pain, and other signs and symptoms should be seen in 48 to 72 hours.

BITE WOUNDS

Approximately half the population in the United States will be bitten by either an animal or another human sometime during their lifetimes.⁷⁹ Bite wounds have a substantial potential for infectious complications. If left untreated, complications such as soft tissue infection and osteomyelitis may occur, possibly requiring extensive débridement or amputation.

ANIMAL BITES**Epidemiology**

Dog bites account for approximately 80% of all animal bite wounds requiring medical attention. Data from U.S. emergency departments reported 368,245 visits for new dog bite-related injuries in 2001.⁸⁰ Based on the data gathered in this study, approximately 1,000 new dog bite injuries are seen in emergency departments every day. Approximately one-half of dog bites occur in individuals younger than 20 years of age, usually males (55%). More than 70% of bites are to the extremities. Facial bites are also seen, particularly in children younger than 5 years of age. Up to 65% of bite wounds in young children involve the head and neck, and can be a lethal event because of blood loss. From 1979 through 1994, 279 deaths were the result of attacks by dogs.⁸¹

Patients at greatest risk of acquiring an infection after a bite have had a puncture wound (usually the hand), have not sought medical attention within 12 hours of the injury, and are older than 50 years of age.^{82,83}

Cat bites, with an estimated incidence of 5% to 15% of all animal bites, are the second most common cause of animal bite wounds in the United States.⁸² Bites and scratches occur most commonly on the upper extremities, with most injuries reported in women.⁷⁹ Infection rates, estimated at 30% to 50%, are more than double those seen with dog bites.^{79,82,83}

Etiology

Infections from dog bite wounds are caused predominantly by mouth flora from the animal.^{84–86} Most infections are polymicrobial, with approximately five bacterial isolates per culture.⁸⁴ *Pasteurella multocida* is the most frequent isolate. Other common aerobes include streptococci, staphylococci, *Moraxella*, and *Neisseria*. The most common anaerobes are *Fusobacterium*, *Bacteroides*, *Porphyromonas*, and *Prevotella*.⁸⁴ Wound-site cultures in both infected and noninfected patients have similar bacteria present, with aerobic organisms isolated from 74% to 90% and anaerobic organisms isolated from 41% to 49% of patients.^{79,82,84}

Infections arising from cat bites or scratches are frequently (75%) caused by *P. multocida*, which has been isolated in the oropharynx of 50% to 70% of healthy cats.^{82,86} Mixed aerobic and anaerobic infections have been reported in 63% of cat bite wounds, whereas approximately one-third of cultures grow aerobes only.⁸⁴ Both tularemia (*Pasteurella tularensis*) and rabies also have been transmitted by cat bites.^{79,82,84}

Pathophysiology

The potential for infection from an animal bite is great owing to the pressure that can be exerted during the bite and the vast number of potential pathogens that make up the normal oral flora.⁸⁵ Cats' teeth are slender and extremely sharp. Their teeth easily penetrate into bones and joints, resulting in a higher incidence of septic arthritis and osteomyelitis.^{79,82} Although a dog's teeth may not be as sharp, they can exert a pressure of 200 to 450 lb/in² and therefore result in a serious crush injury with much devitalized tissue.⁸⁵ Known human pathogens such as *S. aureus*, *P. multocida*, and anaerobes are among the more than 64 species of bacteria that are harbored in the average dog mouth.⁸⁵ In addition, the polymicrobial (aerobic and anaerobic) nature of animal bites provides a synergistic relationship, thus making an infection harder to eradicate.⁸⁵

CLINICAL PRESENTATION

General

- Health care providers see two distinct groups of patients seeking medical attention for dog bites.
- The first group presents within 12 hours of the injury; these patients require general wound care, repair of tear wounds, or rabies and/or tetanus treatment. The second group of patients presents more than 12 hours after the injury has occurred; these patients usually have clinical signs of infection and seek medical attention for infection-related complaints.

Symptoms

- Patients seek medical care for infection-related complaints (i.e., pain, purulent discharge, and swelling).

Signs

- Patients with infected dog bite wounds generally present with a localized cellulitis and pain at the site of injury.

- Cellulitis usually spreads proximally from the initial site of injury, and a gray malodorous discharge may be encountered.
- If *P. multocida* is present, a rapidly progressing cellulitis is observed, with pain and swelling developing within 24 (70%) to 48 (90%) hours of initial injury.
- Fever is uncommon.
- Fewer than 20% of patients have a concomitant adenopathy or lymphangitis.

Laboratory Tests

- Samples for bacterial cultures (aerobic and anaerobic) should be obtained.
- Wounds seen less than 8 hours or more than 24 hours after injury that show no signs of infection may not need to be cultured.

Other Diagnostic Tests

- A roentgenogram of the affected part should be considered when infection is documented in proximity to a bone or joint.

TREATMENT

Dog and Cat Bites

Table 114–4 lists the recommended drugs and dosing regimens for animal bite wounds.

Cultures obtained from early, noninfected bite wounds are not of great value in predicting the subsequent development of infection. Documentation of the mechanism of injury is important; if possible, an immunization history of the animal should be obtained. It is also important for the patient's tetanus immune status to be determined.

Wounds should be irrigated thoroughly with a copious volume (>150 mL) of sterile normal saline. Proper irrigation reduces the bacterial count in the wound. Antibiotic or iodine solutions do not offer any advantage over saline and actually may increase tissue irritation. Several management techniques used in the treatment of bite wounds remain controversial, including the extent and type of debridement,^{82,87,88} suturing wounds within 8 hours of the injury,¹¹ and indications for the use of antibiotics.

The role of prophylactic antimicrobial therapy for the early, noninfected bite wound remains controversial.^{82,86,89,90} Unfortunately, suggestions concerning the use of prophylactic antibiotics are based on minimal data because few clinical trials have been performed. Most reports are of retrospective studies or observations of complicated cases. A systematic review of eight randomized trials of bite wounds (caused by both animals and humans) evaluated the use of antibiotics for the prevention of infectious complications and concluded that antibiotics did not significantly reduce the risk of infection in patients with dog or cat bites, but that wounds involving the hands may benefit from antimicrobial prophylaxis.⁹⁰ However, this review also concluded that additional studies are required to support these conclusions.⁹⁰

Controlled studies have not shown benefits definitively with prophylactic antibiotics for noninfected bites. Because up to 20% of bite wounds may become infected, a 3- to 5-day course of antimicrobial therapy generally is recommended.^{11,79,82,86} This is especially important for patients at greater risk for infection (patients older than 50 years of age and those with puncture wounds and wounds to the hands, and those who are immunocompromised).^{86,89} Treatment should be directed at the typical aerobic and anaerobic oral flora of dogs, as well as at potential pathogens from the skin flora of the bite victim. The length of antimicrobial therapy depends on the severity of the injury/infection.^{11,82}

CLINICAL CONTROVERSY

To date, there is no single, universally agreed-on treatment regimen for bite wounds. Penicillin provides excellent coverage for *P. multocida* but not for *S. aureus* and most of the other staphylococci that are commonly isolated from bite wounds. Although penicillinase-resistant penicillins, first-generation cephalosporins, erythromycin, and clindamycin have excellent activity against staphylococci, these agents are not active against most strains of *P. multocida*.

Amoxicillin-clavulanic acid is commonly recommended for oral outpatient therapy.^{11,82,86,91} Alternative oral agents include doxycycline or the combination of penicillin VK and dicloxacillin. Trimethoprim-sulfamethoxazole and fluoroquinolones have activity against *P. multocida* and are recommended as alternatives for patients who are allergic to penicillins.^{11,82,91} However, these agents should not be used in children and/or pregnant women; trimethoprim-sulfamethoxazole also should be avoided during pregnancy. Macrolides or azalides may be considered as alternatives in growing children or pregnant women.^{11,82,87} If erythromycin or similar-class agent is selected, bacterial sensitivities should be obtained and clinical response monitored carefully because most strains of *P. multocida* are resistant. Cefuroxime is another viable alternative for patients with mild penicillin allergies. Many of these alternative agents will likely require an additional agent (metronidazole, clindamycin) with activity against anaerobes. Failure to provide adequate initial treatment of bite wounds results in treatment failures and increased need for hospitalization for administration of parenteral antibiotics.⁹²

Treatment options for patients requiring intravenous therapy include β -lactam- β -lactamase inhibitor combinations (ampicillin-sulbactam, piperacillin-tazobactam), second-generation cephalosporins with antianaerobic activity (cefotaxime), and carbapenems.^{11,79,82,86,91}

In addition to irrigation and antibiotics, when indicated, the injured area should be immobilized and elevated. Clinical failures due to edema have occurred despite appropriate antibiotic therapy.⁸² Therefore, it is important to stress to patients that the affected area should be elevated for several days or until edema has resolved.

Tetanus does not occur commonly after dog bites; however, it is possible. If the immunization history of a patient with anything other than a clean, minor wound is unknown, tetanus-diphtheria (TD) toxoids should be administered (0.5 mL intramuscularly).⁹³ Both TD toxoids and tetanus immune globulin (250 units intramuscularly) should be administered to patients who have never been immunized.^{86,94}

Because the rabies virus can be transmitted via saliva, rabies may be a potential complication of a bite. When the symptoms of rabies develop after a bite, the prognosis for survival is poor. Roughly 3% of rabies cases documented in animals were in dogs (the most frequent vectors are skunks, raccoons, and bats).⁹⁵

After a patient has been exposed to rabies, the treatment objectives consist of thorough irrigation of the wound, tetanus prophylaxis, antibiotic prophylaxis, if indicated, and immunization. Prompt, thorough irrigation of the wound with soap or iodine solution may reduce the development of rabies.⁹⁵ Postexposure prophylaxis immunization against rabies consists of the administration of both passive antibody and vaccine.^{94,95} The vaccine is administered as a series of five 1-mL intramuscular injections given on days 0, 3, 7, 14, and 28, beginning on the day of exposure or as soon as possible afterward. Rabies hyperimmune globulin is administered at a dose of 40 international units/kg; as much of the total dose as possible should be infiltrated into and around the wound, with the remainder being injected intramuscularly at a site different from that of the vaccine.⁹⁴ The only exceptions to administration of hyperimmune globulin are patients who were immunized previously and who have the appropriate

degree of documented rabies antibody titers. However, even individuals who have been fully vaccinated should receive two doses of vaccine on days 0 and 3 after actual rabies exposure.^{94,95}

The management of cat bites is similar to that discussed for dog bites. Cat scratches typically involve the same organisms as bites and should be treated accordingly.

Evaluation of Therapeutic Outcomes

Bite victims treated on an outpatient basis with oral antimicrobials should be followed up within 24 hours either by phone or office visit.¹¹ Hospitalization or change to intravenous therapy should be considered if the infection has progressed. For hospitalized patients with no improvement in signs and symptoms following 24 hours of appropriate therapy, then surgical debridement may be needed.

HUMAN BITES

Epidemiology

Human bites are the third most frequent type of bite. Infected human bites can occur as bites from the teeth or from blows to the mouth (clenched-fist injuries). Human bites generally are more serious than animal bites and carry a higher likelihood of infection than do most animal bites. Infectious complications occur in 10% to 50% of patients with human bites.^{82,96,97}

Self-inflicted bites most commonly occur on the lips or around the fingernails (from sucking or biting the nails). Bites by others can occur to any part of the body, but most often involve the hands. Bites to the hand are most serious and become infected more frequently. The clenched-fist injury is a traumatic laceration caused by one person hitting another in the mouth and is a very serious bite wound. The areas most commonly affected by this injury are the third and fourth metacarpophalangeal joints.

Etiology

Infections caused by these injuries are similar and are caused most often by the normal oral flora, which include both aerobic and anaerobic microorganisms. *Streptococcus* spp. (especially *Streptococcus anginosus*) are the most common isolates, followed by *Staphylococcus* spp. (predominately *S. aureus*).⁹⁸ *Eikenella corrodens* is isolated from human bite wounds approximately 30% of the time.^{82,98} Anaerobic microorganisms have been isolated in approximately 40% of human bites and 55% of clenched-fist injuries. Common anaerobes recovered from human bite infections include *Fusobacterium*, *Prevotella*, *Porphyromonas*, and *Peptostreptococcus* species.⁹⁸

Pathophysiology

Human bites generally are more serious and more prone to infection than animal bites, particularly clenched-fist injuries.⁸⁵ While the force of a punch may sever a tendon or nerve or break a bone, it most often causes a breach in the capsule of the metacarpophalangeal joint, leading to direct inoculation of bacteria into the joint or bone.⁸² When the hand is relaxed, the tendons carry bacteria into deeper spaces of the hand, resulting in more extensive infection.⁸²

CLINICAL PRESENTATION

General

- Most clenched-fist injuries are already infected by the time patients seek medical care, and most require hospitalization.

Symptoms

- Patients with infected bites to the hand may develop a painful, throbbing, swollen extremity.

- Wounds often have a purulent discharge, and the patient complains of a decreased range of motion.

Signs

- Signs of infection include erythema, swelling, and clear or pussy discharge.
- Adjacent lymph nodes may be enlarged.
- In clenched-fist injuries, edema may limit the ability of tendons to glide in their sheaths, thereby limiting a joint's range of motion.

Laboratory Tests

- Samples for bacterial cultures (aerobic and anaerobic) should be collected as per animal bites.
- In severe infections, a peripheral leukocytosis of 15,000 to 30,000 cells/mm³ may be seen; therefore, the white blood count should be monitored for resolution of infection.

Other Diagnostic Tests

- If damage to a bone or joint is suspected, radiographic evaluation should be undertaken.

TREATMENT

Human Bites

Table 114-4 lists the recommended drugs and dosing regimens for human bite wounds.

9 Management of bite wounds consists of aggressive irrigation and topical wound cleansing. Surgical debridement and immobilization of the affected area is often required. Prophylactic antimicrobial agents should be given as soon as possible to all patients, regardless of the appearance of the wound, unless it can be documented that the wound does not involve hands, feet, or joints and penetrates no deeper than the epidermis.^{11,83} Patients with clenched-fist injuries should be seen by a specialist in hand care to evaluate for penetration into the synovium, joint capsule, and bone.^{11,82} Primary closure for human bites generally is not recommended. Tetanus toxoid and antitoxin may be indicated. Because transmission of viruses (HIV, herpes, hepatitis B and C) is a possibility with human bites, information about the biter is important. Although the possibility of acquiring HIV through bites is believed to be unlikely, the presence of the virus in the saliva makes disease transmission possible. If the biter is HIV-positive, the victim should have a baseline blood specimen drawn to determine preexposure HIV status and then be retested in 3 months and 6 months.⁹⁷ The bite wound should be irrigated thoroughly and vigorously with a virucidal agent such as povidone-iodine.^{79,82} Bite victims exposed to blood-tainted saliva should be offered antiretroviral chemoprophylaxis.

10 Patients with human bite injuries should receive prophylactic antibiotic therapy for 3 to 5 days.⁹⁹ First-generation cephalosporins, macrolides, clindamycin, and aminoglycosides are not recommended because the sensitivity of these agents to *E. corrodens* is variable.^{79,82,89} Amoxicillin-clavulanic acid (500 mg every 8 hours) is commonly recommended. Alternatives for penicillin-allergic patients include fluoroquinolones or trimethoprim-sulfamethoxazole in combination with clindamycin or metronidazole.^{11,79,82,89}

Hospitalization for minor wounds is unnecessary if surgical repair of vital structures has not been performed. Patients suffering serious injuries or clenched-fist injuries should be started on intravenous antibiotics. Recommended agents include cefoxitin (1 g every 6 to 8 hours), ampicillin-sulbactam (1.5 to 3 g every 6 hours), or ertapenem (1 g every 24 hours).^{11,91} Therapeutic failures have been documented when either first-generation cephalosporins or penicillinase-resistant penicillins have been used alone, most likely

because of their poor and variable activity against *E. corrodens*. Therapy should be continued from 7 to 14 days.⁹⁹

Evaluation of Therapeutic Outcomes

Evaluation of treatment should follow the same general guidelines as discussed for animal bite wounds. Complications with clenched-fist injuries are common and may result in residual joint stiffness and loss of function. Physical therapy can be needed to improve these complications.

ABBREVIATIONS

HIV: human immunodeficiency virus

MRSA: methicillin-resistant *Staphylococcus aureus*

CA-MRSA: community-associated methicillin-resistant *S. aureus*

SSTI: skin and soft-tissue infection

TD: tetanus-diphtheria

MICHAEL A. CROUCH AND ANGIE VEVERKA

KEY CONCEPTS

- 1 Infective endocarditis is an uncommon infection usually occurring in persons with preexisting cardiac valvular abnormalities (e.g., prosthetic heart valves) or with other specific risk factors (e.g., intravenous drug abuse).
- 2 Three groups of organisms cause a majority of infective endocarditis cases: streptococci, staphylococci, and enterococci.
- 3 The clinical presentation of infective endocarditis is highly variable and nonspecific, although a fever and murmur usually are present. Classic peripheral manifestations (Osler nodes) may or may not occur.
- 4 The diagnosis of infective endocarditis requires the integration of clinical, laboratory, and echocardiographic findings. The two major diagnostic criteria are bacteremia and echocardiographic changes (e.g., valvular vegetation).
- 5 Treatment of infective endocarditis involves isolation of the infecting pathogen and determination of antimicrobial susceptibilities, followed by high-dose, parenteral, bactericidal antibiotics for an extended period.
- 6 Surgical replacement of the infected heart valve is an important adjunct to endocarditis treatment in certain situations (e.g., patients with acute heart failure).
- 7 β -Lactam antibiotics, such as penicillin G (or ceftriaxone), nafcillin, and ampicillin, remain the drugs of choice for streptococcal, staphylococcal, and enterococcal endocarditis, respectively.
- 8 Aminoglycosides are essential to obtain a synergistic bactericidal effect in the treatment of enterococcal endocarditis. Adjunctive aminoglycosides also may decrease the emergence of resistant organisms (e.g., prosthetic valve endocarditis caused by coagulase-negative staphylococci) and hasten the pace of clinical and microbiologic response (e.g., some streptococcal and staphylococcal infections).
- 9 Vancomycin is reserved for patients with immediate β -lactam allergies and the treatment of resistant organisms.
- 10 Antimicrobial prophylaxis is used as an attempt to prevent infective endocarditis in patients who are at the highest risk (such as persons with prosthetic heart valves) before a bacteremia-causing procedure (e.g., dental extraction).

Endocarditis is an inflammation of the endocardium, the membrane lining the chambers of the heart and covering the cusps of the heart valves.^{1,2} More commonly, *endocarditis* refers to infection of the heart valves by various microorganisms. Although it typically affects native valves, it also may involve nonvalvular areas or implanted mechanical devices (e.g., mechanical heart valves). Bacteria primarily cause endocarditis, but fungi and other atypical microorganisms can lead to the disease; hence, the more encompassing term *infective endocarditis* is preferred.

Endocarditis is often referred to as acute or subacute depending on the pace and severity of the clinical presentation. The acute, fulminating form is associated with high fevers and systemic toxicity. Virulent bacteria, such as *Staphylococcus aureus*, frequently cause this syndrome, and if untreated, death may occur within days to weeks. On the other hand, subacute infective endocarditis is more indolent and it is caused by less-invasive organisms, such as viridans streptococci, usually occurring in preexisting valvular heart disease. Although infective endocarditis is often referred to as acute or subacute, it is best classified based on the etiologic organism, the anatomic site of infection, and pathogenic risk factors.² Infection also may follow surgical insertion of a prosthetic heart valve, resulting in prosthetic-valve endocarditis (PVE).³

EPIDEMIOLOGY AND ETIOLOGY

Infective endocarditis is an uncommon, but not rare, infection affecting about 10,000 to 20,000 persons annually in the United States. The infection accounts for approximately 1 in every 1,000 hospital admissions.¹ Yet, the incidence of infective endocarditis may be increasing, and it is now the fourth leading cause of infectious disease syndromes that are life-threatening, after urosepsis, pneumonia, and intraabdominal sepsis.⁴ The mean male-to-female ratio is 1.7:1. Overall, most cases occur in individuals older than 50 years of age, and it is uncommon in children.^{1,2} PVE accounts for 10% to 30% of cases of infective endocarditis.⁵ As the population ages, and as valve replacement surgery becomes more common, the mean age of patients with infective endocarditis increases. However, those with a history of intravenous drug abuse (IVDA) are also at high risk of infective endocarditis. Other conditions associated with a higher incidence of infective endocarditis include diabetes, long-term hemodialysis, and poor dental hygiene.^{6,7}

1 Most persons with infective endocarditis have risk factors, such as preexisting cardiac valvular abnormalities. Many types of structural heart disease result in turbulent blood flow that increases the risk for infective endocarditis. A predisposing risk factor, however, may be absent in up to 25% of cases. Some of the more important risk factors include⁶:

- Presence of a prosthetic valve (highest risk)
- Previous endocarditis (highest risk)

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

- Complex cyanotic congenital heart disease (e.g., single-ventricle states)
- Surgically constructed systemic pulmonary shunts or conduits
- Acquired valvular dysfunction (e.g., rheumatic heart disease)
- Hypertrophic cardiomyopathy
- Mitral valve prolapse with regurgitation
- IVDA

In the past, rheumatic heart disease was a prevalent risk factor for infective endocarditis, but the incidence of this disease continues to decline. The risk of infective endocarditis in persons with mitral valve prolapse and regurgitation is small; however, because the condition is prevalent, it is an important contributor to the overall number of infective endocarditis cases.^{6,7} Prosthetic valve endocarditis occurs in 1% to 3% of patients undergoing valve replacement surgery in the first postoperative year.^{3,5,8}

2 Nearly every organism causing human disease has been reported to cause infective endocarditis, but three groups of organisms result in a majority of cases: streptococci, staphylococci, and enterococci (Table 115-1).^{1,5} The incidence of staphylococci, particularly *S. aureus*, continues to increase, and recent case series document staphylococci have surpassed viridans streptococci as the leading cause of infective endocarditis.^{6,8,9} In general, streptococci cause infective endocarditis in patients with underlying cardiac abnormalities, such as mitral valve prolapse or rheumatic heart disease. Staphylococci (*S. aureus* and coagulase-negative staphylococci) are the most common cause of PVE within the first year after valve surgery, and *S. aureus* is common in those with a history of IVDA. Although polymicrobial infective endocarditis is uncommon, it is encountered most often in association with IVDA.^{5,6,7} Enterococcal endocarditis tends to follow genitourinary manipulations (older men) or obstetric procedures (younger women).⁵ There are many exceptions to the preceding generalizations; thus, isolation of the causative pathogen and determination of its antimicrobial susceptibilities offer the best chance for successful therapy.

The mitral and aortic valves are affected most commonly in cases involving a single valve. Subacute endocarditis tends to involve the mitral valve, whereas acute disease often involves the aortic valve. Up to 35% of cases involve concomitant infections of both the aortic and the mitral valves. Infection of the tricuspid valve is less common, with a majority of these cases occurring in patients with a history of IVDA. It is rare for the pulmonary valve to be infected.^{1,2}

PATHOPHYSIOLOGY

The development of infective endocarditis via hematogenous spread, the most common route, requires the sequential occurrence of several factors. These components are complex and not fully elucidated.^{1,2,5}

- *The endothelial surface of the heart is damaged.* This injury occurs with turbulent blood flow associated with the valvular lesions previously described.
- *Platelet and fibrin deposition occurs on the abnormal epithelial surface.* These platelet-fibrin deposits are referred to as *nonbacterial thrombotic endocarditis*.
- *Bacteremia gives organisms access to and results in colonization of the endocardial surface.* Bacteremia is the result of trauma to a mucosal surface with a high concentration of resident bacteria, such as the oral cavity and gastrointestinal tract. Transient bacteremia commonly follows certain dental, gastrointestinal, urologic, and gynecologic procedures. Staphylococci, viridans streptococci, and enterococci are most likely to adhere to nonbacterial thrombotic endocarditis, probably because of

TABLE 115-1 Etiologic Organisms in Infective Endocarditis

Agent	Percentage of Cases (%)
Streptococci	60–80
Viridans streptococci	30–40
Other streptococci	15–25
Staphylococci	20–35
Coagulase positive	10–27
Coagulase negative	1–3
Enterococci	5–18
Gram-negative aerobic bacilli	1.5–13
Fungi	2–4
Miscellaneous bacteria	<5
Mixed infections	1–2
“Culture negative”	<5–24

Adapted from Fowler G, Scheld WM, Bayer AJ. Endocarditis and intravascular infection. In Mandell GL, Bennett JE, Dolin R, eds., *Principles and Practice of Infectious Diseases*, 6th Ed. New York: Churchill-Livingstone, 2005, 975–1022.

production of specific adherence factors, such as dextran by some oral streptococci and glycocalyx for staphylococci.^{2,8,86} Gram-negative bacteria rarely adhere to heart valves and are uncommon causes of infective endocarditis.

- *After colonization of the endothelial surface, a “vegetation” of fibrin, platelets, and bacteria forms.* The protective cover of fibrin and platelets allows unimpeded bacterial growth to concentrations as high as 10⁹ to 10¹⁰ organisms per gram of tissue.

The pathogenesis of early PVE differs from the infective endocarditis acquired by the hematogenous route because surgery may directly inoculate the valve with bacteria from the patient’s skin or operating room personnel. The recently placed nonendothelialized valve is more susceptible to bacterial colonization than are native valves. Bacteria also may colonize the new valve from contaminated bypass pumps, cannulas, and pacemakers, or from a nosocomial bacteremia subsequent to an intravascular catheter.^{3,10} The mechanism of bacterial colonization and pathogenesis in late PVE is similar to native-valve endocarditis.³

The vegetations seen in infective endocarditis may be single or multiple and vary in size from a few millimeters to centimeters. Bacteria within the vegetation grow slowly and are protected from antibiotics and host defenses. The adverse effects of infective endocarditis and the resulting lesions can be far-reaching and include (a) local perivalvular damage, (b) embolization of septic fragments with potential hematogenous seeding of remote sites, and (c) formation of antibody complexes.^{1,2,5}

Formation of vegetations may destroy valvular tissue, and continued destruction can lead to acute heart failure via perforation of the valve leaflet, rupture of the chordae tendineae or papillary muscle, or in patients with PVE, valve dehiscence. Occasionally, valvular stenosis may occur. Abscesses can develop in the valve ring or in myocardial tissue itself. Even with resolution of the process, fibrosis of tissue with some residual dysfunction is possible.

Vegetations may be friable, and fragments may be released downstream. These infected particles, termed *septic emboli*, can result in organ abscess or infarction. Septic emboli from right-sided endocarditis commonly lodge in the lungs, causing pulmonary abscesses. Emboli from left-sided vegetations commonly affect organs with high blood flow, such as the kidneys, spleen, and brain.^{1,2,5}

Circulating immune complexes consisting of antigen, antibody, and complement may deposit in organs, producing local inflammation and damage (e.g., glomerulonephritis in the kidneys). Other potential pathologic changes that result from immune-complex deposition or septic emboli include the development of “mycotic” aneurysms (although the aneurysm is usually bacterial in origin, not fungal), cerebral infarction, splenic infarction and abscess, and

skin manifestations such as petechiae, Osler nodes, and Janeway lesions.^{1,2,5}

CLINICAL PRESENTATION

3 The clinical presentation of infective endocarditis is highly variable and nonspecific. Fever is the most common finding and is often accompanied by other vague symptoms (Table 115–2). Fever may be relatively low grade, particularly in subacute cases. Heart murmurs are found in a majority of patients, most often preexisting, with some documented as new or changing. Infective endocarditis usually begins insidiously and worsens gradually. Patients may present with nonspecific findings, such as fever, chills, weakness, dyspnea, night sweats, weight loss, or malaise. In contrast, patients with acute disease, such as those with a history of IVDA and *S. aureus* infective endocarditis, may appear with classic signs of sepsis.

Splenomegaly is a frequent finding in patients with prolonged endocarditis. Other important clinical signs especially prevalent in subacute illness may include the following peripheral manifestations (“stigmata”) of endocarditis^{1,2,6}:

- **Osler nodes**—Purplish or erythematous subcutaneous papules or nodules on the pads of the fingers and toes. These lesions are 2 to 15 mm in size and are painful and tender. These nodes are not specific for infective endocarditis and may be the result of embolism, immunologic phenomena, or both.
- **Janeway lesions**—Hemorrhagic, painless plaques on the palms of the hands or soles of the feet. These lesions are believed to be embolic in origin.
- **Splinter hemorrhages**—Thin, linear hemorrhages found under the nail beds of the fingers or toes. These lesions are not specific for infective endocarditis and more commonly are the result of traumatic injuries. Distal lesions are more likely the result of trauma, whereas proximal lesions tend to be associated with infective endocarditis.
- **Petechiae**—Small (usually 1 to 2 mm in diameter), erythematous, painless, hemorrhagic lesions. These lesions appear anywhere on the skin but more frequently on the anterior trunk, buccal mucosa and palate, and conjunctivae. Petechiae are nonblanching and resolve after a few days.
- **Clubbing of the fingers**—Proliferative changes in the soft tissues about the terminal phalanges observed in long-standing endocarditis.
- **Roth spots**—Retinal infarct with central pallor and surrounding hemorrhage.
- **Emboli**—Embolic phenomena occur in up to one-third of cases and may result in significant complications. Left-sided endocarditis can result in renal artery emboli causing flank pain with hematuria, splenic artery emboli causing abdominal pain, and cerebral emboli, which may result in hemiplegia or alteration in mental status. Right-sided endocarditis may result in pulmonary emboli, causing pleuritic pain with hemoptysis.

Patients with infective endocarditis typically have laboratory abnormalities; however, none of these changes is specific for the disease.⁶ Anemia (normocytic, normochromic), leukocytosis, and thrombocytopenia may be present. The white blood cell count is often normal or only slightly elevated, sometimes with a mild left shift. Acute bacterial endocarditis, however, may present with an elevated white blood cell count, consistent with a fulminant infection. The erythrocyte sedimentation rate is elevated in 90% to 100% of patients, and the level of C-reactive protein also may be elevated.^{1,6} Often the urinary analysis is abnormal, with proteinuria and microscopic hematuria occurring in approximately 50% of individuals.

TABLE 115-2 Clinical Presentation of Infective Endocarditis

General
The clinical presentation of infective endocarditis is highly variable and nonspecific.
Symptoms
The patient may complain of fever, chills, weakness, dyspnea, night sweats, weight loss, and/or malaise.
Signs
Fever is common, as is a heart murmur (sometimes new or changing). The patient may or may not have embolic phenomenon, splenomegaly, or skin manifestations (e.g., Osler nodes, Janeway lesions).
Laboratory tests
The patient's white blood cell count may be normal or only slightly elevated. Nonspecific findings include anemia (normocytic, normochromic), thrombocytopenia, an elevated erythrocyte sedimentation rate or C-reactive protein, and altered urinary analysis (proteinuria/microscopic hematuria). The hallmark laboratory finding is continuous bacteremia; three sets of blood cultures should be collected over 24 hours.
Other diagnostic tests
An electrocardiogram, chest radiograph, and echocardiogram are commonly performed. Echocardiography to determine the presence of valvular vegetations plays a key role in the diagnosis of infective endocarditis; it should be performed in all suspected cases.

The hallmark of infective endocarditis is a continuous bacteremia caused by bacteria shedding from the vegetation into the bloodstream; more than 95% of patients with infective endocarditis have positive blood cultures.^{1,2} Three sets of blood cultures, each from separate venipuncture sites, should be collected over 24 hours, and antibiotics should be withheld until adequate blood cultures are obtained. On the other hand, if a patient has a toxic appearance, several blood cultures should be collected promptly, followed by immediate empirical antimicrobial treatment. The blood cultures in patients who have received previous antibiotics should be monitored more closely because pathogen growth may be suppressed.^{1,2} “Culture negative” endocarditis describes a patient in whom a clinical diagnosis of infective endocarditis is likely but blood cultures do not yield a pathogen.¹¹ This condition is often the consequence of previous antibiotic therapy, improperly collected blood cultures, or unusual organisms.⁹ When blood cultures from patients suspected of having infective endocarditis show no growth after 48 to 72 hours, the laboratory should be advised and cultures held for up to a month to detect growth of fastidious organisms.^{1,2}

An electrocardiogram, chest radiograph, and echocardiogram are performed in patients suspected of endocarditis. The electrocardiogram rarely shows important diagnostic findings but may reveal heart block, suggesting extension of the infection. The chest radiograph may provide more diagnostic information, especially in a patient with right-sided endocarditis. Septic pulmonary emboli may occur, leading to multiple lung foci. The echocardiogram is the most important test and should be performed in all patients suspected of this infection.

Echocardiography plays an important role in the diagnosis and management of infective endocarditis.⁹ The chosen approach, transthoracic echocardiography (TTE) or transesophageal echocardiography (TEE), depends on the clinical setting. The TEE technique is more sensitive for detecting vegetations (90% to 100%) as compared with TTE (58% to 63%), and TEE maintains good specificity (85% to 95%).^{2,5,9} TTE appears reasonable in the evaluation of children or adults in whom the clinical suspicion of infective endocarditis is relatively low.^{9,12} TEE is preferred in high-risk patients such as those with prosthetic heart valves, many congenital heart diseases, previous endocarditis, new murmur, heart failure, or other stigmata of endocarditis.^{9,13,14} The lack of vegetation on echocardiogram does not exclude infection even if the transesophageal approach is used. Conversely, the test may reveal an unsuspected large vegetation, extension of the disease into surrounding

tissue, valvular defects, abscess formation, cordial rupture, or an intracardiac fistula. Thus, in addition to helping in the diagnosis of infective endocarditis, the echocardiogram allows the physician to evaluate hemodynamic stability and the need for urgent surgical intervention; it also provides a rough estimate of the likelihood of embolism.^{9,15,16}

DIAGNOSIS

4 The signs and symptoms of infective endocarditis are not specific, and the diagnosis is often unclear. The identification of infective endocarditis requires the integration of clinical, laboratory, and echocardiographic findings. The Duke diagnostic criteria include major and minor variables (Table 115–3).^{17,18} Based on the number of major and minor criteria that are fulfilled, patients suspected of infective endocarditis are categorized into three separate groups: definite infective endocarditis, possible infective endocarditis, or infective endocarditis rejected.¹⁸

TABLE 115-3 Diagnosis of Infective Endocarditis According to the Modified Duke Criteria

Major Criteria

Blood culture positive for infective endocarditis

- Typical microorganisms consistent with infective endocarditis from two separate blood cultures:
 - Viridans streptococci, *Streptococcus bovis*, HACEK group, *Staphylococcus aureus*; or
 - Community-acquired enterococci, in the absence of a primary focus; or
- Microorganisms consistent with infective endocarditis from persistently positive blood cultures, defined as follows:
 - At least two positive cultures of blood samples drawn greater than 12 h apart; or
 - All of three or a majority of four or more separate cultures of blood (with first and last sample drawn at least 1 h apart)
- Single positive blood culture for *Coxiella burnetii* or antiphase I immunoglobulin G antibody titer greater than 1:800

Evidence of endocardial involvement

- Echocardiogram positive for infective endocarditis (transesophageal echocardiography recommended in patients with prosthetic valves, rated at least “possible infective endocarditis” by clinical criteria, or complicated infective endocarditis [paravalvular abscess]; transthoracic echocardiography as first test in other patients), defined as follows:
 - Oscillating intracardiac mass on valve or supporting structures, in the path of regurgitant jets, or on implanted material in the absence of an alternative anatomic explanation; or
 - Abscess; or
 - New partial dehiscence of prosthetic valve
- New valvular regurgitation (worsening or changing of preexisting murmur not sufficient)

Minor Criteria

- Predisposition, predisposing heart condition or injection drug use
- Fever, temperature greater than 38°C (100.4°F)
- Vascular phenomena, major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhages, and Janeway lesions
- Immunologic phenomena: glomerulonephritis, Osler nodes, Roth spots, and rheumatoid factor
- Microbiologic evidence: positive blood culture but does not meet a major criterion as noted above or serologic evidence of active infection with organism consistent with infective endocarditis
- Echocardiographic minor criteria eliminated

HACEK, *Haemophilus* species (*H. parainfluenzae*, *H. aphrophilus*, *H. paraphrophilus*), *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella kingae*.
Note: Cases are defined clinically as definite if they fulfill two major criteria, one major criterion plus three minor criteria, or five minor criteria; cases are defined as possible if they fulfill one major and one minor criterion or three minor criteria; cases are rejected if there is a firm alternate diagnosis explaining evidence of infective endocarditis; resolution of infective endocarditis syndrome with antibiotic therapy for less than 4 days; or no pathologic evidence of infective endocarditis at surgery or autopsy, with antibiotic therapy for less than 4 days; or does not meet criteria for possible infective endocarditis, as above.
Adapted from Durack et al.,¹⁷ and Li et al.¹⁸

PROGNOSIS

The outcome for endocarditis is improved with rapid diagnosis, appropriate treatment (i.e., antimicrobial therapy, surgery, or both), and prompt recognition of complications should they arise. Factors associated with increased mortality include (a) heart failure, (b) culture-negative endocarditis, (c) endocarditis caused by resistant organisms such as fungi or gram-negative bacteria, (d) left-sided endocarditis caused by *S. aureus*, and (e) prosthetic-valve endocarditis.^{1,6,19} The presence of heart failure has the greatest negative impact on the short-term prognosis.⁹ For native-valve infective endocarditis, mortality rates range from 20% to 25%; lower rates occur with viridans streptococci (4% to 16%), and higher rates occur with left-sided infective endocarditis caused by enterococci (15% to 25%) and staphylococci (25% to 47%). Even higher rates of mortality are seen with unusually encountered organisms (e.g., mortality greater than 50% for *Pseudomonas aeruginosa*). The mortality rate for right-side infective endocarditis associated with IVDA is generally low (e.g., 10%).⁶ For those who relapse after treatment for infective endocarditis, most will do so within the first 2 months after discontinuation of antimicrobials. Relapse rates for viridans streptococcus are generally low (2%), whereas relapse is more likely in those with enterococcal infection (8% to 20%) and PVE (10% to 15%).⁶ After appropriate treatment and recovery, the risk of morbidity and mortality following infective endocarditis persist for years, although it gradually declines annually. Morbidity remains elevated because of a greater likelihood of recurrent infective endocarditis, heart failure, and embolism or, if a valve is replaced, the risk of anticoagulation, valve thrombosis, or additional valve surgery.²⁰

TREATMENT

Infective Endocarditis

■ DESIRED OUTCOMES

The desired outcomes for treatment and prophylaxis of infective endocarditis are to

- Relieve the signs and symptoms of the disease.
- Decrease morbidity and mortality associated with the infection.
- Eradicate the causative organism with minimal drug exposure.
- Provide cost-effective antimicrobial therapy determined by the likely or identified pathogen, drug susceptibilities, hepatic and renal function, drug allergies, and anticipated drug toxicities.
- Prevent infective endocarditis from occurring or recurring in high-risk patients with appropriate prophylactic antimicrobials.

■ GENERAL APPROACH TO TREATMENT

5 The most important approach in the treatment of infective endocarditis is isolation of the infecting pathogen and determination of antimicrobial susceptibilities, followed by high-dose, parenteral, bactericidal antibiotics for an extended period.^{1,2} Identification of susceptibilities is crucial given the escalating level of antibiotic resistance to commonly encountered pathogens. Treatment usually is started in the hospital, but in selected patients it is often completed in the outpatient setting so long as defervescence has occurred and followup blood cultures show no growth.⁶ Large doses of parenteral antimicrobials usually are necessary to achieve bactericidal concentrations within vegetations. An extended duration of therapy is required, even for susceptible pathogens, because microorganisms are enclosed within valvular vegetations and fibrin deposits. These barriers impair host defenses and protect microbes from phagocytic

cells. In addition, high bacterial concentrations within vegetations may result in an inoculum effect that further resists killing (see Chap. 108 for additional discussion). Many bacteria are not actively dividing, further limiting the rate of bacterial death. For most patients, 4 to 6 weeks of therapy is required.^{5,7}

■ NONPHARMACOLOGIC THERAPY

6 Surgery is an important adjunct in the management of endocarditis. In most surgical cases, valvectomy and valve replacement are performed to remove infected tissue and to restore hemodynamic function. Echocardiographic features that suggest the need for surgery include persistent vegetation or an increase in vegetation size after prolonged antibiotic treatment, valve dysfunction, or perivalvular extension (e.g., abscess).⁹ Surgery also may be considered in cases of PVE endocarditis caused by resistant organisms (e.g., fungi or gram-negative bacteria), or if there is persistent bacteremia or other evidence of failure despite appropriate antimicrobial therapy.^{3,5,21} The major indications for surgical intervention in the past have been heart failure in left-sided infective endocarditis and persistent infection in right-sided infective endocarditis.¹

■ PHARMACOLOGIC THERAPY

Specific treatment recommendations from the American Heart Association (AHA) provide guidance for the management of infective endocarditis and these were updated in 2005,⁹ with slight modification.²² A new aspect of the revised guidelines is the use of the AHA evidence-based scoring system where recommendations are given a classification as well as level of evidence. Class I

recommendations are conditions for which there is evidence, general agreement, or both that a given procedure or treatment is useful and effective. Class II recommendations are conditions for which there is conflicting evidence, a divergence of opinion, or both about the usefulness/efficacy of a procedure or treatment (IIa implies the weight of evidence/opinion is in favor of usefulness/efficacy whereas IIb implies usefulness/efficacy is less-well established by evidence/opinion). Class III recommendations are conditions for which there is evidence, general agreement, or both that the procedure/treatment is not useful/effective and in some cases may be harmful. Level of evidence is listed as A (data derived from multiple randomized clinical trials), B (data derived from a single randomized trial or nonrandomized studies), and C (consensus opinion of experts).

7 β -Lactam antibiotics, such as penicillin G (or ceftriaxone), nafcillin, and ampicillin, remain the drugs of choice for streptococcal, staphylococcal, and enterococcal endocarditis, respectively. Tables 115–4 through 115–11 summarize these recommendations, which are discussed in more detail in the following sections. Because these guidelines focus on common causes of endocarditis, readers are referred to other references for more in-depth discussion of unusually encountered organisms.^{4,9}

8 For some pathogens, such as enterococci, the use of synergistic antimicrobial combinations (including an aminoglycoside) is essential to obtain a bactericidal effect. Combination antibiotics also may decrease the emergence of resistant organisms during treatment (e.g., PVE caused by coagulase-negative staphylococci) and hasten the pace of clinical and microbiologic response (e.g., some streptococcal and staphylococcal infections). Occasionally, combination treatment will result in a shorter treatment course.

TABLE 115-4 Therapy of Native Valve Endocarditis Caused by Highly Penicillin-Susceptible Viridans Group Streptococci and *Streptococcus bovis*

Regimen	Dosage ^a and Route	Duration (wk)	Strength of Recommendation	Comments
Aqueous crystalline penicillin G sodium	12–18 million units/24 h IV either continuously or in four or six equally divided doses	4	I A	Preferred in most patients older than age 65 years or patients with impairment of 8th cranial nerve function or renal function
or				
Ceftriaxone sodium	2 g/24 h IV/IM in one dose <i>Pediatric dose^b:</i> penicillin 200,000 units/kg per 24 h IV in four to six equally divided doses; ceftriaxone 100 mg/kg per 24 h IV/IM in 1 dose	4	I A	
Aqueous crystalline penicillin G sodium	12–18 million units/24 h IV either continuously or in six equally divided doses	2	I B	2-wk regimen not intended for patients with known cardiac or extracardiac abscess or for those with creatinine clearance of less than 20 mL/min, impaired 8th cranial nerve function, or <i>Abiotrophia</i> , <i>Granulicatella</i> , or <i>Gemella</i> spp. infection;
or				
Ceftriaxone sodium	2 g/24 h IV/IM in 1 dose	2	I B	gentamicin dosage should be adjusted to achieve peak serum concentration of 3–4 mcg/mL and trough serum concentration of less than 1 mcg/mL when three divided doses are used (second option to single daily dose)
plus				
Gentamicin sulfate ^c	3 mg/kg per 24 h IV/IM in 1 dose <i>Pediatric dose:</i> penicillin 200,000 units/kg per 24 h IV in four to six equally divided doses; ceftriaxone 100 mg/kg per 24 h IV/IM in 1 dose; gentamicin 3 mg/kg per 24 h IV/IM in 1 dose or 3 equally divided doses ^d	2		
Vancomycin hydrochloride ^e	30 mg/kg per 24 h IV in two equally divided doses not to exceed 2 g/24 h unless concentrations are inappropriately low <i>Pediatric dose:</i> 40 mg/kg per 24 h IV in two to three equally divided doses	4	I B	Vancomycin therapy recommended only for patients unable to tolerate penicillin or ceftriaxone; vancomycin dosage should be adjusted to obtain peak (1 h after infusion completed) serum concentration of 30–45 mcg/mL and a trough concentration range of 10–15 mcg/mL

Minimum inhibitory concentration less than 0.12 mcg/mL.

^aDosages recommended are for patients with normal renal function.

^bPediatric dose should not exceed that of a normal adult.

^cOther potentially nephrotoxic drugs (e.g., nonsteroidal antiinflammatory drugs) should be used with caution in patients receiving gentamicin therapy.

^dData for once-daily dosing of aminoglycosides for children exist, but no data for treatment of infective endocarditis exist.

^eVancomycin dosages should be infused during course of at least 1 h to reduce risk of histamine-release “red man” syndrome.

TABLE 115-5 Therapy of Native Valve Endocarditis Caused by Strains of Viridans Group Streptococci and *Streptococcus bovis* Relatively Resistant to Penicillin

Regimen	Dosage ^a and Route	Duration (wk)	Strength of Recommendation	Comments
Aqueous crystalline penicillin G sodium	24 million units/24 h IV either continuously or in four to six equally divided doses	4	I B	Patients with endocarditis caused by penicillin-resistant (MIC greater than 0.5 mcg/mL) strains should be treated with regimen recommended for enterococcal endocarditis (see Table 115-9)
or Ceftriaxone sodium	2 g/24 h IV/IM in one dose	4	I B	
plus Gentamicin sulfate ^b	3 mg/kg per 24 h IM/IV in one dose <i>Pediatric dose</i> ^c : penicillin 300,000 units/24 h IV in four to six equally divided doses; ceftriaxone 100 mg/kg per 24 h IV/IM in one dose; gentamicin 3 mg/kg per 24 h IV/IM in one dose or three equally divided doses	2		Although it is preferred that gentamicin (3 mg/kg) be given as a single daily dose to adult patients, as a second option, gentamicin can be administered daily in three equally divided doses
Vancomycin hydrochloride ^c	30 mg/kg per 24 h IV in two equally divided doses not to exceed 2 g/24 h unless serum concentrations are inappropriately low <i>Pediatric dose</i> : 40 mg/kg 24 h in two or three equally divided doses	4	I B	Vancomycin ^d therapy recommended only for patients unable to tolerate penicillin or ceftriaxone therapy

Minimum inhibitory concentration (MIC) greater than 0.12 mcg/mL to less than or equal to 0.5 mcg/mL.

^aDosages recommended are for patients with normal renal function.

^bSee Table 115-4 for appropriate dosage of gentamicin.

^cPediatric dose should not exceed that of a normal adult.

^dSee Table 115-4 for appropriate dosage of vancomycin.

From Baddour LM, Wilson WR, Bayer AS, et al. Infective endocarditis diagnosis, antimicrobial therapy, and management of complications. *Circulation* 2005;111:e394–e433, with permission. Copyright 2005, American Medical Association. Modified based on reference 22.

TABLE 115-6 Therapy for Endocarditis of Prosthetic Valves or Other Prosthetic Material Caused by Viridans Group Streptococci and *Streptococcus bovis*

Regimen	Dosage ^a and Route	Duration (wk)	Strength of Recommendation	Comments
Penicillin-susceptible strain (minimum inhibitory concentration ≤0.12 mcg/mL)				
Aqueous crystalline penicillin G sodium	24 million units/24 h IV either continuously or in four to six equally divided doses	6	I B	Penicillin or ceftriaxone together with gentamicin has not demonstrated superior cure rates compared with monotherapy with penicillin or ceftriaxone for patients with highly susceptible strain; gentamicin therapy should not be administered to patients with creatinine clearance of less than 30 mL/min
or Ceftriaxone sodium	2 g/24 h IV/IM in one dose	6	I B	
with or without Gentamicin sulfate ^b	3 mg/kg per 24 h IM/IV in one dose <i>Pediatric dose</i> ^c : penicillin 300,000 units/24 h IV in four to six equally divided doses; ceftriaxone 100 mg/kg per 24 h IV/IM in one dose; gentamicin 3 mg/kg per 24 h IV/IM in one dose or three equally divided doses	2		
Vancomycin hydrochloride ^d	30 mg/kg per 24 h IV in two equally divided doses <i>Pediatric dose</i> : 40 mg/kg 24 h in two or three equally divided doses	6	I B	Vancomycin therapy recommended only for patients unable to tolerate penicillin or ceftriaxone therapy
Penicillin relatively or fully resistant strain (minimum inhibitory concentration >0.12 mcg/mL)				
Aqueous crystalline penicillin sodium	24 million units/24 h IV either continuously or in four to six equally divided doses	6	I B	
or Ceftriaxone	2 g/24 h IV/IM in one dose	6	I B	
plus Gentamicin sulfate	3 mg/kg per 24 h IV/IM in one dose <i>Pediatric dose</i> : penicillin 300,000 units/kg per 24 h IV in four to six equally divided doses	6		
Vancomycin hydrochloride	30 mg/kg per 24 h IV in two equally divided doses <i>Pediatric dose</i> : 40 mg/kg per 24 h IV in two or three equally divided doses	6	I B	Vancomycin therapy recommended only for patients unable to tolerate penicillin or ceftriaxone therapy

^aDosages recommended are for patients with normal renal function.

^bSee Table 115-4 for appropriate dosage of gentamicin.

^cPediatric dose should not exceed that of a normal adult.

^dSee text and Table 115-4 for appropriate dosage of vancomycin.

TABLE 115-7 Therapy for Endocarditis Caused by Staphylococci in the Absence of Prosthetic Materials

Regimen	Dosage ^a and Route	Duration	Strength of Recommendation	Comments
Oxacillin-susceptible strains				
Nafcillin or oxacillin ^b with	12 g/24 h IV in four to six equally divided doses	6 wk	I A	For complicated right-sided infective endocarditis and for left-sided infective endocarditis; for uncomplicated right-sided infective endocarditis, 2 wk (see text)
Optional addition of gentamicin sulfate ^c For penicillin-allergic (nonanaphylactoid type) patients:	3 mg/kg per 24 h IV/IM in two or three equally divided doses	3–5 days		Clinical benefit of aminoglycosides has not been established
Cefazolin with	6 g/24 h IV in three equally divided doses	6 wk	I B	Consider skin testing for oxacillin-susceptible staphylococci and questionable history of immediate-type hypersensitivity to penicillin
Optional addition of gentamicin sulfate	3 mg/kg per 24 h IV/IM in two or three equally divided doses <i>Pediatric dose:</i> cefazolin 100 mg/kg per 24 h IV in three equally divided doses; gentamicin 3 mg/kg per 24 h IV/IM in three equally divided doses	3–5 days		Cephalosporins should be avoided in patients with anaphylactoid-type hypersensitivity to β -lactams; vancomycin should be used in these cases ^d Clinical benefit of aminoglycosides has not been established
Oxacillin-resistant strains				
Vancomycin ^e	30 mg/kg per 24 h IV in two equally divided doses <i>Pediatric dose:</i> 40 mg/kg per 24 h IV in two or three equally divided doses	6 wk	I B	Adjust vancomycin dosage to achieve 1-h serum concentration of 30–45 mcg/mL and trough concentration of 10–15 mcg/mL

^aDosages recommended are for patients with normal renal function.

^bPenicillin G 24 million units/24 h IV in four to six equally divided doses may be used in place of nafcillin or oxacillin if strain is penicillin susceptible (minimum inhibitory concentration ≤ 0.1 mcg/mL) and does not produce β -lactamase.

^cGentamicin should be administered in close temporal proximity to vancomycin, nafcillin, or oxacillin dosing. See Table 115-4 for appropriate dosage of gentamicin.

^dPediatric dose should not exceed that of a normal adult.

^eFor specific dosing adjustment and issues concerning vancomycin, see Table 115-4 footnotes.

CLINICAL CONTROVERSY

In the past, the AHA guidelines recommended traditional aminoglycoside dosing (three times daily) whenever clinicians use these antibiotics. Extended-interval dosing (once-daily administration) is an intriguing dosing strategy, but data only support this approach for the treatment of streptococcal infective endocarditis.

■ STREPTOCOCCAL ENDOCARDITIS

Streptococci are a common cause of infective endocarditis, with most isolates being viridans streptococci. *Viridans streptococci* refer to a large number of different species, such as *Streptococcus sanguinis*, *Streptococcus oralis*, *Streptococcus salivarius*, *Streptococcus mutans*, and *Gemella morbillorum*.⁹ These bacteria are common inhabitants of the human mouth and gingiva, and they are especially common causes of endocarditis involving native valves.^{1,23}

During dental surgery, and even when brushing the teeth, these organisms can cause a transient bacteremia. In susceptible individuals, this may result in infective endocarditis. Streptococcal endocarditis is usually subacute, and the response to medical treatment is good. *Streptococcus bovis* is not a viridans streptococcus, but it is included in this group because it is penicillin sensitive and requires the same treatment as viridans streptococci. *S. bovis* is a nonenterococcal group D *Streptococcus* that resides in the gastrointestinal tract. Infective endocarditis caused by this organism is often associated with a gastrointestinal pathology, especially colon carcinoma. Endocarditis caused by *Streptococcus pneumoniae*, *Streptococcus pyogenes*, and groups B, C, and G streptococci are uncommon, and their treatment is not well defined.¹

Antimicrobial regimens for viridans streptococci are well studied, and in uncomplicated cases, response rates as high as 98% can be expected. Viridans streptococci are penicillin-susceptible, although some are more susceptible than others. Most are exquisitely sensitive

TABLE 115-10 Therapy for Both Native and Prosthetic Valve Endocarditis Caused by HACEK^a Microorganisms

Regimen	Dosage and Route	Duration (wk)	Strength of Recommendation	Comments
Ceftriaxone ^b sodium or Ampicillin-sulbactam ^c or Ciprofloxacin ^{c,d}	2 g/24 h IV/IM in one dose 12 g/24 h IV in four equally divided doses 1,000 mg/24 h orally or 800 mg/24 h IV in two equally divided doses <i>Pediatric dose^e</i> : Ceftriaxone 100 mg/kg per 24 h IV/IM once daily; ampicillin-sulbactam 300 mg/kg per 24 h IV divided into four or six equally divided doses; ciprofloxacin 20–30 mg/kg per 24 h IV/orally in two equally divided doses	4 4 4	I B IIa B IIb C	Cefotaxime or another third- or fourth-generation cephalosporin may be substituted Fluoroquinolone therapy recommended only for patients unable to tolerate cephalosporin and ampicillin therapy; levofloxacin, gatifloxacin, or moxifloxacin may be substituted; fluoroquinolones generally not recommended for patients younger than 18 y old Prosthetic valve: patients with endocarditis involving prosthetic cardiac valve or other prosthetic cardiac material should be treated for 6 wk

^a*Haemophilus parainfluenzae*, *H. aphrophilus*, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella kingae*.

^bPatients should be informed that IM injection of ceftriaxone is painful.

^cDosage recommended for patients with normal renal function.

^dFluoroquinolones are highly active in vitro against HACEK microorganisms. Published data on use of fluoroquinolone therapy for endocarditis caused by HACEK are minimal.

^ePediatric dose should not exceed that of a normal adult.

TABLE 115-11 Therapy for Culture-Negative Endocarditis Including *Bartonella* Endocarditis

Regimen	Dosage ^a and Route	Duration (wk)	Strength of Recommendation	Comments
Native valve				
Ampicillin-sulbactam	12 g/24 h IV in four equally divided doses	4–6	IIb C	Patients with culture-negative endocarditis should be treated with consultation with an infectious diseases specialist
plus				
Gentamicin sulfate ^b	3 mg/kg per 24 h IV/IM in three equally divided doses	4–6	IIb C	Vancomycin recommended only for patients unable to tolerate penicillins
Vancomycin ^c	30 mg/kg per 24 h IV in 2 equally divided doses	4–6		
plus				
Gentamicin sulfate	3 mg/kg per 24 h IV/IM in three equally divided doses	4–6		
plus				
Ciprofloxacin	1,000 mg/24 h orally or 800 mg/24 h IV in two equally divided doses	4–6		
<i>Pediatric dose^d: ampicillin-sulbactam 300 mg/kg per 24 h IV in four to six equally divided doses; gentamicin 3 mg/kg per 24 h IV/IM in three equally divided doses; vancomycin 40 mg/kg per 24 h in two or three equally divided doses; ciprofloxacin 20–30 mg/kg per 24 h IV/orally in two equally divided doses</i>				
Prosthetic valve (early, <1 y)				
Vancomycin	30 mg/kg per 24 h IV in two equally divided doses	6	IIb C	Same regimens as listed above for native valve endocarditis with the addition of rifampin
plus				
Gentamicin sulfate	3 mg/kg per 24 h IV/IM in three equally divided doses	2		
plus				
Cefepime	6 g/24 h IV in three equally divided doses	6		
plus				
Rifampin	900 mg/24 h orally/IV in three equally divided doses	6		
<i>Pediatric dose: vancomycin 40 mg/kg per 24 h IV in two or three equally divided doses; gentamicin 3 mg/kg per 24 h IV/IM in three equally divided doses; cefepime 150 mg/kg per 24 h IV in three equally divided doses; rifampin 20 mg/kg per 24 h orally/IV in three equally divided doses</i>				
Prosthetic valve (late, >1 y)		6	IIb C	
Suspected <i>Bartonella</i>, culture negative				
Ceftriaxone sodium	2 g/24 h IV/IM in one dose	6	IIa B	Patients with <i>Bartonella</i> endocarditis should be treated in consultation with an infectious diseases specialist
plus				
Gentamicin sulfate	3 mg/kg per 24 h IV/IM in three equally divided doses	2		
with/without				
Doxycycline	200 mg per 24 h IV/orally in two equally divided doses	6		
Documented <i>Bartonella</i>, culture positive				
Doxycycline	200 mg/24 h IV or orally in two equally divided doses	6	IIa B	If gentamicin cannot be given, then replace with rifampin, 600 mg/24 h orally/IV in two equally divided doses
plus				
Gentamicin sulfate	3 mg/kg per 24 h IV/IM in three equally divided doses	2		
<i>Pediatric dose: ceftriaxone 100 mg/kg per 24 h IV/IM once daily; gentamicin 3 mg/kg per 24 h IV/IM in three equally divided doses; doxycycline 2–4 mg/kg per 24 h IV/orally in two equally divided doses; rifampin 20 mg/kg per 24 h orally/IV in two equally divided doses</i>				

^aDosages recommended are for patients with normal renal function.^bSee text and Table 115-4 for appropriate dosing of gentamicin.^cSee Table 115-4 for appropriate dosing of vancomycin.^dPediatric dose should not exceed that of a normal adult.From Baddour LM, Wilson WR, Bayer AS, et al. Infective endocarditis diagnosis, antimicrobial therapy, and management of complications. *Circulation* 2005;111:e394–e433, with permission. Copyright 2005, American Medical Association. Modified based on reference 22.

to penicillin G and have minimal inhibitory concentrations (MICs) of less than 0.12 mcg/mL.^{9,23} Approximately 10% to 20% are moderately susceptible (MIC 0.12 to 0.5 mcg/mL). This difference in in vitro susceptibility led to recommendations that the MIC be determined for all viridans streptococci and that the results be used to guide therapy. Some streptococci are deemed tolerant to the killing effects of penicillin, where the minimal bactericidal concentration

(MBC) exceeds the MIC by 32 times. A tolerant organism is inhibited but not killed by an antibiotic normally considered bactericidal.²⁴ Bactericidal activity is required for successful treatment of infective endocarditis; therefore, infections with a tolerant organism may relapse after treatment. Despite some animal studies of endocarditis suggesting that tolerant strains do not respond as readily to β -lactam therapy as nontolerant ones, this phenomenon is primarily a

laboratory finding with little clinical significance.^{9,25} Treatment for tolerant strains is identical to that for nontolerant organisms, and measurement of the MBC is not recommended.⁹

An assortment of regimens can be used to treat uncomplicated, native-valve endocarditis caused by fully susceptible viridans streptococci (Table 115–4). Two single-drug regimens consist of high-dose parenteral penicillin G or ceftriaxone for 4 weeks. If a shorter course of therapy is desired, the guidelines suggest high-dose parenteral penicillin G plus an aminoglycoside.⁹ When used in select patients, this combination is as effective as 4 weeks of penicillin alone. Although streptomycin was listed in previous guidelines, gentamicin is the preferred aminoglycoside because serum drug concentrations are obtained easily, clinicians are more familiar with its use, and the few strains of streptococci resistant to the effects of streptomycin-penicillin remain susceptible to gentamicin-penicillin. Other aminoglycosides are not recommended.

The decision of which regimen to use depends on the perceived risk versus benefit. For example, a 2-week course of gentamicin in an elderly patient with renal impairment may be associated with ototoxicity, worsening renal function, or both. Furthermore, the 2-week regimen is not recommended for patients with known extracardiac infection. On the other hand, a 4-week course of penicillin alone generally entails greater expense, especially if the patient remains in the hospital. Monotherapy with once-daily ceftriaxone offers ease of administration, facilitates home health care treatment, and may be cost-effective.^{9,26}

The British Society for Antimicrobial Chemotherapy guidelines suggest that all of the following conditions be present to consider a 2-week treatment regimen for penicillin-sensitive streptococcal endocarditis:²⁷

- Penicillin-sensitive viridans streptococcus or *S. bovis* (penicillin MIC <0.1 mcg/mL)
- No cardiovascular risk factors such as heart failure, aortic insufficiency, or conduction abnormalities
- No evidence of thromboembolic disease
- Native-valve infection
- No vegetation of greater than 5 mm diameter on echocardiogram
- Clinical response within 7 days (the temperature should return to normal, the patient should feel well, and the patient's appetite should return to normal)

⁹ When a patient has a history of an immediate-type hypersensitivity to penicillin, vancomycin is chosen for infective endocarditis caused by viridans streptococci. When vancomycin is used, the addition of gentamicin is not recommended.⁹ Most patients who report a penicillin allergy have a negative penicillin skin test and consequently are at low risk of anaphylaxis.²⁸ The published experience with penicillin is more extensive than with alternative regimens; consequently, a thorough allergy history must be obtained before a second-line therapy is administered.

In patients with complicated infections (e.g., extracardiac foci) or when the streptococcus has an MIC of 0.12 to less than or equal to 0.5 mcg/mL, combination therapy with an aminoglycoside and penicillin (higher dose) or ceftriaxone for the first 2 weeks is recommended, followed by penicillin or ceftriaxone alone for an additional 2 weeks (Table 115–5).⁹ Some viridans streptococci have biologic characteristics that complicate diagnosis and treatment, previously referred to as nutritionally variant streptococci. *Abiotrophia defectiva* and *Granulicatella* species have nutritional deficiencies that hinder growth in routine culture media.^{2,9} These organisms require special broth supplemented with pyridoxal hydrochloride or cysteine. For patients infected with nutritionally variant streptococci or when the *Streptococcus* has an MIC of more than 0.5 mcg/mL,

treatment should follow the enterococcal endocarditis treatment guidelines.⁹

The rationale for combination therapy of penicillin-susceptible viridans streptococci is that enhanced activity against these organisms usually is observed when cell wall active agents are combined with aminoglycosides in vitro.²⁵ Combined treatment results in quicker sterilization of vegetations in animal models of endocarditis and probably explains the high response rates observed in patients treated for a total of 2 weeks.⁹ The combined treatment, however, is not superior to penicillin alone. Some authors question the need for combination therapy in relatively resistant streptococci, emphasizing that few human data suggest that patients with endocarditis caused by these organisms respond less well to penicillin alone.²⁹

In patients with endocarditis of prosthetic valves or other prosthetic material caused by viridans streptococci and *S. bovis*, choices of treatment are similar to those without prosthetic material (e.g., penicillin or ceftriaxone); however, treatment courses are extended to 6 weeks (Table 115–6). In fact, if the organism is relatively resistant, gentamicin is recommended for 6 weeks.

Whether or not extended-interval aminoglycoside dosing has a role in infective endocarditis continues to be debated. At this time, data support extended-interval dosing for the treatment of streptococcal infective endocarditis, and as compared with three times-daily dosing this approach may have greater efficacy.^{30–33} One study specifically evaluated the combination of ceftriaxone (2 g daily) with gentamicin (3 mg/kg daily) for 2 weeks compared with ceftriaxone (2 g daily) alone for 4 weeks for penicillin-sensitive streptococci. Both regimens were safe and effective with similar clinical cure rates at 3 months following treatment.³⁴

■ STAPHYLOCOCCAL ENDOCARDITIS

Endocarditis caused by staphylococci has become more prevalent, mainly because of increased IVDA, more frequent use of peripheral and central venous catheters, and increased frequency of valve-replacement surgery.^{35,36} *S. aureus* is the most common organism causing infective endocarditis among those with IVDA and persons with venous catheters. Coagulase-negative staphylococci (usually *Staphylococcus epidermidis*) are prominent causes of PVE.

Staphylococcal endocarditis is not a homogeneous disease; appropriate management requires consideration of several questions: Is the organism methicillin resistant? Should combination therapy be used? Is the infection on a native or prosthetic valve? Does the patient have a history of IVDA? Is the infection on the left or right side of the heart? Another consideration in staphylococcal endocarditis is that some organisms may exhibit tolerance to antibiotics. Similar to streptococci, however, the concern for tolerance among staphylococci should not affect antibiotic selection.⁹

Any patient who develops staphylococcal bacteremia is at risk for endocarditis. Many investigators have attempted to develop criteria that identify the bacteremic patient likely to have infective endocarditis.³⁶ In the past, patients were considered to be at high risk for infective endocarditis if *S. aureus* bacteremia was community acquired versus hospital acquired.¹⁷ However, more recent evidence has resulted in nosocomial *S. aureus* bacteremia being considered as a major criterion for development of infective endocarditis.¹⁸ In hospitalized patients with *S. aureus* bacteremia and an identified focus of infection, such as a vascular catheter, the risk of concomitant infective endocarditis is low, and treatment of the bacteremia can be reduced to 2 weeks. This approach applies only if the patient does not have a prosthetic valve or additional clinical evidence for endocarditis.^{35,36} Additionally, the following parameters predict higher risk of infective endocarditis in patients with *S. aureus* bacteremia: (a) the absence of a primary site of infection, (b) metastatic signs of infection, and (c) valvular vegetations detected by echocardiography.^{1,4}

The recommended therapy for patients with left-sided, native-valve infective endocarditis caused by methicillin-sensitive *S. aureus* (MSSA) is 6 weeks of nafcillin or oxacillin, often combined with a short course of gentamicin (Table 115–7). Four weeks of monotherapy with nafcillin or oxacillin may be sufficient for uncomplicated infections (no perivalvular abscess or septic metastatic complications). From in vitro studies, the combination of an aminoglycoside and penicillinase-resistant penicillin or vancomycin enhances the activity of these drugs for MSSA. In animal models of endocarditis, combinations of penicillin with an aminoglycoside eradicate organisms from vegetations more rapidly than penicillins alone.³⁵ In human studies, the addition of an aminoglycoside to nafcillin hastens the resolution of fever and bacteremia, but it does not affect survival or relapse rates and can increase renal toxicity.³⁷ Traditional twice or three times-daily dosing of aminoglycosides is recommended when administered for staphylococcal infective endocarditis, albeit initial data have evaluated gentamicin given once a day.³⁸

If a patient has a mild, delayed allergy to penicillin, first-generation cephalosporins (such as cefazolin) are effective alternatives, but they should be avoided in patients with a history of immediate-type hypersensitivity reactions to penicillins (see Table 115–7). The potential for a true immediate-type allergy should be assessed carefully. A penicillin skin test should be conducted before giving antibiotic treatment to any patient with infective endocarditis caused by MSSA if there is a questionable penicillin allergy.³⁹ 9 In a patient with a positive skin test or a history of immediate hypersensitivity to penicillin, vancomycin is chosen. Vancomycin, however, kills *S. aureus* slowly and is regarded as inferior to penicillinase-resistant penicillins for MSSA.³⁶ Alternatively, patients with immediate-type hypersensitivity reactions to penicillin who fail to respond to vancomycin therapy should be considered for penicillin desensitization.⁹ Generally, antibiotic therapy should be continued for 6 weeks. Unfortunately, left-sided infective endocarditis caused by *S. aureus* continues to have a poor prognosis, with a mortality rate of 25% to 47%.⁶ For reasons discussed in the following section, those with infective endocarditis associated with IVDA have a more favorable response to therapy.

During the past decade, greater numbers of staphylococci became resistant to penicillinase-resistant penicillins (e.g., methicillin). 9 Vancomycin is used in this situation because most methicillin-resistant *S. aureus* (MRSA) and coagulase-negative staphylococci are susceptible to it (see Table 115–7). Reports of *S. aureus* strains resistant to vancomycin are emerging.⁴⁰ This is concerning as there are currently no standard treatment regimens to treat *S. aureus* infective endocarditis if the strain is resistant to both methicillin and vancomycin. There is emerging literature documenting success with daptomycin or linezolid in these patients.^{41–44} The presence or lack of a prosthetic heart valve in patients with a methicillin-resistant organism guides therapy and determines whether vancomycin should be used alone or, if a prosthetic valve is present, whether combination therapy is necessary (Table 115–8).^{3,9}

Staphylococcus Endocarditis: Intravenous Drug Abuser

Infective endocarditis in those with IVDA is frequently (60% to 70%) caused by *S. aureus*, although other organisms may be common in certain geographic locations.⁴⁵ In this setting, the tricuspid valve is frequently infected, resulting in right-sided infective endocarditis. Most patients have no history of valve abnormalities, are usually otherwise healthy, and have a good response to medical treatment. Nonetheless, surgery may be required.

An uncomplicated, left-sided MSSA endocarditis may be treated sufficiently with 4 weeks of monotherapy with penicillinase-resistant penicillin.⁹ In the intravenous drug abuser, however, the

clinical response with right-sided MSSA endocarditis is usually excellent. These patients may be treated effectively (clinical and microbiologic cure exceeding 85%) with a 2-week course of nafcillin or oxacillin plus an aminoglycoside.^{45–51} Short-course vancomycin, in place of nafcillin or oxacillin, appears ineffective.⁴⁹ Another trial suggested that a 2-week regimen of a penicillinase-resistant penicillin alone, without the addition of an aminoglycoside, is as effective as combined therapy in MSSA tricuspid valve endocarditis.⁵² Although these data suggest that an aminoglycoside is unnecessary for short-course treatment in the intravenous drug abuser with right-sided infective endocarditis, most clinicians are uncomfortable with monotherapy and choose combination treatment so long as there are no reasons to avoid an aminoglycoside. Short-course therapy should not be used in left-sided endocarditis, and it is inappropriate in patients with underlying acquired immunodeficiency syndrome, renal failure, meningitis or substantial pulmonary complications, such as lung abscess from right-sided infective endocarditis.⁹

An intriguing therapeutic approach for staphylococcal endocarditis in those with IVDA is oral treatment. Preliminary data suggest that short-course intravenous treatment (primarily nafcillin; mean: 16 days) followed by oral treatment (dicloxacillin or oxacillin; mean: 26 days) might be effective for tricuspid valve MSSA endocarditis.⁵³ The positive results of this trial can be explained by the duration of intravenous antibiotics (>2 weeks), which may be a sufficient treatment course. Yet, two other studies that predominantly used oral therapy (ciprofloxacin and rifampin) found this approach to be effective (cure rates exceeding 90%) in addicts with uncomplicated right-sided endocarditis caused by MSSA.^{54,55} At this time, concerns with resistance (e.g., ciprofloxacin) and limited published data preclude routine use of oral antibacterial regimens for the treatment of infective endocarditis in the intravenous drug abuser.⁹

Staphylococcal Endocarditis: Prosthetic Valves

PVE accounts for approximately 15% of all infective endocarditis cases.⁵⁶ An episode of PVE occurring within 2 months of surgery strongly suggests that the cause is staphylococci implanted during the procedure.³ Yet the risk of staphylococcal endocarditis remains elevated for up to 12 months after valve replacement. Because this type of infective endocarditis is typically a nosocomial infection, methicillin-resistant organisms are common, and vancomycin is the cornerstone of therapy. Combination antimicrobials are recommended because of the high morbidity and mortality associated with PVE and its refractoriness to therapy.^{3,9} Although the addition of rifampin to a penicillinase-resistant penicillin or vancomycin does not result in predictable bacterial synergism, rifampin may have unique activity against staphylococcal infection that involves prosthetic material, where its addition results in a higher microbiologic cure rate.² Combination therapy also decreases the emergence of resistance to rifampin, which frequently occurs when it is used alone. For methicillin-resistant staphylococci (both MRSA and coagulase-negative staphylococci), vancomycin is recommended with rifampin for 6 weeks or more (see Table 115–8). An aminoglycoside is added for the first 2 weeks if the organism is aminoglycoside-susceptible. For MSSA, a penicillinase-resistant penicillin is administered in place of vancomycin. PVE responds poorly to medical treatment and has a higher mortality compared with native-valve endocarditis. Valve dehiscence and incompetence can result in acute heart failure, and surgery is often a component of treatment.^{3,9}

Twelve months or more after valve replacement the likely organism for PVE parallels that of native-valve endocarditis. As with native-valve endocarditis, antimicrobial therapy should be based on the identified organism and in vitro susceptibility. If an organism is identified other than staphylococci, the treatment regimen should

be guided by susceptibilities and should be at least 6 weeks in duration.^{3,9} Additionally, a concomitant aminoglycoside is recommended if streptococci or enterococci are identified. Once-daily aminoglycoside regimens have not been adequately evaluated in PVE and are not recommended.³

The use of anticoagulation is controversial in PVE. In general, those who require anticoagulation for a prosthetic valve should continue the anticoagulant cautiously during endocarditis therapy, unless a contraindication to therapy exists. It is recommended to hold all anticoagulation for at least 2 weeks in patients with *S. aureus* PVE if a recent CNS embolic event has occurred.⁹

CLINICAL CONTROVERSY

Oral antibiotics for the treatment of infective endocarditis have been assessed primarily in those with IVDA. Although treating infective endocarditis with oral antibiotics would decrease adverse events associated with prolonged use of intravenous catheters, the paucity of data preclude this being a routine treatment. Oral rifampin is used as part of combination therapy in PVE caused by staphylococci. The AHA guidelines recently added ciprofloxacin orally as an option for treatment of infective endocarditis caused by the HACEK group of organisms.

ENTEROCOCCAL ENDOCARDITIS

Enterococci are normal inhabitants of the human gastrointestinal tract and, occasionally, of the anterior urethra. These organisms are usually of low virulence but can become pathogens in predisposed patients following genitourinary manipulations (older men) or obstetric procedures (younger women).² Historically, enterococci were considered group D streptococci, but they have been reclassified into the genus *Enterococcus* (*E. faecalis* and *E. faecium*). *E. faecalis* is the most common clinical isolate (approximately 90%) of the two species. Enterococci cause 5% to 18% of endocarditis cases, but they are more resistant to therapy than staphylococci and streptococci. Enterococci are noteworthy for these reasons: (a) no single antibiotic is bactericidal, (b) MICs to penicillin are relatively high (1 to 25 mcg/mL), (c) intrinsic resistance occurs to all cephalosporins and relative resistance occurs to aminoglycosides (e.g., “low-level” aminoglycoside resistance), (d) combinations of a cell wall active agent such as a penicillin or vancomycin and an aminoglycoside are necessary for killing, and (e) resistance to all available drugs is increasing.^{1,9}

Monotherapy with penicillin for infective endocarditis caused by enterococci results in relapse rates of 50% to 80%. When used alone, penicillins are only bacteriostatic against enterococci, and combination therapy is always recommended for susceptible strains.⁹ The relapse rate following penicillin-gentamicin therapy for susceptible strains is less than 15%.¹⁶ The killing of enterococci by the bactericidal combination of an aminoglycoside and a penicillin is the best clinical example of antibiotic synergy. Because the aminoglycoside cannot penetrate the bacterial cell in the absence of the penicillin, enterococci usually will appear to be resistant to aminoglycosides by routine susceptibility testing (low-level resistance). However, in the presence of an agent that disrupts the cell wall such as penicillin, the aminoglycoside can gain entry, attach to bacterial ribosomes, and cause rapid cell death. An aminoglycoside-vancomycin combination is also synergistic against enterococci and is appropriate therapy for the penicillin-allergic patient.⁵⁷

Enterococcal endocarditis ordinarily requires 4 to 6 weeks of ampicillin or high-dose penicillin G plus an aminoglycoside for cure (Table 115–9). Ampicillin has greater in vitro activity than penicillin G, although there are no clinical data to document differences in efficacy. A 6-week course is recommended for patients with symptoms lasting longer than 3 months and those with PVE. Streptomy-

cin has been the most extensively studied aminoglycoside, but gentamicin is presently favored. Because of resistance, other aminoglycosides, such as tobramycin and amikacin, cannot be substituted routinely. In the treatment of enterococcal endocarditis, relatively low serum concentrations of aminoglycosides appear adequate for successful therapy, such as a gentamicin peak concentration of approximately 3 to 4 mcg/mL.^{9,58} Treatment of enterococcal endocarditis does not have the high success rate seen with infective endocarditis caused by viridans streptococci presumably because the organism is more resistant to killing.

Although some data support the use of extended-interval aminoglycoside dosing for other types of endocarditis (i.e., streptococci), the data are more vague regarding this strategy in enterococcal infective endocarditis.⁵⁹ Even though some studies suggest that extended-interval aminoglycoside dosing and short-interval (traditional) dosing are clinically equivalent,^{60–62} discordant studies imply otherwise.^{63,64} The paucity of human data precludes routine use of extended-interval aminoglycoside dosing in this setting and the guidelines recommend three-times daily dosing.⁹

Resistance among enterococci to penicillins and aminoglycosides is increasing.⁹ Enterococci that exhibit high-level resistance to streptomycin (MIC >2000 mcg/mL) are not synergistically killed by penicillin and streptomycin because the aminoglycoside either no longer binds to the ribosome or is inactivated by an aminoglycoside-modifying enzyme, streptomycin adenylase. Because enterococci will appear resistant to aminoglycosides on routine susceptibility testing, the only way to distinguish high-level from low-level resistance is by performing special susceptibility tests using 500 to 2,000 mcg/mL of the aminoglycoside. High-level streptomycin-resistant enterococci occur with a frequency approaching 60%, and high-level resistance to gentamicin is now found in 10% to 50% of isolates. Although most gentamicin-resistant enterococci are resistant to all aminoglycosides (including amikacin), 30% to 50% remain susceptible to streptomycin.^{1,5} High-level gentamicin resistance is mediated by a bifunctional aminoglycoside-modifying enzyme, 6-acetyltransferase/2-phosphotransferase, and most strains also possess streptomycin adenylase. These organisms do not commonly cause infective endocarditis; data on appropriate therapy are sparse, and therapeutic options are few. Case reports indicate that some patients will respond to high doses of ampicillin, as observed in the early trials of penicillin monotherapy.⁶⁵

In addition to isolates with high-level aminoglycoside resistance, β -lactamase-producing enterococci (especially *E. faecium*) have been reported.⁶⁶ If these organisms are discovered, use of vancomycin or ampicillin-sulbactam in combination with gentamicin should be considered. Vancomycin-resistant enterococci are reported increasingly, primarily with *E. faecium*. Vancomycin resistance occurs when the bacterium replaces the normal vancomycin target with a peptidoglycan precursor that does not bind vancomycin.⁶⁷ Because of the difficulty of treating multidrug-resistant enterococci, surgery and replacement of the infected cardiac valve may be the only cure.

HACEK Group

Fastidious gram-negative bacteria from the HACEK group account for up to 10% of native valve, community-acquired infective endocarditis.⁹ Frequently, these types of infective endocarditis present as subacute illnesses with large vegetations and emboli.⁶⁸ These oropharyngeal organisms typically are slow growing and should be considered as possible causes of “culture negative” endocarditis. In the past, high-dose ampicillin with gentamicin for 4 weeks was an acceptable treatment regimen for HACEK endocarditis, but β -lactamase-producing organisms are occurring more often; hence, HACEK organisms should be considered resistant to ampicillin alone. Numerous treatments are reasonable for the treatment of HACEK infective endocarditis, including ceftriaxone and ampicil-

lin-sulbactam; the newest addition to the guidelines is oral ciprofloxacin for selected patients (Table 115–10).⁹ Treatment is usually for 4 weeks, but it should be extended to 6 weeks in PVE caused by one of these organisms.

■ LESS-COMMON TYPES OF INFECTIVE ENDOCARDITIS

Atypical Microorganisms

Endocarditis caused by organisms such as *Bartonella*; *Coxiella burnetii*; *Brucella*, *Candida*, and *Aspergillus* spp.; *Legionella*; and gram-negative bacilli (e.g., *Pseudomonas*) is relatively uncommon. Medical therapy for infective endocarditis caused by these organisms is usually unsuccessful.^{6,9} Consultation with an infectious disease expert is warranted when these microorganisms are identified.

In addition to *Pseudomonas* spp., other gram-negative bacilli that have been implicated include *Salmonella* spp., *Escherichia coli*, *Citrobacter* spp., *Klebsiella-Enterobacter* spp., *Serratia marcescens*, *Proteus* spp., and *Providencia* spp.¹ Generally, these infections have a poor prognosis, with mortality rates as high as 60% to 80%.¹⁹ Cardiac surgery in concert with extended course antibacterial therapy is the recommended course (Class IIa; Level of Evidence: B) for most patient with gram-negative bacillary infective endocarditis. Readers are referred to the AHA guidelines for more extensive review of *Pseudomonas* spp. infective endocarditis and unusual gram-negative bacteria treatment regimens.⁹

Fungi cause between 2% and 4% of endocarditis cases; most patients with fungal endocarditis have undergone recent cardiovascular surgery, are intravenous drug abusers, have received prolonged treatment with intravenous catheters or antibiotics, or are immunocompromised.^{1,2,69} *Candida* spp. and *Aspergillus* spp. are the most commonly involved, and the mortality rate is high (greater than 80%) for these reasons: (a) large, bulky vegetations that often form, (b) systemic septic embolization that may occur, (c) the tendency for fungi to invade the myocardium, (d) poor penetration of vegetations by antifungals, (e) the low toxic-to-therapeutic ratio of agents such as amphotericin B, and (f) the lack of consistent fungicidal activity of available antifungal agents.^{1,70} When fungal infective endocarditis is identified, the combined medical–surgical approach is recommended. Because these infections occur infrequently, scant clinical data are available to make solid treatment recommendations; however, the use of antifungal agents alone has been globally unsuccessful. Amphotericin B has been the mainstay pharmacologic approach. The availability of newer antifungal agents challenges this historical approach, although clinical trial data are lacking.⁹

C. burnetii (Q fever) was recently recovered from blood cultures, but infection is more likely to be identified via serologic tests. It is a common cause of infective endocarditis in certain areas of the world where goat, cattle, and sheep farming are widespread. The most favorable therapy for Q fever is unknown but may include doxycycline with trimethoprim-sulfamethoxazole, rifampin, or fluoroquinolones.⁴ *Brucella* are facultative intracellular gram-negative bacilli. Humans are infected by this organism after ingesting infected unpasteurized milk or undercooked meat, inhalation of infectious aerosols, or contact with infected tissues. This type of infective endocarditis is more common in veterinarians and livestock handlers. Cure requires valve replacement and antimicrobial agents including doxycycline with streptomycin or gentamicin or doxycycline with trimethoprim-sulfamethoxazole or rifampin for an extended period (8 weeks to months).⁴

Culture-Negative Endocarditis

Sterile blood cultures are reported in 5% to 20% of patients with infective endocarditis if strict diagnostic criteria are used.^{1,6,71} This

type of infective endocarditis may occur as a result of unidentified subacute right-sided infective endocarditis, previous antibiotic therapy, slow-growing fastidious organisms, nonbacterial etiologies (e.g., fungi), and improperly collected blood cultures. When blood cultures from patients suspected of infective endocarditis show no growth after 48 to 72 hours, the laboratory should be advised and cultures held for up to a month to detect growth of fastidious organisms.⁹

The AHA guidelines provide general recommendations for culture-negative infective endocarditis (Table 115–11), although clinicians should individualize therapy, as necessary. Selection of treatment can be difficult, balancing the need to cover all likely organisms against potential toxic drug effects (e.g., aminoglycosides). Antimicrobial selection should be in consultation with an infectious diseases specialist. Irrespective of the chosen treatment, extended antimicrobial therapy is required. The preceding empirical approaches for culture-negative infective endocarditis highlight the need for proper collection and monitoring of blood cultures and an extensive medication history.

PHARMACOECONOMIC CONSIDERATIONS

Infective endocarditis remains an uncommon disease, but the cost of treatment can be substantial. In the past, the long duration of hospitalization required to administer intravenous antimicrobials was the major expense. In selected cases, abbreviated and/or outpatient, and perhaps oral antimicrobial therapy may appreciably reduce the cost of care.

Shorter-course antimicrobial regimens are advocated when possible. For instance, in exquisitely sensitive streptococcal endocarditis (MICs less than 0.12 mcg/mL), a 2-week regimen of high-dose parenteral penicillin G or ceftriaxone in combination with an aminoglycoside is as effective as 4 weeks of penicillin alone.⁹ Uncomplicated right-sided MSSA endocarditis in the intravenous drug abuser may be treated with a 2-week course. Treatment with nafcillin or oxacillin in combination with an aminoglycoside appears to be cost-effective.

The initiation of outpatient parenteral antibiotics should be considered early in the treatment of infective endocarditis, after the patient is stable clinically and responds favorably to initial antibiotics. Outpatient treatment is safe and cost-effective in select situations.⁷² Patients considered for home therapy must be hemodynamically stable, compliant with therapy, have careful medical monitoring, understand the potential complications of the disease, and have immediate access to medical care. Advances in technology allow for the outpatient administration of complex antibiotic regimens that significantly reduce the cost of therapy. Simple regimens, such as single daily doses of ceftriaxone for streptococcal infective endocarditis, are particularly attractive. Although endocarditis is common in those with a history of IVDA and home healthcare would substantially reduce the cost of treatment, many clinicians are uncomfortable with outpatient intravenous therapy because central venous access is required. Sudden cardiac decompensation in an outpatient setting is also of concern.⁹

EVALUATION OF THERAPEUTIC OUTCOMES

The evaluation of patients treated for infective endocarditis includes assessment of disease signs and symptoms, blood cultures, microbiologic tests, serum drug concentrations, and other tests that evaluate organ function.

SIGNS AND SYMPTOMS

Fever usually subsides within 1 week of initiating therapy.^{1,2} Persistence of fever may indicate ineffective antimicrobial therapy, emboli, infections of intravascular catheters, or drug reactions. In some

patients, low-grade fever may persist even with appropriate antimicrobial therapy. With defervescence, the patient should begin to feel better, and other symptoms, such as lethargy or weakness, should subside. Echocardiography should be performed when antibiotic therapy has been completed to determine new baseline cardiac function (i.e., ventricular size and function). A TTE is usually sufficient.

BLOOD CULTURES

Blood cultures should be negative within a few days, although microbiologic response to vancomycin may be slower.^{1,2} If bacteria continue to be isolated from blood beyond the first few days of therapy, it may indicate that the antimicrobials are inactive against the pathogen or that the doses are not producing adequate concentrations at the site of infection. After the initiation of therapy, blood cultures should be rechecked until negative. During the remainder of therapy, frequent blood culturing is not necessary. Additional blood cultures should be rechecked after successful treatment (e.g., once or twice within the 8 weeks after treatment) to ensure cure.

MICROBIOLOGIC TESTS

For all isolates from blood cultures, MICs should be determined; MBCs are no longer recommended.⁹ The agent currently being used should be tested, as well as alternatives that may be required if intolerance, allergy, or resistance occurs. Occasionally, it is useful to determine whether synergy exists for antimicrobial combinations, although synergistic regimens usually can be predicted from the literature. Chapter 108 summarizes the methods for in vitro determinations of synergy.

Serum bactericidal titers (SBTs; also called *Schlichter tests*) have been used in the past in association with a number of infectious diseases. The SBT is the greatest dilution of a patient’s serum sample that is obtained while receiving antimicrobial treatment that kills greater than 99.9% of an inoculum of the infecting pathogen in vitro over 18 to 24 hours.

Although specific SBTs have been evaluated in endocarditis, at present, SBTs have little value in monitoring treatment of common types of infective endocarditis and should not be recommended routinely.^{9,73,74} This test may be useful when the causative organisms are only moderately susceptible to antimicrobials, when less-well-established regimens are used, or when response to therapy is suboptimal and dosage escalation is being considered.

SERUM DRUG CONCENTRATIONS

Of the agents used commonly for infective endocarditis, measurement of serum drug concentrations is routinely available for aminoglycosides (except streptomycin) and vancomycin. Few data, however, support attaining any specific serum concentrations in patients with infective endocarditis. In general, serum concentrations of the antimicrobial should exceed the MBC of the organisms. Aminoglycoside concentrations rarely exceed the MBC for certain organisms, such as streptococci and enterococci, and concentrations have not been correlated with response, such as aminoglycosides and vancomycin for staphylococci.^{74,75}

When aminoglycosides are administered for infective endocarditis caused by gram-positive cocci with a traditional three times-daily regimen, peak serum concentrations are recommended to be on the low side of the traditional ranges (3 to 4 mcg/mL for gentamicin). If extended-interval dosing is used, which is only recommended in streptococcal infective endocarditis, the most appropriate method of monitoring has not been determined. When vancomycin is administered, the most recent treatment guidelines recommend serum drug monitoring.⁹ Although the guidelines recommend that clinicians obtain a peak serum concentrations when using vanco-

mycin, measuring peak concentrations has limited applicability. The primary goal of serum vancomycin monitoring clinically is to ensure adequate trough concentrations are achieved.

PREVENTION

10 Antimicrobial prophylaxis is used as an attempt to prevent infective endocarditis in patients who are at the highest risk.^{76,77} The use of antimicrobials for this purpose requires consideration of (a) cardiac conditions associated with endocarditis, (b) procedures causing bacteremia, (c) organisms likely to cause endocarditis, and (d) pharmacokinetics, spectrum, cost, adverse effects, and ease of administration of available antimicrobial agents. The objective of prophylaxis is to diminish the likelihood of infective endocarditis in high-risk individuals from procedures that result in bacteremia. Although there are no prospective, controlled human trials demonstrating that prophylaxis in high-risk individuals protects against the development of endocarditis during bacteremia-induced procedures, animal studies suggest possible benefit.⁷⁶ Many causes of infective endocarditis, however, appear not to be secondary to an invasive procedure. Bacteremia as a consequence of daily activities in fact may be the major culprit, and the value of antibiotic prophylaxis before bacteremia-causing procedures has been questioned.⁷⁸ Retrospective human studies, though, support that a reduction of endocarditis occurs in selected patients following dental surgery where prophylaxis is employed.⁷⁹ The common practice of using antimicrobial therapy in this setting remains controversial. The mechanism of a beneficial effect in humans is unclear, but antibiotics may decrease the number of bacteria at the surgical site, kill bacteria after they are introduced into the blood, and prevent adhesion of bacteria to the valve. Prophylaxis does not reduce the frequency of bacteremia immediately following tooth extraction as compared with a control group, suggesting that a reduction in adhesion or effects after the bacteria adhere to the endocardium are more likely mechanisms.^{80,81} Other studies have further questioned the benefit of antibiotic prophylaxis.⁸²

CLINICAL CONTROVERSY

The common practice of administering antibiotics to high-risk individuals before a bacteremia-causing procedure is controversial. Despite limited data supporting this approach and the fact that 100% compliance with AHA preventative guidelines would have only a modest benefit, the use of single-dose antibiotics for the prevention of endocarditis remains a standard of care.

TABLE 115-12 Cardiac Conditions Associated with the Highest Risk of Adverse Outcome from Endocarditis for Which Prophylaxis with Dental Procedures Is Recommended

Prosthetic cardiac valves
Previous infective endocarditis
Congenital heart disease (CHD) ^a
Unrepaired cyanotic CHD, including palliative shunts and conduits
Completely repaired congenital heart defect with prosthetic material or device, whether placed by surgery or by catheter intervention, during the first 6 months after the procedure ^b
Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device (which inhibit endothelialization)
Cardiac transplantation recipients who develop cardiac valvulopathy

^aExcept for the conditions listed above, antibiotic prophylaxis is no longer recommended for any other form of CHD.
^bProphylaxis is recommended because endothelialization of prosthetic material occurs within 6 months after the procedure.

TABLE 115-13 Dental Procedures for Which Endocarditis Prophylaxis Is Recommended for Patients in Table 115-12

All dental procedures that involve manipulation of gingival tissue or the periapical region of teeth or perforation of the oral mucosa^a

^aThe following procedures and events do not need prophylaxis: routine anesthetic injections through noninfected tissue, taking dental radiographs, placement of removable prosthodontic or orthodontic appliances, adjustment of orthodontic appliances, placement of orthodontic brackets, shedding of deciduous teeth, and bleeding from trauma to the lips or oral mucosa.

From Wilson W, Taubert KA, Gewitz M, et al. Prevention of infective endocarditis. *Circulation* 2007;116:1736–1754 with permission. Copyright 2007, American Medical Association.

Regardless of the controversy about whether prophylactic antibiotics should be used, infective endocarditis prophylaxis is recommended in selected situations, specifically dental procedures, in those with underlying high-risk cardiac conditions. Recently the American Heart Association released new guidelines that better define who should and should not receive infective endocarditis prophylaxis.⁸³ This update is timely as data show overuse of infective endocarditis prophylaxis occurs in low-risk patients, and underuse occurs in those at greater risk.⁸⁴

Key points of this report are that (a) only a small number of cases of infective endocarditis might be prevented with antibiotic prophylaxis for dental procedures, even if 100% effective; (b) infective endocarditis prophylaxis for dental procedures should be recommended only for patients with underlying cardiac conditions associated with the highest risk; (c) in those with high-risk underlying cardiac conditions, prophylaxis is recommended for all dental procedures involving manipulation of gingival tissue or the periapical region of teeth or perforation of the oral mucosa; (d) prophylaxis is not recommended based solely on an increased lifetime risk of acquisition of infective endocarditis; and (e) administration of antibiotics solely to prevent endocarditis is not recommended for patients who undergo a genitourinary or gastrointestinal tract procedure.

To determine whether a patient should receive prophylactic antibiotics, one needs to assess the patient's risk (Table 115-12) and if they

are undergoing a procedure resulting in bacteremia (Table 115-13). When antibiotic prophylaxis is appropriate a single 2-g dose of amoxicillin is recommended for adult patients at risk, given 30 to 60 minutes before undergoing procedures associated with bacteremia (Table 115-14). Because the duration of antimicrobial prophylaxis appears to be relatively short, these guidelines do not advocate a second oral dose of amoxicillin, which was recommended previously. Alternative prophylaxis regimens for patients allergic to penicillins or those unable to take oral medications are also provided.

ABBREVIATIONS

AHA: American Heart Association

HACEK: The group of bacteria including *Haemophilus parainfluenzae*, *Haemophilus aphrophilus*, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella kingae*

CHARLES A. PELOQUIN

KEY CONCEPTS

- 1 Tuberculosis (TB) is the most prevalent communicable infectious disease on earth; it remains out of control in many developing nations. These nations require medical and financial assistance from developed nations in order to control the spread of TB globally.
- 2 In the United States, TB disproportionately affects ethnic minorities as compared with whites, reflecting greater ongoing transmission in ethnic minority communities. Additional TB surveillance and preventive treatment are required within these communities.
- 3 Coinfection with human immunodeficiency virus (HIV) and TB accelerates the progression of both diseases, thus requiring rapid diagnosis and treatment of both diseases.
- 4 Mycobacteria are slow-growing organisms; in the laboratory, they require special stains, special growth media, and long periods of incubation to isolate and identify.
- 5 TB can produce atypical signs and symptoms in infants, the elderly, and immunocompromised hosts, and it can progress rapidly in these patients.
- 6 Latent TB infection (LTBI) can lead to reactivation disease years after the primary infection occurred.
- 7 The patient suspected of having active TB disease must be isolated until the diagnosis is confirmed and the patient is no longer contagious. Often, isolation takes place in specialized “negative-pressure” hospital rooms to prevent the spread of TB.
- 8 Isoniazid and rifampin are the two most important TB drugs; organisms resistant to both these drugs (multidrug-resistant TB [MDR-TB]) are much more difficult to treat.
- 9 Never add a single drug to a failing regimen!
- 10 Directly observed treatment should be used whenever possible to reduce treatment failures and the selection of drug-resistant isolates.

1 Tuberculosis (TB) remains a leading infectious killer globally. TB is caused by *Mycobacterium tuberculosis*, which can produce either a silent, latent infection or a progressive, active disease.¹ Left untreated or improperly treated, TB causes progressive tissue destruction and,

eventually, death. Because of renewed public health efforts, TB rates in the United States continue to decline. In contrast, TB remains out of control in many developing countries—to the point that one-third of the world’s population currently is infected.¹ Approximately 1 person dies of TB in India each minute (*Times of India*, August 29, 2003). Given increasing drug resistance, it is critical that a major effort be made to control TB before the most effective drugs are lost permanently.

M. tuberculosis preferentially infects humans, and the closely related *Mycobacterium bovis* causes a similar disease in cattle and other livestock. Although uncommon today, humans frequently developed TB by drinking milk contaminated with *M. bovis*—a threat that spurred the development of pasteurization. Today, airborne *M. tuberculosis* is the main threat to humans.

Evidence of TB has been found in ancient human remains, and ancient texts describe it.^{1–3} TB commonly was known as “consumption” because of the pronounced weight loss that it caused.¹ Other common names included “wasting disease” and the “white plague.” As the term *plague* implies, TB had a profound impact on human history, most notably in Europe. (Note: The “black plague,” or bubonic plague, is a separate disease caused by *Yersinia pestis*.)

TB rates generally have risen with increasing urbanization and overcrowding because it is easier for an airborne disease to spread when people are packed closely together.³ Hence TB became a significant pathogen in Europe during the Middle Ages and peaked during the Industrial Revolution, when it caused approximately 25% of all deaths in Europe and in the United States.^{1–3} This dire threat led to the rise of public health departments and to procedures such as the isolation of infected patients. Thus TB was directly responsible for many of the healthcare practices that we take for granted today. Unfortunately, in developing nations, some of these practices are not widely available, and TB continues to rage unabated.

EPIDEMIOLOGY

Globally, roughly 2 billion people are infected by *M. tuberculosis*, and roughly 2 to 3 million people die from active TB each year despite the fact that it is curable.^{1,2,4} In the United States, about 13 million people are latently infected with *M. tuberculosis*, meaning that they are not currently sick but that they could fall ill with TB at any time. The United States had 14,093 new cases of active TB in 2005 and about 1,500 deaths.⁵ (For detailed data analysis, visit the Centers for Disease Control and Prevention [CDC] website at www.cdc.gov/nchstp/tb.) The annual incidence of TB in the United States declined by approximately 5% per year from 1953 to 1983⁶ (Fig. 116–1). In 1984, this decline slowed, and then the incidence of TB rose from 1988 to 1992, reaching 10.5 cases per 100,000 population. Since 1992, more effective infection control practices and treatment protocols have reduced TB rates to 4.8 per 100,000 population as of 2005.⁵ Despite this good news, the eradication of TB from the United States remains very

difficult. One reason is that we continue to import new cases from countries where TB remains out of control.^{4,5}

RISK FACTORS FOR INFECTION

Location and Place of Birth

TB can infect anyone, but the risk is not evenly distributed across the U.S. population. The major points of entry into the United States have the most TB cases. Seven states (California, Florida, Georgia, Illinois, New Jersey, New York, and Texas) reported more than 400 cases each for 2005; combined, these seven states accounted for 59.7% (8,414 cases) of the national total.⁵ Within these states, TB is most prevalent in large urban areas.⁴

The TB rate among foreign-born persons was 8.7 times that of U.S.-born persons in 2005.⁵ The percentage of foreign-born TB patients in the United States has increased annually since 1986, reaching 54% in 2005.⁵ More than half (56.0%) of the foreign-born cases in 2005 were reported in persons from Mexico (1,930), the Philippines (826), Vietnam (576), India (563), and China (389).⁵ Therefore, healthcare workers must “think TB” when caring for patients from these countries who experience symptoms such as cough, fever, and weight loss.

Close contacts of pulmonary TB patients are most likely to become infected.^{2,4} These include family members, coworkers, or coresidents in places such as prisons, shelters, or nursing homes. The more prolonged the contact, the greater is the risk, with infection rates as high as 30%.^{5,6} Although many circumstances exist, TB patients frequently have limited access to healthcare, live in crowded conditions, or are homeless.^{2,4} Many patients have histories of alcohol abuse or illicit drug use, and many are coinfectd with hepatitis B or human immunodeficiency virus (HIV). These concurrent social and health problems make treating some TB patients particularly difficult.

Race, Ethnicity, Age, and Gender

2 In the United States, TB disproportionately affects ethnic minorities. Hispanics, blacks, and Asians had TB rates 7.3, 8.3, and 19.6 times higher than whites in 2005.⁵ Hispanics accounted for 28.4% of all TB cases, followed by blacks at 27.9%.⁵ Asians and Pacific Islanders accounted for 22.5%, whereas non-Hispanic whites accounted for only 21.2% of the new TB cases.⁵

TB is most common among people 25 to 44 years of age (35% of all U.S. cases in 2002), followed by those 45 to 64 years of age (28%) and 65 years of age and older (21%).⁶ TB is more common in older whites and Asians compared with younger people from these groups. This reflects reactivation of latent infection acquired many years earlier when TB was very common. Older blacks and Hispanics also have more TB than younger individuals, but the differences by age are not as pronounced.⁶ This reflects a greater recent transmission among younger blacks and

Hispanics compared with younger whites and Asians. Until the age of 15 years, TB rates are similar for males and females, but after that, the male predominance increases with each decade of life.⁶

Coinfection with Human Immunodeficiency Virus (HIV)

3 HIV is the most important risk factor for active TB, especially among people 25 to 44 years of age.^{2,4,6,7} TB and HIV seem to act synergistically within patients and across populations, making each disease worse than it might otherwise be. Roughly 10% of U.S. TB patients are coinfectd with HIV, and roughly 20% of TB patients ages 25 to 44 years are coinfectd.^{5,6} HIV coinfection may not increase the risk of acquiring *M. tuberculosis* infection, but it does increase the likelihood of progression to active disease.^{1,7} Furthermore, TB and HIV patients share a number of behavioral risk factors that contribute to the high rates of coinfection.^{2,8,9}

RISK FACTORS FOR DISEASE

Once infected with *M. tuberculosis*, a person’s lifetime risk of active TB is approximately 10%.^{2,4,7} The greatest risk for active disease occurs during the first 2 years after infection. Children younger than 2 years of age and adults older than 65 years of age have two to five times greater risk for active disease compared with other age groups. Patients with underlying immune suppression (e.g., renal failure, cancer, and immunosuppressive drug treatment) have 4 to 16 times greater risk than other patients. Finally, HIV-infected patients with *M. tuberculosis* infection are 100 times more likely to develop active TB than normal hosts.^{4,10} HIV-infected patients have an annual risk of active TB of approximately 10%, rather than a lifetime risk at that rate. Therefore, all patients with HIV infection should be screened for tuberculous infection, and those known to be infected with *M. tuberculosis* should be tested for HIV infection.

ETIOLOGY

M. tuberculosis is a slender bacillus with a waxy outer layer.^{2,7} It is 1 to 4 microns in length, and under the microscope, it is either straight or slightly curved in shape.^{1,11,12} It does not stain well with Gram stain, so the Ziehl-Neelsen stain or the fluorochrome stain must be used instead.^{1,2,7} After Ziehl-Neelsen staining with carbol-fuchsin, mycobacteria retain the red color despite acid-alcohol washes. Hence they are called *acid-fast bacilli*.¹¹ After staining, microscopic examination (“smear”) detects about 8,000 to 10,000 organisms per milliliter of specimen, so a patient can be “smear negative” but still grow *M. tuberculosis* on culture. Microscopic examination also cannot determine which of the 100+ mycobacterial species is present or whether the organisms in the original samples were alive or dead.^{1,11,12} On smear, they are all dead. On culture, *M. tuberculosis* grows slowly, doubling about every 20 hours. This is very slow compared with gram-positive and gram-negative bacteria, which double about every 30 minutes.

Among the mycobacteria, only *M. tuberculosis* is a frequent human pathogen. Some nontuberculous mycobacteria such as *Mycobacterium kansasii*, *Mycobacterium fortuitum*, and *Mycobacterium avium* complex (MAC) cause infections in patients with other medical problems, especially the acquired immunodeficiency syndrome (AIDS). Chapter 129 discusses the treatment of these infections.

CULTURE AND SUSCEPTIBILITY TESTING

4 Direct susceptibility testing involves inoculating specialized media with organisms taken directly from a concentrated, smear-positive specimen.^{1,11,12} This approach produces susceptibility results in 2 to 3

weeks. Indirect susceptibility testing involves inoculating the test media with organisms obtained from a pure culture of the organisms, which can take several more weeks. The most common agar method, known as the *proportion method*, uses the ratio of colony counts on drug-containing agar to that on drug-free agar.^{1,12} In the United States, the critical proportion for resistance is 1%. That means that if a drug-containing plate shows only 2% of the growth seen on a drug-free plate, some of the organisms from the specimen were resistant to that drug. Therefore, it is likely that many of the organisms in the patient also are resistant to that drug, and it should not be used to treat that patient.

The proportion method's limitations include many weeks to obtain results, drug degradation during the incubation, and a qualitative result (susceptible or resistant). The BACTEC system (Becton-Dickinson, Sparks, MD) uses liquid medium (7H12 broth) and detects live mycobacteria based on the release of radiolabeled CO₂.¹¹ Advantages of the BACTEC system include reduced incubation time (as few as 9 to 14 days), reduced drug loss in the medium, and when multiple concentrations are tested, a truly quantitative end point (minimal inhibitory concentration [MIC]).^{1,11,12} Newer, nonradiometric rapid methods such as the MGIT system are now being used by some laboratories.¹³

Rapid-identification tests are now available.¹³ Nucleic acid probes such as the AccuProbe (Gen-Probe, San Diego, CA) use DNA probes to identify the presence of complementary rRNA (ribosomal ribonucleic acid) for several mycobacterial species.^{7,11,14} DNA fingerprinting using restriction-fragment-length polymorphism analysis has been used to identify clusters of cases.^{1,11,14} Amplification of the genetic material can be achieved through polymerase chain reaction (Roche Molecular Systems, Branchburg, NJ), the amplified *M. tuberculosis* direct (MTD) test (Gen-Probe, San Diego, CA), and strand-displacement amplification (SDA; Becton-Dickinson, Sparks, MD).^{11,15} Thin-layer chromatography, high-performance liquid chromatography for mycolic acid identification, and gas chromatography for short-chain fatty acids (methyl esters) have been used to speciate mycobacterial isolates.^{1,11,14} Other tests are designed to detect common genetic changes associated with drug resistance, such as changes in the *katG* gene associated with isoniazid resistance and the *rpoB* gene associated with rifampin resistance.^{7,16–18} These tests offer clinicians a chance to know rapidly what organism they are treating and what drugs might be good initial choices.

TRANSMISSION

M. tuberculosis is transmitted from person-to-person by coughing or sneezing.^{2,7,13} This produces “droplet nuclei” that are dispersed in the air. Each droplet nuclei contains one to three organisms. Riley and colleagues showed that air circulated from a hospital TB ward could cause disease in guinea pigs.¹⁹ When this air was filtered or treated with ultraviolet radiation, the animals were not infected. Approximately 30% of individuals who experience prolonged contact with an infectious TB patient will become infected.

A person with cavitary, pulmonary TB and a cough may infect roughly one person per month until that person is treated effectively, although this number can vary significantly. A person with the uncommon laryngeal form of TB can spread organisms even when talking, so the transmission rates can be very high. HIV-infected patients acquire the organisms through the lungs just like normal hosts, but their weakened immune system puts them at very high risk for active disease.^{2,4,7,13}

PATHOPHYSIOLOGY

IMMUNE RESPONSE

Good T-lymphocyte responses are essential to controlling *M. tuberculosis* infections.^{2,7,20,21} In the mouse model, two different T-cell

responses—the T-helper type 1 (TH₁) response and the T-helper type 2 (TH₂) response—have been described. The TH₁ response is the preferred response to TB, and the TH₂ response, including the potentially subversive influence of interleukin (IL) 4, is undesirable.^{2,20,21} Some workers have argued that this dichotomy is clearer in the mouse model, and in many humans, the T-cell response may be classified as TH₀ (elements of both TH₁ and TH₂).²⁰ In either case, T-lymphocytes activate macrophages that, in turn, engulf and kill mycobacteria. T lymphocytes also destroy immature macrophages that harbor *M. tuberculosis* but are unable to kill the invaders.^{20,21} CD4+ cells are the primary T cells involved, with contributions by γδ T cells and CD8+ T cells.²⁰ CD4+ T cells produce interferon γ (INF-γ) and other cytokines, including IL-2 and IL-10, that coordinate the immune response to TB.²⁰ Because CD4+ cells are depleted in HIV-infected patients, these patients are unable to mount an adequate defense to TB.^{20,21}

Although B-cell responses and antibody production can be demonstrated in TB-infected mammals, these humoral responses do not appear to contribute much to the control of TB within the host.^{2,7,20} T cells are responding to certain mycobacterial antigens, but the key antigen(s) invoking the immune response have not been identified.²⁰ Tumor necrosis factor-α (TNF-α) and INF-γ are important cytokines involved in coordinating the host's cell-mediated response. Rheumatoid arthritis patients treated with TNF-α inhibitors (infliximab) have high rates of reactivation TB.²² Therefore, patients known to be deficient in the activity of TNF-α or INF-γ should be screened for TB infection and offered appropriate treatment.

M. tuberculosis has several ways of evading or resisting the host immune response.^{20,21} In particular, *M. tuberculosis* can inhibit the fusion of lysosomes to phagosomes inside macrophages. This prevents the destructive enzymes found in the lysosomes from getting to the bacilli captured in the phagosomes. This stay of execution allows time for *M. tuberculosis* to escape into the cytoplasm. Virulent *M. tuberculosis* are able to multiply in the macrophage cytoplasm, thus perpetuating their spread. Finally, lipoarabinomannan, the principal structural polysaccharide of the mycobacterial cell wall, inhibits the host immune response.^{20,21} Lipoarabinomannan induces immunosuppressive cytokines, thus blocking macrophage activation; additionally, lipoarabinomannan scavenges O₂, thus preventing attack by superoxide anions, hydrogen peroxide, singlet oxygen, and hydroxyl radicals.^{20,21} These survival mechanisms make *M. tuberculosis* a particularly difficult organism to control. Any defects in the host immune system make it likely that *M. tuberculosis* will not be controlled and that active disease will ensue.

PRIMARY INFECTION

Primary infection usually results from inhaling airborne particles that contain *M. tuberculosis*.^{2,7,21} These particles, called *droplet nuclei*, contain one to three bacilli and are small enough (1 to 5 μm) to reach the alveolar surface. Ingestion (swallowing) and inoculation (puncture wound) are other rare pathways to acquire *M. tuberculosis* infection.²¹

The progression to clinical disease depends on three factors: (a) the number of *M. tuberculosis* organisms inhaled (infecting dose), (b) the virulence of these organisms, and (c) the host's cell-mediated immune response.^{2,5,7,13,21,23} At the alveolar surface, the bacilli that were delivered by the droplet nuclei are ingested by pulmonary macrophages.²¹ If these macrophages inhibit or kill the bacilli, infection is aborted.²¹ If the macrophages cannot do this, the organisms continue to multiply. The macrophages eventually rupture, releasing many bacilli, and these mycobacteria are then phagocytized by other macrophages. This cycle continues over several weeks until the host is able to mount a more coordinated response.²¹ During this early phase of infection, *M. tuberculosis* multiplies logarithmically.²¹

Some of the intracellular organisms are transported by the macrophages to regional lymph nodes in the hilar, mediastinal, and retroperitoneal areas. The cycle of phagocytosis and cell rupture continues. During lymph node involvement, the mycobacteria may be held in check. More frequently, *M. tuberculosis* spreads throughout the body through the bloodstream.^{2,7,21} When this intravascular dissemination occurs, *M. tuberculosis* can infect any tissue or organ in the body. Most commonly, *M. tuberculosis* infects the posterior apical region of the lungs. This may be so because of the high oxygen content, and it may be because of a less-vigorous immune response in this area.

After about 3 weeks of infection, T lymphocytes are presented with *M. tuberculosis* antigens. These T cells become activated and begin to secrete INF- γ and the other cytokines noted earlier. The processes described in the immune response section earlier then begin to occur. First, T-lymphocytes stimulate macrophages to become bactericidal.²¹ Large numbers of activated microbicidal macrophages surround the solid caseous (cheese-like) tuberculous foci (the necrotic area of infection).²¹ This process of creating activated microbicidal macrophages is known as *cell-mediated immunity*.²¹

At the same time that cell-mediated immunity occurs, delayed-type hypersensitivity also develops through the activation and multiplication of T lymphocytes. Delayed-type hypersensitivity refers to the cytotoxic immune process that kills nonactivated immature macrophages that are permitting intracellular bacillary replication.²¹ These immature macrophages are killed when the T-lymphocytes initiate Fas-mediated apoptosis (programmed cell death).²¹ The bacilli released from the immature macrophages then are killed by the activated macrophages.²¹

By this time (>3 weeks), macrophages have begun to form granulomas to contain the organisms. In a typical tuberculous granuloma, activated macrophages accumulate around a caseous lesion and prevent its further extension.²¹ At this point, the infection is largely under control, and bacillary replication falls off dramatically. Depending on the inflammatory response, tissue necrosis and calcification of the infection site plus the regional lymph nodes may occur.

Over 1 to 3 months, activated lymphocytes reach an adequate number, and tissue hypersensitivity results. This is shown by a positive tuberculin skin test. Any remaining mycobacteria are believed to reside primarily within granulomas or within macrophages that have avoided detection and lysis, although some residual bacilli have been found in various types of cells.^{2,7,20}

Approximately 90% of infected patients have no further clinical manifestations. Most patients only show a positive skin test (70%), whereas some also have radiographic evidence of stable granulomas (approximately 20%). This radiodense area on chest radiograph is called a *Ghon complex*. Approximately 5% of patients (usually children, the elderly, and the immunocompromised) experience “progressive primary” disease that occurs before skin test conversion.^{24,25} This presents as a progressive pneumonia, usually in the lower lobes. Disease frequently spreads, leading to meningitis and other severe forms of TB.^{24,25} Because of this risk of severe disease, very young, elderly, and immunocompromised patients, including those with HIV, should be evaluated and treated for latent or active TB.

REACTIVATION DISEASE

6 Roughly 10% of infected patients develop reactivation disease at some point in their lives. Nearly half of these cases occur within 2 years of infection.^{2,7,13} In the United States, most cases of TB are believed to result from reactivation. Reinfection is uncommon in the United States because of the low rate of exposure and because previously sensitized individuals possess some degree of immunity to reinfection.^{2,21} Exceptions include patients coinfecting with HIV who live in areas of higher exposure to *M. tuberculosis*.

The apices of the lungs are the most common sites for reactivation (85% of cases).² This reflects the fact that *M. tuberculosis* prefers areas

with high oxygen content and possibly because the immune response may not be as effective in this region.^{2,21} For reasons that are not entirely known (waning cellular immunity, loss of specific T-cell clones, blocking antibody), organisms within granulomas emerge and begin multiplying extracellularly.²⁴ The inflammatory response produces caseating granulomas, which eventually will liquefy and spread locally, leading to the formation of a hole (cavity) in the lungs.

The immune response contributes to the severity of the lung damage. There is targeted killing of immature macrophages that are allowing mycobacterial multiplication (delayed-type hypersensitivity).^{20,21} In addition, there is “innocent bystander” killing of host cells and locally thrombosed blood vessels.²¹ The killing of mycobacteria, macrophages, and neutrophils that have entered the battle releases cytokines and lysozymes into the infectious foci. This toxic mixture can be too much for the surrounding alveoli and airway cells, causing regional necrosis and structural collapse.^{2,21} These unstable foci liquefy, spreading the infection to neighboring areas of the lung, creating a cavity. Some of this necrotic material is coughed out, producing droplet nuclei. Bacterial counts in the cavities can be as high as 10^8 per milliliter of cavitary fluid. Partial healing may result from fibrosis, but these lesions remain unstable and may continue to expand.^{2,21} If left untreated, pulmonary TB continues to destroy the lungs, resulting in hypoxia, respiratory acidosis, and eventually death.

EXTRAPULMONARY AND MILIARY TUBERCULOSIS

Caseating granulomas at extrapulmonary sites can undergo liquefaction, releasing tubercle bacilli and causing symptomatic disease.^{2,7} Extrapulmonary TB without concurrent pulmonary disease is uncommon in normal hosts but more common in HIV-infected patients. Because of these unusual presentations, the diagnosis of TB is difficult and often delayed in immunocompromised hosts.^{2,4,7} Lymphatic and pleural diseases are the most common forms of extrapulmonary TB, followed by bone, joint, genitourinary, meningeal, and other forms.^{2,7} Left untreated, these forms will spread to other organs and may result in death.

Occasionally, a massive inoculum of organisms enters the bloodstream, causing a widely disseminated form of the disease known as *miliary TB*. It is named for the millet seed appearance of the small granulomas seen on chest radiographs, and it can be rapidly fatal.²⁰ Miliary TB is a medical emergency requiring immediate treatment.

INFLUENCE OF HIV INFECTION ON PATHOGENESIS

3 HIV infection is the largest risk factor for active TB.^{2,7,20} As CD4+ lymphocytes multiply in response to the mycobacterial infection, HIV multiplies within these cells and selectively destroys them. In turn, the TB-fighting lymphocytes are depleted.²⁰ This vicious cycle puts HIV-infected patients at 100 times the risk of active TB compared with HIV-negative people.²⁵ In addition, the combination of HIV infection and certain social behaviors increases the risk of newly acquired TB. In selected areas of the United States, up to 50% of new TB cases are the result of recent infection, particularly among HIV-infected individuals.^{26–28}

As mycobacteria spread throughout the body, HIV replication accelerates in lymphocytes and macrophages. This leads to progression of HIV disease.^{20,29} HIV-infected patients who are infected with TB deteriorate more rapidly unless they receive antimycobacterial chemotherapy.^{30,31} Most clinicians elect to begin TB treatment first, and once this is under control, begin HIV treatment as well. Starting both treatments at the same time can lead to paradoxical worsening of the TB.^{13,32} This appears to result from a reinvigorated inflammatory response to TB. Because TB can be very dangerous in HIV-

positive patients, they should be screened for tuberculous infection or disease soon after they are shown to be HIV-positive.^{2,4,7,20}

CLINICAL PRESENTATION

The classical presentation of TB is shown below. The onset of TB may be gradual, and the diagnosis may not be considered until a chest radiograph is performed. Unfortunately, many patients do not seek medical attention until more dramatic symptoms, such as frank hemoptysis, occur. At this point, patients typically have large cavitory lesions in the lungs. These cavities are loaded with *M. tuberculosis*. Expectoration or swallowing of infected sputum may spread the disease to other areas of the body.^{1,2,7,23} Physical examination is nonspecific but suggestive of progressive pulmonary disease.

CLINICAL PRESENTATION OF TUBERCULOSIS

Signs and Symptoms

- Patients typically present with weight loss, fatigue, a productive cough, fever, and night sweats^{1,2,7,23}
- Frank hemoptysis

Physical Examination

- Dullness to chest percussion, rales, and increased vocal fremitus are observed frequently on auscultation

Laboratory Tests

- Moderate elevations in the white blood cell (WBC) count with a lymphocyte predominance

Chest Radiograph

- Patchy or nodular infiltrates in the apical areas of the upper lobes or the superior segment of the lower lobes^{2,7,23}
- Cavitation that may show air-fluid levels as the infection progresses

5 Patients coinfecting with HIV may have atypical presentations.^{1,2,7,23,33} As their CD4+ counts decline, HIV-positive patients are less likely to have positive skin tests, cavitory lesions, or fever. Pulmonary radiographic findings may be minimal or absent. HIV-positive patients have a higher incidence of extrapulmonary TB and are more likely to present with progressive primary disease. Because their symptoms are not specific to TB, a thorough workup for TB is essential.^{2,7,20,23}

Extrapulmonary TB typically presents as a slowly progressive decline in organ function.^{2,7,23} Patients may have low-grade fever and other constitutional symptoms. Patients with genitourinary TB may present with sterile pyuria and hematuria. Lymphadenitis often involves the cervical and supraclavicular nodes and may appear as a neck mass with spontaneous drainage. Tuberculous arthritis and osteomyelitis occur most commonly in the elderly and usually affect the lower spine and weight-bearing joints. TB of the spine is known as *Pott's disease*.² Abnormal behavior, headaches, or convulsions suggest tuberculous meningitis. Involvement of the peritoneum, pericardium, larynx, and adrenal glands also occurs.^{2,7,23}

THE ELDERLY

5 TB in the elderly is easily confused with other respiratory diseases. Many clinical findings are muted or absent altogether. Compared with younger patients, TB in the elderly is far less likely to present with positive skin tests, fevers, night sweats, sputum production, or hemoptysis.^{2,23,34,35} Weight loss may occur but is nonspecific. In contrast, mental status changes are twice as common in the elderly, and mortality is six times higher.^{2,23,34} TB is a preventable cause of death in the elderly that should not be overlooked.

CHILDREN

5 TB in children, especially those younger than 12 years of age, may present as a typical bacterial pneumonia and is called *progressive primary TB*.^{23–25} Clinical disease often begins 1 to 2 months after exposure and precedes skin-test positivity. Unlike adults, pulmonary TB in children often involves the lower and middle lobes.^{23–25} Dissemination to the lymph nodes, gastrointestinal and genitourinary tracts, bone marrow, and meninges is fairly common. Because of delays in recruitment of cellular immunity, cavitory disease is infrequent, and the number of organisms present typically is smaller than in an adult. Because cavitory lesions are uncommon, children do not spread TB readily. However, TB can be rapidly fatal in a child, and it requires prompt chemotherapy.

DIAGNOSIS

SKIN TESTING

The key to stopping the spread of TB is early identification of infected individuals.^{1,2,7,23} Table 116–1 lists the populations most likely to benefit from skin testing (column 1 patients are at highest risk for TB, followed by those in column 2). Members of these high-risk groups should be tested for TB infection and educated about the disease.

The Mantoux test is the preferred TB skin test. It uses tuberculin purified protein derivative (PPD), and unlike the Heaf or tine test, the Mantoux test is quantitative. The standard 5-tuberculin-unit PPD dose is placed intracutaneously on the volar aspect of the forearm with a 26- or 27-gauge needle.^{2,23,30} This injection should produce a small, raised, blanched wheal. An experienced professional should read the test in 48 to 72 hours. The area of induration (the “bump”) is the important end point, not the area of redness. Table 116–1 lists the criteria for interpretation.^{1,2,7,23,30} The CDC does not recommend the routine use of anergy panels.^{30,36} Aplisol and Tubersol 5-tuberculin-unit products are available commercially, but because of more predictable results, Tubersol appears to be the preferred product.

The “booster effect” occurs in patients who do not respond to an initial skin test but show a positive reaction if retested about a week later.^{23,36} Patients with past *M. tuberculosis* infection and some patients with past immunization with bacillus Calmett -Guerin (BCG) vaccine or past infection with other mycobacteria may “boost” with a second skin test. Individuals who require periodic skin testing, such as healthcare workers, should receive a two-stage test initially.^{23,36,37} Once they are shown to be skin-test-negative, any positive skin test later shows recent infection, and this requires treatment.

The PPD skin test is an imperfect diagnostic tool. Up to 20% of patients with active TB are falsely skin-test-negative, presumably because their immune systems are overwhelmed.^{20,36} False-positive results are more common in low-risk patients and those recently vaccinated with BCG. Despite BCG vaccination, one should not ignore a positive PPD result. These patients require careful evaluation for active disease, and they may be offered preventive treatment because many come from areas where TB infection is common.

The QuantiFERON-TB Gold test measures the release of INF- in whole blood.³⁸ For latently infected persons, INF-  is released in response to in vitro stimulation by PPD, whereas no release occurs in blood samples taken from uninfected persons. This test can provide a diagnosis of latent TB infection within hours, instead of the 2 to 3 days required for the traditional PPD skin test. Also, QuantiFERON-TB testing does not require a return visit by the patient to the clinic for reading of the PPD skin test, making it more convenient for the patient. Ongoing research seeks to find a diagnostic test that will confirm TB infection within minutes, allowing for immediate treatment decisions while the patient is still in the

TABLE 116-1 Criteria for Tuberculin Positivity by Risk Group

Reaction 5 mm of Induration	Reaction ≥10 mm of Induration	Reaction ≥15 mm of Induration
Human immunodeficiency virus (HIV)-positive persons Recent contacts of tuberculosis (TB) case patients Fibrotic changes on chest radiograph consistent with prior TB	Recent immigrants (i.e., within the last 5 y) from high-prevalence countries Injection-drug users Residents and employees ^a of the following high-risk congregate settings: prisons and jails; nursing homes and other long-term care facilities for the elderly; hospitals and other healthcare facilities; residential facilities for patients with acquired immunodeficiency syndrome (AIDS); homeless shelters Mycobacteriology laboratory personnel Persons with the following clinical conditions that place them at high risk: silicosis; diabetes mellitus; chronic renal failure; some hematologic disorders (e.g., leukemias and lymphomas); other specific malignancies (e.g., carcinoma of the head or neck and lung); weight loss of ≥10% of ideal body weight; gastrectomy; jejunioileal bypass Children younger than 4 y of age or infants, children, and adolescents exposed to adults at high risk	Persons with no risk factors for TB
Patients with organ transplants and other immunosuppressed patients (receiving the equivalent of ≥15 mg/day of prednisone for 1 mo or more) ^b		

^aFor persons who are otherwise at low risk and who are tested at the start of employment, a reaction of ≥15 mm induration is considered positive.
^bRisk of TB in patients treated with corticosteroids increases with higher dose and longer duration.

clinic. Another related test, T-SPOT.TB, is available in Europe, and is undergoing review by the FDA here in the United States.³⁹

ADDITIONAL TESTS

When active TB is suspected, attempts should be made to isolate *M. tuberculosis* from the site of infection.^{2,7,23,36} Sputum collected in the morning usually has the highest yield.^{2,11,23} Daily sputum collection over 3 consecutive days is recommended.

For patients unable to expectorate, sputum induction with aerosolized hypertonic saline may produce a diagnostic sample. Bronchoscopy, or aspiration of gastric fluid via a nasogastric tube, may be attempted in selected patients.²³ For patients with suspected extrapulmonary TB, samples of draining fluid, biopsies of the infected site, or both may be attempted. Blood cultures are positive occasionally, especially in AIDS patients.^{23,33,40}

TREATMENT

Tuberculosis

DESIRED OUTCOMES

The desired outcomes for the treatment of tuberculosis are

- 1. Rapid identification of a new TB case
- 2. Initiation of specific antituberculosis treatment
- 3. Prompt resolution of the signs and symptoms of disease
- 4. Achievement of a noninfectious state in the patient, thus ending isolation
- 5. Adherence to the treatment regimen by the patient
- 6. Cure of the patient as quickly as possible (generally at least 6 months of treatment)

It is also important that patients with active disease are isolated to prevent spread of the disease and that appropriate samples for smears and cultures are collected. Secondary goals are identification of the index case that infected the patient, identification of all persons infected by both the index case and the new case of TB (“contact investigation”), and completion of appropriate treatments for those individuals.

GENERAL APPROACHES TO TREATMENT

Drug treatment is the cornerstone of TB management.^{2,7,13,41} Monotherapy can be used only for infected patients who do not have active TB (latent infection, as shown by a positive skin test). Once active disease is present, a minimum of two drugs, and generally three or four drugs, must be used simultaneously.^{2,7,13,41} The duration of treatment depends on the condition of the host, extent of disease, presence of drug resistance, and tolerance of medications. The shortest duration of treatment generally is 6 months, and 2 to 3 years of treatment may be necessary for cases of multidrug-resistant TB (MDR-TB).^{2,7,13,41} Because the duration of treatment is so long, and because many patients feel better after a few weeks of treatment, careful followup is required. Directly observed therapy by a healthcare worker is a cost-effective way to ensure completion of treatment.^{2,7,13,41–43}

PRINCIPLES FOR TREATING LATENT INFECTION AND FOR TREATING DISEASE

Asymptomatic patients with tuberculous infection have a bacillary load of about 10³ organisms, compared with 10¹¹ organisms in a patient with cavitary pulmonary TB.^{2,7,44} As the number of organisms increases, the likelihood of naturally occurring drug-resistant mutants also increases. Naturally occurring mutants are found at rates of 1 in 10⁶ to 1 in 10⁸ organisms for the antituberculosis drugs.^{2,41,44} When treating asymptomatic latent infection with isoniazid monotherapy, the risk of selecting out isoniazid-resistant organisms is low. The isoniazid mutation rate is about 1 in 10⁶, but only about 10³ organisms are present in the body. In contrast, the risk of selecting out isoniazid-resistant organisms is unacceptably high in patients with cavitary TB. One can prevent selection of these resistant mutants by adding more drugs because the rates for resistance mutations to multiple drugs are additive functions of the individual rates. For example, only 1 in 10¹³ organisms would be naturally resistant to both isoniazid (1 in 10⁶) and rifampin (1 in 10⁷).^{2,41,44} It is unlikely that such rare organisms are present in a previously untreated patient.

Combination chemotherapy is required for treating active TB disease. The patient should receive at least two drugs to which the isolate is susceptible, and generally four drugs are given at the outset of treatment. Rifampin and isoniazid are the best drugs for preventing drug resistance, followed by ethambutol, streptomycin, and pyrazinamide.^{2,7,41,44,45}

Three subpopulations of mycobacteria are proposed to exist within the body, and each appears to respond to certain drugs.^{2,41,44} Most numerous are the extracellular, rapidly dividing bacteria, often found within cavities (about 10^7 to 10^9 organisms). These are killed most readily by isoniazid, followed by rifampin, streptomycin, and the other drugs. A second group resides within caseating granulomas (possibly 10^5 to 10^7 organisms). These organisms appear to be in a semidormant state, with occasional bursts of metabolic activity. Pyrazinamide, through its conversion within *M. tuberculosis* to pyrazinoic acid, appears most active against these organisms. Rifampin and isoniazid also may be active against this subpopulation. The third subset is the intracellular mycobacteria present within macrophages (10^4 to 10^6). Rifampin, isoniazid, and the quinolones appear to be most active against intracellular *M. tuberculosis*. While this appears to explain what happens during the treatment of TB, there is no practical way to quantitate these populations within a given patient.

■ NONPHARMACOLOGIC THERAPY

7 Nonpharmacologic interventions aim to (a) prevent the spread of TB, (b) find where TB has already spread using contact investigation, and (c) replenish the weakened (consumptive) patient to a state of normal weight and well-being. The first two items are performed by public health departments. Clinicians involved in the treatment of TB should verify that the local health department has been notified of all new cases of TB.

Workers in hospitals and other institutions must prevent the spread of TB within their facilities.^{2,4,13,30} All such workers should learn and follow each institution's infection control guidelines. This includes using personal protective equipment, including properly fitted respirators, and closing doors to "negative pressure" rooms. These hospital isolation rooms draw air in from surrounding areas rather than blowing air (and *M. tuberculosis*) into these surrounding areas. The air from the isolation room may be treated with ultraviolet lights and then vented safely outside. However, these isolation rooms work properly only if the door is closed.

Debilitated TB patients may require therapy for other medical problems, including substance abuse and HIV infection, and some may need nutritional support. Therefore, clinicians involved in substance abuse rehabilitation and nutritional support services should be familiar with the needs of TB patients.

Surgery may be needed to remove destroyed lung tissue, space-occupying infected lesions (*tuberculomas*), and certain extrapulmonary lesions.^{2,13,41} Vaccines against TB include BCG and *M. vaccae*.⁴¹ However, these vaccines are of limited value, and neither can prevent infection by *M. tuberculosis*. BCG (discussed below) may prevent

extreme forms of TB in infants, whereas *Mycobacterium vaccae* cannot be recommended.^{41,46}

■ PHARMACOLOGIC THERAPY

Treating Latent Infection

Isoniazid is the preferred drug for treating latent TB infection.^{2,7,13,41} Generally, isoniazid alone is given for 9 months. The treatment of latent TB infection (LTBI) reduces a person's lifetime risk of active TB from approximately 10% to approximately 1%. Because TB is spread easily through the air, each case prevented also prevents a second wave of cases that each prevented case would have produced. Historically, the treatment of LTBI has been called *prophylaxis*, *chemoprophylaxis*, or *preventive treatment*. By any name, it is one of the primary mechanisms for reducing TB in the United States. Table 116-2 lists the LTBI treatment options.

Because young children, the elderly, and HIV-positive patients are at greater risk of active disease once infected with *M. tuberculosis*, they require careful evaluation. Once active TB is ruled out, they should receive treatment for latent infection.^{2,22,23,41}

The keys to successful treatment of LTBI are (a) infection by an isoniazid-susceptible isolate, (b) adherence to the 9-month regimen, and (c) no exogenous reinfection.² Isoniazid adult doses are usually 300 mg daily (5 to 10 mg/kg of body weight)⁵⁵ (see Table 116-2). Lower doses are less effective.^{2,52} Isoniazid should be given on an empty stomach, and antacids should be avoided within 2 hours of dosing. When adherence is an issue, twice-weekly isoniazid (900 mg in an adult) can be given using directly observed treatment. Nine months of treatment is recommended, but 6 months still provides considerable benefit.

Rifampin 600 mg daily for 4 months can be used when isoniazid resistance is suspected or when the patient cannot tolerate isoniazid.^{2,25,51,52} Rifabutin 300 mg daily might be substituted for rifampin for patients at high risk of drug interactions. The combination of pyrazinamide plus rifampin is no longer recommended because of higher than expected rates of hepatotoxicity. When resistance to isoniazid and rifampin is suspected in the isolate causing infection, there is no regimen proved to be effective.^{2,41} Regimens that *might* be effective include ethambutol plus levofloxacin, but data regarding efficacy are lacking.

For recent skin-test converters of all ages, the risk of active TB outweighs the risk for drug toxicity.^{30,41} Pregnant women, alcoholics, and patients with poor diets who are treated with isoniazid should receive pyridoxine (vitamin B₆) 10 to 50 mg daily to reduce the incidence of central nervous system (CNS) effects or peripheral neu-

TABLE 116-2 Recommended Drug Regimens for Treatment of Latent Tuberculosis (TB) Infection in Adults

Drug	Interval and Duration	Comments	Rating ^a (Evidence) ^b	
			HIV-	HIV+
Isoniazid	Daily for 9 mo ^{c,d}	In human immunodeficiency virus (HIV)-infected patients, isoniazid may be administered concurrently with nucleoside reverse transcriptase inhibitors (NRTIs), protease inhibitors, or nonnucleoside reverse transcriptase inhibitors (NNRTIs)	A (II)	A (II)
Isoniazid	Twice weekly for 9 mo ^{c,d}	Directly observed therapy (DOT) must be used with twice-weekly dosing	B (II)	B (II)
	Daily for 6 mo ^d	Not indicated for HIV-infected persons, those with fibrotic lesions on chest radiographs, or children	B (I)	C (I)
	Twice weekly for 6 mo ^d	DOT must be used with twice-weekly dosing	B (II)	C (I)
Rifampin	Daily for 4 mo	For persons who are contacts of patients with isoniazid-resistant, rifampin-susceptible TB who cannot tolerate pyrazinamide	B (II)	B (III)

^aStrength of recommendation: A, preferred; B, acceptable alternative; C, offer when A and B cannot be given.

^bQuality of evidence: I, randomized clinical trial data; II, data from clinical trials that are not randomized or were conducted in other populations; III, expert opinion.

^cRecommended regimen for children younger than 18 years of age.

^dRecommended regimen for pregnant women. Some experts would use rifampin and pyrazinamide for 2 months as an alternative regimen in HIV-infected pregnant women, although pyrazinamide should be avoided during the first trimester.

Adapted from Centers for Disease Control and Prevention. Targeted tuberculin testing and treatment of latent tuberculosis infection. *MMWR* 2000;49(RR-6):31.

ropathies. All patients who receive treatment of LTBI should be monitored monthly for adverse drug reactions and for possible progression to active TB.

Treating Active Disease

8 The treatment of active TB requires the use of multiple drugs. There are two primary antituberculosis drugs, isoniazid and rifampin, with the rest of the drugs having specific roles.^{41,44,45} Isoniazid and rifampin should be used together whenever possible. Typically, *M. tuberculosis* is either very susceptible or very resistant to a given drug. This contrasts with *M. avium*, where moderately resistant organisms are a frequent occurrence. Theoretically, MIC results could be used to guide dosing in the treatment of moderately resistant *M. tuberculosis*, but this remains to be studied prospectively.^{2,13,41}

Drug-susceptibility testing should be done on the initial isolate for all patients with active TB. These data should guide the selection of drugs over the course of treatment.^{2,7,13,41} However, some patients are unable to provide a suitable specimen for laboratory testing. If susceptibility data are not available for a given patient, the drug-susceptibility data for the suspected source case or regional susceptibility data should be used.^{2,41}

Drug resistance should be expected in patients presenting for the retreatment of TB. These patients require retesting of drug susceptibility using freshly collected specimens. It is imperative to learn what drugs the patient received and for how long the patient received them.^{2,13,41} A treatment history, often called a “drug-o-gram,” shows the start and stop dates of all antimycobacterial drugs

on a horizontal bar graph.^{2,41} A “drug-o-gram” should be constructed for all retreatment patients.

10 The standard TB treatment regimen is isoniazid, rifampin, pyrazinamide, and ethambutol for 2 months, followed by isoniazid and rifampin for 4 months, for a total of 6 months of treatment.^{2,13,41} If susceptibility to isoniazid, rifampin, and pyrazinamide is shown, ethambutol can be stopped at any time. Without pyrazinamide, a total of 9 months of isoniazid and rifampin treatment is required. Table 116–3 shows the recommended treatment regimens. When intermittent therapy is used, directly observed treatment is essential. Doses missed during an intermittent TB regimen decrease its efficacy and increase the relapse rate. Note that Table 116–3 shows recommendations that differ for HIV-negative and HIV-positive patients. HIV-positive patients should not receive highly intermittent regimens. In general, regimens given daily five times each week or three times weekly can be used for HIV-positive patients. Less-frequent dosing is associated with higher failure and relapse rates and the selection of rifampin-resistant organisms.⁴¹

CLINICAL CONTROVERSY

The recommended duration of treatment often is the same for HIV-negative and HIV-positive patients. However, some clinicians believe that therapy should be extended for patients with weakened immune systems. These clinicians treat HIV-positive patients with drug-susceptible TB for 9 months rather than the usual 6 months.

TABLE 116-3 Drug Regimens for Culture-Positive Pulmonary Tuberculosis Caused by Drug-Susceptible Organisms

Initial Phase			Continuation Phase			Rating ^a (Evidence) ^b	
Regimen	Drugs	Interval and Doses ^c (Minimal Duration)	Regimen	Drugs	Interval and Doses ^{c,d} (Minimal Duration)	Range of Total Doses (Minimal Duration)	HIV– HIV+
1	Isoniazid, rifampin, pyrazinamide, ethambutol	Seven days per week for 56 doses (8 wk) or 5 days/wk for 40 doses (8 wk) ^c	1a	Isoniazid/ rifampin	Seven days per week for 126 doses (18 wk) or 5 days/wk for 90 doses (18 wk) ^c	182–130 (26 wk)	A (I) A (II)
			1b	Isoniazid/ rifampin	Twice weekly for 36 doses (18 wk)	92–76 (26 wk)	A (I) A (II) ^f
			1c ^g	Isoniazid/ rifapentine	Once weekly for 18 doses (18 wk)	74–58 (26 wk)	B (I) E (I)
2	Isoniazid, rifampin, pyrazinamide, ethambutol	Seven days per week for 14 doses (2 wk), then twice weekly for 12 doses (6 wk) or 5 days/wk for 10 doses (2 wk) ^e then twice weekly for 12 doses (6 wk)	2a	Isoniazid/ rifampin	Twice weekly for 36 doses (18 wk)	62–58 (26 wk)	A (II) B (II) ^f
			2b ^g	Isoniazid/ rifapentine	Once weekly for 18 doses (18 wk)	44–40 (26 wk)	B (I) E (I)
3	Isoniazid, rifampin, pyrazinamide, ethambutol	Three times weekly for 24 doses (8 wk)	3a	Isoniazid/ rifampin	Three times weekly for 54 doses (18 wk)	78 (26 wk)	B (I) B (II)
4	Isoniazid, rifampin, ethambutol	Seven days per week for 56 doses (8 wk) or 5 days/wk for 40 doses (8 wk) ^c	4a	Isoniazid/ rifampin	Seven days per week for 217 doses (31 wk) or 5 days/wk for 155 doses (31 wk) ^e	273–195 (39 wk)	C (I) C (II)
			4b	Isoniazid/ rifampin	Twice weekly for 62 doses (31 wk)	118–102 (39 wk)	C (I) C (II)

^aRatings: A, preferred; B, acceptable alternative; C, offer when A and B cannot be given; E, should never be given.

^bEvidence ratings: I, randomized clinical trial; II, data from clinical trials that were not randomized or were conducted in other populations; III, expert opinion.

^cWhen directly observed therapy is used, drugs may be given 5 days per week and the necessary number of doses adjusted accordingly. Although there are no studies that compare five with seven daily doses, extensive experience indicates this would be an effective practice.

^dPatients with cavitation on initial chest radiograph and positive cultures at completion of 2 months of therapy should receive a 7-month (31-week; either 217 doses [daily] or 62 doses [twice weekly]) continuation phase.

^eFive-day-a-week administration is always given by directly observed therapy. Rating for 5 day per week regimens is A (III).

^fNot recommended for HIV-infected patients with CD4+ cell counts <100 cells/μL.

^gOptions 1c and 2b should be used only in HIV-negative patients who have negative sputum smears at the time of completion of 2 months of therapy and who do not have cavitation on initial chest radiograph (see text). For patients started on this regimen and found to have a positive culture from the 2-month specimen, treatment should be extended an extra 3 months.

From Centers for Disease Control and Prevention. *Treatment of tuberculosis*. MMWR 2003;52 (RR-11).

When a patient's sputum smears convert to a negative, the risk of the patient infecting others is greatly reduced, but it is not zero.^{2,21,41} Such patients can be removed from respiratory isolation, but they must be careful not to cough on others and should meet with others only in well-ventilated places. Smear-negative patients still may be culture-positive, so they still can transmit TB to others.

Patients who are slow to respond clinically, those who remain culture-positive at 2 months of treatment, those with cavitary lesions on chest radiograph, and perhaps HIV-positive patients should be treated for a total of 9 months and for at least 6 months from the time that they convert to smear and culture negativity.^{2,7,13,41} Some authors recommend therapeutic drug monitoring for such patients.^{2,41,45,47} When isoniazid and rifampin cannot be used, treatment durations become 2 years or more regardless of immune status.^{2,13,41,45}

Adjustments to the regimen should be made once the susceptibility data are available.^{2,13,41} If the organism is drug-resistant, careful consideration of the remaining therapeutic options must be made. Two or more drugs with in vitro activity against the patient's isolate and that the patient has not received previously should be added to the regimen, as needed.^{2,13,41} TB specialists should be consulted regarding cases of drug-resistant TB.^{2,13,41}

9 There is no standard regimen for MDR-TB.^{2,13,41} Each patient's exposure history, previous treatment history (including toxicity and adherence issues), and current susceptibility data must be considered simultaneously. *It is critical to avoid monotherapy, and it is critical to avoid adding a single drug to a failing regimen.*^{2,13,41} Adding one drug at a time leads to the sequential selection of drug resistance until there are no drugs left. The treatment of MDR-TB should be managed by TB specialists. It may take several months for a patient with MDR-TB to become culture-negative because the drugs used lack the potency of isoniazid and rifampin.^{2,44,45} Consequently, prolonged respiratory isolation may be required.

Drug resistance should be suspected in the following situations:

- Patients who have received prior therapy for TB
- Patients from areas with a high prevalence of resistance (New York City, Mexico, Southeast Asia, the Baltic countries, and the former Soviet states)
- Patients who are homeless, institutionalized, intravenous drug abusers, or infected with HIV
- Patients who still have acid-fast bacilli-positive sputum smears after 1 to 2 months of therapy
- Patients who still have positive cultures after 2 to 4 months of therapy
- Patients who fail treatment or relapse after treatment
- Patients known to be exposed to MDR-TB cases

The patients just listed should be considered infected with drug-resistant TB until proved otherwise. Empirical therapy with four or

more drugs may be needed for acutely ill patients.^{2,13,41} These regimens may be altered when the susceptibility pattern becomes known. If the index case is known, then the same effective regimen should be employed for the new case. Again, MDR-TB cases should be referred to specialists. A new term in use, "XDR-TB," refers to "extensively drug-resistant TB." Such organisms are resistant to at least isoniazid, rifampin, a fluoroquinolone and one second-line injectable drug (amikacin, capreomycin, or kanamycin).⁴⁸

Special Populations

Tuberculous Meningitis and Extrapulmonary Disease

Patients with CNS tuberculosis usually are treated for longer periods (9 to 12 months instead of 6 months) (Table 116-4).^{2,13,41} In general, isoniazid, pyrazinamide, ethionamide, and cycloserine penetrate the cerebrospinal fluid readily, but rifampin, ethambutol, and streptomycin have variable CNS penetration.⁴⁹ Of the quinolones, levofloxacin may be preferred based on current data. Extrapulmonary TB of the soft tissues can be treated with conventional regimens.^{2,13,41} TB of the bone typically is treated for 9 months, occasionally with surgical debridement.^{2,13,41}

Children TB in children may be treated with regimens similar to those used in adults, although some physicians still prefer to extend treatment to 9 months.^{2,13,23,24,41,50,51} Pediatric doses of isoniazid and rifampin on a milligram-per-kilogram basis are higher than those used in adults (Table 116-5).⁴¹

Pregnancy Women with TB should be cautioned against becoming pregnant because the disease poses a risk to the fetus and to the mother. If already pregnant, the usual treatment is isoniazid, rifampin, and ethambutol for 9 months.⁴¹ Isoniazid or ethambutol are relatively safe for use in pregnant women.^{2,41,49-51} B vitamins are particularly important during pregnancy and should be provided to women being treated for TB. Rifampin is associated rarely with birth defects, including limb reduction and CNS lesions.⁴⁹ In general, rifampin is used in pregnant women with TB. Pyrazinamide has not been studied in large numbers of pregnant women, but anecdotal data suggest that it may be safe.⁴¹

Streptomycin use during pregnancy may lead to hearing loss in the newborn, including complete deafness. Streptomycin and the other aminoglycosides must be reserved for critical situations where alternatives do not exist.^{2,41} Although the polypeptide capreomycin has not been studied, it probably carries the same risks.

Ethionamide may cause premature delivery and congenital deformities when used during pregnancy.^{41,49} Mongolism also has been reported with ethionamide, so it cannot be recommended in this setting. *p*-Aminosalicylic acid has been used safely in pregnancy, but specific data are lacking.^{41,49} Cycloserine is known to cross the placenta, but the effects on the developing fetus are not known. Therefore, cycloserine generally cannot be recommended during pregnancy.⁴⁹

TABLE 116-4 Evidence-Based^a Guidelines for the Treatment of Extrapulmonary Tuberculosis and Adjunctive Use of Corticosteroids^b

Site	Length of Therapy (mo)	Rating (Duration)	Corticosteroids ^c	Rating (Corticosteroids)
Lymph node	6	A (I)	Not recommended	D (III)
Bone and joint	6-9	A (I)	Not recommended	D (III)
Pleural disease	6	A (II)	Not recommended	D (I)
Pericarditis	6	A (II)	Strongly recommended	A (I)
CNS tuberculosis including meningitis	9-12	B (II)	Strongly recommended	A (I)
Disseminated disease	6	A (II)	Not recommended	D (III)
Genitourinary	6	A (II)	Not recommended	D (III)
Peritoneal	6	A (II)	Not recommended	D (III)

^aFor rating system, see Table 116-3.

^bDuration of therapy for extrapulmonary tuberculosis caused by drug-resistant organisms is not known.

^cCorticosteroid preparations vary among studies.

TABLE 116-5 Doses^a of Antituberculosis Drugs for Adults and Children^b

Drug	Preparation	Adults/Children	Doses			
			Daily	1×/wk	2×/wk	3×/wk
First-line drugs						
Isoniazid	Tablets (50 mg, 100 mg, 300 mg); elixir (50 mg/5 mL); aqueous solution (100 mg/mL) for intravenous or intramuscular injection	Adults (max) Children (max)	5 mg/kg (300 mg) 10–15 mg/kg (300 mg)	15 mg/kg (900 mg) —	15 mg/kg (900 mg) 20–30 mg/kg (900 mg)	15 mg/kg (900 mg) —
Rifampin	Capsule (150 mg, 300 mg); powder may be suspended for oral administration; aqueous solution for intravenous injection	Adults ^c (max) Children (max)	10 mg/kg (600 mg) 10–20 mg/kg (600 mg)	— —	10 mg/kg (600 mg) 10–20 mg/kg (600 mg)	10 mg/kg (600 mg) —
Rifabutin	Capsule (150 mg)	Adults ^c (max) Children	5 mg/kg (300 mg) Appropriate dosing for children is unknown	— Appropriate dosing for children is unknown	5 mg/kg (300 mg) Appropriate dosing for children is unknown	5 mg/kg (300 mg) Appropriate dosing for children is unknown
Rifapentine	Tablet (150 mg, film coated)	Adults Children	— The drug is not approved for use in children	10 mg/kg (continuation phase) (600 mg usual adult dose) The drug is not approved for use in children	— The drug is not approved for use in children	— The drug is not approved for use in children
Pyrazinamide	Tablet (500 mg, scored)	Adults	1,000 mg (40–55 kg) 1,500 mg (56–75 kg) 2,000 mg (76–90 kg) ^k	— — —	2,000 mg (40–55 kg) 3,000 mg (56–75 kg) 4,000 mg (76–90 kg) ^k	1,500 mg (40–55 kg) 2,500 mg (56–75 kg) 3,000 mg (76–90 kg) ^k
Ethambutol	Tablet (100 mg, 400 mg)	Children (max) Adults Adults Children ^d (max)	15–30 mg/kg (2 g) 800 mg (40–55 kg) 1,200 mg (56–75 kg) 1,600 mg (76–90 kg) ^k 15–20 mg/kg daily (1 g)	— — — — —	50 mg/kg (2 g) 2,000 mg (40–55 kg) 2,800 mg (56–75 kg) 4,000 mg (76–90 kg) ^k 50 mg/kg (2.5 g)	— 1,200 mg (40–55 kg) 2,000 mg (56–75 kg) 2,400 mg (76–90 kg) ^k —
Second-line drugs						
Cycloserine	Capsule (250 mg)	Adults (max) Children (max)	10–15 mg/kg/day (1 g in two doses), usually 500–750 mg/day in two doses ^e 10–15 mg/kg/day (1 g/day)	There are no data to support intermittent administration —	There are no data to support intermittent administration —	There are no data to support intermittent administration —
Ethionamide	Tablet (250 mg)	Adults ^f (max) Children (max)	15–20 mg/kg/day (1 g/day), usually 500–750 mg/day in a single daily dose or two divided doses ^f 15–20 mg/kg/day (1 g/day)	There are no data to support intermittent administration There are no data to support intermittent administration	There are no data to support intermittent administration There are no data to support intermittent administration	There are no data to support intermittent administration There are no data to support intermittent administration
Streptomycin	Aqueous solution (1-g vials) for intravenous or intramuscular administration	Adults (max) Children (max)	^g 20–40 mg/kg/day (1 g)	^g —	^g 20 mg/kg	^g —
Amikacin-kanamycin	Aqueous solution (500-mg and 1-g vials) for intravenous or intramuscular administration	Adults (max) Children (max)	^g 15–30 mg/kg/day (1 g) intravenous or intramuscular as a single daily dose	^g —	^g 15–30 mg/kg	^g —
Capreomycin	Aqueous solution (1-g vials) for intravenous or intramuscular administration	Adults (max) Children (max)	^g 15–30 mg/kg/day (1 g) as a single daily dose	^g —	^g 15–30 mg/kg	^g —
p-Aminosalicylic acid (PAS)	Granules (4-g packets) can be mixed with food; tablets (500 mg) are still available in some countries, but not in the United States; a solution for intravenous administration is available in Europe	Adults Children (max)	8–12 g/day in two or three doses 200–300 mg/kg/day in two to four divided doses (10 g)	There are no data to support intermittent administration There are no data to support intermittent administration	There are no data to support intermittent administration There are no data to support intermittent administration	There are no data to support intermittent administration There are no data to support intermittent administration

		Children	<i>i</i>	<i>i</i>	<i>i</i>	<i>i</i>

^aDose per weight is based on ideal body weight. Children weighing more than 40 kg should be dosed as adults.

^bFor purposes of this document adult dosing begins at age 15 years.

^cDose may need to be adjusted when there is concomitant use of protease inhibitors or nonnucleoside reverse transcriptase inhibitors.

^dThe drug can likely be used safely in older children but should be used with caution in children less than 5 years of age, in whom visual acuity cannot be monitored. In younger children, ethambutol at the dose of 15 mg/kg per day can be used if there is suspected or proven resistance to isoniazid or rifampin.

^eIt should be noted that, although this is the dose recommended generally, most clinicians with experience using cycloserine indicate that it is unusual for patients to be able to tolerate this amount. Serum concentration measurements are often useful in determining the optimal dose for a given patient.

^fThe single daily dose can be given at bedtime or with the main meal.

^gDose: 15 mg/kg per day (1 g), and 10 mg/kg in persons older than 59 years of age (750 mg). Usual dose: 750–1,000 mg administered intramuscularly or intravenously, given as a single dose 5–7 days/week and reduced to two or three times per week after the first 2–4 months or after culture conversion, depending on the efficacy of the other drugs in the regimen.

^hThe long-term (more than several weeks) use of levofloxacin in children and adolescents has not been approved because of concerns about effects on bone and cartilage growth. However, most experts agree that the drug should be considered for children with tuberculosis caused by organisms resistant to both isoniazid and rifampin. The optimal dose is not known.

ⁱThe long-term (more than several weeks) use of moxifloxacin in children and adolescents has not been approved because of concerns about effects on bone and cartilage growth. The optimal dose is not known.

^jThe long-term (more than several weeks) use of gatifloxacin in children and adolescents has not been approved because of concerns about effects on bone and cartilage growth. The optimal dose is not known.

^kMaximum dose regardless of weight.

Ciprofloxacin, levofloxacin, moxifloxacin, and the other quinolones are associated with permanent damage to cartilage in the weight-bearing joints of immature animals, especially dogs and rabbits.^{41,49} Although these drugs have not been shown to frequently cause joint problems in humans, other antituberculosis agents should be used during pregnancy.

Pregnant women with LTBI are not at the same level of risk compared with those with active disease. Therapy with isoniazid for LTBI may be delayed until after pregnancy or, if recent skin-test conversion has occurred, started during the second trimester of pregnancy.^{41,49–51} Although most antituberculosis drugs are excreted in breast milk, the amount of drug received by the infant through nursing is insufficient to cause toxicity. Quinolones should be avoided in nursing mothers, if possible.

HIV Infection Patients with AIDS and other immunocompromised hosts may be managed with chemotherapeutic regimens similar to those used in immunocompetent individuals, although treatment is often extended to 9 months (see Table 116–3).^{2,13,41} The precise duration to recommend remains a matter of debate. Highly intermittent regimens (twice or once weekly) are not recommended for HIV-positive TB patients. Prognosis has been particularly poor for HIV-infected patients infected with MDR-TB. Differentiation must be made between infection with *M. tuberculosis* and nontuberculous mycobacteria, such as MAC, because the drugs used are different. While awaiting laboratory results, the patient can be treated empirically for TB if there is any doubt about the causative organism. Some patients with AIDS malabsorb their oral medications; this is discussed under Therapeutic Drug Monitoring below.^{2,41,45,47} The major issue of drug interactions is discussed further below under Rifampin.

Renal Failure In nearly all patients, isoniazid and rifampin do not require dose modification in renal failure. They are eliminated primarily by the liver.^{45,49,52} In the unlikely event that peripheral neuropathies develop, the frequency of isoniazid dosing may be reduced. Pyrazinamide and ethambutol typically require a reduction in dosing frequency from daily to three times weekly (Table 116–6).^{41,52}

TABLE 116-6 Dosing Recommendations for Adult Patients with Reduced Renal Function and for Adult Patients Receiving Hemodialysis

Drug	Change in Frequency?	Recommended Dose and Frequency for Patients with Creatinine Clearance <30 mL/min or for Patients Receiving Hemodialysis
Isoniazid	No change	300 mg once daily, or 900 mg three times per week
Rifampin	No change	600 mg once daily, or 600 mg three times per week
Pyrazinamide	Yes	25–35 mg/kg per dose three times per week (not daily)
Ethambutol	Yes	15–25 mg/kg per dose three times per week (not daily)
Levofloxacin	Yes	750–1,000 mg per dose three times per week (not daily)
Cycloserine	Yes	250 mg once daily, or 500 mg/dose three times per week ^a
Ethionamide	No change	250–500 mg/dose daily
<i>p</i> -Aminosalicylic acid	No change	4 g/dose, twice daily
Streptomycin	Yes	12–15 mg/kg per dose two or three times per week (not daily)
Capreomycin	Yes	12–15 mg/kg per dose two or three times per week (not daily)
Kanamycin	Yes	12–15 mg/kg per dose two or three times per week (not daily)
Amikacin	Yes	12–15 mg/kg per dose two or three times per week (not daily)

Standard doses are given unless there is intolerance.

The medications should be given after hemodialysis on the day of hemodialysis.

Monitoring of serum drug concentrations should be considered to ensure adequate drug absorption, without excessive accumulation, and to assist in avoiding toxicity.

Data currently are not available for patients receiving peritoneal dialysis. Until data become available, begin with doses recommended for patients receiving hemodialysis and verify adequacy of dosing, using serum concentration monitoring.

^aThe appropriateness of 250-mg daily doses has not been established. There should be careful monitoring for evidence of neurotoxicity.

Renally cleared TB drugs include the aminoglycosides (amikacin, kanamycin, and streptomycin), capreomycin, ethambutol, cycloserine, and levofloxacin.^{41,49,52,53} Dosing intervals need to be extended for these drugs (see Table 116–6). Ciprofloxacin and moxifloxacin are approximately 50% cleared by the kidneys but may not require a change in dose from once daily, as used for TB. The metabolites of isoniazid, pyrazinamide, and *p*-aminosalicylic acid are cleared primarily by the kidneys. The role of these metabolites in causing toxicity is unknown, so their accumulation in renal failure may carry some risk.

Ethionamide and its sulfoxide metabolite are hepatically cleared, so dosing is unchanged.^{41,53} *p*-Aminosalicylic acid is converted largely to metabolites prior to renal elimination; these metabolites may accumulate in renal failure.⁵³ For patients on hemodialysis, the usual 12-hour dosing interval for *p*-aminosalicylic acid granules seems to be safe. Dialysis will remove the metabolites. Serum concentration monitoring must be performed for cycloserine to avoid dose-related toxicities in renal failure patients.^{45,47,53}

Hepatic Failure Antituberculosis drugs that rely on hepatic clearance for most of their elimination include isoniazid, rifampin, pyrazinamide, ethionamide, and *p*-aminosalicylic acid.⁴⁹ Ciprofloxacin and moxifloxacin are approximately 50% cleared by the liver. Elevations of serum transaminase concentrations generally are not correlated with the residual capacity of the liver to metabolize drugs, so these markers cannot be used as guides for drug dosing. Furthermore, isoniazid, rifampin, pyrazinamide, and, to a lesser degree, ethionamide, *p*-aminosalicylic acid, and, rarely, ethambutol may cause hepatotoxicity.^{41,45,49} For some patients with drug-susceptible TB, a “liver-sparing” regimen of streptomycin, levofloxacin, and ethambutol may be used, at least temporarily.^{41,45,49} Because this regimen requires 18 or more months of treatment to be successful, patients usually are switched to isoniazid- and rifampin-containing regimens as soon as they are able.

Morbid Obesity Data are not available for dosing the TB drugs in patients with morbid obesity.⁴⁹ Relatively hydrophilic drugs (isoniazid, pyrazinamide, the aminoglycosides, capreomycin, ethambutol, *p*-aminosalicylic acid, and cycloserine) can be dosed initially based on ideal body weight. Very low or very high serum concentrations can be avoided by checking the serum concentrations.

The TB Drugs

The interested reader is referred to several other publications for more detailed information regarding these drugs.^{2,12,41,44,45,47,49,54–56} Note that although the American Thoracic Society (ATS)/CDC guidelines recommend “maximum” doses, I disagree with this approach to therapy (see Table 116–5).⁴¹ In my view, the “maximum” dose for a given patient is the dose that produces the desired response with an acceptable level of toxicity.^{45,47} This can only be determined on a case-by-case basis. Artificially capping doses may deprive patients of needed drug.

Primary Antituberculosis Drugs Isoniazid. Isoniazid is one of the two most important TB drugs. It is highly specific for mycobacteria, with a MIC against *M. tuberculosis* of 0.01 to 0.25 mcg/mL. Most nontuberculous mycobacteria such as *M. avium* are resistant to isoniazid, although *M. kansasii* and *Mycobacterium xenopi* are susceptible. The most common mechanisms of resistance result from mutations in the *katG* or *inhA* genes.

Isoniazid is readily absorbed from the gastrointestinal tract and from intramuscular injection sites. It also can be given as a short intravenous infusion over 5 minutes if diluted in about 20 mL of normal saline.⁵⁷ Isoniazid should be given on an empty stomach whenever possible.⁵⁸ *N*-acetyltransferase 2 forms the principal metabolite acetylisoniazid, which lacks antimycobacterial activity. The rate at which humans acetylate isoniazid is determined genetically; slow

acetylation is an autosomal recessive trait and reflects a relative lack of *N*-acetyltransferase 2. Fast acetylators have isoniazid half-lives of less than 2 hours. Approximately 50% of whites and blacks and 80% to 90% of Asians and Eskimos are rapid acetylators. Slow acetylators have isoniazid half-lives of 3 to 4 hours and may be at an increased risk of neurotoxicity. The association of acetylator status and risk of hepatotoxicity, however, appears to be weak.⁵⁹ Poor absorption and rapid clearance of isoniazid in patients receiving highly intermittent therapy are associated with poor clinical outcomes.^{60,61}

Transient elevations of the serum transaminases occur in 12% to 15% of patients receiving isoniazid and usually occur within the first 8 to 12 weeks of therapy.⁴¹ Overt hepatotoxicity, however, occurs in only 1% of cases. Risk factors for hepatotoxicity include patient age, preexisting liver disease, excessive alcohol intake, pregnancy, and the postpartum state. Isoniazid also may result in neurotoxicity, most frequently presenting as peripheral neuropathy or, in overdose, as seizures and coma. Patients with pyridoxine deficiency, such as pregnant women, alcoholics, children, and the malnourished, are at increased risk. Isoniazid may inhibit the metabolism of phenytoin, carbamazepine, primidone, and warfarin.⁴⁵ Patients who are being treated with these agents should be monitored closely, and appropriate dose adjustments should be made when necessary.

Rifampin. The introduction of rifampin into routine use during the 1970s allowed for true short-course treatment of TB (6 to 9 months).^{2,13,41} Without rifampin, treatment is generally 18 months or longer. Drug resistance to rifampin is an ominous prognostic factor because it is frequently associated with isoniazid resistance and leaves the patient with few good therapeutic options. Clinicians *must* take care to protect susceptibility to rifampin by carefully treating their patients. Rifampin shows bactericidal activity against *M. tuberculosis* and several other mycobacterial species, including *M. bovis* and *M. kansasii*.⁶² Other nontuberculous mycobacteria, including MAC, show variable susceptibility to rifampin. Rifampin also is active against a broad array of other bacteria. Alteration of the target site on RNA polymerase, primarily through changes in the *rpoB* gene, leads to most forms of rifampin resistance.^{41,62}

Rifampin usually is given orally, but it also can be given as a 30-minute intravenous infusion.^{54,62} Oral doses are best given on an empty stomach.⁶³ Patients with AIDS, diabetes, and other gastrointestinal problems appear to have difficulty absorbing rifampin after oral doses, and this has been associated with therapeutic failures in some cases.^{45,47,61} Rifampin is metabolized to 25-desacetyl-rifampin, which retains most of rifampin's activity; most of rifampin and its metabolite are cleared in the bile. Rifampin generally is given at 600 mg daily or intermittently, although this dose does not take full advantage of rifampin's concentration-dependent killing.^{45,47} Higher doses should be tested in humans within the context of clinical trials.

CLINICAL CONTROVERSY

Rifampin shows concentration-dependent killing. Larger doses produce higher concentrations that more effectively kill bacteria and mycobacteria. High-dose rifampin fell out of favor because high doses given once or twice weekly caused flu-like symptoms. However, high doses (900 to 1,200 mg and possibly higher) can be given safely daily. Studies should be performed in humans with TB to take full advantage of rifampin's potent activity.

Elevations in hepatic enzymes have been attributed to rifampin in 10% to 15% of patients, with overt hepatotoxicity occurring in less than 1%.^{41,62} More frequent adverse effects of rifampin include rash, fever, and gastrointestinal distress. Allergic reactions to rifampin have been reported and occur more frequently with intermittent rifampin doses 900 mg or more twice weekly. These reactions may

TABLE 116-7 Clinically Significant Drug–Drug Interactions Involving the Rifamycins

Drug Class	Drugs Whose Concentrations Are Substantially Decreased by Rifamycins (References)	Comments
Antiinfectives	HIV-1 protease inhibitors (saquinavir, indinavir, nelfinavir, amprenavir, ritonavir, lopinavir-ritonavir)	Can be used with rifabutin. Ritonavir, 400–600 mg twice daily, probably can be used with rifampin. The combination of saquinavir and ritonavir can also be used with rifampin.
	Nonnucleoside reverse transcriptase inhibitors (delavirdine, nevirapine, efavirenz)	Delavirdine should not be used with any rifamycin. Doses of nevirapine and efavirenz need to be increased if given with rifampin; no dose increase needed if given with rifabutin.
	Macrolide antibiotics (clarithromycin, erythromycin)	Azithromycin has no significant interaction with rifamycins.
	Doxycycline	May require use of a drug other than doxycycline.
	Azole antifungal agents (ketoconazole, itraconazole, voriconazole)	Itraconazole, ketoconazole, and voriconazole concentrations may be subtherapeutic with any of the rifamycins. Fluconazole can be used with rifamycins, but the dose of fluconazole may have to be increased.
Hormone therapy	Atovaquone	Consider alternate form of <i>Pneumocystis carinii</i> treatment or prophylaxis.
	Chloramphenicol	Consider an alternative antibiotic.
	Mefloquine	Consider alternate form of malaria prophylaxis.
	Ethinylestradiol, norethindrone	Women of reproductive potential on oral contraceptives should be advised to add a barrier method of contraception when taking a rifamycin.
	Tamoxifen	May require alternate therapy or use of a nonrifamycin-containing regimen.
Narcotics	Levothyroxine	Monitoring of serum thyroid-stimulating hormone recommended; may require increased dose of levothyroxine.
	Methadone	Rifampin and rifapentine use may require methadone dose increase; rifabutin infrequently causes methadone withdrawal.
Anticoagulants	Warfarin	Monitor prothrombin time; may require two- to threefold dose increase.
Immunosuppressive agents	Cyclosporine, tacrolimus	Rifabutin may allow concomitant use of cyclosporine and a rifamycin; monitoring of cyclosporine serum concentrations may assist with dosing.
Anticonvulsants	Corticosteroids	Monitor clinically; may require two- to threefold increase in corticosteroid dose.
Cardiovascular agents	Phenytoin, lamotrigine	Therapeutic drug monitoring recommended; may require anticonvulsant dose increase.
	Verapamil, nifedipine, diltiazem (a similar interaction is also predicted for felodipine and nisoldipine)	Clinical monitoring recommended; may require change to an alternate cardiovascular agent.
	Propranolol, metoprolol	Clinical monitoring recommended; may require dose increase or change to an alternate cardiovascular drug.
	Enalapril, losartan	Monitor clinically; may require a dose increase or use of an alternate cardiovascular drug.
	Digoxin (among patients with renal insufficiency), digitoxin	Therapeutic drug monitoring recommended; may require digoxin or digitoxin dose increase.
Bronchodilators	Quinidine	Therapeutic drug monitoring recommended; may require quinidine dose increase.
Sulfonylurea hypoglycemics	Mexiletine, tocainide, propafenone	Clinical monitoring recommended; may require change to an alternate cardiovascular drug.
Hypolipidemics	Theophylline	Therapeutic drug monitoring recommended; may require theophylline dose increase.
Psychotropic drugs	Tolbutamide, chlorpropamide, glyburide, glimepiride, repaglinide	Monitor blood glucose; may require dose increase or change to an alternate hypoglycemic drug.
	Simvastatin, fluvastatin	Monitor hypolipidemic effect; may require use of an alternate hypolipidemic drug.
	Nortriptyline	Therapeutic drug monitoring recommended; may require dose increase or change to alternate psychotropic drug.
	Haloperidol, quetiapine	Monitor clinically; may require a dose increase or use of an alternate psychotropic drug.
	Benzodiazepines (e.g., diazepam, triazolam), zolpidem, buspirone	Monitor clinically; may require a dose increase or use of an alternate psychotropic drug.

take the form of a flu-like syndrome with development of fever, chills, headache, arthralgias, and, rarely, hypotension and shock.^{41,55} Alternatively, hemolytic anemia or acute renal failure may occur, requiring permanent discontinuation.

Rifampin's potent induction of hepatic enzymes, especially cytochrome P450 3A4, may enhance the elimination of many other drugs, most notably the protease inhibitors used to treat HIV (Table 116–7). HIV-positive patients may benefit from the use of rifabutin instead of rifampin (see below).^{41,64–67} Also, women who use oral contraceptives must use another form of contraception during therapy because increased clearance of the hormones may lead to unexpected pregnancies. Patient records should be reviewed for potential drug interactions before dispensing rifampin.⁵⁴ Rifampin may turn urine and other secretions orange-red and may permanently stain some types of contact lenses.

Other Rifamycins. Rifabutin is used for disseminated *M. avium* infection in AIDS patients and is quite active against *M. tuberculosis*. Most rifampin-resistant organisms are resistant to rifabutin. Because rifabutin is a less-potent enzyme inducer than rifampin, it may be

used in patients who are receiving protease inhibitors.^{41,64–67} For HIV-positive patients, the ATS/CDC recommends regimens with three or more doses of the TB drugs per week (see Table 116–3). Rifapentine is a long-acting rifamycin that can be used once weekly in the continuation phase of treatment (after the first 2 months) in carefully selected HIV-negative patients. Rifapentine is approximately 85% as potent an enzyme inducer as rifampin, so similar drug interactions are likely.^{41,64–67}

Pyrazinamide. Adding pyrazinamide to the first 2 months of treatment with isoniazid and rifampin shortens the duration to 6 months for most patients.^{2,41} It is usually well absorbed and displays a fairly long half-life.^{68,69} The most common toxicities of pyrazinamide are gastrointestinal distress, arthralgias, and elevations in the serum uric acid concentrations.^{41,55} Most patients do not experience true gout. Hepatotoxicity is the major limiting adverse effect and is dose-related when pyrazinamide is given daily.

A fixed-combination product (Rifater, Aventis) of rifampin 120 mg, isoniazid 50 mg, and pyrazinamide 300 mg is designed to prevent drug resistance by keeping the self-medicating patient from using only one

drug at a time. If the patient is receiving directly observed treatment, there is no particular advantage to this product. The typical dose of Rifater will be five to six tablets daily. When pyrazinamide is discontinued after 2 months of treatment, the combination product Rifamate (isoniazid 150 mg and rifampin 300 mg) can be substituted.

Ethambutol. Ethambutol replaced *p*-aminosalicylic acid as a first-line agent in the 1960s because it was better tolerated by patients.^{2,41} Ethambutol is used as a fourth drug for TB while awaiting susceptibility data.⁴¹ If the organism is susceptible to isoniazid, rifampin, and pyrazinamide, ethambutol can be stopped. Ethambutol is active against most mycobacteria, including *M. tuberculosis* and *M. avium*, but it is generally bacteriostatic.

Ethambutol should not be given with antacids.⁷⁰ In patients with renal failure, the ethambutol dose should be reduced to three times per week.^{52,71} Retrobulbar neuritis is the major adverse effect. Patients may complain of a change in visual acuity, the inability to see the color green, or both. They should be monitored monthly while on the drug using Snellen wall charts for visual acuity and Ishihara red-green color discrimination cards.^{41,54,55}

Second-Line Antituberculosis Drugs Streptomycin. Streptomycin is one of three aminoglycoside antibiotics (along with amikacin and kanamycin) that are active against mycobacteria. Streptomycin is quite active against MAC and several other mycobacteria, enterococci, *Brucella*, *Yersinia*, and various other bacteria. Although labeled only for intramuscular dosing, streptomycin can be given safely as intravenous infusions (100 mL of dextrose 5% water or normal saline) over 30 minutes, similar to the other aminoglycosides.⁷² Streptomycin, like other aminoglycosides, is renally cleared by glomerular filtration and must be given less often in patients with renal dysfunction.^{41,45,54}

Streptomycin occasionally causes nephrotoxicity, although it tends to be mild and reversible. It also is capable of causing ototoxicity (vestibular and cochlear), which may become permanent with continued use.^{41,55} Older patients and those receiving long durations of treatment are most likely to experience hearing loss, whereas vestibular toxicity is highly unpredictable.

Resistance to amikacin and kanamycin is frequently linked but independent of resistance to streptomycin and independent of resistance to capreomycin. Therefore, susceptibility tests should guide the selection of these injectable drugs.

***p*-Aminosalicylic Acid.** In the United States, only the enteric-coated, sustained-release granule form (Paser) is available.^{73–75} Gastrointestinal disturbances are the most common adverse effects from *p*-aminosalicylic acid. Diarrhea is usually self-limited, with symptoms improving after the first 1 to 2 weeks of therapy. Occasionally, a few doses of an opioid will resolve the problem. It is also important to tell the patient that the empty granules will appear in the stool. Although FDA approved for three daily doses, pharmacokinetic data support twice-daily dosing.⁷⁴

Various types of malabsorption, including steatorrhea, were reported with previous dosage forms of *p*-aminosalicylic acid. Hypersensitivity may occur and, rarely, severe hepatitis. *p*-Aminosalicylic acid is known to produce goiter, with or without myxedema, that seems to occur more frequently with concomitant ethionamide therapy.

Cycloserine. Cycloserine is only used to treat MDR-TB. It is well absorbed orally and is best taken on an empty stomach.⁷⁶ It is cleared primarily through the kidneys by glomerular filtration and requires dosage reduction in renal failure. Cycloserine can produce dose-related CNS toxicity, including lethargy, confusion, or unusual behavior. Seizures, although reported, are exceedingly rare.^{2,41,54} Therapy is improved by maintaining 2-hour postdose serum concentrations between 20 and 35 mcg/mL.^{45,47} Most patients reach a maximum dose of 750 mg daily, divided unevenly into two doses.

This can be achieved by starting with 250 mg daily for 2 days, followed by 250-mg increments over 2-day intervals. This dose of cycloserine can be maintained if the patient complains of only occasional mild CNS effects, such as difficulty concentrating. Serum concentrations can be checked 1 to 2 weeks into therapy. The addition of pyridoxine 50 mg daily may improve patient tolerance of cycloserine.

Ethionamide. Ethionamide shares structural features with two other antimycobacterial agents, isoniazid and, more distantly, thiacetazone, a drug not used in the United States. Prothionamide, the *n*-propyl derivative of ethionamide, is used in Europe. Ethionamide is only active against organisms of the genus *Mycobacterium*, and it should be considered primarily bacteriostatic because it is difficult to achieve serum concentrations that would be bactericidal.^{41,45,47}

Gastrointestinal toxicity is the dose-limiting adverse effect. The drug should be introduced gradually in 250-mg increments, as described earlier for cycloserine. Rarely will a patient tolerate more than 1,000 mg daily in divided oral doses. Ethionamide may be administered with a light snack or prior to bedtime to minimize gastrointestinal intolerance. Food does not affect absorption significantly.⁷⁷ Little ethionamide is recovered in the urine, so doses remain the same in renal failure. Ethionamide may cause goiter, with or without hypothyroidism (especially when given with *p*-aminosalicylic acid), gynecomastia, alopecia, impotence, menorrhagia, photodermatitis, and acne. The management of diabetes also may be more difficult in patients receiving ethionamide. Because of these problems, ethionamide is only used when absolutely necessary.

Clofazimine. Clofazimine is a drug with good activity against *Mycobacterium leprae* and weak activity against *M. tuberculosis* and *M. avium*. It is used in doses of 100 to 200 mg daily in advanced cases of MDR-TB or MAC, especially when therapeutic options are limited.^{41,45} The drug has a terminal elimination half-life that is weeks long. Gastrointestinal distress and skin discoloration are the most important adverse reactions. Although uncommon, severe gastrointestinal pain may occur because of deposition of clofazimine crystals within the intestines; this may require surgical correction.

Thiacetazone. Thiacetazone is a weak agent used rarely in parts of the developing world because of its low cost. Skin reactions, including rash and Stevens-Johnson's syndrome, may occur. Thiacetazone must be discontinued permanently as soon as a rash appears. Similar to trimethoprim-sulfamethoxazole, the incidence of skin reactions is much higher in AIDS patients.⁷⁸

Quinolones. Levofloxacin, ciprofloxacin, and moxifloxacin are sometimes used to treat MDR-TB. Moxifloxacin also is being studied as a possible replacement for certain first line agents.^{2,13,41,45,79} Quinolones are useful because most are available in oral and intravenous dosage forms, so they can be used in critically ill patients.

β -Lactam and β -Lactamase Inhibitor Combinations. The β -lactams have limited activity against mycobacteria because of β -lactamases and because β -lactams fail to enter macrophages.^{41,45,80} Cefoxitin, a β -lactamase-stable cephalosporin, has useful activity against rapidly growing mycobacteria, such as *M. fortuitum* and *Mycobacterium chelonae*. Combinations of β -lactam with β -lactamase inhibitors have been used in salvage regimens for TB patients with no other options, but are not used routinely to treat TB.

Macrolides/Azalides. The macrolide clarithromycin and azalide azithromycin represent substantial advances in the treatment of MAC but demonstrate limited activity against *M. tuberculosis* and are not used frequently for TB.^{2,13,41,45}

New Drugs and Delivery Systems. The nitroimidazopyran PA 824, which is chemically related to metronidazole and tinidazole, has activity against *M. tuberculosis* in vitro.^{81,82} This class, along with the oxazolidinones, may produce useful agents for TB. Linezolid has been

used in a few patients with TB.⁹⁶ Long-term use of linezolid requires careful monitoring of hematologic indices for potential anemia and thrombocytopenia. Although not proved conclusively, it may be possible to reduce the incidences of these toxicities by giving linezolid 600 mg daily for the slow-growing *M. tuberculosis* rather than the usual twice-daily dose used for gram-positive organisms. Chemical modification of existing compounds, such as pyrazinamide, may produce new TB drugs. Finally, continuing research on the construction of the mycobacterial cell wall and intracellular pathways may lead to agents with unique activity against this genus.

Liposomes have been investigated as delivery systems for various agents against mycobacteria, including isoniazid, rifampin, and the aminoglycosides. Liposomes also could be used to deliver β -lactams or other agents that generally are excluded from macrophages. By changing the pharmacokinetic profile of such agents, their use in the treatment of mycobacterial infections could be enhanced greatly. Currently, no such product is licensed for use against TB.

Corticosteroids. Adjunctive therapy with corticosteroids may be of benefit in some patients with tuberculous meningitis or pericarditis to relieve inflammation and pressure (see Table 116-4).^{2,41} They should be avoided in most other circumstances because they detract from the immune response to TB.

Bacille Calmette-Guérin Vaccine. The BCG vaccine is an attenuated, hybridized strain of *M. bovis*. It was developed in 1921 and is used as a prophylactic vaccine against TB. Administration of BCG vaccine is compulsory in many developing countries and is officially recommended in many others. Vaccination with BCG produces a subclinical infection resulting in sensitization of T lymphocytes and cross-immunity to *M. tuberculosis*, as well as cutaneous hypersensitivity and, in many cases, a positive tuberculin skin test.

In the published clinical trials, several different BCG preparations were used, and the efficacy of these vaccinations ranged from negative 56% (some patients did worse with the vaccine) to positive 80%.^{2,41} Trials within the United States and Puerto Rico have shown efficacy rates of 6% to 29%. The primary benefit of BCG vaccination appears to be the prevention of severe forms of TB in children. Data from the BCG trials show that the incidence of tuberculous meningitis and miliary TB is 52% to 100% lower and that the incidence of pulmonary TB is 2% to 80% lower in vaccinated children younger than 15 years of age than it was in unvaccinated controls.

Unfortunately, BCG does not appear to be very reliable in preventing disease by *M. tuberculosis* in other segments of the population. Side effects occur in 1% to 10% of vaccinated persons and usually include severe or prolonged ulceration at the vaccination site, lymphadenitis, and lupus vulgaris. It is recommended that pregnant women and patients with impaired immune systems, including those with HIV infection, avoid vaccination. The World Health Organization has recommended, however, that in populations where the risk of TB is high, HIV-infected infants who are asymptomatic should receive BCG vaccine at birth or as soon as possible thereafter. Because BCG infection has occurred in AIDS patients given the vaccine, individuals with symptomatic HIV infection should not be vaccinated.^{2,41}

In the United States, BCG vaccination is recommended only for uninfected children who are at unavoidable risk of exposure to TB and for whom other methods of prevention and control have failed or are not feasible.^{2,41} Its use is very limited.

PHARMACOECONOMIC CONSIDERATIONS

The World Health Organization and the World Bank agree that the control of TB is one of the most cost-effective health interventions any nation can pursue. Early identification of TB cases and the effective use of isoniazid, rifampin, and pyrazinamide (plus ethambutol) while the isolate is still drug-susceptible always should be the

primary goals of public health departments. Contact investigation and treatment of those infected but without disease are important secondary goals to reduce the number of future cases.

Patients who complete all their treatment for drug-susceptible TB have cure rates over 95%. Noncompliance (nonadherence), drug resistance, extrapulmonary disease, and concomitant disease states reduce the overall effectiveness of chemotherapy of TB to approximately 75%.

The treatment of TB is not particularly expensive, especially if hospitalization is not required.⁸³ Furthermore, TB is quite curable. Because the various TB drugs each have a role to play in the treatment of TB or MDR-TB, all the antituberculosis drugs approved by the Food and Drug Administration should be on institutional formularies. Centers that see little MDR-TB need not keep stocks of the second-line drugs, provided that they are readily available should the need arise. Because the treatment of MDR-TB is difficult, and because missteps are potentially disastrous, such patients should be referred to centers experienced in the management of MDR-TB.^{2,41,84,85}

EVALUATION OF THERAPEUTIC OUTCOMES

MONITORING OF THE PHARMACEUTICAL CARE PLAN

The most serious problem with TB therapy is patient nonadherence to the prescribed regimens.^{86,87} Unfortunately, there is no reliable way to identify such patients a priori. In the study by Brudney and Dobkin,⁸⁶ 89% of the patients were noncompliant with therapy. It is critical to the control of TB that such adherence rates be improved dramatically. The most effective way to achieve this end is with directly observed treatment.^{2,13,41} Despite criticisms that it will cost more money, it is far cheaper in the long run to prevent the further spread of disease with directly observed treatment than to track down and treat additional cases of TB continuously.

The homeless and other underprivileged individuals are assumed to constitute the group of patients considered “unreliable,” and directly observed treatment should be reserved for them; it is also assumed that “responsible” patients cared for by private physicians may be treated with daily, unsupervised therapy. A study conducted in Baltimore, however, compared outcomes (sputum culture conversion to negative at 3 months) in patients with pulmonary TB who were treated by private physicians with outcomes in patients treated via directly observed treatment in a city-run clinic. Surprisingly, 3-month culture conversion occurred in only 40% of the private-care patients, compared with 90% in the city clinic-care patients.⁸⁸ Clearly, expansion of the use of directly observed treatment to nearly all patients with TB may be of benefit.

For patients who are acid-fast bacilli smear positive, they should have sputum samples sent for acid-fast bacilli stains every 1 to 2 weeks until two consecutive smears are negative. This provides early evidence of a response to treatment.⁴¹ Once on maintenance therapy, sputum cultures can be performed monthly until two consecutive cultures are negative, which generally occurs over 2 to 3 months. If sputum cultures continue to be positive after 2 months, drug susceptibility testing should be repeated, and serum concentrations of the drugs should be checked.

Serum chemistries, including blood urea nitrogen, creatinine, aspartate transaminase, and alanine transaminase, and a complete blood count with platelets should be performed at baseline and periodically thereafter, depending on the presence of other factors that may increase the likelihood of toxicity (e.g., advanced age, alcohol abuse, pregnancy).^{2,41} Hepatotoxicity should be suspected in patients whose transaminases exceed five times the upper limit of normal or whose total bilirubin concentration exceeds 3 mg/dL and in patients with symptoms such as nausea, vomiting, or jaundice. At this point, the offending agent(s) should be discontinued. Sequential reintroduc-

tion of the drugs with frequent testing of liver enzymes is often successful in identifying the offending agent; other agents may be continued. Alternative agents should be selected as needed. Audiometric testing should be performed at baseline and monthly in patients who must receive streptomycin for more than 1 to 2 months. Vision testing (Snellen visual acuity charts and Ishihara color discrimination plates) should be performed on all patients who receive ethambutol. All patients diagnosed with TB should be tested for HIV infection.

THERAPEUTIC DRUG MONITORING

Therapeutic drug monitoring (TDM) or applied pharmacokinetics is the use of serum drug concentrations to optimize therapy.^{41,45,47,88,89} Non-AIDS patients with drug-susceptible TB generally do well, and TDM generally should be used if they are failing appropriate directly observed treatment (no clinical improvement after 2 to 4 weeks or smear-positive after 4 to 6 weeks). On the other hand, patients with AIDS, diabetes, cystic fibrosis, and various gastrointestinal disorders often fail to absorb these drugs properly and are candidates for TDM. Also, patients with hepatic or renal disease should be monitored, given their potential for overdoses.

In the treatment of MDR-TB, the differences between the maximum serum concentration (C_{\max}) and the minimal inhibitory concentration (MIC) for the second-line agents are much smaller than with isoniazid and rifampin. Therefore, alterations in the absorption of these drugs can have significant impact on the outcome of therapy.^{45,47} Although the optimal serum concentrations for TB are not known, target serum peak concentrations have been proposed.^{45,47} Blood samples collected at 2 and 6 hours after a dose have been used with some success, although they may not be the optimal sampling times for all the drugs. Long-half-life drugs (e.g., pyrazinamide and cycloserine) can be sampled at 2 and 10 hours if an estimate of the half-life is desired. Finally, TDM of the TB and HIV drugs is perhaps the most logical way to untangle the complex drug interactions that take place (see Table 116–7).⁹¹

CLINICAL CONTROVERSY

Some TB centers employ TDM for many of their patients at the outset of treatment in order to identify drug-delivery problems early. Other centers wait to see how the patient responds and perform TDM only if problems arise. An argument can be made for either approach. The latter can save money, but delays in effective treatment can affect the patient's outcome adversely. Most otherwise healthy TB patients will absorb their drugs adequately. Patients who are critically ill or who have MDR-TB can benefit from early TDM.

CONCLUSIONS

Good patient adherence to treatment regimens is the cornerstone to effective antimycobacterial chemotherapy. Pharmacists should monitor TB therapy with particular interest in drug-drug interactions, drug malabsorption, and avoiding the error of adding a single drug to a failing regimen. They should educate patients on the importance of continuing their chemotherapy despite symptomatic improvement. Pharmacists should become part of a multidisciplinary team (with nurses, physicians, social workers) devoted to successful chemotherapy of TB patients and their families.

ABBREVIATIONS

ATS: American Thoracic Society

Gastrointestinal Infections and Enterotoxigenic Poisonings

STEVEN MARTIN AND ROSE JUNG

KEY CONCEPTS

- 1 The etiology of infectious diarrhea includes bacteria, viruses, and protozoans. Viral infections are the leading cause of diarrhea in the world.
- 2 Fluid and electrolyte replacement is the cornerstone of therapy. Oral rehydration therapy is preferred in most cases of mild and moderate diarrhea. The necessary components of oral replacement therapy are glucose, sodium, potassium, chloride, and water.
- 3 Antimicrobial therapy often is not indicated for enteritis because many cases are mild and self-limited or are viral in nature.
- 4 Diarrheal illness can be prevented by following simple rules of personal hygiene and safe food preparation.
- 5 The most common pathogens for traveler's diarrhea include enterotoxigenic *Escherichia coli*, *Shigella*, *Campylobacter*, *Salmonella*, and viruses.
- 6 Patient education and prevention strategies are important in preventing and treating traveler's diarrhea. Prophylaxis with antibiotics is not recommended in most situations.
- 7 Common pathogens responsible for food poisoning include *Staphylococcus*, *Salmonella*, *Shigella*, and *Clostridium*.

Gastrointestinal (GI) infections encompass a wide variety of syndromes from mild gastroenteritis to life-threatening systemic infections. Dehydration from GI infections is the second leading cause of morbidity and mortality worldwide, especially in infants and children younger than 5 years of age. From 1992 to 2000, the median incidence of diarrhea for all children younger than 5 years of age was 3.2 episodes per child per year. The incidence of diarrhea was higher in younger children, with 4.8 episodes per child per year among children ages 6 to 11 months in comparison with 1.4 episodes per child per year for 4-year-olds. Younger children also had a higher risk for death from acute dehydrating diarrhea. For children younger than 1 year of age and those ages 1 to 4 years, the median mortality rates were 8.5 and 3.8 per 1,000 children per year, respectively.¹ Although this was a decrease from 13.6 per 1,000 children per year during 1955–1979 and 5.6 per 1,000 children per

year during 1980 to 1989, diarrhea remains a major health problem in children, especially in those younger than 1 year of age.^{2,3}

Although outbreaks of infectious diarrhea and deaths in the United States are not as prevalent, the economic burden of GI infections still remains high. The estimates by the Centers for Disease Control and Prevention (CDC) suggest that 211 million episodes of acute gastroenteritis occur each year in the United States, resulting in more than 900,000 hospitalizations and more than 6,000 deaths.⁴ In contrast to the developing world where the risk of death is highest among young children, in the United States most of those who die of diarrheal illness are elderly. According to the National Center for Health Statistics, during 1979 to 1987, 51% of deaths caused by diarrheal illness were among patients older than 74 years of age, and 27% were among 55- to 74-year-olds, while 11% were in those younger than 5 years.⁵ Similarly, a study of the McDonnell-Douglas Health Information System database revealed that 25% of all hospitalizations and 85% of all mortality associated with diarrhea involved the elderly (≥ 60 years old).⁶ In addition to children and elderly, other groups at risk for GI infections include travelers and campers, immunocompromised patients such as those with acquired immunodeficiency syndrome (AIDS), patients in chronic care facilities, and military personnel assigned overseas.

Fortunately, diarrheal mortality has declined substantially in the past two decades, especially among children younger than 1 year of age. Interventions for diarrheal disease such as breast-feeding, better weaning practices, improved sanitation, and higher use of oral rehydration therapy are responsible for the decrease in case-fatality rates. Although reassuring, diarrhea still accounts for 1.6 to 2.5 million deaths annually.¹ To achieve further declines in mortality, a more complex approach needs to be adopted that includes distinguishing acute watery diarrhea from dysentery and persistent diarrhea and providing appropriate case management for each syndrome.

1 A variety of pathogens are responsible for acute infectious diarrhea. Viruses are suspected to be the most common cause of gastroenteritis, especially in children. However, bacterial species are the most commonly identified cause of infectious diarrhea in the United States. This chapter focuses on the bacterial and viral etiologies of GI infections such as *Vibrio cholerae*, *Escherichia coli*, *Salmonella*, *Shigella*, *Campylobacter jejuni*, rotaviruses, noroviruses, astrovirus, and enteric adenovirus. Clinical presentation, diagnosis, treatment and prevention strategies are discussed in general terms initially for all GI infections and further elaborated in regards to specific etiologies in subsequent sections.

CLINICAL PRESENTATION AND DIAGNOSIS

Appropriate management of moderate to severe cases requires an organism-specific diagnosis and thus, stool cultures are often ordered. Unfortunately, the yield of such cultures is very low. Unlike cultures of sterile sites, normal feces contain many enteric pathogens

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

and differential and selective media are required to isolate pathogenic bacteria from among those that are nonpathogenic. A routine stool culture will screen for presence of *C. jejuni*, *Salmonella* species, and *Shigella* species. Although other pathogens such as *Yersinia enterocolitica* and *Vibrio* species may also be detected, the yield of positive cultures for nonroutine organisms is increased if requested specifically based on clinical suspicion of likely etiologies.

Current guidelines recommend selective approaches to identify patients who are likely to have positive cultures and those who would benefit from organism-specific diagnosis in order to improve the usefulness of stool cultures.⁷ A careful history and physical examination are crucial in providing clues to the likely etiology. Fecal testing is recommended in patients with a recent use of antibiotics, daycare center attendance, hospitalization, or illness accompanied by fever, bloody stools, systemic illness, or dehydration if they have community-acquired diarrheal illnesses lasting for more than 1 day. For community-acquired or traveler's diarrhea, stool samples should be sent for culture of *Salmonella*, *Shigella*, *Campylobacter*, and *E. coli* O157:H7.

A careful history may further point to other etiologic agents. Bloody diarrhea may indicate enterohemorrhagic *E. coli*. Outbreaks should prompt consideration of *Staphylococcus aureus*, *Bacillus cereus*, *Clostridium perfringens*, *Vibrio*, *Salmonella*, *Campylobacter*, *Shigella*, or *E. coli* infection. Ingestion of inadequately cooked seafood should increase suspicions for infections with *Vibrio* or noroviruses. Use of antibiotics predisposes patients to cytotoxigenic *Clostridium difficile*. Travel to tropical areas increases the chances of developing enterotoxigenic *E. coli*, viral (norovirus or rotavirus), and parasitic infections (*Giardia*, *Entamoeba*, *Strongyloides*, and *Cryptosporidium*).

In hospitalized patients, fecal testing for routine bacterial pathogens or ova and parasites is not recommended for diarrhea that occurs 3 days after the start of hospitalization owing to low yield. Instead, 15% to 20% of cases are caused by *C. difficile*, thus the stool specimen should be tested for *C. difficile* toxin(s), especially in those who are exposed to antimicrobial therapy or chemotherapy. Stool culture is recommended, however, in persons 65 years of age and older with comorbid diseases, neutropenia, or human immunodeficiency virus (HIV) infection. In immunocompromised hosts, a wide range of viral, bacterial, and parasitic agents should be tested. Microscopic examination for fecal polymorphonuclear cells or a simple immunoassay for the neutrophil marker lactoferrin can

further provide evidence of an inflammatory process and increase the yield of culture for invasive pathogens in patients presenting with fever or bloody stool.

TREATMENT

Diarrhea

■ GENERAL APPROACHES TO MANAGEMENT

Rehydration Therapy

2 Initial assessment of fluid loss is essential for rehydration and should include acute weight loss as it is the most reliable means of determining the extent of water loss. However, if accurate baseline weight is not available, clinical signs are helpful in determining approximate deficits (Table 117-1). Physical assessment generally is more reliable in young children and infants than in adults.⁸

2 Fluid replacement is the cornerstone of therapy for diarrhea regardless of etiology. Oral rehydration therapy (ORT) reverses dehydration in nearly all patients with mild to moderate diarrhea; treatment failure with ORT is infrequent (3% to 6%).⁹ ORT offers the advantages of being inexpensive and noninvasive and does not require hospitalization for administration. In those who are able to take oral fluids, ORT is superior to administration of intravenous (IV) fluids. Moreover, thirst drives use of ORT and provides a safeguard against overhydration.

The American Academy of Pediatrics recommends rehydration with an electrolyte-concentrated rehydration phase followed by a maintenance phase using dilute electrolyte solutions and larger volumes (see Table 117-1).¹⁰ The necessary components of glucose-based ORT include glucose, sodium, potassium, chloride, and water (Table 117-2). Glucose-based ORT takes advantage of glucose-coupled sodium transport in the small bowel. Glucose enhances sodium and subsequently water transport across intestinal walls. In children with vomiting and diarrhea, ORT may be given as 5 mL every 2 to 3 minutes in a teaspoon or oral syringe. Nasogastric administration of ORT is an alternative method of administration in a child with persistent vomiting. After starting rehydration therapy, patients should be observed for a reversal of the signs of dehydration, increased stool consistency, and decreased stool frequency.

TABLE 117-1 Clinical Assessment of Degree of Dehydration in Children Based on Percentage of Body Weight Loss^a

Variable	Mild: 3%–5%	Moderate: 6%–9%	Severe: ≥10%
Blood pressure	Normal	Normal	Normal to reduced
Quality of pulses	Normal	Normal or slightly decreased	Moderately decreased
Heart rate	Normal	Increased	Increased (bradycardia in severe cases)
Skin turgor	Normal	Decreased	Decreased
Fontanelle	Normal	Sunken	Sunken
Mucous membranes	Slightly dry	Dry	Dry
Eyes	Normal	Sunken orbits/decreased tears	Deeply sunken orbits/decreased tears
Extremities	Warm, normal capillary refill	Delayed capillary refill	Cool, mottled
Mental status	Normal	Normal to listless	Normal to lethargic or comatose
Urine output	Slightly decreased	<1 mL/kg/h	<1 mL/kg/h
Thirst	Slightly increased	Moderately increased	Very thirsty or too lethargic to indicate
Fluid replacement	ORT 50 mL/kg over 2–4 h	ORT 100 mL/kg over 2–4 h	Ringer lactate 40 mL/kg in 15–30 min, then 20–40 mL/kg if skin turgor, alertness, and pulse have not returned to normal or Ringer lactate or NS 20 mL/kg, repeat if necessary, and then replace water and electrolyte deficits over 1–2 days Followed by ORT 100 mL/kg over 4 h. Replace ongoing losses with low-sodium ORT (40–60 mEq/L Na ⁺) at 10 mL/kg per stool or emesis

ORT, oral rehydration therapy.

^aPercentages vary among authors for each dehydration category; hemodynamic and perfusion status is most important; when unsure of category, therapy for more severe category is recommended.

Data from American Academy of Pediatrics¹⁰ and Holliday et al.¹²

TABLE 117-2 Comparison of Common Solutions Used in Oral Rehydration and Maintenance

Product	Na (mEq/L)	K (mEq/L)	Base (mEq/L)	Carbohydrate (mmol/L)	Osmolality (mOsm/L)
Naturalyte (unlimited beverage)	45	20	48	140	265
Pediatric electrolyte (NutraMax)	45	20	30	140	250
Pedialyte (Ross)	45	20	30	140	250
Infalyte (formerly Ricelyte; Mead Johnson)	50	25	30	70	200
Rehydralyte (Ross)	75	20	30	140	310
WHO/UNICEF oral rehydration salts	90	20	30	111	310
Cola ^a	2	0	13	700	750
Apple juice ^a	5	32	0	690	730
Chicken broth ^a	250	8	0	0	500
Sports beverage ^a	20	3	3	255	330

^aThese solutions should be avoided.

From American Academy of Pediatrics.¹⁰

Maintenance rehydration requires sodium concentrations of 40 to 60 mEq/L, compared to 50 to 90 mEq/L for initial rehydration. ORT solutions with high sodium content may be alternated with water if a low-sodium fluid is not available. The maintenance phase should provide 100 to 150 mL/kg per day plus additional replacement for stool losses. Clear fluids, such as soda, apple juice, broth, and Gatorade should be avoided in both the rehydration and maintenance phase of dehydration. Those solutions are hyperosmolar and may draw free water into the gut lumen and cause hypernatremia. In addition, high glucose concentrations may produce an osmotic diarrhea (see Table 117-2).

Glucose-based ORT primarily prevents dehydration without much influence on the duration of diarrhea or stool volume; low-osmolality ORT solutions (rice- or cereal-based), however, reduce the diarrhea stool number, volume, and frequency, as well as the duration of diarrhea, and the replacement volume requirements.¹¹ The efficacy of rice-based ORT solutions may be a result, in part, of their hypotonicity, which promotes intestinal water absorption. Also, slow rice hydrolysis allows some rice (glucose) absorption to take place before hydrolysis occurs. Starch and simple proteins provide more cotransport molecules with a lower intraluminal osmotic load, thus increasing fluid and electrolyte uptake by enterocytes and reducing stool losses. Therefore, a larger carbohydrate load can be given with rice solutions, resulting in a greater nutritional advantage.

If ORT does not improve the fluid status and the patient continues to produce frequent, large-volume watery stools, close supervision with medical support is warranted. Weight loss of 9% to 10% is considered severe and requires IV fluid replacement with Ringer lactate or normal saline. Intravenous fluid therapy is also indicated in patients with uncontrolled vomiting, the presence of a paralytic ileus, stool output greater than 10 mL/kg per hour, shock, or loss of consciousness. Rapid IV rehydration is preferred over more prolonged deficit-replacement regimens for restoring extracellular fluids and electrolytes because it more effectively reestablishes gastrointestinal and renal perfusion.¹² Table 117-1 summarizes fluid-replacement guidelines for each dehydration category.

Early refeeding as tolerated is recommended.¹³ The American Academy of Pediatrics guidelines recommend age-appropriate diet resumption as soon as dehydration is corrected.¹⁰ Breast milk, lactose-free soy formula, and cow's-milk-based formulas often can be continued.^{8,13} Early initiation of feeding has shortened the course of diarrhea. In a study of severely malnourished children younger than 5 years of age with diarrhea, using a standardized protocol of slower oral rehydration, immediate feeding, and intensive management of complications resulted in a significant reduction of mortality as compared with standard therapy. Initially, easily digested foods, such as bananas, applesauce, and cereal, may be added. Foods high in fiber, sodium, and sugar should be avoided. Lactase deficiency may be exacerbated among known lactase-deficient patients and may persist up to 10 days.

Antimicrobial Therapy

The indiscriminate use of antimicrobial therapy in GI infections produces increases in antimicrobial resistance, side effects of antimicrobial agents, and the threat of superinfections owing to eradication of normal flora. Increasing fluoroquinolone resistance in *Campylobacter* and multidrug resistance in *Salmonella* species worldwide reinforce the importance of judicious use of antibiotics and prudent infection control measures.^{14,15} Furthermore, it stresses the need to take local susceptibility patterns into account in the selection of initial choice of antimicrobial regimen.

3 Antibiotics are not essential in the treatment of most mild diarrheas, and empirical therapy for acute GI infections may result in courses of unnecessary antibiotics. However, appropriate antibiotic therapy shortens the duration of illness and reduces morbidity in some bacterial (cholera, enterotoxigenic *E. coli*, shigellosis, campylobacteriosis, yersiniosis) infections and can be lifesaving in invasive infections (*C. difficile*, salmonellosis). Antibiotic treatment also reduces the duration and shedding of organisms in infections with susceptible *Shigella* species and possibly in infection with susceptible *Campylobacter* species.¹⁶ Table 117-3 summarizes antibiotic recommendations, and further details in the treatment of specific infections are discussed in appropriate sections.

It is also important to note that outcomes of some bacterial diarrheal illnesses may be worsened by the use of antibiotics. Antibiotic treatment may prolong asymptomatic carriage of *Salmonella*.¹⁷ In patients infected with *E. coli* O157, use of an antimicrobial agent may worsen the risk of hemolytic uremic syndrome (HUS), which is defined by the triad of acute renal failure, thrombocytopenia, and microangiopathic hemolytic anemia, by increasing the production of shiga-like toxin.¹⁸

Antimotility Agents

Antiperistaltic drugs such as diphenoxylate and loperamide offer symptomatic relief in patients with mild diarrhea. However, these agents are contraindicated in most toxin-mediated diarrheal illnesses (enterohemorrhagic *E. coli*, pseudomembranous colitis, shigellosis) and thus should be avoided in patients with high fever and bloody diarrhea. Slowing of fecal transit time is thought to result in extended toxin-associated damage.

PREVENTION OF GASTROINTESTINAL INFECTIONS

4 Public health measures of improved water supply and sanitation facilities and the quality control of commercial products are important for the control of the majority of enteric infections. In addition, many diarrheal diseases can be prevented by following simple rules of personal hygiene and safe food preparation. Handwashing with soap is instrumental in preventing the spread of illness and should

TABLE 117-3 Recommendations for Antibiotic Therapy

Pathogen	First-Line Agents	Alternative Agents
Enterotoxigenic (cholera-like) diarrhea		
<i>Vibrio cholerae</i> O1 or O139	Doxycycline 300 mg oral single dose; tetracycline 500 mg orally four times daily × 3 days; or trimethoprim-sulfamethoxazole DS tablet twice daily × 3 days; norfloxacin 400 mg orally twice daily × 3 days; or ciprofloxacin 500 mg orally twice daily × 3 days or 1 g orally single dose	Chloramphenicol 50 mg/kg IV every 6 hours, erythromycin 250–500 mg orally every 6–8 hours, and furazolidone
Enterotoxigenic <i>Escherichia coli</i>	Norfloxacin 400 mg or ciprofloxacin 500 mg orally twice daily × 3 days	Trimethoprim-sulfamethoxazole DS tablet every 12 hours
<i>Clostridium difficile</i>	Metronidazole 250 mg four times daily to 500 mg three times daily × 10 days	Vancomycin 125 mg orally four times daily × 10 days; bacitracin 20,000–25,000 units four times daily × 7–10 days
Invasive (dysentery-like) diarrhea		
<i>Shigella</i> species ^a	Trimethoprim-sulfamethoxazole DS twice daily × 3–5 days	Ofloxacin 300 mg, norfloxacin 400 mg, or ciprofloxacin 500 mg twice daily × 3 days, or nalidixic acid 1 g/day × 5 days; azithromycin 500 mg orally × 1, then 250 mg orally daily × 4 days
<i>Salmonella</i> Nontyphoidal ^a	Trimethoprim-sulfamethoxazole DS twice daily; ofloxacin 300 mg, norfloxacin 400 mg, or ciprofloxacin 500 mg twice daily × 5 days; or ceftriaxone 2 g IV daily or cefotaxime 2 g IV three times daily × 5 days	Azithromycin 1,000 mg orally × 1 day, followed by 500 mg orally once daily × 6 days
Enteric fever	Ciprofloxacin 500 mg orally twice daily × 3–14 days (ofloxacin and pefloxacin equally efficacious)	Azithromycin 1,000 mg orally × 1 day, followed by 500 mg daily × 5 days; or cefixime, cefotaxime, and cefuroxime; or chloramphenicol 500 mg four times daily orally or IV × 14 days
<i>Campylobacter</i> ^a	Erythromycin 500 mg orally twice daily × 5 days; azithromycin 1,000 mg orally × 1 day, followed by 500 mg daily or clarithromycin 500 mg orally twice daily	Ciprofloxacin 500 mg or norfloxacin 400 mg orally twice daily × 5 days
<i>Yersinia</i> species ^a	A combination therapy with doxycycline, aminoglycosides, trimethoprim-sulfamethoxazole, or fluoroquinolones	
Traveler's diarrhea		
Prophylaxis ^a	Norfloxacin 400 mg or ciprofloxacin 500 mg orally daily (in Asia, Africa, and South America); trimethoprim-sulfamethoxazole DS tablet orally daily (in Mexico)	Rifaximin 200 mg one to three times daily × 2 weeks
Treatment	Norfloxacin 400 mg or ciprofloxacin 500 mg orally twice daily × 3 days, or trimethoprim-sulfamethoxazole DS tablet orally twice daily × 3 days (in Mexico), or azithromycin 500 mg orally once daily × 3 days (only in areas of high prevalence of quinolone-resistant <i>Campylobacter</i> species, such as Thailand)	Rifaximin 200 mg three times a day or 400 mg twice a day × 3 days

^aFor high-risk patients only. See the preceding text for the high-risk patients in each infection.

be emphasized for caregivers and persons with diarrheal illnesses. Safe food handling and preparation practices can significantly decrease the incidence of certain types of enteric infections.

Reporting suspected outbreaks and cases of notifiable illness to local health authorities is vital in investigation of threats of enteric infection arising from increasingly global and industrialized food supplies. The reporting of specific infectious diseases to the appropriate public health authorities is the cornerstone of public health surveillance, outbreak detection, and prevention and control efforts.

Vaccines are used to boost specific immune processes directed against the bacteria themselves or against adherence appendages, cytotoxins, or enterotoxins. Unfortunately, there are only a few vaccines available for prevention of gastroenteritis. Currently available vaccines for typhoid fever are the parenteral Vi capsular polysaccharide vaccine and the oral live-attenuated Ty21a vaccine.¹⁹ Both vaccines have efficacy of 50% to 80%.³¹ A new rotavirus vaccine, RotaTeq, licensed in 2006, is intended for infants ages 6 weeks through 32 weeks. The three-dose regimen's efficacy is 74%.²⁰

PATIENT ASSESSMENT

Appropriate followup care of patients with acute diarrhea is based on successful restoration of fluid losses. The clinical signs and symptoms (see Table 117–1) that led to the diagnosis also can indicate adequate rehydration and should be assessed frequently. Because oral rehydration therapy is now preferred, routine labora-

tory testing often is unnecessary. Electrolytes should be measured in those receiving parenteral fluids, when oral replacement fails, or when signs of hypernatremia or hypokalemia are present. Followup stool samples to ensure complete evacuation of the infecting pathogen may be necessary only in patients who are at high risk to initiate or contribute to a community outbreak. All patients should be monitored for complications associated with the infecting pathogen, resolution of the diarrhea, and adverse reactions to the pharmacologic agents used. One panel suggests prompt discharge of hospitalized children when rehydration is achieved, IV fluids have not been required, oral intake equals or exceeds losses, or adequate family education and medical followup are ensured. For most patients, discharge can occur in 16 to 24 hours.

BACTERIAL INFECTIONS

Bacterial agents are important causes of GI infections, and syndromes caused by these pathogens are better understood than viral gastroenteritis. For a simple generalization, the bacterial pathogens presented in this section are divided into either those that cause watery (enterotoxigenic) diarrhea or those that cause dysentery (invasive diarrhea). Watery diarrhea is usually self-limiting, whereas those who present with dysenteric symptoms, such as fever, tenesmus, and blood and/or pus in the stool, require close monitoring and intensive follow-up. Table 117–4 lists the clinical signs and symptoms of these two broad categories.

TABLE 117-4 Acute Infectious Diarrhea Clinical Syndromes: Watery vs. Dysenteric

	Watery	Dysenteric
Percentage of patients	90	5–10
Stools		
Appearance	Watery	Bloody
Volume	Increased: ++/+++	Increased: +/-
Number per day	<10	>10
Reducing substances	0 to +++	0
pH	5.0–7.5	6.0–7.5
Occult blood	Negative	Positive
Fecal polymorphonuclear cells	Absent or few	Many
Mechanisms	Toxins Reduced absorption	Mucosal invasion
Complications		
Dehydration	Could be severe	Mild
Others	Acidosis, shock, electrolyte imbalance	Tenesmus, rectal prolapse, seizures
Etiology	Rotaviruses Enterotoxigenic <i>Escherichia coli</i> <i>Vibrio cholerae</i>	<i>Shigella</i> spp. <i>Campylobacter</i> spp. <i>Salmonella enteritidis</i>

From Guerrant et al.⁷ and Armon et al.⁸

ENTEROTOXIGENIC (CHOLERA-LIKE) DIARRHEA

Cholera (*Vibrio cholerae*)

Epidemiology Cholera has been endemic in the Ganges delta, West Bengal, Bangladesh, and southern Asia (including Southeast Asia) since at least 1817.²¹ A 1994 outbreak of a multidrug-resistant strain of cholera among Rwandan refugees resulted in more than 20,000 deaths. Cholera epidemics in 1991 and 1998 caused more than 1 million deaths in Latin America. As international travel has increased, cholera has also been reported in all major regions of the United States. However, the incidence, 1 case per 1 million persons, is extremely low.²²

V. cholerae O1 is the most common serogroup associated with epidemics and pandemics. Within this serogroup, there are two biotypes, classic and El Tor.²¹ In 1992, a new serogroup, *V. cholerae* O139 Bengal, appeared in India and spread rapidly through Southeast Asia. Four mechanisms for transmission have been proposed, including animal reservoirs, chronic carriers, asymptomatic or mild disease victims, and water reservoirs.

A relatively large inoculum of 10^3 to 10^6 organisms is required for infection if water is the vehicle and 10^2 to 10^4 if the vehicle is food. Approximately half the people infected with *V. cholerae* O1 are symptomatic, whereas only 1% to 5% of those infected with *V. cholerae* O139 manifest symptoms. The hallmark of cholera is the production of watery diarrhea, and severe dehydration may develop within a few hours, causing death within 24 hours. An estimated 25% to 50% of cases are fatal if left untreated. The prevention of cholera transmission depends on the provision of clean drinking water and public sanitation, which is difficult in impoverished developing countries.²¹

Pathogenesis *V. cholerae* is a gram-negative bacillus sharing similar characteristics with the family Enterobacteriaceae. Most pathology of cholera results from an enterotoxin (cholera toxin) produced by the bacteria.²¹ Conditions that reduce gastric acidity, such as the use of antacids, histamine receptor blockers, or proton pump inhibitors or infections with *Helicobacter pylori*, increase the risk for clinical disease. Cholera toxin stimulates adenylate cyclase, which increases intracellular cyclic adenosine monophosphate (cAMP) and results in inhibition of sodium and chloride absorption by microvilli and promotes the secretion of chloride and water by

crypt cells. The toxin likely acts along the entire intestinal tract, but most fluid loss occurs in the duodenum.²³ The net effect of the cholera toxin is isotonic fluid secretion (primarily in the small intestine) that exceeds the absorptive capacity of the intestinal tract (primarily the colon). This results in the production of watery diarrhea with electrolyte concentrations similar to that of plasma.

Clinical Presentation The average incubation period for *V. cholerae* infection is 1 to 3 days.²³ The clinical presentation can vary from asymptomatic to life-threatening dehydration owing to watery diarrhea. Patients may lose up to 1 L of isotonic fluid every hour. The onset of diarrhea is abrupt and is followed rapidly or sometimes preceded by vomiting. Fever occurs in less than 5% of patients, and the physical examination correlates well with the severity of dehydration. In some cases, fluid accumulates within the intestinal lumen causing abdominal distension and ileus and may cause intravascular depletion without diarrhea. In the most severe state, this disease can progress to death in 2 to 4 hours if not treated.

Laboratory abnormalities, such as increased packed red blood cell volume and total protein, magnesium, and calcium levels, are a result of hemoconcentration. Hypoglycemia, seizures, fever, and mental alterations are seen more often in children, perhaps as a reflection of the greater degree of dehydration and electrolyte losses observed with diarrhea in children.^{21,23} Other complications include metabolic acidosis, prerenal azotemia, iatrogenic water intoxication from overhydration, and aspiration pneumonia. Children, the elderly, and pregnant women are at an increased risk of complications caused by cholera.

TREATMENT

Cholera

Regardless of the serotypes, the primary goal of therapy is restoration of fluid and electrolyte losses caused by watery diarrhea. ORT is the preferred method of rehydration, and several studies showed reduction in fluid requirements by 32% to 35% when rice-based instead of glucose-based ORT solutions are used (50 to 80 g rice instead of 20 g glucose/L).²⁴ In patients who cannot tolerate ORT, IV Ringer lactate solution can be used. Normal saline is not recommended because it does not correct metabolic acidosis. After rehydration, maintenance fluid is given based on accurate recording of intake and output volumes.

Antibiotics shorten the duration of diarrhea, decrease fluid loss, and shorten the duration of the carrier state.²³ There appears to be substantial mobility in genetic elements encoding antibiotic resistance in *V. cholerae*, and the drug resistance patterns may change between outbreaks. For example, O139 strains isolated during 1992 and 1993 showed a trend toward increased resistance to trimethoprim-sulfamethoxazole, but those isolated in India during 1996 and 1997 showed susceptibility to the same agent.²³ A single dose of doxycycline is the preferred agent, especially in endemic areas, although it has been associated with prolonged fecal excretion of bacteria. In children younger than 7 years of age, trimethoprim-sulfamethoxazole, erythromycin, and furazolidone are preferred. In pregnant women, erythromycin or furazolidone can be used. In areas of high tetracycline resistance, fluoroquinolones such as ciprofloxacin are effective. Ciprofloxacin has been studied more extensively than other fluoroquinolones.²⁵

The manufacture of the only licensed whole-cell cholera vaccine in the United States has been discontinued. Two oral vaccines are available in other countries.²³ Dukoral consists of killed *V. cholerae* organisms and the cholera B subunit, and Orochol is an avirulent mutant of *V. cholerae* strain CVD103HgR. Both vaccines are effective in field trials and volunteer studies, but their cost-effectiveness

in endemic settings is uncertain. The World Health Organization does not require vaccination for international travel to or from endemic areas because the series of two injections is effective in only 50% of people and immunity wanes in 6 months or less.

Escherichia coli

Diarrheagenic *E. coli* is differentiated into several distinct categories based on pathogenic features of diarrheal disease: enterotoxigenic *E. coli* (ETEC), enteroinvasive *E. coli* (EIEC), enteropathogenic *E. coli* (EPEC), enteroaggregative *E. coli* (EAEC), and enterohemorrhagic *E. coli* (EHEC).²⁶ The most common diarrheagenic *E. coli* infection is caused by ETEC manifested by watery (enterotoxigenic) diarrhea. Dysentery is caused by EHEC. In this section, commonly known categories of diarrheagenic *E. coli* that cause watery diarrhea are discussed separately from EHEC that cause bloody diarrhea.²⁶

Epidemiology ETEC occurs most commonly, and accounts for about half of all cases of *E. coli* diarrhea. There are an estimated 79,420 cases in the United States each year.^{26,27} ETEC is the most common cause of traveler's diarrhea and a common cause of food- and water-associated outbreaks. Infections with EIEC and EPEC are primarily a disease of children in developing countries. EAEC strains are implicated in persistent diarrhea (≥ 14 days) in HIV-infected patients.

Recognized as a common and potentially deadly cause of infectious diarrhea, EHEC is believed to be the major etiologic factor responsible for the development of hemorrhagic colitis and HUS.²⁸ The CDC estimates the annual disease burden of *E. coli* O157:H7 in the United States to be more than 20,000 infections and as many as 250 deaths, but the failure of many clinical laboratories to screen for this organism greatly complicates any estimates. In the United States, serotype O157:H7 causes 50% to 80% of all EHEC infections, but in the southern hemisphere, such as Argentina, Australia, Chile, and South Africa, non-O157:H7 serotypes are often more important.²⁸ Transmission usually occurs via food and water, and outbreaks have been associated with undercooked ground beef and feces-contaminated vegetables.²⁸

Pathogenesis *E. coli* is a gram-negative bacillus commonly found in the human GI tract as well as in intestines of healthy cattle, deer, goats, and sheep. Enterotoxigenic *E. coli* are capable of producing either or both plasmid-mediated enterotoxins: heat-labile toxin and heat-stable toxin.²⁹ A cholera-like toxin, heat-labile toxin has two subunits (A and B) that have similar antigenic properties and action on the gut mucosa. The net effect is luminal accumulation of electrolytes that draws water into the intestine, and production of a cholera-like secretory diarrhea. Heat-stable toxin is nonantigenic and produces watery diarrhea by acting on the small intestine.²⁸

The mode of pathogenesis of the non-ETEC varieties is less-well understood. The hallmark histopathologic lesions of EPEC infections is the effacing of microvilli and intimate adherence between the bacterium and the epithelial cell membrane throughout the intestine. These attaching and effacing lesions disrupt the integrity of the intestinal epithelium, leading to diarrhea. EAEC adheres to intestinal mucosal cells by mucus production and deposition of bacteria in a bacterium-mucus biofilm. This persistent colonization of EAEC potentially leads to cytotoxic damage of intestinal cells, resulting in persistent diarrhea. EIEC closely resembles *Shigella* species and penetrates the intestinal mucosa; predominantly the lining of the large intestine. The resulting histological damage is inflammation and mucosal ulceration which are characteristic of bacillary dysentery.²⁶

The pathogenicity of EHEC is related to the production of shiga-like toxins, so named because of their resemblance to the shiga toxin of *Shigella dysenteriae*.²⁸ The cytotoxic effect of shiga-like toxins disrupts the mucosal integrity of the large intestine causing diar-

rrhea. In addition, the toxin is able to pass through the intestinal epithelium to reach the endothelial cells lining small blood vessels that supply the gut, kidney, and other viscera, causing the myriad metabolic events that eventually lead to HUS.

Clinical Presentation Nausea and watery stools, with or without abdominal cramping, are characteristic of the disease caused by ETEC.²⁶ Usually there is no blood or pus in the stool. Signs and symptoms depend directly on the extent of fluid loss, which in most cases is subclinical. Most ETEC diarrhea is typically abrupt in onset and resolves within 24 to 48 hours without complication. Common symptoms of EPEC infection include acute onset of profuse watery diarrhea, vomiting, and low-grade fever. The clinical features of EAEC diarrhea are characterized as persistent, watery, mucoid, secretory diarrhea with low-grade fever and little or no vomiting. EIEC infection presents most commonly as watery diarrhea, which can be indistinguishable from the secretory diarrhea seen with ETEC. However, in a minority of cases, patients experience the dysentery syndrome, manifested as blood, mucus, and leukocytes in the stool with tenesmus and fever.

Symptoms from EHEC infection can be severe, with as many as 11 to 12 bloody stools per day.²⁹ Initially EHEC infections typically manifest as cramping abdominal pain, abdominal distension, and watery diarrhea. Nausea occurs in about two-thirds of patients, and vomiting occurs in less than half. The white blood cell count is elevated and accompanied by a left shift, but patients often remain afebrile. Within 1 to 2 days the diarrhea becomes bloody with increased abdominal pain. The illness typically resolves in 1 week; however in approximately 2% to 7% of cases, particularly in children younger than 5 years of age and the elderly, the disease causes a complication termed HUS. This syndrome is defined by a triad of hemolytic anemia, thrombocytopenia, and renal failure. Death may occur rarely, usually as a result of HUS.²⁸

TREATMENT

***Escherichia coli* Diarrhea**

The cornerstone of management of all diarrheagenic *E. coli* infection is to prevent dehydration by correcting fluid and electrolyte imbalances. ORT is often lifesaving in infants and children.²⁷ Although antimicrobial prophylaxis with doxycycline, trimethoprim-sulfamethoxazole, or a fluoroquinolone is effective in preventing ETEC diarrhea, the growing problem of antibiotic resistance and the possibility of adverse effects from antimicrobial agents deter recommendations of prophylaxis. Instead, experts recommend avoiding risk factors while traveling. In addition, if significant disease occurs, bismuth subsalicylate and loperamide are effective in decreasing the severity of ETEC diarrhea, and empirical antibiotics shorten the duration of the disease.³⁰ Fluoroquinolones (e.g., ciprofloxacin, norfloxacin, and ofloxacin) are the most commonly recommended agents owing to increasing antimicrobial resistance among other drug classes.

CLINICAL CONTROVERSY

Loperamide should not be used in patients with fever or dysentery because antimotility agents are contraindicated in the management of diarrhea caused by EHEC. There is evidence that the use of such agents can increase the risk for development of HUS, possibly by delaying intestinal clearance of the organism and thereby increasing toxin absorption.

The use of antibiotics remains controversial in EHEC infection.³¹ Their use may be harmful because of lysis of bacteria leading to

increased release of toxin and alteration of normal intracolonic bacterial flora, thereby increasing the systemic absorption of the toxin. Treatment of EHEC infection is primarily limited to supportive care, which may include dialysis, hemofiltration, transfusion of packed erythrocytes, platelet infusions, and other interventions as indicated clinically.²⁹ Severe disease may cause chronic kidney failure and require renal transplant.

Pseudomembranous Colitis (*Clostridium difficile*)

Epidemiology Pseudomembranous colitis (PMC) was first reported in 1893 and was associated with antibiotic therapy in 1955. Although described in the preantibiotic era, the incidence increasingly has been associated with antibiotic administration. *C. difficile* is thought to be the cause in 10% to 20% of patients experiencing antibiotic-associated diarrhea, in 50% to 75% of those with antibiotic-associated colitis, and in greater than 90% of those with antibiotic-associated PMC.³² It is also the most common cause of nosocomial diarrhea, infecting 16% to 20% of inpatients, one-third of whom are symptomatic.³³

The incidence of intestinal colonization is variable, ranging from 30% to 70% in infants to 3% to 5% in healthy adults.³² The relationship between the colonized state and active disease is poorly understood. Many people are colonized with the bacteria yet do not go on to develop PMC. It occurs most often in high-risk groups, such as the elderly, debilitated patients, cancer patients, surgical patients, patients receiving antibiotics, patients with nasogastric tubes, and patients who frequently use laxatives.³³ PMC is associated with use of broad-spectrum antimicrobials, including clindamycin, ampicillin, and third-generation cephalosporins.³² Other agents that have been implicated, albeit at a lower incidence rate, include aminoglycosides, erythromycin, fluoroquinolones, trimethoprim-sulfamethoxazole, and, surprisingly, vancomycin and metronidazole, two of the most commonly used antimicrobials for treatment of *C. difficile*.³²

Pathogenesis *C. difficile* is a gram-positive spore-forming anaerobic bacillus and causes a toxin-mediated disease. Once antibiotics disrupt normal colonic flora and colonization of *C. difficile* occurs, two toxins (A and B) are released to mediate diarrhea and colitis. This toxin production is essential in disease manifestation. Toxin A is the major pathogenic factor and has been characterized as an enterotoxin that causes intestinal fluid secretion, mucosal injury, and inflammation through actin disaggregation, intracellular calcium release, and damage to neurons. Toxin B is a nonenterotoxic cytotoxin that causes depolymerization of filamentous actin and mediates more potent damage to human colonic mucosa than toxin A. Initially, raised white and yellowish plaques form, and the surrounding mucosa may be inflamed. With progression of disease, these pseudomembranous plaques become enlarged and scattered over the colorectal mucosa.³⁴

Clinical Presentation *C. difficile* infection may cause a spectrum of disease from mild antibiotic-associated diarrhea to pseudomembranous enterocolitis.³⁴ In colitis without pseudomembrane formation, patients present with malaise, abdominal pain, nausea, anorexia, watery diarrhea, low-grade fever, and leukocytosis. PMC is characterized by more severe illness, with severe abdominal pain, profuse diarrhea, high fever, marked leukocytosis, and classic pseudomembrane formation evident with sigmoidoscopic examination. Symptoms can start a few days after the start of antibiotic therapy or several weeks after antibiotics have been discontinued.

C. difficile infection should be suspected in patients experiencing diarrhea with a recent history of antibiotic use (within the previous 2 months) or in those whose diarrhea began 72 hours after hospitalization. Diagnosis can be established by detection of toxin A or B, stool culture for *C. difficile*, or endoscopy. If the stool sample is negative, a second analysis is recommended because the testing

sensitivity may be increased with repeat testing. Endoscopy should be reserved for situations where rapid diagnosis is needed, ileus is present, a stool is not available, or other colonic diseases are in the differential diagnosis.³⁵

TREATMENT

Pseudomembranous Colitis

Initial therapy should include discontinuation of the offending agent with a change to an alternative antibiotic if possible.³² Fluid and electrolyte replacement therapy is necessary. Although diarrhea will resolve in 15% to 23% of patients without therapy, most patients require antibiotics. Both vancomycin and metronidazole are effective, but metronidazole 250 mg orally four times daily is the drug of choice.³² It is similar to vancomycin in time to resolution of diarrhea, incidence of side effects, and relapse rates. However, it is less expensive than vancomycin, and the concern for vancomycin resistance promotes metronidazole use.

Oral vancomycin 125 mg four times daily is second-line therapy. Its use is appropriate in the following situations: the patient has not responded to oral metronidazole; the organism is resistant to metronidazole; the patient is allergic or intolerant to metronidazole; treatment includes ethanol-containing solutions; the patient is either pregnant or younger than 10 years of age; the patient is critically ill because of *C. difficile* diarrhea or colitis; and there is evidence suggesting that the diarrhea is caused by *S. aureus*.³² The duration of diarrhea is reduced to 3 versus 4.6 days with metronidazole. Vancomycin must be administered orally because IV vancomycin does not achieve gut lumen concentrations high enough for effective bacterial elimination.

Bacitracin is third-line treatment. In resolving symptoms, 80,000 units of bacitracin orally daily is as effective as vancomycin but is not as effective in eradicating the organism. Bacitracin's poor taste, which reduces patient adherence, limits its use.³⁵ Teicoplanin and fusidic acid have been effective in resolving symptoms and eradicating the organism.³⁵

Relapse after antibiotic treatment occurs in approximately 20% to 25% of patients and does not appear to be influenced by the choice of initial therapy, dose of drug used, or duration of treatment.³² Recurrences occur because of the persistence of the spore forms of *C. difficile* that are not killed by antibiotic therapy or reinfection by a new strain. Recurrences usually occur 3 to 21 days after antibiotics are stopped. Retreatment with metronidazole or vancomycin at the previous dose for 10 to 14 days generally is successful. The addition of rifampin to vancomycin also has been effective.³²

CLINICAL CONTROVERSY

Some investigators have found prophylaxis with competing, nonpathogenic organisms such as *Lactobacillus* spp. or *Saccharomyces* spp. to be helpful in preventing relapse in small numbers of patients.³⁶ It is thought that these organisms help to restore the natural flora in the gut and make patients more resistant to colonization by *C. difficile*.

Vancomycin has been used in combination with anion-exchange resins dosed to avoid drug-resin binding, and this has been used successfully in a small number of cases.³⁵ Cholestyramine 4 g orally three to four times daily and colestipol 5 g orally twice daily have been used as alternatives to antibiotics in mild cases.

Drugs that inhibit peristalsis, such as diphenoxylate, are contraindicated in PMC.³² Slowing of fecal transit time is thought to result in extended toxin-associated damage. Strict handwashing and con-

tact precautions are imperative measures in preventing the spread of the organism. *C. difficile* can be cultured in rooms of infected individuals up to 40 days after discharge.³⁵

INVASIVE (DYSENTERY-LIKE) DIARRHEA

Bacillary Dysentery (Shigellosis)

Epidemiology Approximately 450,000 cases of shigellosis occur in the United States and 165 million cases occur in the world annually, resulting in more than 1 million deaths worldwide each year.³⁷ Shigellosis is primarily a disease of children, with the highest incidence in children between the ages of 6 months and 5 years. Only a third of all cases occur in adults. Most cases result from fecal–oral transmission. A few well-documented food- and water-associated outbreaks have been reported. Peak incidence in the United States is in late summer.

The shigellae have worldwide distribution, with regional differences in prevalence of subgroups responsible for disease. Four species most often associated with disease are *S. dysenteriae* type I, *Shigella flexneri*, *Shigella boydii*, and *Shigella sonnei*.³⁷ In the United States, the common causes of shigellosis are *S. sonnei* and *S. flexneri*. Cases caused by other shigellae are successfully acquired during travel to developing countries. Because of overuse of antibiotics in human and animal feed, Southeast Asia and India have higher levels of resistance. Poor sanitation, poor personal hygiene, inadequate water supply, malnutrition, and increased population density are associated with an increased risk of *Shigella* gastroenteritis epidemics, even in developed countries.

Pathogenesis The shigellae are gram-negative bacilli belonging to the family Enterobacteriaceae. Ingestion of as few as 10 to 200 viable organisms of the *Shigella* species causes disease in healthy adults, explaining the ease with which the disease is transmitted from person to person.³⁸ The bacteria multiply and spread within the submucosa of the small bowel, but they rarely extend beyond the mucosa. Penetration of the mucosa is conferred genetically by large “invasion plasmids” and results in distortion of the crypts, death to intestinal epithelium, causing focal ulceration, sloughing of mucosal cells, bloody mucoid exudate into the gut lumen, and submucosal accumulation of inflammatory cells with microabscess formation.³⁹ Microabscesses eventually may coalesce, forming larger abscesses. Infection frequently involves the entire colon. In addition to the virulence characteristics of invasiveness, *S. dysenteriae* type 1 and, to lesser degree, *S. flexneri* and *S. sonnei* produce a cytotoxin, or shiga toxin, the pathogenic role of which is unclear, although it is thought to damage endothelial cells of the lamina propria, resulting in microangiopathic changes that can progress to HUS.⁴⁰

Clinical Presentation Initial signs and symptoms include abdominal pain, cramping, and fever followed by frequent watery stools.⁴¹ Within a few days, patients experience a decrease in fever, severe abdominal pain, and tenderness prior to the development of bloody diarrhea and other signs of dysentery (see Table 117–4). Stools are often greenish in color and contain leukocytes. Fluid and electrolyte losses may be significant, particularly in infants and elderly patients. In the early stages of the disease, stool cultures are positive. A rapid diagnostic test kit that uses DNA amplification by the polymerase chain reaction is also available.

If left untreated, bacillary dysentery usually lasts about 1 week (range: 1 to 30 days). Complications are unusual but may include severe dehydration, generalized seizures, septicemia, toxic megacolon, perforated colon, arthritis, protein-losing enteropathy, and HUS. Mortality is rare, but it may be more likely with *S. dysenteriae* type I. Less than 3% of persons who are infected with *S. flexneri* will later develop Reiter syndrome, characterized by pains in the joints,

irritation of the eyes, and painful urination. This can lead to chronic arthritis.⁴²

TREATMENT

Bacillary Dysentery (Shigellosis)

Shigellosis is usually a self-limiting disease. Most patients recover in 4 to 7 days, although 10% may experience a recurrence. Oral fluid and electrolyte replacement is the foundation of treatment (dysentery is not generally associated with significant fluid loss). However, intravenous fluid replacement therapy may be necessary, especially in children and the elderly.

Owing to the self-limiting nature of the illness and rapid development of antimicrobial resistance on completion of therapy, antibiotic treatment is reserved for the elderly and infirm, those who are immunocompromised, children in daycare centers, malnourished children, and healthcare workers. Antibiotics shorten the period of fecal shedding and attenuate the clinical illness. The choice of agent depends on location (see Table 117–3). For infections acquired in the United States, the agent of choice is trimethoprim-sulfamethoxazole (only 4% resistance). For infections acquired outside the United States, the agents of choice are ciprofloxacin, norfloxacin, and azithromycin.¹⁶

Antimotility agents such as diphenoxylate are not recommended because they can worsen bacillary dysentery and could be involved in the development of toxic dilatation of the colon. Oral vaccines currently in development contain attenuated strains of *Shigella* and provide protection against shigellosis in human challenges.⁴³

Salmonellosis

Epidemiology *Salmonella* species are gram-negative bacilli belonging to the family Enterobacteriaceae. As a result of DNA hybridization experiments, the classification and nomenclature of *Salmonella* spp. have been changing, causing much confusion.⁴⁴ Owing to a high degree of DNA similarity, all important *Salmonella* isolates have been classified into a single species, *Salmonella enterica*, with approximately 2,500 different serotypes. Because various serotypes were known formally as species, it has been acceptable to refer to serotypes as species. For example *S. enterica* serotype Typhi is commonly referred to as *Salmonella typhi*.

Specific *Salmonella* serotypes produce characteristic human disease.⁴⁵ *S. enterica* serotypes Typhimurium or Enteritidis causes gastroenteritis, whereas serotypes Typhi or Paratyphi causes enteric fever. Clinical manifestations produced by *Salmonella* serotypes commonly include acute gastroenteritis (enterocolitis), bacteremia, extraintestinal localized infection, enteric fever (typhoid and paratyphoid fever), and a chronic carrier state.

In the United States, approximately 1.4 million cases of salmonellosis, 16,000 hospitalizations, and 600 deaths occur annually.⁴ There is decreasing incidence in rates of salmonellosis in the United States, which is believed to be a result of improved food-handling practices and water treatment. Salmonellosis is a disease primarily of infants, children, and adolescents. Children younger than 5 years of age account for approximately 25% of all diagnosed cases.¹⁷ Conditions that may predispose to infection include those which decrease gastric acidity, antibiotic use, malnutrition, and immunodeficiency states. Contaminated food or water has been implicated in the majority of cases. Direct fecal–oral transmission occurs less frequently but is particularly important in children. Foods most often implicated in human salmonellosis are poultry, poultry products, beef, pork, and dairy products. Pets, particularly reptiles, are a common source of infection.

Pathogenesis The incubation period, symptoms, and disease severity depend on the amount of organism ingested. The inoculum necessary for infection is estimated to less than 1,000 organisms, and this

infectious dose is lowered in patients with achlorhydria (gastric pH >4.0). If the organisms survive the gastric acid barrier, mucosal invasion of the small intestine begins.⁴⁶ After penetration, microorganisms translocate to the intestinal lymphoid follicles and the draining mesenteric lymph nodes, in addition to the reticuloendothelial cells of the liver and spleen. Thereafter, the ability of organisms to survive and multiply within the mononuclear phagocytic cells of the lymphoid follicles, liver, and spleen plays an instrumental role in the pathogenesis. In the asymptomatic phase, the organisms are sequestered intracellularly. Once the critical number of organisms has been reached, bacteria are released into the bloodstream, and the symptoms of enteric fever are manifested. This dissemination of organisms via bloodstream also causes secondary infection in the liver, spleen, bone marrow, gallbladder, and Peyer patches of the terminal ileum. After several weeks of infection, recruitment of mononuclear cells and lymphocytes induced by *Salmonella* is thought to be responsible for necrosis of Peyer patches and the abdominal pain observed in enteric fever.⁴⁶

The mechanism by which nontyphoidal salmonellae cause enterocolitis is less-well understood. Although a number of enterotoxins have been described in salmonellae, their role remains illusive.⁴⁷ Some salmonellae, such as *S. enterica* serotype Choleraesuis, which is the most invasive, are frequently associated with bacteremia and metastatic localization, whereas others seldom cause disease. Enterocolitis often is characterized by massive neutrophil infiltration into both the large and small bowel mucosa. The serotypes that are responsible for human illness cause intestinal epithelial cells to secrete interleukin 8, a potent neutrophil chemotactic factor. Degranulation and release of toxic substances by neutrophils may contribute to inflammation and result in tissue damage, fluid secretion, or leakage across the intestinal mucosa.

Clinical Presentation Enterocolitis. Most patients experience symptoms within 72 hours of ingestion of contaminated food or water.⁴⁷ Patients often complain of nausea and vomiting followed by abdominal cramps, headache, fever, and diarrhea, although the actual presentation is quite variable. Some patients do not have increased stool frequency, whereas others have more than 1 stool per hour. Stools generally are loose and may be mucoid or bloody (dysentery-like) or both. Febrile episodes usually range between 37.7°C and 38.8°C (100°F and 102°F) but may be higher. Some evidence suggests that fever of 40°C (104°F) or higher is associated with shorter bacterial excretion.⁴⁸ Diarrhea and fever usually resolve spontaneously within 1 to 5 days but may last 2 weeks.

Stool cultures inevitably yield the causative organism if obtained early (i.e., in patients hospitalized less than 3 days).⁷ Recovery of organisms continues to decrease with time so that by 3 to 4 weeks, only 5% to 15% of adult patients are passing *Salmonella*. Infants and children tend to pass bacteria for longer periods than adults. Some patients may continue to shed *Salmonella* for a year or longer. These “chronic carrier” states are rare for serotypes other than Typhi.⁴⁶

Bacteremia. Salmonellae can produce bacteremia without classic enterocolitis or enteric fever. Bacteremia rarely occurs in older adults, but it can occur in up to 40% of infants.⁴⁹ It is also reported more frequently in persons with severe underlying illness or immunosuppression, including AIDS. The clinical syndrome is characterized by persistent bacteremia and prolonged intermittent fever with chills. Stool cultures frequently are negative. This clinical syndrome is most frequent with serotype Choleraesuis infections (50%). Leukocyte counts are often within the normal range.

Localized Infections. Localized infections develop in 5% to 10% of patients with bacteremia.⁴⁷ Extraluminal infection or abscess formation or both can occur at any site. They may follow any of the other syndromes, or they may be the primary presentation. Metastatic infections involve bone, cysts, heart, kidney, liver, lungs, pericardium, spleen, and tumors. The clinical presentation usually

is determined by the organ systems involved. Polymorphonuclear leukocyte counts often are elevated.

Enteric Fever (Typhoid and Paratyphoid). Enteric fever caused by serotype Typhi is called typhoid fever.⁴⁶ If caused by any other serotype, it is referred to as paratyphoid fever. The clinical presentations of typhoid fever and paratyphoid fever generally are indistinguishable, although paratyphoid fever tends to be less severe than typhoid fever. The incubation period can range from 10 to 14 days. The onset of symptoms is gradual. Nonspecific symptoms of fever, dull headache, malaise, anorexia, and myalgia are most common. Initially, fever tends to be remittent, but it progresses gradually over the first week to temperatures that are often sustained higher than 40°C (104°F). Other frequently encountered symptoms include chills, nausea, vomiting, cough, weakness, and sore throat. Symptoms subside slowly within 4 weeks.

Physical examination generally reveals an acutely ill patient. An erythematous maculopapular rash known as *rose spots* appears primarily on the abdomen in 15% to 50% of patients. The abdomen also may be tender, particularly in the lower quadrants. Hepatomegaly, splenomegaly, or both also may be present in 50% of the cases, and cervical lymph nodes may be enlarged.

A normochromic anemia may develop rapidly without evidence of GI blood loss, although intestinal bleeding may be contributory. Leukopenia may be reflective of a relative decrease in polymorphonuclear leukocytes. White blood cell counts may range from 1,200 to 20,000 cells/mm³. As many as one-third of the patients have elevated levels of the liver enzymes glutamic-oxaloacetic transaminase and alkaline phosphatase in serum. Approximately 80% of patients have positive blood cultures. Bacteremia persists in about a third of cases for several weeks if not treated. Intestinal perforation, intestinal hemorrhage, thrombophlebitis, toxemia with circulatory collapse, encephalopathy, and pneumonia all contribute to a fatality rate of 1% to 2%. Without treatment, mortality may be 10%.⁴⁶

TREATMENT

Salmonellosis

■ ENTEROCOLITIS

Fluid and electrolyte replacement is the primary mode of treatment. Most patients respond well to ORT (self-limited illness).⁴⁷ Antimotility drugs should be avoided because they increase the risk of mucosal invasion and complications. Antibiotic therapy is not indicated in healthy adults. Antibiotics have no effect on the duration of fever or diarrhea, and their frequent use increases the likelihood of resistance and the duration of fecal shedding. Antibiotics should be used in (a) neonates or infants younger than 6 months of age because young children have an increased risk of complicated infection, (b) patients with primary or secondary immunodeficiency such as AIDS or chemotherapy patients, (c) severely symptomatic patients with fever and bloody diarrhea, and (d) patients after splenectomy.⁴⁷ Susceptibility testing is recommended because many drug-resistant strains of *Salmonella* have emerged. Recommended antibiotics include the fluoroquinolones, trimethoprim-sulfamethoxazole, ampicillin, and third-generation cephalosporins. If susceptibility results are not available, a fluoroquinolone or third-generation cephalosporins should be instituted owing to resistance with trimethoprim-sulfamethoxazole and ampicillin. Azithromycin and aztreonam also have been studied and may be used as alternative agents.

■ BACTEREMIA AND LOCALIZED INFECTIONS

Owing to increasing resistance, empirical therapy for life-threatening bacteremia or focal infections following nontyphoidal *Salmonella*

infection should include both a third-generation cephalosporin (such as ceftriaxone 2 g IV daily) and a fluoroquinolone (ciprofloxacin 500 mg orally twice daily) until the susceptibilities are known.⁴⁹ The duration of antibiotic therapy is dictated by the site of infection. Bacteremia without endovascular infection should be treated for 7 to 14 days. In documented or suspected endovascular infection, 6 weeks of intravenous therapy with ampicillin or ceftriaxone is recommended. Chloramphenicol is no longer recommended in patients with endovascular infection owing to high rates of failure.

■ ENTERIC FEVER (TYPHOID AND PARATYPHOID)

Antibiotic choice is dictated by susceptibility testing.⁴⁶ Fluoroquinolones are the drugs of choice for the treatment of enteric fever.⁵⁰ A short course of 3 to 5 days is effective in uncomplicated enteric fever, but a minimum of 10 days is recommended in severe cases. In patients who are infected with fluoroquinolone-susceptible *S. enterica* serotype Typhi, the average time for defervescence is less than 4 days, and the cure rates exceed 96%, with fewer than 2% of treated patients having persistent fecal carriage or relapse. Unfortunately, fluoroquinolone resistance is increasing in some areas, and these strains are also often multidrug-resistant, limiting the choice of antibiotics. Among patients with fluoroquinolone-resistant *S. enterica* serotype Typhi infection, fluoroquinolones still can be used but at the maximal possible dose for a minimum of 10 to 14 days. These patients should be monitored carefully to determine whether they are excreting the organism in their feces. High-dose fluoroquinolone regimens have been successful in 90% to 95% of patients with multidrug-resistant infection.⁵¹ However, the average time to defervescence is 7 days, and the rate of fecal carriage during convalescence can be as high as 20%.

The third-generation cephalosporins (e.g., ceftriaxone, cefixime, cefotaxime, and cefoperazone) and azithromycin are also effective drugs for typhoid. Chloramphenicol, amoxicillin, and trimethoprim-sulfamethoxazole remain appropriate for the treatment of typhoid fever in areas of the world where the bacterium is still fully susceptible to these drugs and where the fluoroquinolones are not available or affordable.⁴⁶ Although fluoroquinolones are not recommended in children, the pediatric use of ciprofloxacin in areas where multidrug-resistant *S. typhi* occurs is acceptable. In pregnant women, the β -lactam antibiotics are safe, and there are some case reports to support fluoroquinolone use.

Adults and children with severe enteric fever characterized by delirium, obtundation, stupor, coma, or shock benefit from prompt administration of dexamethasone 1 mg/kg every 6 hours for 24 to 48 hours.⁵² Two vaccines against *S. typhi* are licensed in the United States: an orally administered vaccine (Ty21a, Vivotif Berna) and a parenteral polysaccharide vaccine (ViCPS, Typhim Vi).¹⁹ The efficacy of these vaccines ranges from 42% to 77%, and immunity persists for 3 to 5 years. The Ty21a and Vi vaccines are recommended for travelers to areas of endemic disease and those in high-risk groups, including household contacts of *S. typhi* carriers, laboratory technicians with repeated exposure, and sanitation workers in endemic areas. Because the Ty21a vaccine is a live-attenuated vaccine, it should not be administered to immunocompromised persons, patients taking antibiotics, or patients with gastroenteritis.

■ "CHRONIC CARRIERS" OF *SALMONELLA*

"Chronic carriers" of *Salmonella* usually have negative stool cultures at 12 weeks after the onset of illness, but some may have continued positive stool cultures at 6 to 12 months. Chronic fecal shedding of *Salmonella* has been associated with chronic biliary infection and cholelithiasis. To alleviate the chronic carrier state, the drug of choice is norfloxacin 400 mg orally twice daily for 28 days. In addition, amoxicillin and trimethoprim-sulfamethoxazole are effective

in eradicating the bacteria in greater than 80% of cases after 6 weeks of therapy.¹⁷ Chronic carriers should take preventative measures (i.e., antibiotics and hygiene) so that they do not serve as reservoirs of infection to the community.

Campylobacteriosis

Epidemiology The *Campylobacter* spp. are flagellated, curved, gram-negative rods that are thought to be one of the most common bacterial causes of diarrheal illnesses worldwide. Although there are 14 different species, *C. jejuni* is the species responsible for more than 99% of *Campylobacter*-associated gastroenteritis.⁵³ In the United States, the incidence of *Campylobacter* infection decreased 26% from 1996 to 1999. However, surveillance studies indicate that *Campylobacter* spp. remain the most commonly isolated enteric pathogen, detected two to seven times more frequently than *Salmonella* or *Shigella*.⁵³ Currently, the CDC estimates that 2.4 million persons are affected each year in the United States, involving almost 1% of the entire population.

In developed countries, the peak incidence of *Campylobacter* infections occurs in children younger than 1 year of age and in young adults 15 to 44 years of age. The incidence is also higher in males than in females, although the reason for this is unknown. Patients with AIDS are particularly susceptible; the incidence in AIDS patients is 40 times that of the general population.⁵³ Most reported cases occur during the summer months, beginning in May and peaking in August. In tropical developing countries, *Campylobacter* infections are common among children younger than 2 years of age, and asymptomatic infections of children and adults are more common than those seen in industrialized nations. This decrease in the case-to-infection ratio suggests that previous exposure confers immunity to the infecting strain.

The transmission of infection occurs primarily by ingestion of contaminated food or water. Although *Campylobacter* spp. have varied reservoirs, such as livestock, dogs, cats, and birds, the consumption of chicken is the major vector of infections in industrialized nations.⁵⁴ Poultry products are nearly always contaminated with *Campylobacter* spp. during the slaughtering process, and it is estimated that 1 drop of chicken juice may contain 500 infectious organisms. Although public education emphasizes safe handling and cooking of chicken, it is easy to see how simple errors may result in human illness.

Pathogenesis *Campylobacter* spp. are labile in acidic environments, much like *Salmonella*. Therefore, an inoculum of approximately 800 organisms is required to initiate infection. Conditions in the upper small intestine are favorable for multiplication. Flagella-mediated adherence and tissue invasion by bacteria have been demonstrated in the jejunum, ileum, and colon. Infection results in an acute inflammatory enteritis. *C. jejuni* can produce an enterotoxin or cytotoxin.⁵⁵ Both cytotoxins and enterotoxins may be produced in many strains. Symptom manifestation depends on immunity. Patients infected with *Campylobacter* develop specific immunoglobulin (Ig) G, IgM, and IgA antibodies in serum and IgA antibodies in intestinal secretions. Volunteer studies indicate that immunity does protect against illness.

Clinical Presentation The average incubation period of *Campylobacter* is 2 to 4 days.⁵³ The most common presenting symptoms include diarrhea, abdominal pain, and fever. Nausea, vomiting, headache, myalgia, and malaise also may occur. Bowel movements may be numerous, bloody (dysentery-like), and foul smelling, and range from loose to watery. Cramping and abdominal pain usually are relieved by defecation. In 75% of cases, leukocytes and red blood cells are detected in the stool samples. Peripheral leukocytosis also may be present. The disease usually is self-limited to about 1 week, but it may persist for several weeks in 10% to 20% of patients. The case-fatality rate is 0.05 per 1,000 infections.

Complications, including pseudoappendicitis, pancreatitis, gastrointestinal hemorrhage, thrombophlebitis, abscess, septicemia, peritonitis, empyema, urinary tract infection, and cholecystitis, are uncommon, but occur more frequently in those who are immunocompromised. *C. jejuni* has been associated with Guillain-Barré syndrome (GBS), but the relationship is not well understood.⁵⁶ *C. jejuni* infections are a common trigger of GBS, accounting for approximately 30% of GBS cases, but the risk of developing GBS after *C. jejuni* infection appears to be low (<1 case of GBS per 1,000 *C. jejuni* infections). A reactive arthritis may develop several weeks after infection in persons with the HLA-B27 histocompatibility antigens.⁴² Diagnosis is made by stool culture, but the bacteria sometimes are identifiable with Gram stain or carbol-fuchsin stain.

TREATMENT

Campylobacteriosis

The primary treatment of campylobacteriosis is oral fluid and electrolyte replacement.⁵³ Most people recover from this self-limiting disease in 4 to 7 days. Antibiotics are *not* useful unless started within 4 days of the start of the illness because they do not shorten the duration or severity of diarrhea but only shorten the duration of bacterial excretion. However, antibiotics are warranted in patients who present with high fevers, severe bloody diarrhea, prolonged illnesses (>1 week), pregnancy, and immunocompromised states, including HIV infection (see Table 117–3).

C. jejuni is susceptible to a wide variety of antimicrobial agents.⁵³ Fluoroquinolone resistance has increased to 10% to 13% in the United States (41% to 88% in Europe and Asia) in recent years, and may be a result of the use of quinolone antibiotics in poultry feed and their frequent use overseas in treating enteric infections. Erythromycin is considered the drug of choice owing to its low cost, high efficacy, safety profile, and ease of administration. Newer macrolides such as clarithromycin and azithromycin are equally effective. Tetracycline, chloramphenicol, clindamycin, and aminoglycosides may be effective.⁵³ Antimotility agents such as loperamide are contraindicated because slowing fecal transit time may extend the duration of infection and increase toxin mucosal invasion.

Yersiniosis

Yersinia spp. are non-lactose-fermenting gram-negative coccobacilli that are widely distributed in nature. The genus *Yersinia* includes six species known to cause disease in humans. *Y. enterocolitica* and, to lesser extent, *Yersinia pseudotuberculosis* are most likely associated with intestinal infection, but overall, both are a relatively infrequent cause of diarrhea and abdominal pain. More than 50 serotypes of *Y. enterocolitica* exist; of these, serotypes 0:3, 0:8, and 0:9 are associated most frequently with enterocolitis.⁵⁷ Infections are reported commonly from northern Europe, and the peak incidence occurs during the winter months.

Children are most likely to experience illness with *Y. enterocolitica* infection.⁵⁸ Transmission of infection occurs frequently by ingestion of contaminated food or water. The organisms have been isolated from a variety of food sources, including pigs and raw goat and cow milk. Refrigeration does not deter the development of adherence and invasive virulence factors.

Y. enterocolitica invade the intestinal epithelium and penetrate the intestinal mucosa.⁵⁹ An inoculum of 10⁹ organisms may be required for infection. Most strains produce an enterotoxin, but the role of toxin production in causing diarrhea is not well established. However, this infection causes mucosal ulcerations in the terminal ileum, necrotic lesions in Peyer patches, and enlargement of mesenteric lymph nodes.

Clinical Presentation These bacteria cause a wide spectrum of clinical syndromes.⁵⁸ Most patients with *Y. enterocolitica* infection present with enterocolitis that is mild and self-limiting. Symptoms include vomiting, abdominal pain, diarrhea, and fever; up to 60% of patients will have blood-streaked stools. Diarrhea resolves after 1 to 3 weeks, but bacteria excretion may continue for up to 3 months after diarrhea subsides. Most patients with this type of infection are younger than 5 years of age. In older children and adolescents, mesenteric adenitis and/or terminal ileitis with fever, right lower quadrant pain, and leukocytosis are common. Mesenteric adenitis, which is difficult to distinguish from acute appendicitis, is also seen in patients infected with *Y. pseudotuberculosis*.

Approximately 10% to 30% of adult patients develop a reactive arthritis 1 to 2 weeks after recovery from enteritis. This arthritis, involving the knees, ankles, toes, fingers, and wrists, usually resolves in 1 to 4 months but may persist in approximately 10% of patients.⁴² This complication is more common in persons with the HLA-B27 antigen. Other postinfection complications include erythema nodosum, exudative pharyngitis, pneumonia, empyema, and lung abscess. Although rare, *Y. enterocolitica* bacteremia has been reported in patients with diabetes mellitus, severe anemia, hemochromatosis, cirrhosis, and malignancy. Other groups at risk include the elderly and those who received frequent red blood cell transfusions (iron overload).⁶⁰ These patients are at increased risk for hepatic or splenic abscesses, peritonitis, septic arthritis, osteomyelitis, wound infections, meningitis, and endocarditis.

TREATMENT

Yersiniosis

Oral fluid and electrolyte replacement is an important initial approach. Owing to the self-limiting nature of the illness, antibiotics may not alter the time to resolution of the diarrhea or the rate of bacteriologic cure. Antibiotics should be used in high-risk patients who develop bacteremia (i.e., infants younger than 3 months of age and patients with cirrhosis or iron overload) or in patients with bone and joint infections.⁵⁸

Drugs of choice are not yet identified. Fluoroquinolones alone or in combination with third-generation cephalosporins or aminoglycosides may be effective for *Yersinia* bacteremia or for those with bone and joint infections.⁵⁸ Other antibiotics effective in vitro are chloramphenicol, tetracyclines, and trimethoprim-sulfamethoxazole. Agents frequently resistant to *Yersinia* are penicillin G, ampicillin, and first-generation cephalosporins.

ACUTE VIRAL GASTROENTERITIS

Acute viral gastroenteritis was unknown until the 1970s. Viruses are now recognized as the leading cause of diarrhea in the world, although in many cases an exact pathogen cannot be determined. In Asia, Africa, and Latin America, viral gastroenteritis accounts for an estimated 3 to 5 billion cases and is associated with 5 to 10 million deaths.⁸² Viruses that cause gastroenteritis include rotavirus, calicivirus, enteric adenovirus, and astrovirus. Other viruses, such as toroviruses, coronaviruses, picobirnaviruses, and pestiviruses, are being identified increasingly as causative agents of diarrhea.

ROTAVIRUSES

Epidemiology

Rotavirus is the most common cause of diarrhea in infants and children worldwide, and 1 million people die annually from the

infection. In the United States, approximately 3.5 million cases of diarrhea, 500,000 physician visits, 50,000 hospitalizations, and 20 deaths occur each year in children younger than 5 years of age.⁶² Serologic surveys show that nearly all children are infected by age 5 years, but dehydrating diarrhea occurs primarily among young children ages 3 to 35 months during their initial infection.⁶³ Thereafter, they are shielded from severity of subsequent infection. In fact, after the initial infection with rotavirus, 40% of children are protected against subsequent infection, 75% are protected against subsequent gastroenteritis, and up to 88% are protected against severe gastroenteritis. Unfortunately, both immunocompromised children and adults are at increased risk for severe, prolonged, and even fatal rotavirus gastroenteritis. The fecal–oral route is thought to be the most common mode of transmission. In the United States, rotavirus infection rates peak from November to May each year.

Pathogenesis

Rotaviruses are double-stranded, wheel-shaped, RNA viruses. The outermost layer contain two structural viral proteins. The protease-cleaved protein (P protein) VP4 and the glycoprotein (G protein) VP7 define the serotype of the virus and are the basis for vaccine development. Once ingested, these strains cause diarrhea by inducing changes in transepithelial fluid balance, malabsorption as a consequence of destruction of epithelial lining of intestine, and vacular damage and ischemia of villi. Changes to the villi include shortening of villus height, crypt hyperplasia, and mononuclear cell infiltration of the lamina propria.⁶⁴

Clinical Presentation

The incubation period of rotavirus infection is typically 1 to 3 days.⁶⁵ Clinical manifestations vary from asymptomatic (which is common in adults) to severe nausea, vomiting, and diarrhea with dehydration. Because the first infection tends to be the most severe, dehydration and electrolyte disturbances occur more frequently in children. The symptoms begin abruptly, with vomiting often preceding the onset of diarrhea. Fever is present in a third of patients. Other signs and symptoms include respiratory symptoms, irritability, lethargy, pharyngeal erythema, rhinitis, red tympanic membranes, and palpable cervical lymph nodes. These gastrointestinal symptoms resolve in 3 to 7 days.

Laboratory findings reflect the degree of vomiting, diarrhea, or both. Transient rises in liver enzymes may be seen in 60% of children hospitalized for rotavirus diarrhea. The white blood cell count is usually normal. Stools rarely contain blood or leukocytes. Rotavirus detection in stool samples is possible with an enzyme immunoassay and a latex agglutination assay, both of which are available commercially.

TREATMENT

Rotavirus Infection

Oral fluid and electrolyte replacement is the cornerstone of treatment.⁶⁶ Oral *Lactobacillus* therapy may reduce the duration of diarrhea and of viral excretion. There is no role for antibiotics in acute infection. Bismuth subsalicylate, although shown to decrease the duration of diarrhea and stool output, is not recommended for routine use because of the self-limiting nature of the disease and the risk of bismuth subsalicylate overdose. Antimotility agents are not recommended because they do not decrease the duration or volume of diarrhea.

The first vaccine (RotaShield) to prevent rotavirus infection was licensed for use in the United States in 1998, but it was withdrawn

after 1 year because of an increased rate of idiopathic intussusception.⁶⁷ Postlicensure surveillance found that the risk for intussusception was the highest within 3 to 14 days after receipt of the first dose, which was estimated to be 1 case per 10,000 vaccine recipients.⁶⁸ There was also a suggestion that the risk was age-dependent, and possibly infants younger than 3 months were in less danger than older ones.

In 2006, a live, oral vaccine (RotaTeq) received its licensure in United States. This is a pentavalent vaccine that contains five reassortant rotaviruses.²⁰ Because these viral strains are derived by inserting the gene encoding capsid protein from G1, G2, G3, or G4 human rotavirus strain into a bovine rotavirus backbone, they contain segmented genome from different parents and are referred to as *reassortant rotaviruses*. Four reassortant rotavirus express one of the outer capsid proteins, G types (G1 to G4), and the fifth expresses the attachment protein, P1A. Therefore, this vaccine provides protection against the serotypes G1, G2, G3, and G4 when administered as a three-dose series to infants between the ages of 6 and 32 weeks. After completion of a three-dose regimen, the vaccine offered protection against any rotavirus infection of 74% and severe gastroenteritis of 98%.⁶⁸ This oral vaccine decreased office visits because of rotavirus infection by 86%, emergency department visits by 94%, and hospitalizations by 96%. Moreover, the vaccinated children showed similar cases of intussusception as nonvaccinated children (six cases versus five cases; adjusted relative risk of 1.6; confidence interval [CI] = 0.4 to 6.4). Other serious side effects, including deaths, were similar among vaccine and placebo recipients. There were small but significantly greater rates of vomiting, diarrhea, nasopharyngitis, otitis media, and bronchospasm among vaccine recipients. Concurrent administration of this rotavirus vaccine did not diminish the immune responses of other vaccines, diphtheria, tetanus toxoids, and acellular pertussis (DTaP), *Haemophilus influenzae* type b vaccine, inactivated poliovirus vaccine, hepatitis B vaccine, and pneumococcal conjugate vaccine.

Another rotavirus vaccine, RotaRix, has completed clinical trials and received licensure in many Latin America countries. A trial of this monovalent vaccine, based on an attenuated human rotavirus strain of P1A G1 specificity, in approximately 60,000 infants, has shown a clinical efficacy of 85% against severe rotavirus disease, and no increase in intussusception among vaccine recipients.⁶⁹

CALICIVIRUSES

The human caliciviruses are assigned to two genera, Norovirus and Sapovirus, responsible for gastroenteritis. The Norovirus causes illness in all age groups, whereas Sapovirus causes illness mainly in children.⁷⁰ Although the relative importance of these viruses as causes of GI infections is unknown, Noroviruses are important causes of outbreaks. The Norwalk virus was the first of norovirus to be described in 1972 in Norwalk, Ohio.

As with most viruses, the epidemiology of the norovirus is not well understood. The disease commonly affects children and adults, but it is not often associated with disease in neonates and preschool children.⁸⁰ Outbreaks occur throughout the year and have been documented in families, healthcare systems, cruise ships, and college dormitories. Noroviruses are often spread from person to person. Other vectors of transmission include contaminated water supplies, fecal–oral spread, and food-borne outbreaks. Almost any food that has come in contact with contaminated water can serve as a vehicle for an outbreak. A major source of food-borne gastroenteritis is contamination of shellfish beds from raw sewage dumped into the water supply.

The pathophysiology of this disease is similar to that caused by the rotavirus. Human volunteer studies show histopathologic changes in the jejunum within 24 hours of viral challenge, and

clinical manifestations appear within 48 hours.⁷⁰ The exact mechanisms of virus-induced vomiting or diarrhea are unknown. Brush-border enzyme activity may be decreased, resulting in lactose intolerance, but it generally returns to preinfection levels within 2 weeks. Virus shedding in the stool can occur over the first 24 to 48 hours after illness.

Gastroenteritis caused by norovirus is characterized by sudden onset of abdominal cramps with nausea, vomiting, or both.⁷¹ Although adults frequently experience nonbloody diarrhea, and children experience vomiting more often than diarrhea. Other complaints are myalgia, headache, and malaise, which are accompanied by fever in approximately 50% of patients. Signs and symptoms generally last 12 to 48 hours.⁷¹

The disease is generally self-limiting. Oral fluid and electrolyte replacement should be used, if necessary.⁷¹ A norovirus vaccine produced via expression of viral antigens in plants is under investigation, but the clinical availability of such a product is several years in the future.

ASTROVIRUSES

Astroviruses increasingly are being recognized as important causes of gastroenteritis. Astroviral illness is often reported in children younger than 3 years of age, but it also been described in adults and elderly.⁷² Astroviruses have been detected in the stools of children, as well as in patients with immunodeficiency conditions such as HIV infection or bone marrow transplantation. Transmission is suspected to occur via the fecal–oral route. Outbreaks have been reported in schools, daycare settings, and pediatric wards. The pathogenesis of astroviral infection is believed to be similar to that noted for rotavirus. The clinical presentation consists of diarrhea, headache, malaise, nausea, and to lesser extent, vomiting. These symptoms appear to be similar to those observed with rotavirus but milder. The incubation period is estimated to be 3 to 4 days, and the disease is usually self-limiting within 5 days. Maintenance of adequate hydration and electrolyte balance is the only therapeutic issue. The duration of viral shedding may be as long as 35 days.⁷³

ENTERIC ADENOVIRUS

Adenovirus is an icosahedral virus previously associated with respiratory, ocular, and genitourinary infections; however, serotypes 40 and 41 are GI pathogens. The peak incidence is in children younger than 2 years of age, and infections occur year-round. Transmission is primarily person to person and fecal–oral, and viral shedding from the gut may occur for extended periods. The incubation time is 8 to 10 days. Diarrhea and vomiting often last 1 to 2 weeks. Low-grade fever and respiratory symptoms are also common.⁷⁴ The diagnosis can be made by enzyme immunoassay that identifies serotypes.

OTHER POTENTIAL VIRAL PATHOGENS

Although less-commonly associated with severe GI disease, pestivirus, torovirus, and coronavirus-like particles have been recovered from diarrheal stools. In HIV-infected patients, the presence of diarrhea is associated with virus in 35% of stool specimens. Astrovirus, picobirnavirus, calicivirus, and adenovirus appear to be the most commonly isolated viral pathogens.⁷⁵ Table 117–5 presents specific characteristics of these agents.

TRAVELER'S DIARRHEA

Traveler's diarrhea describes the clinical syndrome manifested by malaise, anorexia, and abdominal cramps followed by the sudden onset of diarrhea that incapacitates many travelers.⁷⁶ Traveler's diarrhea interferes with planned activities or work in 30% of those affected, accounting for unknown but substantial direct and indirect lost dollars because of decreased productivity.⁷⁷ In particular, an increased risk lies with North Americans and northern Europeans traveling to Latin America, southern Europe, Africa, and Asia. The highest risk is observed with patients with immunocompromised conditions, achlorhydria, or inflammatory bowel disease, and people taking diuretics, digoxin, lithium, or insulin (because of the need for appropriate hydration). Overall, an estimated 20% to 50% of people traveling to high-risk areas will develop the illness.

5 The onset of symptoms usually occurs during the first week of travel but can occur anytime during the visit or after returning home.⁷⁶ Traveler's diarrhea is caused by contaminated food or water. Foods at high risk for contamination include raw or undercooked meat and seafood and raw fruits and vegetables. Tap water, ice, and unpasteurized milk and dairy products are also associated with increased risk. The most common pathogens are bacterial in nature and include ETEC (20% to 72%), *Shigella* (3% to 25%), *Campylobacter* (3% to 17%), and *Salmonella* (3% to 7%).⁷⁶ Viruses (0% to 30%) are also potential causes, as are parasites, although they are rare during short-term travels, accounting for less than 5% of cases. The severity of the syndrome is determined by the number of stools per day and the presence or absence of cramping, nausea, and vomiting. Mild diarrhea is defined as 1 to 4 loose stools per day that are associated with abdominal cramps lasting less than 14 days. Moderate diarrhea indicates more than 4 loose stools daily associated with dehydration and severe diarrhea is defined as presence of fever or blood in stools. Traveler's diarrhea is rarely life-threatening and in most cases, symptoms resolve in 1 to 2 days without treatment. Travelers to high-risk areas should pack a kit that includes a thermometer, loperamide, 3 days of antibiotics (see Prevention below), oral rehydration solution salts, and a water purification method.⁷⁸

TABLE 117-5 Agents Responsible for Acute Viral Gastroenteritis and Diarrhea

Virus	Peak Age of Onset	Time of Year	Duration	Mode of Transmission	Symptoms
Rotavirus	6 mo–2 y	October to April	3–8 days	Fecal–oral, water, food	Vomiting, diarrhea, fever, abdominal pain, lactose intolerance
Enteric adenovirus	<2 y	Year-round	7–9 days	Fecal–oral	Diarrhea, respiratory symptoms, vomiting, fever
Calicivirus	3 mo–6 y	Peak in winter	4 days	Fecal–oral, water, shellfish	Vomiting, diarrhea
Astrovirus	<7 y	Winter	1–4 days	Fecal–oral, water, shellfish	Vomiting, diarrhea, fever, abdominal pain
Pestivirus	<2 y	NR	3 days	NR	Mild
Coronavirus-like particles	<2 y	Fall and early winter	7 days	NR	Respiratory disease
Enterovirus	NR	NR	NR	NR	Mild diarrhea, secondary organ damage
Norwalk	>5 y	Variable	12–24 h	Fecal–oral, food, aerosol	Nausea, vomiting, diarrhea, abdominal cramps, headache, fever, chills, myalgia

NR, not reported.

PREVENTION

6 Patient education in avoiding high-risk food and beverages is the best method for minimizing the risk. High-risk foods and beverages include moist foods served at room temperature, fruit that cannot be peeled, milk from a questionable source, hot sauces on the table, tap water, unsealed bottle water, iced drinks, and food from a street vendor. Slogans such as “Peel it, boil it, cook it, or forget it” remind travelers to avoid contaminated food and to use water purification or reliable bottled beverages.⁷⁸ These measures can decrease the risk to less than 15%, even in endemic areas.

Bismuth subsalicylate 524 mg (2 tablets, caplets, tablespoonfuls) orally four times daily for up to 3 weeks is a commonly recommended prophylactic regimen.⁷⁹ Bismuth subsalicylate may inhibit enterotoxin activity and prevent diarrhea. Persons taking this regimen should be informed of adverse events, including temporary black discoloration of tongue and stools, and, rarely, tinnitus.

Although efficacy of prophylactic antibiotics have been documented, their uses are discouraged owing to the increased risk of selection of drug-resistant organisms, side effects of antibiotics (e.g., photosensitivity), and possible acquisition of more severe infections. Prophylactic antibiotics (see Table 117–3) are recommended only in high-risk individuals or in situations in which short-term illness could ruin the purpose of the trip, such as a military mission.⁷⁶

A nonabsorbed oral rifamycin, rifaximin, has activity against enteric pathogens and may have a role in prevention of traveler’s diarrhea. A randomized, double-blind trial of rifaximin 200 mg once, twice, or three times daily with meals for 2 weeks resulted in equal protection of 72% with each of the three dosing regimens compared to placebo.⁸⁰ Notably, rifaximin did not alter colonic flora and coliform or enterococcal antimicrobial susceptibility patterns. Consequently, chemoprophylaxis with rifaximin may be beneficial in high-risk individuals with underlying medical conditions or those on tight schedules where short-term illness could ruin the purpose of the trip. Rifaximin has a tolerability and safety profile comparable to that of placebo.

TREATMENT

Traveler’s Diarrhea

Fluid and electrolyte replacement should be initiated at the onset of diarrhea. (ORT generally is not required in otherwise healthy individuals; flavored mineral water offers a good source of sodium and glucose.⁷⁶) For symptom relief, loperamide (preferred because of its quicker onset and longer duration of relief relative to bismuth) should be taken (4 mg orally initially and then 2 mg with each subsequent loose stool to a maximum of 16 mg/day in patients without bloody diarrhea and discontinued if symptoms persist for more than 48 hours). Other symptomatic therapy includes bismuth subsalicylate 525 mg every 30 minutes up to 8 doses.

Antibiotics (see Table 117–3) are recommended in addition to loperamide in travelers who develop three or more loose stools in an 8-hour period, especially with nausea, vomiting, abdominal cramps, fever, or blood in stools. Currently, the drug of choice is a fluoroquinolone usually given for 3 to 5 days.⁷⁶ In clinical trials, 3 days of antibiotic therapy is as effective as 5 days, and some studies indicate that single-dose treatment may be effective in most cases.^{81,82} In pregnant women and children younger than 16 years of age, a combination of trimethoprim-sulfamethoxazole and erythromycin has been suggested. Macrolides are the drugs of choice only in areas of high prevalence of *Campylobacter* species resistant to quinolones, such as Thailand.

Rifaximin was as effective as a 3-day course of ciprofloxacin in shortening the duration of diarrhea in noninvasive traveler’s diar-

reha.⁸³ However, rifaximin was not as effective in patients with fever and bloody diarrhea and in those with invasive pathogens. Therefore, rifaximin 200 mg three times a day for 3 days has been approved for the treatment of traveler’s diarrhea caused by noninvasive strains of *E. coli*. A dosage of 400 mg two times per day for 3 days has also been shown to be effective.⁸⁴

FOOD POISONING

7 Food poisoning results from the ingestion of food containing pathogenic microorganisms, preformed toxins that were produced by microorganisms, or other toxic compounds. In the United States, food-borne disease causes approximately 76 million illnesses, 325,000 hospitalizations, and 5,200 deaths each year.⁴ Food-borne transmission may account for up to 35% of acute gastroenteritis cases caused by unknown agents. A number of bacteria can cause food poisoning (Table 117–6). Common bacterial (*Campylobacter*, *Salmonella*, *Shigella*, *E. coli*, *Yersinia*, *Vibrio*) and viral (Norovirus) causes of GI infections were discussed in the preceding sections. Other common food-borne pathogens that cause gastroenteritis include *S. aureus*, *Bacillus cereus*, *C. perfringens*, and *Clostridium botulinum*. Unfortunately, sporadic illnesses caused by these agents are not reportable through passive or active systems, and thus it is difficult to determine their disease burden.

Because food-borne disease can appear as sporadic cases or outbreaks, the diagnosis should be suspected whenever two or more people present with acute gastrointestinal or neurologic manifestations after sharing a meal within the previous 72 hours. Important clues about etiologic agents can be gathered from demographic information (age, gender, etc.), the clinical syndrome, incubation period, medical history, type of foods consumed, seasonality, and geographic location of the outbreak.

Staphylococcal food poisoning results from the ingestion of food contaminated by an enterotoxin produced by certain strains of *S. aureus* growing within the food.⁸⁵ Enterotoxin production generally results from leaving foods at room temperature, allowing the staphylococci to grow. Symptoms are rapid in onset, generally occurring within 1 to 6 hours of ingestion of preformed toxin-containing foods. The condition is characterized by nausea and vomiting (75%), although abdominal cramps and diarrhea also may be present. Symptoms resolve in less than 12 hours. ORT should be provided in severe cases, but antibiotics are not indicated.

B. cereus causes two different types of clinical syndromes.⁸⁶ The first one is characterized by a short incubation period with vomiting, abdominal cramps, and to a lesser extent, diarrhea within 1 to 6 hours of ingestion of contaminated food. This syndrome is caused by a preformed heat-stable toxin. Similar to staphylococcal food poisoning, illnesses caused by *B. cereus* usually last less than 12 hours. The second syndrome has a longer incubation period (8 to 16 hours) and is caused by toxins produced in vivo after the ingestion of contaminated food. In this syndrome, patients experience diarrhea, abdominal cramps, and less frequently, vomiting. The heat-labile enterotoxin produced in this syndrome activates intestinal adenylate cyclase and causes intestinal fluid secretion. This illness usually resolves within 24 hours, but symptom durations of several days to weeks also have been observed.

Food-borne *C. perfringens* infection may present as two distinct syndromes.⁸⁷ Type A organisms are seen in Western nations and result in a 24-hour illness characterized by watery diarrhea and epigastric pain. Symptoms generally resolve within 24 hours. This enterotoxin-related syndrome damages the brush borders of epithelial cells at the villus tips to cause a noninflammatory diarrhea. Type C organisms can be found in undercooked pork and occur in underdeveloped tropical regions. Type C organisms can produce a toxin-related syndrome called *enteritis necroticans*, which is a coag-

TABLE 117-6 Food Poisonings

Organism	Time to Symptoms (h)	Principal Foods	Peak Incidence (U.S.)	Principal Mechanism of Pathophysiology	Duration	Treatment
<i>Staphylococcus aureus</i>	1–6	Salad, pastries, ham, poultry	Summer	Preformed toxins A–E (heat stable)	12 h	Supportive
<i>Bacillus cereus</i>	1–6	Meats, vegetables, fried rice	None	Preformed toxin	12 h	Supportive
<i>Clostridium perfringens</i> (type A)	8–16	Meats, poultry	Fall, winter, spring	Toxin production (in vivo)	24 h	Supportive
	6–24			Toxin production (in vivo)	24 h	Supportive
<i>Vibrio parahaemolyticus</i>	16–72	Shellfish	Spring, summer, fall	Toxin production and tissue invasion	2–7 days	Supportive
<i>Salmonella</i> spp.	16–48	Beef, poultry, water, eggs, dairy products	Summer	Tissue invasion	2–7 days	Supportive
<i>Shigella</i> spp.	16–48	Salad, water	Summer	Tissue invasion	2–7 days	Supportive
EPEC	16–48	Water	None	Tissue invasion	2–7 days	Supportive
<i>Campylobacter</i>	16–48	Poultry, dairy products, clams, water	Spring, summer	Tissue invasion	2–7 days	Supportive
ETEC	16–72	Water	None	Toxin production (in vivo)	1–7 days	Supportive
<i>Vibrio cholerae</i>	16–72	Water		Toxin production (in vivo)	2–12 days	Supportive, antibiotics
<i>Yersinia enterocolitica</i>	16–48	Dairy products		Toxin production and/or tissue invasion	1–30 days	Supportive
<i>Clostridium botulinum</i>	12–72	Canned fruits, vegetables, meats, honey	None	Preformed toxins A, B, and E (children and adults) Toxin production (in vivo) (infants)		Supportive (including mechanically assisted ventilation), trivalent antitoxin

EPEC, enteropathogenic *E. coli*; ETEC, enterotoxigenic *E. coli*.

ulative transmural necrosis of the intestinal wall. This syndrome can result in intestinal perforation leading to sepsis and mortality in approximately 40% of victims.

Food-borne botulism results from the ingestion of food contaminated with preformed toxins or toxin-producing spores from *C. botulinum*. *C. botulinum* poisoning is relatively rare; only 110 cases are reported per year in the United States. Botulism is almost always associated with improper preparation or storage of food. Seven distinct toxins (A to G) have been described. The toxins, which are produced by the bacteria and released on lysis, are the most potent biologic or chemical toxins known to humans. The toxin prevents the release of acetylcholine at the peripheral cholinergic nerve terminal. Toxin activity has prompted the use of minute locally injected doses to treat select spastic disorders, such as blepharospasm, hemifacial spasm, and certain dystonias.⁸⁸

Food-borne botulism is suspected when patients present with acute GI symptoms concurrently or just prior to the onset of a symmetric descending paralysis without sensory or central nervous system involvement. Symptoms usually begin 18 to 24 hours after ingestion and progress over days to weeks. Other symptoms can include blurred vision, photophobia (90%), dysphagia (76%), generalized weakness (58%), nausea and vomiting (56%), and dysphonia (55%). Diagnosis is made by culturing *C. botulinum* from the stool.⁸⁹ Guillain-Barré syndrome associated with *C. jejuni* infection has been a common differential diagnosis in patients who present with these symptoms. The difference lies in the onset of neurologic symptoms, which typically occur 1 to 3 weeks after the onset of *C. jejuni* infection, and the condition usually is manifested by an ascending paralysis in *C. jejuni*-associated Guillain-Barré syndrome.⁵⁶

Treatment consists primarily of respiratory support and use of botulinum antitoxin.⁹⁰ Respiratory failure may occur prior to involvement of other upper muscle groups. If evaluation is performed within several hours of ingestion, gastric lavage or induction of vomiting is suggested. Cathartics and enemas also can be used to remove residual toxin from the bowel, but they are contraindicated in cases of ileus. Although the effectiveness of antitoxins is unknown, patients diagnosed with botulism should receive botulinum antitoxin. Botulinum antitoxin is a concentrated preparation

of equine globulins obtained from horses immunized with toxins A, B, and E. Because trivalent antitoxin is equine in origin, patients should be tested for hypersensitivity before receiving the product intravenously. Other agents used experimentally as adjunctive therapy are guanidine, which antagonizes the effect of botulinum toxin at the neuromuscular junction, and 4-aminopyridine, which increases acetylcholine release.⁹¹ Newer and more effective methods of treatment and prevention are under development, including a botulinum toxin vaccine consisting of nontoxic botulinum fragments. Prevention always should be stressed. Botulinum toxins are heat labile and readily destroyed by 10 minutes of boiling. All home-canned foods should be processed according to directions and boiled, not just warmed, prior to consumption.

In food-borne illnesses, the cornerstone of therapy remains supportive care. ORT is preferred in replenishing and maintaining fluid and electrolyte balance, and intravenous fluid therapy should be reserved for those who are severely ill and cannot tolerate oral therapy. Antiemetics and antiperistaltic agents offer symptomatic relief, but the latter should not be given in patients who present with high fever, bloody diarrhea, or fecal leukocytes. Antimicrobial therapy is not effective in the management of *S. aureus*, *C. perfringens*, or *B. cereus* food poisonings. In developed countries, many of the food-borne illness can be prevented with proper food selection, preparation, and storage. However, in developing countries, sanitation and clean water supply are larger concerns.

JOSEPH T. DIPIRO AND THOMAS R. HOWDIESHELL

KEY CONCEPTS

- 1 Most intraabdominal infections are “secondary” infections that are polymicrobial and are caused by a defect in the gastrointestinal tract that must be treated by surgical drainage, resection, and/or repair.
- 2 Primary peritonitis generally is caused by a single organism (*Staphylococcus aureus* in patients undergoing chronic ambulatory peritoneal dialysis [CAPD] or *Escherichia coli* in patients with cirrhosis).
- 3 Secondary intraabdominal infections usually are caused by a mixture of bacteria including enteric gram-negative bacilli and anaerobes, which enhances the pathogenic potential of the bacteria.
- 4 For peritonitis, early and aggressive intravenous fluid resuscitation and electrolyte replacement therapy are essential. A common cause of early death is hypovolemic shock caused by inadequate intravascular volume and tissue perfusion.
- 5 Cultures of secondary intraabdominal infection sites generally are not useful for directing antimicrobial therapy. Treatment generally is initiated on a “presumptive” or empirical basis.
- 6 Antimicrobial regimens for secondary intraabdominal infections should include coverage for enteric gram-negative bacilli and anaerobes. Antimicrobials that may be used for the treatment of secondary intraabdominal infections include (a) a β -lactam- β -lactamase inhibitor combination (such as piperacillin-tazobactam), (b) a carbapenem (imipenem or meropenem), (c) quinolone (ciprofloxacin) plus metronidazole, or an aminoglycoside (gentamicin) plus clindamycin (or metronidazole).
- 7 Treatment of primary peritonitis for CAPD patients should include an antistaphylococcal antimicrobial such as a first-generation cephalosporin (cefazolin) or vancomycin (usually given by the intraperitoneal route).
- 8 The duration of antimicrobial treatment should be for a total of 5 to 7 days for most secondary intraabdominal infections.
- 9 Patients treated for intraabdominal infections should be assessed for the occurrence of drug-related adverse effects, particularly hypersensitivity reactions (β -lactam antimicrobials), diarrhea (most agents), fungal infections (most agents), and nephrotoxicity (aminoglycosides).

Intraabdominal infections are those contained within the peritoneal cavity or retroperitoneal space. The peritoneal cavity extends from the undersurface of the diaphragm to the floor of the pelvis and contains the stomach, small bowel, large bowel, liver, gallbladder, and spleen. The duodenum, pancreas, kidneys, adrenal glands, great vessels (aorta and vena cava), and most mesenteric vascular structures reside in the retroperitoneum. Intraabdominal infections may be generalized or localized. They may be contained within visceral structures, such as the liver, gallbladder, spleen, pancreas, kidney, or female reproductive organs. Two general types of intraabdominal infection are discussed throughout this chapter: peritonitis and abscess. *Peritonitis* is defined as the acute inflammatory response of the peritoneal lining to microorganisms, chemicals, irradiation, or foreign-body injury. This chapter deals only with peritonitis of infectious origin.

An *abscess* is a purulent collection of fluid separated from surrounding tissue by a wall consisting of inflammatory cells and adjacent organs. It usually contains necrotic debris, bacteria, and inflammatory cells. These processes differ considerably in presentation and approach to treatment.

EPIDEMIOLOGY

Peritonitis may be classified as primary, secondary, or tertiary.¹⁻³ Primary peritonitis, also called *spontaneous bacterial peritonitis*, is an infection of the peritoneal cavity without an evident source in the abdomen. Bacteria may be transported from the bloodstream to the peritoneal cavity, where the inflammatory process begins. In secondary peritonitis, a focal disease process is evident within the abdomen. Secondary peritonitis may involve perforation of the gastrointestinal (GI) tract (possibly because of ulceration, ischemia, or obstruction), postoperative peritonitis, or posttraumatic peritonitis (blunt or penetrating trauma). Tertiary peritonitis occurs in critically ill patients and is infection that persists or recurs at least 48 hours after apparently adequate management of primary or secondary peritonitis.

1 Primary peritonitis develops in up to 10 to 30% of patients with alcoholic cirrhosis.⁴ Patients undergoing chronic ambulatory peritoneal dialysis (CAPD) average one episode of peritonitis every 2 years.⁵ Epidemiologic data for secondary and tertiary intraabdominal infections are limited. Secondary peritonitis may be caused by perforation of a peptic ulcer; traumatic perforation of the stomach, small or large bowel, uterus, or urinary bladder; appendicitis; pancreatitis; diverticulitis; bowel infarction; inflammatory bowel disease, cholecystitis; operative contamination of the peritoneum; or diseases of the female genital tract, such as septic abortion, postoperative uterine infection, endometritis, and salpingitis. Appendicitis is one of the most common causes of intraabdominal infection. In 1998, 278,000 appendectomies were performed in the United States for suspected appendicitis.⁶

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

TABLE 118-1 Primary Bacterial Peritonitis

Primary bacterial peritonitis

Peritoneal dialysis
Cirrhosis with ascites
Nephrotic syndrome

Secondary bacterial peritonitis

Miscellaneous causes
Diverticulitis
Appendicitis
Inflammatory bowel diseases
Salpingitis
Biliary tract infections
Necrotizing pancreatitis
Neoplasms
Intestinal obstruction
Perforation
Mechanical gastrointestinal problems
Any cause of small bowel obstruction (adhesions, hernia)
Vascular causes
Mesenteric arterial or venous occlusion (atrial fibrillation)
Mesenteric ischemia without occlusion
Trauma
Blunt abdominal trauma with rupture of intestine
Penetrating abdominal trauma
Iatrogenic intestinal perforation (endoscopy)
Intraoperative events
Peritoneal contamination during abdominal operation
Leakage from gastrointestinal anastomosis

ETIOLOGY

Primary peritonitis in adults occurs most commonly in association with alcoholic cirrhosis, especially in its end stage, or with ascites caused by postnecrotic cirrhosis, chronic active hepatitis, acute viral hepatitis, congestive heart failure, malignancy, systemic lupus erythematosus, or nephritic syndrome. It also may result from the use of a peritoneal catheter for dialysis or central nervous system ventriculoperitoneal shunting for hydrocephalus. Rarely, primary peritonitis occurs without apparent underlying disease.

Table 118-1 summarizes many of the potential causes of bacterial peritonitis. Causes include inflammatory processes of the GI tract or abdominal organs, bowel obstruction, vascular occlusions that may lead to gangrene of the intestines, and neoplasia that may cause intestinal perforation or obstruction. Other possible causes include those resulting from traumatic injuries or postoperative infections.

Abscesses are the result of chronic inflammation and may occur without preceding generalized peritonitis. They may be located within one of the spaces of the peritoneal cavity or within one of the visceral organs, and may range from a few milliliters to a liter or more in volume. These collections often have a fibrinous capsule and may take from a few weeks to years to form.

The causes of intraabdominal abscess overlap those of peritonitis and, in fact, may occur sequentially or simultaneously. Appendicitis

is the most frequent cause of abscess. Other potential causes of intraabdominal abscess include pancreatitis, diverticulitis, lesions of the biliary tract, genitourinary tract infections, perforating tumors in the abdomen, trauma, and leaking intestinal anastomoses. In addition, pelvic inflammatory disease in women may lead to tuboovarian abscess. For some diseases, such as appendicitis and diverticulitis, abscesses occur more frequently than generalized peritonitis.

MICROFLORA OF THE GASTROINTESTINAL TRACT AND FEMALE GENITAL TRACT

A full appreciation of intraabdominal infection requires an understanding of the normal microflora within the GI tract. There are striking differences in bacterial species and concentrations of flora within the various segments of the GI tract (Table 118-2), and this bacterial environment usually determines the severity of infectious processes in the abdomen. Generally, the low gastric pH eradicates bacteria that enter the stomach. With achlorhydria, bacterial counts may rise to 10^5 to 10^7 organisms/mL. The normally low bacterial count also may increase by 1,000- or 10,000-fold with gastric outlet obstruction, hemorrhage, gastric cancer, and in patients receiving histamine 2 (H_2)-receptor antagonists, proton pump inhibitors, or antacids.

The biliary tract (gallbladder and bile ducts) is sterile in most healthy individuals, but in people older than 70 years of age, those with acute cholecystitis, jaundice, or common bile duct stones, it is likely to be colonized by aerobic gram-negative bacilli (particularly *Escherichia coli* and *Klebsiella* spp.) and enterococci.⁷ Patients with biliary tract bacterial colonization are at greater risk of intraabdominal infection.

In the distal ileum, bacterial counts of aerobes and anaerobes are quite high. In the colon, there may be 500 to 600 different types of bacteria in stool, with concentrations often reaching 10^{11} organisms/mL and anaerobic bacteria outnumbering aerobic bacteria by more than 1,000 to 1.² In fact, up to 50% of the dry mass of stool is bacteria. Fortunately, most colonic bacteria are not pathogens because they cannot survive in environments outside the colon. Perforation of the colon results in the release of large numbers of anaerobic and aerobic bacteria into the peritoneum. The colonic flora generally are consistent unless broad-spectrum antimicrobials have been used, in which case there are increases in *Candida* or gram-negative bacteria.

The lower female genital tract generally is colonized by a large number of aerobic and anaerobic bacteria. Anaerobes may number 10^9 organisms per milliliter and often include lactobacilli, eubacteria, clostridia, anaerobic streptococci, and, less frequently, *Bacteroides fragilis*. Aerobic bacteria most often are streptococci and *Staphylococcus epidermidis*, and these may number 10^8 organisms per milliliter.

PATHOPHYSIOLOGY

Intraabdominal infection results from bacterial entry into the peritoneal or retroperitoneal spaces or from bacterial collections within intraabdominal organs. In primary peritonitis, bacteria may enter

TABLE 118-2 Usual Microflora of the Gastrointestinal Tract

Site	Commonly Found Bacteria	Approximate Concentration (Log No. Organisms/mL)	
		Aerobes	Anaerobes
Stomach ^a	<i>Streptococcus</i> , <i>Lactobacillus</i>	10–100	Rare
Biliary tract	Normally sterile (<i>Escherichia coli</i> , <i>Klebsiella</i> , or enterococci in some patients)	0	0
Proximal small bowel	<i>Streptococcus</i> (including enterococci), <i>E. coli</i> , <i>Klebsiella</i> , <i>Lactobacillus</i> , diphtheroids	100	Few
Distal ileum	<i>E. coli</i> , <i>Klebsiella</i> , <i>Enterobacter</i> , enterococci, <i>Bacteroides fragilis</i> , <i>Clostridium</i> , peptostreptococci	10^4 – 10^6	10^5 – 10^7
Colon	<i>Bacteroides</i> spp., peptostreptococci, <i>Clostridium</i> , <i>E. coli</i> , <i>Klebsiella</i> , enterococci, <i>Enterobacter</i> , and many others	10^5 – 10^8	10^9 – 10^{11}

^aWith achlorhydria, H_2 -antagonist therapy, gastric cancer, or gastric outlet obstruction, bacterial counts may rise to 10^5 /mL.

the abdomen via the bloodstream or the lymphatic system by transmigration through the bowel wall, through an indwelling peritoneal dialysis catheter, or via the fallopian tubes in females. Hematogenous bacterial spread (through the bloodstream) occurs more frequently with tuberculosis peritonitis or peritonitis associated with cirrhotic ascites. When peritonitis results from peritoneal dialysis, skin surface flora are introduced via the peritoneal catheter. In secondary peritonitis, bacteria most often enter the peritoneum or retroperitoneum as a result of perforation of the GI or female genital tracts caused by diseases or traumatic injuries. Also, peritonitis or abscess may result from contamination of the peritoneum during a surgical procedure or following anastomotic leak.

The physiologic characteristics of the peritoneal cavity determine the nature of the response to infection or inflammation within it.¹ The peritoneum is lined by a highly permeable serous membrane with a surface area approximately that of skin. The peritoneal cavity is lubricated with less than 100 mL of sterile, clear yellow fluid, normally with fewer than 300 cells/mm³, a specific gravity below 1.016, and protein content below 3 g/dL. These conditions change drastically with peritoneal infection or inflammation, as described below.

After bacteria are introduced into the peritoneal cavity, there is an immediate response to contain the insult. Humoral and cellular defenses respond first; then the omentum adheres to the affected area. A limited bacterial inoculum is handled rapidly by defense mechanisms, including complement activation. Under certain conditions, the bacterial insult is not contained, and bacteria disseminate throughout the peritoneal cavity, resulting in peritonitis. This is more likely to occur in the presence of a foreign body, hematoma, dead tissue, a large bacterial inoculum, continuing bacterial contamination, and contamination involving a mixture of synergistic organisms. Protein-calorie malnutrition, antecedent steroid therapy, and diabetes mellitus also may contribute to the formation of an intraabdominal abscess.

When bacteria become dispersed throughout the peritoneum, the inflammatory process involves most of the peritoneal lining. There is an outpouring into the peritoneum of fluid containing leukocytes, fibrin, and other proteins that form exudates on the inflamed peritoneal surfaces and begin to form adhesions between peritoneal structures. This process, combined with a paralysis of the intestines (ileus), may result in confinement of the contamination to one or more locations within the peritoneum. Fluid also begins to collect in the bowel lumen and wall, and distension may result.

The fluid and protein shift into the abdomen (called *third-spacing*) may be so dramatic that circulating blood volume is decreased, which causes decreased cardiac output and hypovolemic shock. Accompanying fever, vomiting, or diarrhea may worsen the fluid imbalance. A reflex sympathetic response, manifested by sweating, tachycardia, and vasoconstriction, may be evident. With an inflamed peritoneum, bacteria and endotoxins are absorbed easily into the bloodstream (translocation), and this may result in septic shock.¹ Other foreign substances present in the peritoneal cavity potentiate peritonitis. These adjuvants, notably feces, dead tissues, barium, mucus, bile, and blood, have detrimental effects on host defense mechanisms, particularly on bacterial phagocytosis.

Many of the manifestations of intraabdominal infections, particularly peritonitis, result from cytokine activity. Inflammatory cytokines, such as tumor necrosis factor- α (TNF- α), interleukin (IL) 1, IL-6, IL-8, and interferon γ (INF- γ), are produced by macrophages and neutrophils in response to bacteria and bacterial products or in response to tissue injury resulting from the surgical incision.^{1,8} These cytokines produce wide-ranging effects on the vascular endothelium of organs, particularly the liver, lungs, kidneys, and heart. With uncontrolled activation of these mediators, sepsis may result (see Chap. 123).⁹

Peritonitis may result in death because of the effects on major organ systems. Fluid shifts and endotoxin may result in hypovolemic

and septic shock. Hypoalbuminemia may result from protein loss into the peritoneum exacerbating intravascular volume loss. Pulmonary function may be compromised by the inflamed peritoneum producing splinting (muscle rigidity caused by pain) that inhibits adequate diaphragmatic movement leading to atelectasis and pneumonia. Increased lung vascular permeability and resulting shunting of blood may induce onset of the respiratory distress syndrome and associated hypoxemia and hypercarbia. With fluid loss, hypotension, endotoxemia, and renal and hepatic perfusion may be compromised, and acute renal and hepatic failure are potential threats.

If peritoneal contamination is localized but bacterial elimination is incomplete, an abscess results. This collection of necrotic tissue, bacteria, and white blood cells may be at single or multiple sites and may be within one of the spaces of the peritoneal cavity or in one of the visceral organs. The location of the abscess often is related to the site of primary disease. For example, abscesses resulting from appendicitis tend to appear in the right lower quadrant or the pelvis; those resulting from diverticulitis tend to appear in the left lower quadrant or pelvis.

An abscess begins by the combined action of inflammatory cells (such as neutrophils), bacteria, fibrin, and other inflammatory mediators. Bacteria may release heparinases that cause local thrombosis and tissue necrosis or fibrinolysins, collagenases, or other enzymes that allow extension of the process into surrounding tissues. Neutrophils gathered in the abscess cavity die in 3 to 5 days, releasing lysosomal enzymes that liquefy the core of the abscess. A mature abscess may have a fibrinous capsule that isolates bacteria and the liquid core from antimicrobials and immunologic defenses.

Within the abscess, the oxygen tension is low, and anaerobic bacteria thrive, and thus the size of the abscess may increase because it is hypertonic, resulting in an additional influx of fluid. Hypertonicity promotes the formation of bacterial L forms, which are resistant to antimicrobial agents that disrupt cell walls. Abscess formation may continue and mature for long periods of time and may not be readily evident to either patient or physician. In some instances, the abscess may resolve spontaneously, and infrequently, it may erode into adjacent organs or rupture and cause diffuse peritonitis. If the abscess erodes through the skin, it may result in an enterocutaneous fistula, connecting bowel to skin, or in a draining sinus tract.

The overall outcome from an intraabdominal infection depends on five key factors: inoculum size, virulence of the contaminating organisms, the presence of adjuvants within the peritoneal cavity that facilitate infection, the adequacy of host defenses, and the adequacy of initial treatment.¹⁰

MICROBIOLOGY OF INTRAABDOMINAL INFECTION

② Primary bacterial peritonitis often is caused by a single organism. In children, the pathogen is usually group A *Streptococcus*, *E. coli*, *Streptococcus pneumoniae*, or *Bacteroides* species.¹¹ When peritonitis occurs in association with cirrhotic ascites, *E. coli* is isolated most frequently. Other potential pathogens are: *Haemophilus pneumoniae*, *Klebsiella*, *Pseudomonas*, anaerobes, and *S. pneumoniae*.¹² Occasionally, primary peritonitis may be caused by *Mycobacterium tuberculosis*. Peritonitis in patients undergoing peritoneal dialysis is caused most often by common skin organisms, such as *S. epidermidis*, *Staphylococcus aureus*, streptococci, and diphtheroids. Occasionally, aerobic gram-negative bacilli may cause infections, particularly in patients undergoing dialysis during hospitalization. Mortality from primary peritonitis caused by gram-negative bacteria is much greater than that from gram-positive bacteria.¹³

③ Because of the diverse bacteria present in the GI tract, secondary intraabdominal infections often are polymicrobial.² The mean number of different bacterial species isolated from infected intraabdominal

TABLE 118-3 Pathogens Isolated from Patients with Secondary Peritonitis

Gram-negative bacteria	
<i>Escherichia coli</i>	32%–61%
<i>Enterobacter</i>	8%–26%
<i>Klebsiella</i>	6%–26%
<i>Proteus</i>	4%–23%
Gram-positive bacteria	
Enterococci	18%–24%
Streptococci	6%–55%
Staphylococci	6%–16%
Anaerobic bacteria	
<i>Bacteroides</i>	25%–80%
<i>Clostridium</i>	5%–18%
Fungi	2%–5%

Data from Marshall JC, Innes M. Intensive care unit management of intraabdominal infection. *Crit Care Med* 2003;31:2228–2237.

sites ranged from 2.9 to 3.7, including an average of 1.3 to 1.6 aerobes and 1.7 to 2.1 anaerobes.^{14,15} With proper anaerobic specimen collection, anaerobic organisms are isolated in most patients. In one report of patients with gangrenous and perforated appendicitis, an average of 10.2 different organisms was isolated from each patient, including 2.7 aerobes and 7.5 anaerobes.¹⁶ Purely aerobic or anaerobic infections are uncommon, as are infections caused by fungi. Table 118-3 gives the frequencies with which specific bacteria were isolated from patients with peritonitis.¹⁷ *E. coli*, *Streptococcus* spp., and *Bacteroides* spp. were isolated most often from the infection site, as well as from blood cultures. In patients diagnosed with severe infections, the pattern of bacterial isolates may change and commonly includes *Candida*, enterococci, Enterobacteriaceae, and *S. epidermidis*.

Visceral organ abscesses differ in character from the typical intraabdominal abscess. Hepatic abscesses may be polymicrobial (involving *E. coli* and anaerobes) or occasionally may be caused by amoeba. Pancreatic abscesses are often polymicrobial, involving enteric bacteria that ascend through the biliary system. Splenic abscesses usually result from hematogenous dissemination of bacteria, such as *S. aureus*, streptococci, and occasionally, *Salmonella* or anaerobic organisms. Pelvic inflammatory disease is associated initially with *Neisseria gonorrhoeae* or *Chlamydia trachomatis*. However, tuboovarian abscesses usually are polymicrobial, having a mix of gram-positive and gram-negative aerobes and anaerobes.

BACTERIAL SYNERGISM

The size of the bacterial inoculum and the number and types of bacterial species present in intraabdominal infections influence patient outcome. The combination of aerobic and anaerobic organisms appears to increase the severity of infection greatly. In animal studies, combinations of aerobic and anaerobic bacteria were much more lethal than infections caused by aerobes or anaerobes alone.

Facultative bacteria may provide an environment conducive to the growth of anaerobic bacteria.² Although many bacteria isolated in mixed infections are nonpathogenic by themselves, their presence may be essential for the pathogenicity of the bacterial mixture.⁴ The role of facultative bacteria in mixed infections can include (a) promotion of an appropriate environment for anaerobic growth through oxygen consumption, (b) production of nutrients necessary for anaerobes, and (c) production of extracellular enzymes that promote tissue invasion by anaerobes.

Rat models of intraabdominal infection demonstrate that uncontrolled infection with an implanted mix of aerobes and anaerobes leads to a two-stage (biphasic) infectious process. There is an early peritonitis phase with a high mortality rate and isolation of *E. coli* from blood and a late abscess formation phase in all survivors with isolation of anaerobes such as *B. fragilis* and *Fusobacterium varium*.

These experiments and others support the concept that aerobic enteric organisms and anaerobes are pathogens in intraabdominal infection. Aerobic bacteria, particularly *E. coli*, appear responsible for the early mortality from peritonitis, whereas anaerobic bacteria are major pathogens in abscesses, with *B. fragilis* predominating.¹⁷

Enterococcus can be isolated from many intraabdominal infections in humans, but its role as a pathogen is not clear. Enterococcal infection occurs more commonly in postoperative peritonitis, in the presence of specific risk factors indicating failure of the host's defenses (immunocompromised patients), or with the use of broad-spectrum antibiotics.^{18,19}

CLINICAL PRESENTATION

Intraabdominal infections have a wide spectrum of clinical features often depending on the specific disease process, the location and magnitude of bacterial contamination, and concurrent host factors. Peritonitis usually is recognized easily, but intraabdominal abscess often may continue for considerable periods of time, either going unrecognized or being attributed to an unrelated disease process. Patients with primary and secondary peritonitis present quite differently (Table 118-4).¹

Primary peritonitis can develop over a period of days to weeks and usually is a more indolent process than secondary peritonitis.

TABLE 118-4 Clinical Presentation of Peritonitis

Primary Peritonitis	
General	
The patient may not be in acute distress, particularly with peritoneal dialysis.	
Signs and symptoms	
The patient may complain of nausea, vomiting (sometimes with diarrhea), and abdominal tenderness.	
Temperature may be only mildly elevated or not elevated in patients undergoing peritoneal dialysis.	
Bowel sounds are hypoactive.	
The cirrhotic patient may have worsening encephalopathy.	
Cloudy dialysate fluid with peritoneal dialysis.	
Laboratory tests	
The patient's white blood cell (WBC) count may be only mildly elevated.	
Ascitic fluid usually contains greater than 300 leukocytes/mm ³ , and bacteria may be evident on Gram stain of a centrifuged specimen.	
In 60% to 80% of patients with cirrhotic ascites, the Gram stain is negative.	
Other diagnostic tests	
Culture of peritoneal dialysate or ascitic fluid should be positive.	
Secondary Peritonitis	
Signs and symptoms	
Generalized abdominal pain.	
Tachypnea.	
Tachycardia.	
Nausea and vomiting.	
Temperature normal initially then increasing to 37.7°C to 38.8°C (100°F to 102°F) within the first few hours and may continue to rise for the next several hours.	
Hypotension and shock if volume is not restored.	
Decreased urine output due to dehydration.	
Physical examination	
Voluntary abdominal guarding changing to involuntary guarding and a "board-like abdomen."	
Abdominal tenderness and distension.	
Faint bowel sounds that cease over time.	
Laboratory tests	
Leukocytosis (15,000–20,000 WBC/mm ³ , with neutrophils predominating and an elevated percentage of immature neutrophils (bands).	
Elevated hematocrit and blood urea nitrogen because of dehydration.	
Patient progresses from early alkalosis because of hyperventilation and vomiting to acidosis and lactic acidemia.	
Other diagnostic tests	
Abdominal radiographs may be useful because free air in the abdomen (indicating intestinal perforation) or distension of the small or large bowel is often evident.	

The first sign of peritonitis may be a cloudy dialysate in patients undergoing peritoneal dialysis or worsening encephalopathy in a cirrhotic patient.

The patient with generalized bacterial peritonitis presents most often in acute distress. The patient lies still, usually on his or her back, possibly with hips slightly flexed. Any movement of the patient, including rocking the bed or breathing, worsens the generalized abdominal pain.

If peritonitis continues untreated, the patient may experience hypovolemic shock from third-space fluid loss into the peritoneum, bowel wall, and lumen. This may be accompanied by sepsis because the inflamed peritoneum absorbs bacteria and toxins into mesenteric blood vessels and lymph nodes, initiating production of inflammatory cytokines. Hypovolemic shock is the major factor contributing to mortality in the early stage of peritonitis.

Intraabdominal abscess may pose a difficult diagnostic challenge because the symptoms are neither specific nor dramatic. The patient may complain of abdominal pain or discomfort, but these symptoms are not reliable. Fever usually is present; often it is low grade, but it may be high, with a spiking pattern. The patient may have a paralytic ileus and abdominal distension. The abdominal examination is unreliable; tenderness and pain may be present, and a mass may be palpated.

Peritonitis may result from an abscess that ruptures, spreading bacteria and toxins throughout the peritoneum. In other patients, the entry of bacterial toxins into the systemic circulation from the abscess may lead to sepsis and progressive multisystem organ failure (e.g., renal, hepatic, pulmonary, or cardiovascular).

Laboratory studies generally are not helpful in the diagnosis of intraabdominal abscess, although most patients will have leukocytosis. Some patients may have positive blood cultures, whereas others, particularly diabetics, may have hyperglycemia. The finding of *Bacteroides* or any two enteric bacteria in the bloodstream is often indicative of an intraabdominal infectious process.

Radiographic methods are used to make the diagnosis of an intraabdominal abscess. Plain radiographs may show air–fluid levels or a shift of normal intraabdominal contents by the abscess mass. GI contrast studies also may demonstrate this displacement of abdominal structures. Both these modalities provide indirect evidence of abscess presence but are not generally helpful in precisely locating the abscess.

Ultrasound is a frequent first diagnostic method used when an intraabdominal abscess is suspected. The procedure may be done at the bedside, which is particularly helpful in the patient in the intensive care unit.

Computed tomography (CT) scanning frequently is used to evaluate the abdomen for the presence of an abscess and is the imaging modality of greatest value. An oral radiocontrast agent should be given to allow differentiation of the abscess from the bowel. Intravenous radiocontrast material will be taken up preferentially in the wall of the abscess, creating a unique radiographic appearance, so-called rim enhancement.

Magnetic resonance imaging is used infrequently to locate an intraabdominal abscess, particularly in the retroperitoneum, but this modality offers no significant advantage when compared with CT scanning.

Radioactive isotope imaging with ^{67}Ga citrate-, $^{99\text{m}}\text{Tc}$ -, or ^{111}In -labeled leukocytes also may be used.²⁰ These studies require long preparation and image acquisition and are not used routinely unless CT scanning fails to demonstrate a suspected abscess.

Intraabdominal infection caused by disease processes at specific sites often produces characteristic manifestations that are helpful in diagnosis. For example, a patient with diverticulitis may exhibit stabbing left-lower-quadrant abdominal pain and constipation. Fever and leukocytosis frequently are present, and a tender mass sometimes is palpable. With appendicitis, the findings may be inconsistent, but

many patients have a sudden onset of periumbilical or epigastric pain that usually is colicky and later shifts to the right lower quadrant. The location of pain may vary because the appendix can be in many locations (e.g., retrocecal or pelvic) in the abdomen. A mass may be palpable on abdominal, pelvic, or rectal examination. The patient's temperature generally is mildly elevated early and then increases. If perforation and peritonitis occur, findings would include diffuse abdominal pain, rigidity, and sustained fever. More often, however, appendiceal perforation results in a local abscess.

TREATMENT

Intraabdominal Infections

■ DESIRED OUTCOME

The primary goals of treatment are correction of the intraabdominal disease processes or injuries that have caused infection and the drainage of purulent collections (abscesses). A secondary objective is to achieve a resolution of infection without major organ system complications (pulmonary, hepatic, cardiovascular, or renal failure) or adverse drug effects. Ideally, the patient should be discharged from the hospital with full function for self-care and routine daily activities.

■ GENERAL APPROACH TO TREATMENT

The treatment of intraabdominal infection most often requires hospitalization and the coordinated use of three major modalities: (a) prompt drainage of the infected site, (b) hemodynamic resuscitation and support of vital functions, and (c) early administration of appropriate antimicrobial therapy to treat infection not eradicated by surgery.²

Antimicrobials are an important adjunct to drainage procedures in the treatment of secondary intraabdominal infections; however, the use of antimicrobial agents without surgical intervention usually is inadequate. For most cases of primary peritonitis, drainage procedures may not be required, and antimicrobial agents become the mainstay of therapy.

4 In the early phase of serious intraabdominal infections, attention should be given to the maintenance of organ system functions. With generalized peritonitis, large volumes of intravenous (IV) fluids are required to restore vascular volume, to improve cardiovascular function, and to maintain adequate tissue perfusion and oxygenation. Adequate urine output should be maintained to ensure adequate resuscitation and proper renal function. Respiratory function can be assisted by a variety of methods, including oxygen therapy, pulmonary physiotherapy, and ventilatory support in severely ill patients. Often the critically ill patient with intraabdominal infection will require intensive care management, particularly if there is cardiovascular or respiratory instability. Also, isolation procedures may be required if the infectious process poses a threat to other hospitalized patients.

An additional important component of therapy is nutrition. Intraabdominal infections often directly involve the GI tract or disrupt its function (paralytic ileus). The return of GI motility may take days, weeks, and occasionally, months. In the interim, enteral or parenteral nutrition as indicated facilitates improved immune function and wound healing to ensure recovery.

■ NONPHARMACOLOGIC TREATMENT

Drainage Procedures

Primary peritonitis is treated with antimicrobials and rarely requires drainage. Secondary peritonitis requires surgical correction of the underlying pathology. The drainage of the purulent material is the

critical component of management of an intraabdominal abscess. Without adequate drainage of the abscess, antimicrobial therapy and fluid resuscitation can be expected to fail.

Secondary peritonitis is treated surgically and this is often called *source control*, which refers to all the physical measures undertaken to eradicate the focus of infection.² At the time of laparotomy (surgical opening and exploration of the abdomen) attempts are made to correct the cause of the peritonitis. This may include patching a perforated ulcer with omentum, removal of a segment of perforated colon, or excision of a portion of gangrenous small intestine. The goal of all these procedures is to repair or remove the inflamed or gangrenous viscus and to prevent further bacterial contamination. The presence of active inflammation increases the difficulty of the surgical procedure, which results in a higher morbidity and mortality rate than if the same procedures were performed in an elective setting without inflammation.

The presence of active inflammation may make it technically impossible to perform the definitive surgical procedure. In this situation, attempts are made to provide drainage of the infected or gangrenous structures. If an intraabdominal abscess, separate from any intraabdominal organ, is discovered during an exploratory laparotomy, it may be debrided, excised, or drained. If the intraabdominal abscess involves an abdominal structure, then a resection of part or all of that organ may be required. An example of this situation is an abscess associated with diverticular disease of the colon. Management may include drainage of the abscess and resection of the involved colon. All foreign material, necrotic tissue, feces, blood, or pus should be removed from the operative field, and the peritoneum should be copiously irrigated with 0.9% sodium chloride to decrease the concentrations of bacteria or other noxious substances.

After an abscess is located, it must be drained. This may be performed surgically or using percutaneous, image-guided techniques.²¹ Typically, image-guided techniques are done using ultrasonography or CT scanning. The management of an intraabdominal abscess with percutaneous catheter drainage may be sufficient to resolve the infection. Some patients may require a subsequent procedure to treat the underlying gastrointestinal conditions; however, a significant advantage is obtained by first draining the abscess percutaneously. This allows the surgical procedure to be performed on a patient who is no longer suffering the systemic manifestations of uncontrolled infection. Drainage techniques may be performed using endoscopy or laparoscopy. These minimal-access techniques may offer advantages when compared with traditional surgery but probably will be used less often than radiologically assisted percutaneous drainage techniques.

The most valuable microbiologic information may be obtained at the time of percutaneous or operative abscess drainage. If pus or fluid is found that is believed to be infected, it is best to aspirate 2 to 3 mL into a syringe, remove any air, and tightly cap the syringe. The specimen should be taken promptly to the microbiology laboratory, where a Gram stain should be performed immediately and cultures prepared for identification of aerobic and anaerobic bacteria. If no fluid is available for collection, culture swab devices may be applied to the infected area; however, anaerobic organisms often are not isolated from swabs.

Fluid Therapy

4 Aggressive fluid repletion and management are required for successful treatment of intraabdominal infections. Fluid therapy is instituted for the purposes of achieving or maintaining proper intravascular volume to ensure adequate cardiac output, tissue perfusion, and correction of acidosis. Loss of fluid through vomiting, diarrhea, or a nasogastric suction contributes to dehydration. Intravascular volume can be assessed by blood pressure and heart rate but more accurately by measurement of central venous pressure, pulmonary

capillary wedge pressure, or urinary output. When a contracted vascular volume is accompanied by hemorrhage, the initial hematocrit may be normal, but if there is no associated hemorrhage, the hematocrit usually is elevated as an indication of hemoconcentration. Urine output should be monitored continuously in severely ill patients by use of a urinary bladder catheter, quantitated hourly, and should equal or exceed 0.5 mL/kg of body weight per hour.

In patients with peritonitis, hypovolemia often is accompanied by acidosis, so a reasonable IV fluid would be lactated Ringer solution, which contains the bicarbonate precursor lactate, as well as sodium, chloride, potassium, and calcium. In the initial hour of treatment, large volumes of solution may be required to restore intravascular volume. Thereafter, fluids may be required at a rate of 1 L/h. Maintenance fluids should be instituted (after intravascular volume is restored) with 0.9% sodium chloride and potassium chloride (20 mEq/L) or 5% dextrose and 0.45% sodium chloride with potassium chloride (20 mEq/L). The administration rate should be based on estimated daily fluid loss through urine and nasogastric suction, including 0.5 to 1.0 L for insensible fluid loss. Potassium would not be included routinely if the patient is hyperkalemic or has renal insufficiency.

In patients with significant blood loss, blood transfusion may be indicated. This is generally in the form of packed red blood cells. The criteria for blood transfusion are controversial, but a hematocrit of 25% generally is accepted. In the individual patient, the decision is often determined by the overall clinical status and the ability of the patient to compensate for the reduction in oxygen-carrying capacity associated with an acute anemia. Additional blood component therapy with fresh-frozen plasma or platelets is also based on the needs of the individual patient. Aggressive fluid therapy often must be continued in the postoperative period because fluid will continue to sequester in the peritoneal cavity, bowel wall, and lumen.

■ PHARMACOLOGIC TREATMENT

Antimicrobial Therapy

The goals of antimicrobial therapy are (a) to control bacteremia and prevent the establishment of metastatic foci of infection, (b) to reduce suppurative complications after bacterial contamination, and (c) to prevent local spread of existing infection. After suppuration has occurred (e.g., an abscess has formed), a cure by antibiotic therapy alone is very difficult to achieve; antimicrobials may serve to improve the results with surgery.

5 An empirical antimicrobial regimen should be started as soon as the presence of intraabdominal infection is suspected. Therefore, antibiotics usually are initiated before identification of the infecting organisms is complete. Therapy must be initiated based on the likely pathogens. Predominant pathogens, as discussed in the preceding section, vary depending on the site of intraabdominal infection and the underlying disease process. Table 118-5 lists the likely pathogens against which antimicrobial agents should be directed.

Antimicrobial Experience Many studies have been conducted evaluating or comparing the effectiveness of antimicrobials for the treatment of intraabdominal infections. Substantial differences in patient outcomes from treatment with a variety of agents generally have not been demonstrated.²²

Important findings from over 20 years of clinical trials regarding selection of antimicrobials for intraabdominal infections are the following:

- Antimicrobial regimens should cover a broad spectrum of aerobic and anaerobic bacteria from the gastrointestinal tract.
- Single-agent regimens (such as antianaerobic cephalosporins, extended-spectrum penicillins with β -lactamase inhibitors, and carbapenems) are as effective as combinations of ami-

TABLE 118-5 Likely Intraabdominal Pathogens

Type of Infection	Aerobes	Anaerobes
Primary bacterial peritonitis		
Children (spontaneous)	Group A <i>Streptococcus</i> , <i>Escherichia coli</i> , pneumococci	—
Cirrhosis	<i>E. coli</i> , <i>Klebsiella</i> , pneumococci (many others)	—
Peritoneal dialysis	<i>Staphylococcus</i> , <i>Streptococcus</i>	—
Secondary bacterial peritonitis		
Gastroduodenal	<i>Streptococcus</i> , <i>E. coli</i>	—
Biliary tract	<i>E. coli</i> , <i>Klebsiella</i> , enterococci	<i>Clostridium</i> or <i>Bacteroides</i> (infrequent)
Small or large bowel	<i>E. coli</i> , <i>Klebsiella</i> spp., <i>Proteus</i> spp.	<i>Bacteroides fragilis</i> and other <i>Bacteroides</i> , <i>Clostridium</i>
Appendicitis	<i>E. coli</i> , <i>Pseudomonas</i>	<i>Bacteroides</i> spp.
Abscesses	<i>E. coli</i> , <i>Klebsiella</i> , enterococci	<i>B. fragilis</i> and other <i>Bacteroides</i> , <i>Clostridium</i> , anaerobic cocci
Liver	<i>E. coli</i> , <i>Klebsiella</i> , enterococci, staphylococci, amoeba	<i>Bacteroides</i> (infrequent)
Spleen	<i>Staphylococcus</i> , <i>Streptococcus</i>	

noglycosides with antianaerobic agents. This is also true for antimicrobial treatment of acute bacterial contamination from penetrating abdominal trauma.^{23,24}

- Clindamycin and metronidazole appear to be equivalent in efficacy when combined with agents effective against aerobic gram-negative bacilli (gentamicin or aztreonam).
- For most patients, antimicrobial treatment can be completed orally with amoxicillin-clavulanate or the combination of ciprofloxacin and metronidazole.
- Five to 7 days of antimicrobial treatment is sufficient for most intraabdominal infections of mild to moderate severity.

Intraabdominal infection presents in many different ways and with a wide spectrum of severity. The regimen employed and duration of treatment depend on the specific clinical circumstances (i.e., the nature of the underlying disease process and the condition of the patient). Compromised patients require more aggressive therapies than do otherwise healthy patients who experience the same intraabdominal infection.

Recommendations **6** For most intraabdominal infections, the antimicrobial regimen should be effective against both aerobic and anaerobic bacteria.²⁵ Although it is impossible to provide antimicrobial activity against every possible pathogen, agents with activity against enteric gram-negative bacilli such as *E. coli* and *Klebsiella*, and anaerobes such as *B. fragilis* and *Clostridium* spp. should be administered. If most of the organisms can be eliminated through drainage or antimicrobials, the synergistic effect may be removed, and the patient's defenses may be able to resolve the remaining infection.

Table 118–6 presents the recommended agents for treatment of community-acquired and complicated intraabdominal infections from the Infectious Diseases Society of America and the Surgical Infection Society.^{25–27} These recommendations were formulated using an evidence-based approach. Table 118–7 lists additional evidence-based recommendations. Most community-acquired infections are “mild to moderate,” whereas healthcare-associated infections tend to be more severe and difficult to treat. Table 118–8 presents guidelines for treatment and alternative regimens for specific

TABLE 118-6 Recommended Agents for the Treatment of Community-Acquired Complicated Intraabdominal Infections

Agents Recommended for Mild to Moderate Infections	Agents Recommended for High-Severity Infections
β-Lactamase inhibitor combinations	
Ampicillin-sulbactam Ticarcillin-clavulanate	Piperacillin-tazobactam
Carbapenems	
Ertapenem	Imipenem/cilastatin Meropenem
Combination regimens	
Cefazolin or cefuroxime plus metronidazole	Third- or fourth-generation cephalosporins (cefotaxime, ceftriaxone, ceftizoxime, ceftazidime, cefepime) plus metronidazole
Ciprofloxacin, levofloxacin, moxifloxacin, or gatifloxacin in combination with metronidazole	Ciprofloxacin in combination with metronidazole Aztreonam plus metronidazole

From Solomkin et al.,²⁵ and Mazuski et al.^{26,27}

situations. These are general guidelines; there are many factors that cannot be incorporated into such a table.

Most patients with severe intraabdominal infection, generalized peritonitis, or sepsis should be placed on a β -lactam- β -lactamase inhibitor combination or carbapenem such as imipenem, ertapenem, or meropenem. Combinations of an aminoglycoside with an antianaerobic agent, such as clindamycin or metronidazole, may be used, but such combinations are considered to be obsolete. Gentamicin is the aminoglycoside of choice based on its lower cost. Other aminoglycosides, such as tobramycin or amikacin have no advantage in intraabdominal infection and generally are not drugs of first choice. Aztreonam may be used as an alternative to an aminoglycoside to avoid potential nephrotoxicity.

The dosage for aminoglycosides should be determined initially based on the patient's weight and renal function. Dosage adjustment should be performed by applying pharmacokinetic principles and by using peak and trough serum drug levels. Unless relatively resistant bacteria are suspected, a gentamicin or tobramycin peak concentration of 5 to 6 mcg/mL usually is effective. To achieve these serum concentrations, gentamicin or tobramycin dosage may range from 1 to 3 mg/kg per dose given as often as every 6 hours or as infrequently as every 48 hours if the patient has renal failure. Because aminoglycosides have concentration-dependent killing and a relatively long postantibiotic effect for aerobic gram-negative bacilli, once-daily administration (5 to 7 mg/kg) is a reasonable alternative and appears to be equivalent to multiple daily dosing.

When used for intraabdominal infection, aminoglycosides should be combined with agents that are effective against the majority of *B. fragilis*. Clindamycin or metronidazole is the agent of first choice, but others, such as antianaerobic cephalosporins (e.g., cefoxitin, cefotetan, or ceftizoxime), piperacillin, mezlocillin, and combinations of extended-spectrum penicillins with β -lactamase inhibitors, would be suitable alternatives. Clindamycin should be administered intravenously in a dosage of 600 or 900 mg every 8 hours. Patients receiving multiple broad-spectrum antimicrobial agents who are immunocompromised should receive an oral antifungal agent (nystatin) for prevention of fungal overgrowth in the mouth and GI tract. The benefits of systemic antifungal prophylaxis (with fluconazole) have not been established for intraabdominal infection and should not be used routinely.

With intraabdominal contamination from the upper GI tract (perforation of a peptic ulcer or biliary tract disease), *B. fragilis* is an uncommon pathogen, and other agents therefore may be substituted for clindamycin or metronidazole. Alternatives include ampicillin, penicillin, or first-generation cephalosporins.

TABLE 118-7 Evidence-Based Recommendations for Treatment of Complicated Intraabdominal Infections

	Grade of Recommendation ^a
Acute contamination as a result of trauma	
Bowel injuries caused by penetrating, blunt, or iatrogenic trauma that are repaired within 12 h and intraoperative contamination of the operative field by enteric contents under other circumstances should be treated with antibiotics ≤ 24 h.	A-1
Acute appendicitis	
Acute appendicitis without evidence of gangrene, perforation, abscess, or peritonitis requires only prophylactic administration of inexpensive regimens active against facultative and obligate anaerobes.	A-1
Community-acquired infections	
Antibiotics used for empirical treatment of community-acquired intraabdominal infections should be active against empiric gram-negative aerobic and facultative bacilli and β -lactam-susceptible gram-positive cocci.	A-1
For patients with mild-to-moderate community-acquired infections, agents that have a narrower spectrum of activity, such as ampicillin-sulbactam, cefazolin, or cefuroxime-metronidazole, ticarcillin-clavulanate, and ertapenem are preferable to more-costly agents that have broader coverage against gram-negative organisms and/or greater risk of toxicity.	A-1
Anaerobic coverage	A-1
Coverage against obligate anaerobic bacilli should be provided for distal small-bowel and colon-derived infections and for more-proximal gastrointestinal perforations when obstruction is present.	
Nosocomial infections	
Agents used to treat nosocomial infections in the intensive care unit (e.g., expanded gram-negative bacterial spectrum) should not be routinely used to treat community-acquired infections.	B-2
If a patient with diagnosed infection has previously been treated with an antibiotic, that patient should be treated as if he or she has had a healthcare-associated (nosocomial) infection.	B-3
Aminoglycosides	
Aminoglycosides are not recommended for routine use in community-acquired intraabdominal infections.	A-1
Oral completion therapy	
Completion of the antimicrobial course with oral forms of a quinolone plus metronidazole,	A-1
or with amoxicillin-clavulanic acid is acceptable for patients who are able to tolerate an oral diet.	B-3
Suspected fungal infection	
Antifungal therapy for <i>Candida</i> should be withheld until the infecting species is identified.	C-3
Enterococcal infection	
Routine coverage against <i>Enterococcus</i> is not necessary for patients with community-acquired intraabdominal infections.	A-1

^aStrength of recommendations: A, B, C = good, moderate, and poor evidence to support recommendation, respectively. Quality of evidence: 1 = Evidence from >1 properly randomized, controlled trial. 2 = Evidence from >1 well-designed clinical trial with randomization, from cohort or case-controlled analytic studies; from multiple time series, or from dramatic results from uncontrolled experiments. 3 = Evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert communities.

From Solomkin et al.,²⁵ and Mazuski et al.^{26,27}

CLINICAL CONTROVERSY

Enterococci often are isolated from intraabdominal infections, and many antimicrobials are ineffective against enterococci (such as cephalosporins and fluoroquinolones). Regimens with-

out activity against enterococci (gentamicin with clindamycin or cephalosporins) generally are effective in treating intraabdominal infections; however, there are numerous reports of enterococcal superinfection in immunocompromised patients, particularly after broad-spectrum antimicrobial use. The Infectious Disease Society of America guidelines state that "Routine coverage against enterococcus is not necessary for patients with community-acquired intraabdominal infections. Antimicrobial therapy for enterococci (e.g., ampicillin, penicillin, or vancomycin) should be given when enterococci are recovered from patients with "healthcare-associated infections."

The failure of host defenses may be a critical factor in the pathogenicity of enterococci. In immunocompromised patients or patients with valvular heart disease or a prosthetic heart valve, there is justification to provide specific antimicrobial activity against enterococci. Ampicillin or other penicillins that are active against enterococci (e.g., penicillin, piperacillin, and mezlocillin) should be used in patients at high risk, patients with persistent or recurrent intraabdominal infection, or patients who are immunosuppressed, such as after organ transplantation. Ampicillin remains the drug of choice for this indication because it is most active in vitro against enterococcus and is relatively inexpensive. Vancomycin is active against most enterococci; however, resistance is increasing, and this agent should be reserved for established infections when first-line therapies cannot be used.

⑦ Intraperitoneal administration of antibiotics is preferred over IV therapy in the treatment of peritonitis that occurs in patients undergoing CAPD. The International Society of Peritoneal Dialysis revised its guidelines for the diagnosis and pharmacotherapy of peritoneal dialysis-associated infections.²⁸ The guidelines provide dosing recommendations for intermittent and continuous therapy based on the modality of dialysis (CAPD or automated peritoneal dialysis) and the extent of the patient's residual renal function.

Antimicrobial agents effective against both gram-positive and gram-negative organisms should be used for initial intraperitoneal empiric therapy for peritonitis in peritoneal dialysis patients. The most important factors to take into consideration for initial antimicrobial selection are the dialysis center's and the patient's history of infecting organisms and their sensitivities. The use of cefazolin (loading dose [LD] 500 mg/L; maintenance dose [MD] 125 mg/L) plus ceftazidime (LD 500 mg/L; MD 125 mg/L) or cefepime (LD 500 mg/L; MD 125 mg/L) or an aminoglycoside (gentamicin-tobramycin LD 8 mg/L; MD 4 mg/L) is suitable for initial empiric therapy; if patients are allergic to cephalosporin antibiotics, vancomycin (LD 1,000 mg/L; MD 25 mg/L) or an aminoglycoside should be substituted. Another option is monotherapy with imipenem-cilastatin (LD 500 mg/L; MD 200 mg/L) or cefepime. Antimicrobial doses should empirically be increased by 25% in patients with residual renal function (more than 100 mL/day urine output).²⁸ Antimicrobial therapy should be continued for at least 1 week after the dialysate fluid is clear and for a total of at least 14 days. The reader is referred to these guidelines for additional information.²⁸

After acute bacterial contamination, such as with abdominal trauma where GI contents spill into the peritoneum, combination antimicrobial regimens are not required. If the patient is seen soon after injury (within 2 hours) and surgical measures are instituted promptly, antianaerobic cephalosporins (such as cefoxitin or cefotetan) or extended-spectrum penicillins are effective in preventing most infectious complications. Antimicrobials should be administered as soon as possible after injury.

For appendicitis, the antimicrobial regimen used should depend on the appearance of the appendix at the time of operation, which may be normal, inflamed, gangrenous, or perforated. Because the condition of the appendix is unknown preoperatively, it is advisable

TABLE 118-8 Guidelines for Initial Antimicrobial Agents for Intraabdominal Infections

Primary Agents		Alternatives
Primary bacterial peritonitis		
Cirrhosis	Cefotaxime	<ol style="list-style-type: none"> 1. Add clindamycin or metronidazole if anaerobes are suspected 2. Other third-generation cephalosporins, extended-spectrum penicillins, aztreonam, and imipenem as alternatives 3. Aminoglycoside with antipseudomonal penicillin
Peritoneal dialysis	Initial empiric regimens Cefazolin or cephalothin plus ceftazidime or cefepime	<ol style="list-style-type: none"> 1. An aminoglycoside may be used in place of ceftazidime or cefepime 2. Imipenem/cilastatin or cefepime may be used alone 3. Quinolones may be used in place of ceftazidime or cefepime if local susceptibilities allow
	<ol style="list-style-type: none"> 1. <i>Staphylococcus</i>: penicillinase-resistant penicillin or first-generation cephalosporin 2. <i>Streptococcus</i> or <i>Enterococcus</i>: ampicillin 3. Aerobic gram-negative bacilli: ceftazidime or cefepime 4. <i>Pseudomonas aeruginosa</i>: two agents with differing mechanisms of actions, such as an oral quinolone plus ceftazidime, cefepime, tobramycin, or piperacillin 	<ol style="list-style-type: none"> 1. Alternative for methicillin resistant staphylococci is vancomycin 2. For vancomycin-resistant <i>Staphylococcus aureus</i>, linezolid, daptomycin, or quinupristin-dalfopristin must be used. 1. An aminoglycoside may be added for enterococcal peritonitis 2. Linezolid or quinupristin-dalfopristin should be used to treat vancomycin-resistant enterococcus not susceptible to ampicillin. 1. The regimen should be based on in vitro sensitivity tests
Secondary bacterial peritonitis		
Perforated peptic ulcer	First-generation cephalosporins	<ol style="list-style-type: none"> 1. Antianaerobic cephalosporins^a 2. Possibly add aminoglycoside if patient condition is poor 3. Aminoglycoside with clindamycin or metronidazole; add ampicillin if patient is immunocompromised or if biliary tract origin of infection
Other	Imipenem-cilastatin, meropenem, ertapenem, or extended-spectrum penicillins with β -lactamase inhibitor	<ol style="list-style-type: none"> 1. Ciprofloxacin with metronidazole 2. Aztreonam with clindamycin or metronidazole 3. Antianaerobic cephalosporins^a
Abscess		
General	Imipenem-cilastatin, meropenem, ertapenem, or extended-spectrum penicillins with β -lactamase inhibitor	<ol style="list-style-type: none"> 1. Aztreonam with clindamycin or metronidazole 2. Ciprofloxacin with metronidazole 3. Aminoglycoside with clindamycin or metronidazole;
Liver	As above but add a first-generation cephalosporin	Use metronidazole if amoebic liver abscess is suspected
Spleen	Aminoglycoside plus penicillinase-resistant penicillin	Alternatives for penicillinase-resistant penicillin are first-generation cephalosporins or vancomycin
Appendicitis		
Normal or inflamed	Antianaerobic cephalosporins ^a (discontinued immediately postoperation)	1. Ampicillin-sulbactam
Gangrenous or perforated	Imipenem-cilastatin, meropenem, ertapenem, antianaerobic cephalosporins, or extended-spectrum penicillins with β -lactamase inhibitor	<ol style="list-style-type: none"> 1. Aztreonam with clindamycin or metronidazole 2. Ciprofloxacin with metronidazole 3. Aminoglycoside with clindamycin or metronidazole
Acute cholecystitis	First-generation cephalosporin	Aminoglycoside plus ampicillin if severe infection
Cholangitis	Aminoglycoside with ampicillin with or without clindamycin or metronidazole	Use vancomycin instead of ampicillin if patient is allergic to penicillin
Acute contamination from abdominal trauma	Antianaerobic cephalosporins ^a or ampicillin-sulbactam	<ol style="list-style-type: none"> 1. A carbapenem 2. Ciprofloxacin plus metronidazole
Pelvic inflammatory disease	Cefotetan or cefoxitin with doxycycline	<ol style="list-style-type: none"> 1. Clindamycin with gentamicin 2. Ampicillin-sulbactam with doxycycline 3. Ciprofloxacin with doxycycline and metronidazole

^aCefoxitin, cefotetan, and ceftizoxime.

to begin antimicrobial agents before the appendectomy is performed. Reasonable regimens would be antianaerobic cephalosporins or, if the patient is seriously ill, a carbapenem or β -lactam- β -lactamase inhibitor combination. If, at operation, the appendix is normal or inflamed, postoperative antimicrobials are not required. If the appendix is gangrenous or perforated, a treatment course of 5 to 7 days with the agents listed in Table 118–8 is appropriate.

8 The necessary duration of treatment for intraabdominal infections is not clearly defined. Acute intraabdominal contamination, such as after a traumatic injury, may be treated with a very short course (24 hours).²⁹ For established infections (i.e., peritonitis or intraabdominal abscess), an antimicrobial course limited to 5 to 7 days is justified. This allows eradication of bacteria remaining in the peritoneum after a surgical procedure that may enter the peritoneum

through healing suture lines. Under certain conditions, therapy for longer than 7 days would be justified (e.g., if the patient remains febrile or is in poor general condition, when relatively resistant bacteria are isolated, or when a focus of infection in the abdomen may still be present). For some abscesses, such as pyogenic liver abscess, antimicrobials may be required for a month or longer.

Intraperitoneal irrigation of antimicrobial agents for treatment of intraabdominal infection has been studied often with conflicting results.³⁰ Intraoperative antimicrobial irrigation does not improve patient outcomes in comparison with copious intraoperative irrigation with normal saline. Possibly the most important aspect of peritoneal irrigation is the dilutional effect on bacteria and adjuvants that promotes infection (intestinal contents and hemoglobin). Most systemically administered antimicrobials easily cross the peri-

toneal membrane so that peritoneal fluid concentrations are similar to serum. Confined areas, such as an abscess, can be expected to attain much lower antimicrobial concentrations.

EVALUATION OF THERAPEUTIC OUTCOMES

Whichever antimicrobial regimen is chosen, the patient should be reassessed continually to determine the success or failure of therapies. The clinician should recognize that there are many reasons for poor patient outcome with intraabdominal infection; improper antimicrobial administration is only one. The patient may be immunocompromised, which decreases the likelihood of successful outcome with any regimen. It is impossible for antimicrobials to compensate for a nonfunctioning immune system. There may be surgical reasons for poor patient outcome. Failure to identify all intraabdominal foci of infection or leaks from a GI anastomosis may cause continued intraabdominal infection. Even when intraabdominal infection is controlled, accompanying organ system failure, most often renal or respiratory, may lead to patient demise.

The outcome from intraabdominal infection is not determined solely by what transpires in the abdomen. Unsatisfactory outcomes in patients with intraabdominal infections may result from complications that arise in other organ systems. Infectious complications commonly associated with mortality after intraabdominal infection are urinary tract infections and pneumonia.³¹ A high APACHE (Acute Physiology and Chronic Health Evaluation) II score, low serum albumin concentration, and high New York Heart Association cardiac function status were significantly and independently associated with increased mortality from intraabdominal infection.³²

9 Once antimicrobials are initiated and the other important therapies described earlier are used, most patients should show improvement within 2 to 3 days. Usually, temperature will return to near normal, vital signs should stabilize, and the patient should not appear in distress, with the exception of recognized discomfort and pain from incisions, drains, and nasogastric tube. At 24 to 48 hours, aerobic bacterial culture results should return. If a suspected pathogen is not sensitive to the antimicrobial agents being given, the regimen should be changed if the patient has not shown sufficient improvement. If the isolated pathogen is extremely sensitive to one antimicrobial and the patient is progressing well, concurrent antimicrobial therapy often may be discontinued.

CLINICAL CONTROVERSY

5 Although some investigators suggest that routine culturing of patients with community-acquired intraabdominal infections contributes little to their management,³³ other investigators suggest that antimicrobial therapy should be based on susceptibility of the bacteria collected from the operative site because this correlates with clinical outcome.³⁴

With anaerobic culturing techniques and the slow growth of these organisms, anaerobes often are not identified until 4 to 7 days after culture, and sensitivity information is difficult to obtain. For this reason, there are usually few data with which to alter the antianaerobic component of the antimicrobial regimen. A report indicating that anaerobes were not isolated should not be the sole justification for discontinuing antianaerobic drugs because anaerobic bacteria that were present in the infectious process may not have been transported properly to the microbiology laboratory, or other problems may have led to cell death in vitro.

Reasons for antimicrobial failure may not always be apparent. Even when antimicrobial susceptibility tests indicate that an organism is susceptible in vitro to the antimicrobial agent, therapeutic failures

may occur. Possibly there is poor penetration of the antimicrobial agent into the focus of infection, or bacterial resistance may develop after initiation of antimicrobial therapy. Also, it is possible that an antimicrobial regimen may encourage the development of infection by organisms not susceptible to the regimen being used. Superinfection in patients being treated for intraabdominal infection can be caused by *Candida*; however, enterococci or opportunistic gram-negative bacilli such as *Pseudomonas* or *Serratia* may be involved.

Treatment regimens for intraabdominal infection can be judged as successful if the patient recovers from the infection without recurrent peritonitis or intraabdominal abscess and without the need for additional antimicrobials. A regimen can be considered unsuccessful if a significant adverse drug reaction occurs, reoperation or percutaneous drainage is necessary, or patient improvement is delayed beyond 1 or 2 weeks.

J. V. ANANDAN

KEY CONCEPTS

- 1 Parasites normally inflict some degree of injury to the host, the extent of which depends on such factors as parasite load, nutritional status, and immunologic competence of the host.
- 2 All symptomatic adults and children older than 8 years of age with giardiasis should be treated with metronidazole 250 mg three times daily for 5 to 7 days.
- 3 Intestinal amebiasis is diagnosed by demonstrating *Entamoeba histolytica* cysts or trophozoites (may contain ingested erythrocytes) in fresh stool or from a specimen obtained by sigmoidoscopy. Three stool samples obtained 24 hours apart will produce a 60% to 90% yield for *E. histolytica*.
- 4 The drug of choice for enterobiasis, hookworm, and ascariasis is mebendazole, and the agent of choice for strongyloidiasis is albendazole.
- 5 The primary reasons for deaths as a result of malaria are failure to take chemoprophylaxis, inappropriate chemoprophylaxis, delay in seeking medical care, and misdiagnosis.
- 6 In adults (including pregnant women) traveling from a non-endemic to an endemic area, the chemoprophylaxis for all species of plasmodia is chloroquine phosphate 300 mg (base) once weekly beginning 1 week prior to departure and continuing for 4 weeks after leaving an endemic area. In an uncomplicated attack of malaria (for all plasmodia except chloroquine-resistant *Plasmodium falciparum*), the recommended regimen is chloroquine 600 mg (base) initially, followed by 300 mg (base) 6 hours later, and then 300 mg (base) daily for 2 days.
- 7 Because falciparum malaria is associated with serious complications, including pulmonary edema, hypoglycemia, jaundice, renal failure, confusion, delirium, seizures, coma, and death, careful monitoring of fluid status and hemodynamic parameters is mandatory.
- 8 In chronic trypanosomiasis (Chagas' disease), patients present with cardiomyopathy and heart failure.
- 9 The resistance of lice to permethrin is increasing, and 0.5% malathion is an effective alternative.

- 10 The treatment of choice for scabies is 5% permethrin cream; oral ivermectin is an alternative therapy.

Parasitic diseases are receiving increasing attention from clinicians in the United States because of the high frequency of travel, deployment of personnel for humanitarian and military missions (e.g., Peace Corps volunteers), inflow of immigrants from a wider geographic distribution, and the presence of immunosuppressed populations (e.g., acquired immune deficiency syndrome [AIDS] and transplant patients). Migrant farm workers who work and live in substandard hygienic conditions, the large and growing Central and South American immigrant population, and other poorly medically screened immigrants from Asia represent significant sources of parasitic infections in the United States.¹⁻⁹ Clinicians need to have a heightened awareness of parasitic diseases and how to treat them. Clinical signs and symptoms, together with the patient's travel history, should be used with other diagnostic aids in the identification of parasitic diseases. Parasitic infections caused by pathogenic protozoa or helminths affect more than 3 billion people worldwide and impose tremendous health and economic burdens on developing countries.⁹

This chapter discusses the major parasitic diseases, including protozoan diseases (giardiasis, amebiasis, malaria, and Chagas' disease), helminthic infections (ascariasis, enterobiasis, hookworm, strongyloidiasis, and cestodiasis), and ectoparasitic infestations (head and body lice). Emphasis is placed on diseases seen more frequently in the United States. World distribution of parasites depends on the presence of suitable hosts, habitats, and environmental conditions.⁹ A human parasite that does not use an intermediate host is likely to be found in any inhabited region of the world as long as the environmental conditions are suitable. *Ascaris* (roundworm) and *Trichuris* (whipworm) require carelessness of habits for transfer and require time outside the body, where they are exposed to heat and dryness, to reach the infective stage. The distribution of the hookworm is more limited because the free-living forms are unprotected by resistant shells or cysts. African trypanosomiasis never occurs outside the range of the tsetse fly; malaria never occurs beyond the range of the infective *Anopheles* mosquito; and schistosomiasis never occurs in the absence of a specific water snail. The prevalence of clonorchiasis (Chinese liver fluke) is an example of the impact of both environmental and geographic factors. Clonorchiasis requires the simultaneous presence of not only humans, specific snail species, and certain fish, but also unsanitary conditions that make the eggs accessible to the snails, an association of the snail and fish, and the established local habit of eating raw fish. The ability of some parasites to infect hosts other than humans may perpetuate an infection even when human habits preclude the possibility of more than occasional access to the human body. In North America, the broad tapeworm (*Diphyllobothrium latum*) would perish if it were not that dogs and other carnivores, such as the brown bear, serve as reservoir hosts.

HOST–PARASITE RELATIONSHIP

Symbiosis is the association of two species for the purpose of obtaining food for either one or the other. *Parasitism* is a symbiotic relationship in which one species, the host, is injured through the activities of the other. Through evolution, parasites have made specific morphologic adaptations. Adaptation to the host has taken a number of forms: loss of locomotor organelles in the protozoan *Sporozoa*; partial and complete lack of digestive systems in the trematodes and cestodes, respectively; elaboration of proteolytic enzymes to penetrate the host intestinal mucosa by *Entamoeba histolytica*; the cercariae of the blood fluke that penetrate the skin of the host by elaborate enzymes; and, finally, the ability to infect an intermediate host to increase reproductive capacity, as seen among the cestodes and trematodes.⁹

1 Parasites normally inflict some degree of injury to the host, the extent of which depends on such factors as parasite load, nutritional status, and immunologic competence of the host. *Entamoeba coli* is considered commensal because it subsists on the bacterial flora of the gut and does not cause any harm to the host. Unlike *Entamoeba coli*, *Fasciolopsis buski*, the giant intestinal fluke, can produce severe local damage to the intestinal wall. *Ascaris*, the roundworm, can perforate the bowel wall, cause intestinal obstruction, and invade the appendix and bile duct. Malarial parasites destroy red cells by multiplying inside them. *D. latum*, or the broad fish tapeworm, removes vitamin B₁₂ from the gastrointestinal tract (GI) tract, resulting in megaloblastic anemia.⁹

PROTOZOAN DISEASES

GIARDIASIS

Epidemiology and Etiology

Giardia lamblia (also known as *Giardia intestinalis* or *Giardia duodenalis*), an enteric protozoan, is the most common intestinal parasite responsible for diarrheal syndromes throughout the world.^{10–12,14} *Giardia* is the most frequently identified intestinal parasite in the United States, with a prevalence rate of 15% in some areas. *G. lamblia* has been identified as the first enteric pathogen seen in children in developing countries, with prevalence rates between 15% and 30%.¹²

There are two stages in the life cycle of *G. lamblia*: the trophozoite and the cyst. *G. lamblia*, which is found in the small intestine, the gallbladder, and biliary drainage, is a pear-shaped trophozoite with four pairs of flagella. Two nuclei lie in the area of the sucking disk, giving the protozoan a characteristic face-like image.

The distribution of giardiasis is worldwide. Children seem to be affected more frequently than adults. Children in daycare centers may infect parents and other family members.¹² In less-developed countries, fecal contamination of the environment and lack of potable water, education, and housing continue to be risk factors for giardiasis among children.

Pathology

Giardiasis results from ingestion of *G. lamblia* cysts in fecally contaminated water or food. The protozoan excysts under the stimulus of low gastric pH to release the trophozoite.¹² Colonization and multiplication of the trophozoite lead to mucosal invasion, localized edema, and flattening of the villi, resulting in malabsorption states in the host.^{10–16}

Lactose intolerance precipitated by giardiasis can persist even after eradication of the protozoan. Achlorhydria, hypogammaglobulinemia, or deficiency in secretory immunoglobulin A (IgA) are

TABLE 119-1 Clinical Presentation of Giardiasis

Acute onset
Diarrhea, cramp-like abdominal pain, bloating, and flatulence ^{10–12}
Malaise, anorexia, nausea, and belching ¹²
Chronic
Diarrhea: foul-smelling, copious, light-colored, fatty stools; weight loss
Periods of diarrhea alternating with constipation
Steatorrhea, lactose intolerance, vitamin B ₁₂ , and fat-soluble vitamin deficiencies ^{12–16}

predispositions for giardiasis.^{10,12,14} Table 119–1 describes the clinical presentation of giardiasis.

Diagnosis of giardiasis is made by examination of fresh stool or a preserved specimen during the acute diarrheal phase. Fresh stool specimens may show the trophozoites, whereas preserved specimens usually yield the cysts. If both the stool examination and string test prove unsuccessful, it may be necessary to attempt duodenal aspiration and biopsy to confirm the diagnosis; this may be more important in AIDS patients and in patients with hypogammaglobulinemia.^{10,12} Most clinicians advocate a clinical trial of the standard therapy before undertaking invasive diagnostic tests. Detection of the trophozoites or cysts in fecal samples by enzyme-linked immunosorbent assay (ELISA) or immunofluorescence or identification of the *Giardia* antigen by counterimmunoelectrophoresis are alternative ways for diagnosis of giardiasis.^{9,10,12}

TREATMENT

Giardiasis

■ DESIRED OUTCOME

To reduce morbidity and to avoid complications in patients identified with prolonged diarrhea and malabsorption and who have a recent history of travel to an endemic area, rapid identification by ova and parasite examination or by antigen detection test should be used to institute appropriate therapy.

■ PHARMACOLOGIC THERAPY

2 All symptomatic adults and children older than 8 years of age should be treated with metronidazole 250 mg three times daily for 5 to 7 days. The alternative drugs include furazolidone 100 mg four times or paromomycin 25 to 30 mg/kg per day in divided doses daily for 1 week.^{11–14} Paromomycin 25 to 30 mg/kg per day in three doses for 7 days is a safe agent in pregnancy.^{11,12} The pediatric dose for metronidazole is 15 mg/kg per day three times daily for 5 to 7 days.¹³ Furazolidone suspension 6 mg/kg per day in four doses for 7 to 10 days and nitazoxanide (Alinia) suspension 100 to 200 mg every 12 hours for 3 days are alternative drugs for children.^{12,13} Quinacrine, which was the drug of choice in giardiasis, has been discontinued by the manufacturer but is obtained in the United States from a specialized pharmacy (see Appendix 119–1). Albendazole 400 mg daily for 5 days has been cited to produce cure rates of 97% and as being equivalent to metronidazole in children. However, other investigators have disputed the efficacy of this agent.¹¹

Evaluation of Therapeutic Outcomes

Patients with symptomatic giardiasis, positive stool samples, or the detection of *Giardia* antigen by counterimmunoelectrophoresis or ELISA should be treated with metronidazole for 5 to 7 days. Metronidazole produces cure rates of between 85% and 95%.^{11,12} Diarrhea will stop within a few days, although in some patients it may take 1 to 2 weeks. Cyst excretion will cease within days; however, intestinal dysfunction (manifested as increased transit time) and radiologic changes (irregular thickening of the folds in

the upper small intestine) may take a few months to resolve.¹⁰ Patients who fail initial therapy with metronidazole should receive a second course of therapy. Nitazoxanide (500 mg twice daily for 3 days) is effective in patients who are not responding to metronidazole.¹² Pregnant patients can receive paromomycin 25 to 30 mg/kg per day in divided doses for 7 days. Metronidazole has been used in the second and third trimesters of pregnancy.¹²

Giardiasis can be prevented by good personal hygiene and by caution in food and drink consumption.

AMEBIASIS

Epidemiology and Etiology

Because of its worldwide distribution and serious gastrointestinal manifestations, amebiasis is one of the most important parasitic diseases of humans.^{9,18–21} The major causative organism in amebiasis is *E. histolytica*, which inhabits the colon and must be differentiated from the *Entamoeba dispar*, which is associated with an asymptomatic carrier state and is considered nonpathogenic. Although *E. histolytica* and *E. dispar* are indistinguishable morphologically, recent research using monoclonal antibodies has been able to separate the two.^{20,21} Invasive amebiasis is almost exclusively the result of *E. histolytica* infection. Approximately 50 million cases of invasive disease result each year worldwide, leading to an excess of 100,000 deaths.^{19,21} In the United States, the incidence of amebiasis is estimated at approximately 4% in the general population.²¹ The highest incidence is found in institutionalized mentally retarded patients, sexually active homosexuals, patients with AIDS, the Native American population, and new immigrants from endemic areas (e.g., Mexico, India, West and South Africa, and portions of Central and South America).^{19,21}

Pathology

E. histolytica invades mucosal cells of colonic epithelium, producing the classic flask-shaped ulcer in the submucosa.^{19–23} The trophozoite has a cytolethal effect on cells through a toxin. If the trophozoite gets into the portal circulation, it will be carried to the liver, where it produces abscess and periportal fibrosis.^{19–23} Amebic ulcerations can affect the colon, perineum, and genitalia, and abscesses may occur in the lung and brain.^{20,21,24}

Clinical Presentation

The most frequent clinical manifestations of the disease are gastrointestinal (Table 119–2).

Liver abscesses can spread to the lungs and pleura.^{20,21} Pericardial infections, although rare, may be associated with extension of the amebic abscess from the left lobe of the liver. Erosion of liver abscesses also present as peritonitis.^{19–22}

3 Review of the patient's history and recent travel should be strongly emphasized. Intestinal amebiasis is diagnosed by demonstrating *E. histolytica* cysts or trophozoites (may contain ingested erythrocytes) in fresh stool or from a specimen obtained by sigmoid-

oscopy. Three stool samples obtained 24 hours apart will produce a 60% to 90% yield for *E. histolytica*. Microscopy may not differentiate between the pathogenic *E. histolytica* and the nonpathogenic *E. dispar* in stools. Sensitive techniques are available to detect *E. histolytica* in stool, including ELISA and antigen detection.^{19–21} Endoscopy with scraping or biopsy may provide more definitive diagnosis where stool examinations do not provide adequate evidence.^{19,21}

When amebic liver abscess is suspected from initial physical examination and history, confirmatory diagnostic procedures will include serology and liver scans (using isotopes by ultrasound or computed tomography) or magnetic resonance imaging.^{20,21} Leukocytosis ($>10,000/\text{mm}^3$) and an elevated alkaline phosphatase concentration ($>75\%$) are common findings. In rare instances, needle aspiration of the hepatic abscess may be attempted using ultrasound guidance.^{20–22}

TREATMENT

Amebiasis

■ DESIRED OUTCOME

In amebiasis, the goals of therapy are initially to eradicate the parasite by use of specific amebicides and then to render supportive therapy.

■ TREATMENT REGIMENS

A number of different regimens have been suggested depending on the category of amebiasis: asymptomatic cyst passers, intestinal amebiasis, and amebic liver abscess.^{13,19–22} Electrolyte replacement, antibiotic therapy, and nutritional support are essential adjunctive treatment modalities. Large hepatic abscess or amebic pericarditis may require needle aspiration, percutaneous catheter drainage, or, rarely, surgery before drug therapy.^{20–22} Most regimens require a combination of drugs administered concurrently or sequentially.^{19,21}

A careful history should be taken when one of the differential diagnoses is ulcerative colitis because corticosteroid administration has the potential to unmask amebiasis and produce toxic megacolon.²²

■ PHARMACOLOGIC THERAPY

Metronidazole (Flagyl), dehydroemetine, and chloroquine (Aralen) are tissue-acting agents, whereas iodoquinol (Yodoxin), diloxanide furoate (Furamide), and paromomycin (Humatin) are luminal amebicides. A systemic agent may be so well absorbed that only small amounts of the drug stay in the bowel, which might prove ineffective as a luminal agent.^{20–22} A luminal-acting agent, on the other hand, may be too poorly absorbed to be effective in the tissue. In the asymptomatic cyst passer, it is necessary to eradicate the causative agent from the lumen to prevent intestinal amebiasis or the development of amebic liver abscess. Drug effectiveness must be monitored by stool examination, that is, from one to three negative specimens from 1 to 3 months after treatment.

Asymptomatic cyst passers and patients with mild intestinal amebiasis should receive one of the following luminal agents: paromomycin 25 to 30 mg/kg per day three times daily for 7 days, iodoquinol 650 mg three times daily for 20 days, or diloxanide furoate 500 mg three times daily for 10 days. These regimens have cure rates of between 84% and 96%.²¹ Diloxanide furoate is available only from Ponorama Compounding Pharmacy [6744 Balboa Blvd., Van Nuys, CA 91406; (800)-247-9767].¹³ The pediatric dose for paromomycin is the same as in adults, whereas the dose of iodoquinol is 30 to 40 mg/kg per day in three doses for 20 days, and the dose of diloxanide furoate is 20 mg/kg per day in three doses for 10 days.¹³ Paromomycin is the preferred luminal agent in pregnant patients.^{13,21}

TABLE 119-2 Most Common Manifestations of Amebiasis

Intestinal disease

Vague abdominal discomfort, malaise to severe abdominal cramps, flatulence, bloody diarrhea (heme-positive in 100% of cases) with mucus^{19–21}
Eosinophilia is usually absent, although moderate leukocytosis is not unusual^{20,21}

Amebic liver abscess

High fever, significant leukocytosis with left shift, elevated alkaline phosphatase, and liver tenderness on palpation^{20–22}
Right-upper-quadrant pain, hepatomegaly, and liver tenderness, with referred pain to the left or right shoulder
Erosion of liver abscesses also present as peritonitis^{19–21}

Patients with severe intestinal disease or liver abscess should receive metronidazole 750 mg three times daily for 10 days, followed by a course of one of the luminal agents indicated earlier.^{13,20–21} Tinidazole 800 mg three times daily for 5 days has been suggested for amebic liver abscess.²² In the pediatric patient, the dose of oral metronidazole is 50 mg/kg per day in divided doses to be followed by a luminal agent.¹³ Patients who are too ill to take oral metronidazole should receive the drug in equivalent doses by the intravenous route.²¹

Evaluation of Therapeutic Outcomes

Followup in patients with amebiasis should include repeat stool examination, serology, colonoscopy (for colitis), or computed tomography (CT) (for liver abscess) between days 5 and 7, at the end of the course of therapy, and a month after the end of therapy.^{19,21} Most patients with either intestinal amebiasis or colitis will respond in 3 to 5 days with amelioration of symptoms. Patients with liver abscesses may take from 7 to 10 days to respond; patients not responding during this period may require aspiration of abscesses or exploratory laparotomy. Serial liver scans have demonstrated healing of liver abscesses over 4 to 8 months after adequate therapy.

Sanitation and Preventive Measures

Travelers and tourists visiting an epidemic area should avoid local tap water, ice, salads, and unpeeled fruits. Water can be disinfected by the use of iodine (tincture of iodine or commercial sources: Potable Aqua tablet, Wisconsin Pharmacal, or Globaline, Wallace & Tremain) or a strong chlorine (laundry bleach) solution, but boiled water is probably the safest. An alternative or additional measure may be to carry a portable water purifier (such as Safewater, Durango, CO; www.outgear.com). Because food handlers in Asia and Latin America may be a source of amebiasis, travelers should avoid eating at food stalls and open markets.

HELMINTHIC DISEASES

Most intestinal helminthic infections may not be associated with clearly defined manifestation of disease, but they can cause significant pathology.^{9,25–33} One factor that determines the pathogenicity of helminths is their population density. Light infections may be fairly well tolerated, whereas high populations of intestinal helminths can result in predictable disease presentations. In the United States, these infections are seen most frequently in recent immigrants from Southeast Asia, the Caribbean, Mexico, and Central America.^{1,2,8,26,27} Other populations that have a high risk of infestation include institutionalized patients (both young and elderly), preschool children in daycare centers, residents of Indian reservations, and homosexual individuals. Certain conditions and drugs (fever, corticosteroids, and anesthesia) can cause atypical localization of worms.^{34–38} Immunocompromised hosts can be overwhelmed by some helminthic infections, such as strongyloidiasis.³⁴

NEMATODES

Hookworm Disease

This is an infection of the small intestine caused by either *Ancylostoma duodenale* or *Necator americanus*. *N. americanus* is found in the southeastern United States, where the temperature and humidity provide the proper environment. *Ancylostoma* is seen rarely in the United States.^{25,27}

The life cycles of both species of hookworm are similar. The adult worms live in the small intestine attached to the mucosa. The females liberate eggs, which are eliminated in the feces and develop into larvae. Infective larva enter the host in contaminated food or

TABLE 119-3 Clinical Presentations of Nematode Infections and Cysticercosis

Hookworm ²⁷
Mild epigastric pain and tenderness, headache, fatigue, anemia, hypoproteinemia, and cutaneous larva migrans
Ascariasis ²⁶
Abdominal pain, right-upper-quadrant pain, biliary coli, cholangitis, pancreatitis, and abdominal obstruction
Enterobiasis ²⁵
Mild abdominal discomfort and perianal itch
Strongyloidiasis ^{34,35,37}
Gastrointestinal: abdominal pain, bloating, nausea, constipation, and small obstruction
Cardiopulmonary: cough, wheezing, pleural effusion, chest pain, and dyspnea
Dermatologic/hematologic: pruritic linear streaks of lower thighs and buttocks and eosinophilia
Central nervous system: headache, altered mental status, and meningitis
Cysticercosis ^{41,42,45}
Abdominal pain, nausea, diarrhea, painless nodules on arms, chest and legs, and myalgia
Neurocysticercosis: headache, intracranial hypertension, hydrocephalus, and seizures

water or penetrate the skin, where a papular eruption with localized edema and erythema can result.

In the small intestine, where the adult worm lives attached to the mucosa, injury is usually caused by mechanical and lytic destruction of tissue. The loss of blood can lead to anemia and hypoproteinemia (Table 119-3).^{26–29}

Stool should be examined for eggs and the rhabditiform larvae. Eosinophilia (30% to 60%) may be present in patients during early infection.

TREATMENT

Hookworm Disease

④ Mebendazole (Vermox), an oral synthetic benzimidazole, is the agent of first choice. It is also effective against ascariasis, enterobiasis, trichuriasis, and hookworm.^{13,25,26} The adult dose for treatment of hookworm infestation is 100 mg twice daily for 3 days. Pediatric patients older than 2 years of age should receive the same dose as adults.¹³ Albendazole is an alternative agent.¹³

Ascariasis

Ascariasis is caused by the giant roundworm *Ascaris lumbricoides*. Female worms range from 20 to 35 cm in length. The worm is found worldwide but more commonly in areas where sanitation is poor. In the United States, endemic areas include southeastern parts of the Appalachian range and the Gulf Coast states.

Clinical Manifestations During migration of the larvae through the lungs, patients can present with pneumonitis, fever, cough, eosinophilia, and pulmonary infiltrates.^{9,25,26} Other symptoms of ascariasis include abdominal discomfort, abdominal obstruction, vomiting, and appendicitis (see Table 119-3).^{9,25,31,32} Diagnosis is made by demonstrating the characteristic egg in the stool.

TREATMENT

Ascariasis

In both adults and pediatric patients older than 2 years of age, the treatment for ascariasis is mebendazole (Vermox) 100 mg twice daily for 3 days.¹³ An alternative drug for ascariasis is albendazole 400 mg as a single dose.¹³

Enterobiasis

Enterobiasis, or pinworm infection, is caused by *Enterobius vermicularis*. The pinworm is a small, thread-like, spindle-shaped worm about 1 cm in length. It is the most widely distributed helminthic infection in the world. There are estimated to be 42 million cases in the United States.²⁵ The majority of those infected are children.

The most common problem with enterobiasis is cutaneous irritation in the perianal region, made by the migrating females or the presence of eggs. However, there are reports of other complications, including appendicitis and intestinal perforation.³³ The intense pruritus and scratching can cause dermatitis and secondary bacterial infections. In children, the itching can cause loss of sleep and restlessness (see Table 119–3).

The most effective method of diagnosing pinworm infections is by the use of perianal swab using adhesive Scotch tape. The Scotch tape, which is applied to the perianal region with a tongue depressor, is examined microscopically for eggs.^{9,25}

TREATMENT

Enterobiasis

The common agents for treatment include pyrantel pamoate, mebendazole, or albendazole (Albenza). The dose of pyrantel pamoate is 11 mg/kg (maximum 1 g) as a single dose that can be repeated in 2 weeks. The dose of mebendazole for adults and children older than 2 years of age is 100 mg as a single dose; this may be repeated in 2 weeks.^{13,25} The dose of albendazole for adults and children older than 2 years of age is 400 mg, and should be repeated in 2 weeks.²⁵ Following treatment, all bedding and underclothes should be sterilized by steaming or washing in the hot water cycle of a regular washing machine; this will eradicate the eggs. Bathroom rugs and toilet accessories also should be cleaned in a similar way.

Strongyloidiasis

Strongyloidiasis is caused by *Strongyloides stercoralis*, which has a worldwide distribution and is predominantly prevalent in South America (Brazil and Columbia) and in Southeast Asia. Strongyloidiasis is primarily seen among institutionalized populations (mental homes, mentally disabled children's homes) and immunocompromised individuals (patients with human immunodeficiency virus [HIV], AIDS, and hematologic malignancies).^{8,34–38} The worm is usually found in the upper intestine where the eggs are deposited and hatch to form the rhabditiform larvae. The rhabditiform larvae (male and female) migrate to the bowel where they may be excreted in the feces. If excreted in the feces, the larvae can evolve into either one of two forms after copulation: (a) free-living noninfectious rhabditiform larvae or (b) infectious filariform larvae. The filariform larvae can penetrate host skin, travel to the lungs via the bronchi and glottis and make their way to the small intestine. At times, the filariform larvae may not pass out in the feces but instead migrate to the lungs and produce progeny, a process called autoinfection. This can result in hyperinfection (i.e., increased number of larvae in intestine, lungs and other internal organs), especially in immunocompromised hosts.^{34–36}

Symptoms with acute infection may appear with localized pruritic rash but heavy infestations can produce eosinophilia (10% to 15%), diarrhea, abdominal pain and intestinal obstruction (see Table 119–3).^{37–39} Administration of corticosteroids or other immunosuppressive drugs to an infected individual can result in hyperinfections and disseminated strongyloidiasis. Diagnosis of strongyloidiasis is made by identification of the rhabditiform larvae in stool, sputum, duodenal fluid, and cerebrospinal fluid, by small bowel biopsy specimens, or by antigen testing (ELISA assay).^{34,37}

TREATMENT

Strongyloidiasis

4 The drug of choice for strongyloidiasis is oral ivermectin 200 mcg/kg/day for 2 days and the alternative is albendazole 400 mg twice daily for 7 days.^{13,34,39,40} In a patient with hyperinfection or disseminated strongyloidiasis, immunosuppressive drugs should be discontinued and treatment initiated with ivermectin 200 mcg/kg/day until all symptoms are resolved (duration: 5 to 14 days). Patients should be tested periodically to ensure the elimination of the larvae. Individuals from endemic areas, who are candidates for organ transplantation, must be screened for *S. stercoralis*.

Taenia solium: Cysticercosis and Neurocysticercosis

Tapeworm infection caused by *Taenia solium* is a result of ingestion of poorly cooked pork that contains the larvae or cysticercus.^{41,42} Cysticercus, when released from the contaminated meat by host digestive juices, matures into the adult tapeworm and attaches to the host jejunum. Cysticercosis is a systemic disease caused by the larva of *T. solium* (oncosphere) and is usually acquired by ingestion of eggs in contaminated food or by autoinfection.^{41–46} The larvae can penetrate the bowel and migrate through the bloodstream to infect different organs including the central nervous system (neurocysticercosis). The larvae matures in about 8 weeks and remain as a semitransparent, oval-shaped, fluid-filled bladder in tissues. In the United States, the highest incidence of cysticercosis has been reported in immigrants from Mexico.^{2,43,44} Cysticercosis in most tissues may not produce major symptoms and usually manifest as subcutaneous nodules, primarily in the arms, legs, and chest. However, penetration of the larval stage (cysticercus) into the central nervous system can produce hydrocephalus, intracranial hypertension, stroke, and seizure activity. Epileptic seizures (50% to 80%) may be the presenting symptoms in patients with neurocysticercosis (see Table 119–3).^{42,45} Clinical presentation, primarily seizure history, together with radiographic demonstration (CT and magnetic resonance imaging) of the cysticercus within the bladder or calcified cysts in the central nervous system, is diagnostic for neurocysticercosis. Serologic diagnosis is made by the use of an enzyme-linked immunoelectrotransfer blot assay, which is considered highly sensitive and specific for cysticercosis.^{41,42,45,46}

TREATMENT

Neurocysticercosis

CLINICAL CONTROVERSY

4 Cysticercosis (excluding neurocysticercosis) is normally not treated. The management for neurocysticercosis remains controversial but may include surgery, anticonvulsants (neurocysticercosis-induced seizures), and antihelminthic therapy.^{2,41,42,45,47} Antihelminthic therapy, if one decides this is an option, is albendazole 400 mg twice daily for 8 to 30 days.¹³ However, the dose and duration of therapy with albendazole is not clearly defined.^{42,47} The pediatric dose of albendazole is 15 mg/kg (maximum: 800 mg) in two divided doses for 8 to 30 days. The doses for both adults and pediatric subjects may be repeated if necessary. Praziquantel is an alternative therapy.¹³

Evaluation of Therapeutic Outcome

Morbidity and disease with intestinal nematodes are related to the intensity of infection or worm burden; subjects with transient

exposure have less-severe disease. The major adverse effects of intestinal nematodes are malnutrition, fatigue, and diminished work capacity. Treatment with antihelmintic agents results in complete eradication and significant change in the well-being of patients. Unlike other nematode infections, strongyloidiasis can perpetuate itself by autoinfection, and in the immunosuppressed host, the filariform larvae can invade various organs (e.g., lungs, central nervous system, and the like) to produce disseminated infection that can be fatal.^{9,34–38}

The most serious complication of cysticercosis is invasion of the central nervous system which results in neurocysticercosis. Neurocysticercosis can cause obstructive hydrocephalus, strokes and seizures; antihelmintic treatment for these conditions remains controversial.^{2,42,45,47}

MALARIA

5 Malaria represents the most devastating disease in terms of human suffering and economics. It affects the largest number of people (between 300 and 500 million new infections are reported annually) in the world, and between 1 to 2 million deaths worldwide.^{3,5,48–50} In the United States, deaths from malaria are preventable. The primary reasons for deaths are failure to take chemoprophylaxis, inappropriate chemoprophylaxis, delay in seeking medical care, and misdiagnosis.^{3,4,7,50}

EPIDEMIOLOGY

The exact geographic distribution of the various species is not well documented; it is reported that *Plasmodium vivax* is more prevalent in India, Pakistan, Bangladesh, Sri Lanka, and Central America, whereas *Plasmodium falciparum* is predominant in Africa, Haiti, Dominican Republic, the Amazon region of South America, and New Guinea. Most of the infections with *Plasmodium ovale* occur in Africa, and the distribution of *Plasmodium malariae* is considered worldwide.^{7,49}

In the United States, most cases of malaria are reported in immigrants from endemic areas and in American travelers. Blood transfusion also has been cited as a cause of malarial infection.^{48,51}

ETIOLOGY

Malaria is transmitted by the bite of an infected *Anopheles* mosquito that introduces the sporozoites (tissue parasites) of the plasmodia (*P. falciparum*, *P. vivax*, *P. malariae*, and *P. ovale*) into the bloodstream. The asexual reproduction stage develops in humans, whereas the sexual stage occurs in the mosquito.^{9,48,49} The sporozoites invade parenchymal hepatocytes, multiply in stages referred to as *exoerythrocytic stages*, and become hepatic vegetative forms or schizonts. Schizonts rupture to release daughter cells, or merozoites, that then infect erythrocytes.

P. falciparum and *P. malariae* remain in the primary exoerythrocytic stage in the liver for about 4 weeks before invading erythrocytes, whereas *P. vivax* and *P. ovale* can exist in the liver in the latent exoerythrocytic form for extended periods, and, therefore, infected subjects can experience relapses. The merozoites that invade the erythrocytes develop sequentially into ring forms, trophozoites, schizonts, and finally, merozoites, which can invade other erythrocytes or can develop into gametocytes, which undergo the sexual stage in the *Anopheles* vector. Because erythrocytic forms never invade the liver without developing into sporozoites in the vector, malaria infections from transfusion never result in the exoerythrocytic, or “liver,” form.^{9,49} *P. falciparum* can result in high levels of parasitemia because of its ability to invade erythrocytes of all ages, unlike *P. vivax* and *P. ovale*, which only invade young cells.^{48,49}

TABLE 119-4 Clinical Presentation of Malaria

Initial presentation
Nonspecific fever, chills, rigors, diaphoresis, malaise, vomiting ^{15,49}
Orthostatic hypotension
Electrolyte abnormalities
Erythrocytic phase
Prodrome: headache, anorexia, malaise, fatigue, myalgia
Nonspecific complaints such as abdominal pain, diarrhea, chest pain, and arthralgia
Paroxysm: high fever, chills, and rigor ^{2,3,9,49,54,55}
Cold phase: severe pallor, cyanosis of the lips and cutis anserina (“goose flesh”) ^{9,49,55}
Hot phase: fever between 40.5°C (104.9°F) and 41°C (105.8°F).
Sweating phase:
Follows hot phase by 2–6 hours
Fever resolves
Marked fatigue and drowsiness, warm, dry skin, tachycardia, cough, severe headache, nausea, vomiting, abdominal pain, diarrhea, and delirium
Lactic acidosis and hypoglycemia (with falciparum malaria) ^{48,49,54,55}
Anemia
Splenomegaly
<i>P. falciparum</i> infections
Hypoglycemia, acute renal failure, pulmonary edema, severe anemia, thrombocytopenia, high-output heart failure, cerebral congestion, seizures and coma, and adult respiratory syndrome ^{49,54,55}

PATHOLOGY

The erythrocytic phase causes extensive hemolysis, which results in anemia and splenomegaly. The most serious complications usually are associated with *P. falciparum* infections.^{48–50,52–59} Infants and children younger than 5 years of age and nonimmune pregnant women are at high risk for severe complications from falciparum malaria.^{52–55} The complications associated with falciparum malaria are primarily a result of the high parasitemia and the ability of the parasites to sequester in capillaries and postcapillary vessels of organs such as the brain and the kidney. It has been postulated that tissue hypoxia from anemia, together with *P. falciparum*-parasitized red blood cell adherence to endothelial cells in capillaries, contributes to extensive vascular disease and severe metabolic effects.^{52,53} *P. malariae* is implicated in immune-mediated glomerulonephritis and nephrotic syndrome (Table 119-4).^{49,52}

To ensure a positive diagnosis, blood smears should be obtained every 12 to 24 hours for 3 consecutive days.^{9,48,52} The presence of parasites in the blood 3 to 5 days after initiation of therapy suggests drug resistance. Recent advances for detecting malaria parasite have included DNA or RNA probes by polymerase chain reaction (PCR) and rapid dipstick tests (*ParaSight F*, Becton-Dickinson, Cockeysville, MD) and *OptiMAL*.^{48,49,52,60} The dipstick is reported to have a sensitivity of 88% and a specificity of 97%; however, microscopy is still considered the optimal test.

TREATMENT

Malaria

■ DESIRED OUTCOME

The primary goal in the management of malaria is the rapid diagnosis of the *Plasmodia* spp. by blood smears (repeated every 12 hours for 3 days) so as to initiate timely antimalarial therapy to eradicate the infection within 48 to 72 hours and to avoid complications such as hypoglycemia, pulmonary edema, and renal failure that are responsible for increased mortality in malaria.

■ PHARMACOLOGIC THERAPY

6 In adults (including pregnant women), the chemoprophylaxis for all species of *Plasmodium* is chloroquine phosphate 300 mg (base) once

weekly beginning 1 week prior to departure and continued for 4 weeks after leaving an endemic area.^{3,13,48,49,52,61–63} The pediatric dose of chloroquine phosphate is 5 mg (base) per kilogram of body weight (maximum: 300 mg). When departing an area endemic for *P. vivax* or *P. ovale*, primaquine phosphate 30 mg (base) daily for 14 days beginning the last 2 weeks of chloroquine prophylaxis should be added to the regimen. The pediatric dose of primaquine is 0.6 mg (base) per kilogram of body weight per day for 14 days. The pediatric doses of chloroquine can be calculated based on body weight, and the tablets can be pulverized and placed in gelatin capsules. Parents can be instructed to suspend the dose in food, simple syrup, chocolate milk, or drink.^{13,61}

In areas where chloroquine-resistant *P. falciparum* strains exist, travelers should receive mefloquine (Lariam) for prophylaxis. The adult dose of mefloquine is 250 mg once weekly beginning 1 week prior to departure and continuing for the full period of exposure, followed by 250 mg for 4 weeks after last exposure.^{13,48,49} The pediatric dose of mefloquine for prophylaxis is based on body weight:

Body Weight (kg)	Dose
15 to 19 kg	5 mg/kg
15 to 19 kg	one-quarter tablet
20 to 30 kg	one-half tablet
31 to 45 kg	three-quarters tablet
>45 kg	1 tablet

In travelers who are at immediate risk for drug-resistant falciparum malaria, a loading dose of mefloquine may be considered. Mefloquine is administered at 250 mg daily for 3 days before travel, followed by 250 mg once weekly while in the endemic area and continued for 4 weeks after last exposure.^{13,48,49} Patients may experience neuropsychiatric reactions from mefloquine and may need to be monitored closely.^{13,62–64}

CLINICAL CONTROVERSY

Because there remains public concern with mefloquine therapy, primarily about its neuropsychiatric effects,⁶³ an alternative regimen for chemoprophylaxis is the combination of atovaquone and proguanil (Malarone): 1 tablet daily beginning 1 to 2 days prior to travel and continuing for the duration of stay and 1 week after leaving the area.^{13,62} Daily primaquine 30 mg (base) also has been recommended for prophylaxis for both *P. vivax* and *P. falciparum* malaria.¹³

An alternative regimen for prophylaxis in chloroquine-resistant areas for those who cannot tolerate mefloquine or Malarone, is to take doxycycline 100 mg daily starting 1 to 2 days prior to departure, during the exposure period, and continuing for 4 weeks after leaving the endemic area.¹³ Children older than 8 years of age should receive 2 mg/kg per day (up to 100 mg) of doxycycline. Doxycycline is contraindicated in children younger than 8 years of age, in pregnant women, and during breast-feeding.^{13,49,63,65}

In an uncomplicated attack of malaria (for all plasmodia except chloroquine-resistant *P. falciparum*), the recommended regimen is chloroquine 600 mg (base) initially, followed by 300 mg (base) 6 hours later, and then 300 mg (base) daily for 2 days. In severe illness or when oral therapy is not tolerated or parenteral quinine is not available, quinidine gluconate 10 mg/kg as a loading dose (maximum 600 mg) in 250 mL normal saline should be administered slowly over 1 to 2 hours, followed by continuous infusion of 0.02 mg/kg per minute until oral therapy can be started.^{13,48,49} In patients who have received either quinine or mefloquine, the loading dose of quinidine should be omitted. Oral quinine (650 mg every 8 hours) together with doxycycline 100 mg twice daily should

follow the intravenous dose of quinidine to complete a total of 7 days of therapy.^{13,48} The pediatric dose of intravenous quinidine gluconate is the same as the dose for adults.¹³ The pediatric dose of quinine is 30 mg/kg per day in three divided doses for 7 days. Children younger than age 8 years and pregnant women should get clindamycin 20 mg/kg/day in divided doses for 7 days instead of doxycycline.^{13,49}

In *P. falciparum* (chloroquine-resistant) infections, a dose of 750 mg mefloquine followed by 500 mg 12 hours later is recommended. The pediatric dose of mefloquine is 15 mg/kg (<45 kg) followed by 10 mg/kg 8 to 12 hours later.¹³ Intravenous quinidine gluconate followed by oral quinine plus doxycycline to complete a total of 7 days of therapy should follow in a severe illness, as already indicated.^{13,49} An alternative oral treatment for chloroquine-resistant *P. falciparum* infection in adults, especially in those with a history of seizures or psychiatric disorders, is the combination of atovaquone 250 mg and proguanil 100 mg (Malarone) (4 tablets daily for 3 days).^{13,48,49} The intravenous quinidine regimen requires close monitoring of the electrocardiogram and other vital signs (e.g., hypotension, QT interval prolongation, and hypoglycemia).^{13,49,55}

⑦ Because falciparum malaria is associated with serious complications, including pulmonary edema, hypoglycemia, jaundice, renal failure, confusion, delirium, seizures, coma, and death, careful monitoring of fluid status and hemodynamic parameters is mandatory.^{48,49,55} Exchange transfusion that may be required in patients with *P. falciparum* malaria in whom parasitemia is 5% to 15% remains a questionable modality.^{13,58} Either hemofiltration or hemodiafiltration is indicated in renal failure.⁵⁵

Malarial infection does not produce immunity in patients, and active research has been initiated to develop a malaria vaccine.^{66–68} A vaccine that blocks the entry of sporozoites into the liver cells will prevent malaria at this stage. However, immunity to sporozoites does not protect the host against parasites in the erythrocytic cycle. Infective sporozoites of *P. falciparum* are covered by a polypeptide, circumsporozoite protein. Isolation and identification of the gene encoding for this circumsporozoite protein have led to the development of a monoclonal antibody by recombinant DNA technology; *P. falciparum* sporozoite vaccine is now under investigation.⁶⁸

EVALUATION OF THERAPEUTIC OUTCOMES

When advising potential travelers on prophylaxis for malaria, be aware of the incidence of chloroquine-resistant *P. falciparum* malaria and the countries where this is prevalent.^{13,62,63} Detailed recommendations for prevention of malaria may be obtained by checking the World Wide Web (e.g., www.cdc.gov/travel/ or www2.cdc.gov/mmwr/)^{63,69} or by calling the Centers for Disease Control and Prevention (CDC) (see Appendix 119–1). A number of newer drugs are under active study and include the water-soluble artesunate and the oil-soluble artemether and combinations with other agents.^{7,13,49,62,63,70–73,75}

Acute *P. falciparum* malaria resistant to chloroquine should be treated with intravenous quinidine. These patients should have a central venous catheter to follow fluid status, and the electrocardiogram should be monitored closely. Hypoglycemia that is associated with *P. falciparum* should be checked and corrected with dextrose infusions.^{48,49,55} Quinidine infusion should be slowed temporarily or stopped if electrocardiogram shows a QT interval of greater than 0.6 seconds, an increase in the QRS complex to greater than 50%, or hypotension unresponsive to fluid challenge results. The suggested quinidine levels should be maintained at 3 to 7 mg/L.⁴⁹ Blood smears should be checked every 12 hours until parasitemia is less than 1%. Resolution of fever should take place between 36 and 48 hours after initiation of the intravenous quinidine therapy and the blood should be clear of parasites in 5

days.^{48,49,52} If parenteral therapy is required for more than 48 hours, the dose of quinidine be lowered by half.¹³

Travelers to endemic areas for malaria should be advised to remain in well-screened areas, to wear clothes that cover most of the body, and to sleep in mosquito nets.^{4,7,71,74} It is prudent to carry the insect repellent DEET (N,N-diethyl-metatol) or Picaridin (Cutter Advanced) insect spray for use in mosquito-infested areas. Readers are urged to check publications from the CDC for the list of countries where chloroquine-resistant *P. falciparum* exist.^{13,63}

AMERICAN TRYPANOSOMIASIS

ETIOLOGY

Two distinct forms of the genus *Trypanosoma* occur in humans. One is associated with African trypanosomiasis (sleeping sickness) and the other with American trypanosomiasis (Chagas’ disease).^{76–79} *Trypanosoma brucei gambiense* and *Trypanosoma brucei rhodesiense* are the causative organisms for the East African and West African trypanosomiasis, respectively. *T. brucei rhodesiense* causes the acute disease and is the more virulent of the two species. Both East and West African trypanosomiasis are transmitted by various species of tsetse fly belonging to the genus *Glossina*. Further discussion of this subject will focus on American trypanosomiasis.

Trypanosoma cruzi is the agent that causes American trypanosomiasis. American trypanosomiasis is transmitted by a number of species of a reduviid bug (*Triatoma infestans*, *Rhodnius prolixus*) that live in wall cracks of houses in rural areas of North, Central, and South America. The reduviid bug is infected by sucking blood from animals (e.g., opossums, dogs, and cats) or humans infected with circulating trypomastigotes (Table 119–5).

8 In chronic trypanosomiasis, patients present with cardiomyopathy and heart failure. Electrocardiograms are usually abnormal, demonstrating extrasystoles, first-degree heart block, right bundle-branch block, and other serious conduction disturbances.^{77–79} Degeneration of the autonomic ganglia in the smooth muscle of the esophagus and colon leads to uncoordinated peristalsis. The end result has been reported to be “megasyndromes” of affected organs.^{78–79} Penetration of central nervous system results in meningoencephalitis, strokes, seizures, and focal paralysis.^{78–80}

A history to verify the possible exposure to *T. cruzi* should be an important initial diagnostic workup. Recovery of *T. cruzi* is definitive, but this is not always possible, especially in chronic disease. Positive serologic tests using indirect immunofluorescent antibody test and ELISA (Chagas’ EIA, Abbott Labs) may be diagnostic for the disease. The only serologic test available in United States is Chagas’ Kit (Hemagen Diagnostics, Inc., Columbia, MD).⁷⁸ A PCR test has been used to diagnosis *T. cruzi*.⁸¹ Specimens may be sent to the CDC for testing. All candidates from an endemic area for Chagas’ disease who are candidates for transplantation should be tested for *T. cruzi*.⁸²

TABLE 119-5 Clinical Presentation of South American Trypanosomiasis

Acute
Unilateral orbital edema (“Romana sign”) ^{76,78,79}
Granuloma or “chagoma”
Fever, hepatosplenomegaly, and lymphadenopathy
Chronic
Cardiac: cardiomyopathy and heart failure
ECG: first-degree heart block, right bundle-branch block, and arrhythmias ^{77,78}
Gastrointestinal: enlargement of esophagus and colon (“mega” syndrome) ^{76,78}
Central nervous system: meningoencephalitis, strokes, seizures, and focal paralysis ^{78–80}

TREATMENT

American Trypanosomiasis

■ DESIRED OUTCOME

The primary goal of drug therapy in trypanosomiasis is to reduce the duration and severity of the illness and to decrease mortality.

■ PHARMACOLOGIC THERAPY

The drugs that have been used to treat *T. cruzi* infections include nifurtimox (Lampit, Bayer 2502) and benznidazole (Rochagan).^{13,78,79,83,84} Oral nifurtimox is available from the CDC, whereas benznidazole is only available in Brazil. Neither of these agents are optimal therapy and there is ongoing search for newer agents.^{76,78} The adult dose of nifurtimox is 8 to 10 mg/kg per day in divided doses for 120 days. Because pediatric patients tolerate the drug better than adults, the dose for children aged 1 to 10 years is 15 to 20 mg/kg per day, and for children aged 11 to 16 years it is 12.5 to 15 mg/kg per day in divided doses.^{13,84} Symptomatic treatment for heart failure includes digitalis and diuretics; the gastrointestinal complications, however, may require surgical revisions and reconstruction.^{78,79}

EVALUATION OF THERAPEUTIC OUTCOMES

American trypanosomiasis (Chagas’ disease), which is endemic in all Latin American countries, can be transmitted congenitally, by blood transfusion, and by organ transplantation.^{78,79} Treatment with nifurtimox of the acute phase (i.e., fever, malaise, edema of face, generalized lymphadenopathy, and hepatosplenomegaly) produces between 10% and 30% cure rates.⁷⁸ Treatment of chronic infection with nifurtimox is not recommended. It is essential to identify *T. cruzi*-infected patients by serology and to monitor the cardiovascular status of these patients by electrocardiogram periodically. The congestive failure of cardiomyopathic Chagas’ disease is treated the same way as cardiomyopathies from other causes.^{76,78}

ECTOPARASITES

A parasite that lives on the outside the body of the host is called an *ectoparasite*. Approximately 6 to 12 million people become infested with pediculosis yearly in the United States.⁸⁵ Pediculosis usually is associated with poor personal hygiene, and infections are passed from person to person through social and sexual contact. The three types of human lice belong to two genera: *Pediculus*, including the head and body lice, and *Phthirus*, with only one species, the crab louse.^{9,85,86} The human louse is detectable to the human naked eye and measures approximately 2 to 3 mm in length.

LICE

The two species that belong to this group include *Pediculus humanus capitis* (head louse) and *Pediculus humanus corporis* (body louse). Female lice deposit eggs on the hair. The eggs (or nits) remain firmly attached to the hair, and in about 10 days, the lice hatch to form nymphs, which mature in 2 weeks. Using both their piercing mouth parts and a pumping device, the larva and adults feed on the blood of the host. The body louse and head louse are essentially identical, although they live on different parts of the body. Unlike the head louse, which lives on the hair, the body louse is more frequently found on clothing of the infected host.

Pubic or crab lice are found on the hairs around the genitals, although they can occur in other areas of the body (e.g., eyelashes,

beards, and axillae). Patients usually complain of severe pruritus from papular lesions produced by the bite of the louse. Hypersensitivity to foreign material injected by the lice can produce macular swellings and occasionally can lead to secondary bacterial infections.⁸⁵

TREATMENT

Lice

The goal of therapy is to eradicate the causative organisms and provide symptomatic relief to patients. The agent of choice for all three infections (body, head, and crab lice) is 1% permethrin (Nix).^{85–90} Permethrin is a derivative of the flowers of the plant *Chrysanthemum cinerariifolium*. The term *pyrethrin* is usually applied to several esters of chrysanthemic acid and pyrethric acid. Permethrin has both pediculicidal and ovicidal activity against *P. humanus* var. *capitis*. The cure rate is reported to be in the range of 85% to 95%.⁸⁵ Individuals who have a history of ragweed or chrysanthemum allergy should use this compound with caution. The side effects reported with permethrin products include itching, burning, stinging, and tingling.⁹⁰ Permethrin 1% is applied to the scalp after the hair has been dried following a shampooing. The scalp should be saturated with permethrin liquid, and a towel should be wrapped around the scalp to allow the application to stay on for 10 minutes. The hair then should be rinsed thoroughly. A cream rinse of permethrin 1% (Nix-Creme Rinse) is also available. To ensure complete eradication, especially of newly hatched lice, it may be necessary to repeat the application.

⁹ Recent reports suggest increasing lice resistance to permethrin 1%.^{87–89} An alternative preparation for lice is 0.5% malathion (Ovide), which is very effective.^{13,85} To ensure complete eradication of lice infestation, the malathion application should be left on the scalp for about 90 minutes.⁹⁰ For the relief of pruritus, a soothing lotion of calamine liniment or lotion with 0.1% menthol may be used. Other members of the family or sexual partners also should be treated. All bedding and clothes should be sterilized by boiling or washing in the hot water cycle of the washing machine to avoid reinfections. Seams of clothes should be examined to verify that all organisms are eradicated. An ocular lubricant (e.g., Lacri-Lube S.O.P.) applied twice daily may be used to remove crab louse infection of the eyelids.

SCABIES

Scabies is caused by the itch mite *Sarcoptes scabiei*, which affects both humans and animals. Mange in domestic animals is caused by the same organism. Infection usually affects the interdigital and popliteal folds, axillary folds, the umbilicus, and the scrotum.^{91–93}

Clinical Presentation

Patients will complain of severe itching and an inability to sleep and may have excoriations in the interdigital web spaces, wrists, elbows, buttocks, groin, and scalp. Excoriations may lead to secondary bacterial infections. The diagnosis is made by looking for burrows formed by the mite and taking skin scrapings, which will demonstrate the mite on a wet mount.

TREATMENT

Scabies

Because these infections cause a great deal of discomfort and distress to patients and families, the goals of therapy are to eradicate the infestations rapidly, to institute symptomatic treatment, and to provide counseling and reassurance. The treatment of choice is

permethrin 5% (Elimite) cream.^{13,91–93} To initiate the treatment, the skin should be scrubbed thoroughly in a warm soapy bath using a soft brush to remove all scabs. The lotion is then applied to the whole body, avoiding the face, mucous membranes, and eyes. The application should be left on for 8 to 14 hours before bathing. A single application eradicates 97% of scabies in subjects.⁹¹ All close contacts should be checked and treated appropriately.

Other agents used to treat scabies include topical crotamiton 10% (Eurax) and oral ivermectin (Stromectol) 200 mcg/kg as a single dose which may be repeated in 2 weeks.^{13,93} Crotamiton and oral ivermectin may be used in patients who have hypersensitivity to permethrin preparations. Topical corticosteroids and antihistamines may be used to decrease pruritus.

¹⁰ Permethrin (1% and 5%) for pediculosis and scabies respectively, is the preferred agent and remains the safest agent, especially in infants and children.^{85,93} One application of permethrin is consistently effective in eradicating more than 90% of all infections. However, pruritus may persist for 2 to 4 weeks because of the remnants of mite parts in the skin. Ivermectin is an alternative therapy for scabies.

ABBREVIATIONS

AIDS: acquired immunodeficiency syndrome

ELISA: enzyme-linked immunosorbent assay

PCR: polymerase chain reaction
