Dyspnea is the consequence of deviations from normal function in the cardiopulmonary systems. Alterations in the respiratory system can be considered in the context of the controller (stimulation of breathing); the ventilatory pump (the bones and muscles that form the chest wall, the airways, and the pleura); and the gas exchanger (the alveoli, pulmonary vasculature, and surrounding lung parenchyma). Similarly, alterations in the cardiovascular system can be grouped into three categories: conditions associated with high, normal, and low cardiac output (Fig. 33-2).

Respiratory System Dyspnea • ***CONTROLLER*** Acute hypoxemia and hypercapnia are associated with increased activity in the controller. Stimulation of pulmonary receptors, as occurs in acute bronchospasm, interstitial edema, and pulmonary embolism, also leads to hyperventilation and air hunger, as well as a sense of chest tightness in the case of asthma. High altitude, high progesterone states such as pregnancy, and drugs such as aspirin stimulate the controller and can cause dyspnea even when the respiratory system is normal.

VENTILATORY PUMP Disorders of the airways (e.g., asthma, emphysema, chronic bronchitis, bronchiectasis) lead to increased airway resis-

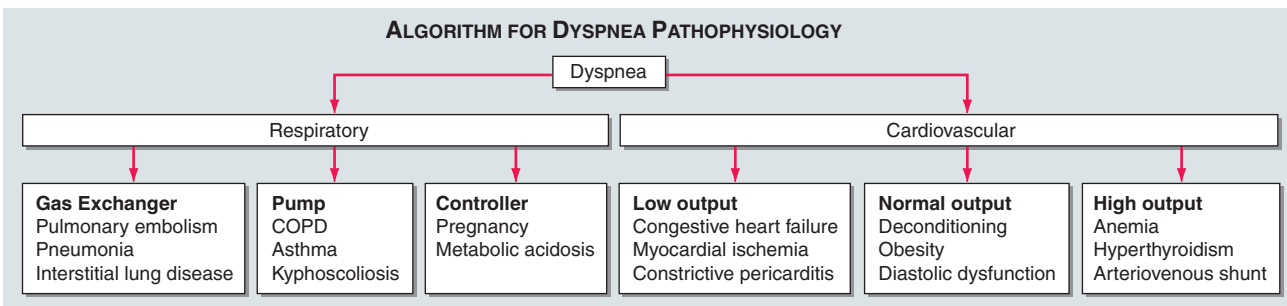

FIGURE 33-2 Pathophysiology of dyspnea. When confronted with a patient with shortness of breath of unclear cause, it is useful to begin the analysis with a consideration of the broad pathophysiologic categories that explain the vast majority of cases. COPD, chronic obstructive pulmonary disease. *(Adapted from Schwartzstein and Feller-Kopman.)*

tance and work of breathing. Hyperinflation further increases the work of breathing and can produce a sense of an inability to get a deep breath. Conditions that stiffen the chest wall, such as kyphoscoliosis, or that weaken ventilatory muscles, such as myasthenia gravis or the Guillain-Barré syndrome, are also associated with an increased effort to breathe. Large pleural effusions may contribute to dyspnea, both by increasing the work of breathing and by stimulating pulmonary receptors if there is associated atelectasis.

GAS EXCHANGER Pneumonia, pulmonary edema, and aspiration all interfere with gas exchange. Pulmonary vascular and interstitial lung disease and pulmonary vascular congestion may produce dyspnea by direct stimulation of pulmonary receptors. In these cases, relief of hypoxemia typically has only a small impact on the intensity of dyspnea.

Cardiovascular System Dyspnea • ***HIGH CARDIAC OUTPUT*** Mild to moderate anemia is associated with breathing discomfort during exercise. Left-to-right intracardiac shunts may lead to high cardiac output and dyspnea, although in their later stages these conditions may be complicated by the development of pulmonary hypertension, which contributes to dyspnea. The breathlessness associated with obesity is probably due to multiple mechanisms, including high cardiac output and impaired ventilatory pump function.

NORMAL CARDIAC OUTPUT Cardiovascular deconditioning is characterized by early development of anaerobic metabolism and stimulation of chemoreceptors and metaboreceptors. Diastolic dysfunction—due to hypertension, aortic stenosis, or hypertrophic cardiomyopathy—is an increasingly frequent recognized cause of exercise-induced breathlessness. Pericardial disease, e.g., constrictive pericarditis, is a relatively rare cause of chronic dyspnea.

LOW CARDIAC OUTPUT Diseases of the myocardium resulting from coronary artery disease and nonischemic cardiomyopathies result in a greater left ventricular end-diastolic volume and an elevation of the left ventricular end-diastolic as well as pulmonary capillary pressures. Pulmonary receptors are stimulated by the elevated vascular pressures and resultant interstitial edema, causing dyspnea.

APPROACH TO THE PATIENT: Dyspnea

(Fig. 33-3) In obtaining a *history*, the patient should be asked to describe in his/her own words what the discomfort feels like, as well as the effect of position, infections, and environmental stimuli on the dyspnea. Orthopnea is a common indicator of congestive heart failure, mechanical impairment of the diaphragm associated with obesity, or asthma triggered by esophageal reflux. Nocturnal dyspnea suggests congestive heart failure or asthma. Acute, intermittent episodes of dyspnea are more likely to reflect episodes of myocardial ischemia, bronchospasm, or pulmonary embolism, while chronic persistent dyspnea is typical of COPD and interstitial lung disease. Risk factors for occupational lung disease and for coronary artery disease should be solicited. Left atrial myxoma or hepatopulmonary syndrome should be considered when the patient complains of *platypnea*, defined as dyspnea in the upright position with relief in the supine position.

The *physical examination* should begin during the interview of the patient. Inability of the patient to speak in full sentences before stopping to get a deep breath suggests a condition that leads to stimulation of the controller or an impairment of the ventilatory pump with reduced vital capacity. Evidence for increased work of breathing (supraclavicular retractions, use of accessory muscles of ventilation, and the tripod position, characterized by sitting with one's hands braced on the knees) is indicative of disorders of the ventilatory pump, most commonly increased airway resistance or stiff lungs and chest wall. When measuring the vital signs, an accurate assessment of the respiratory rate should be obtained and examination for a pulsus paradoxus carried out (Chap. 232); if it is >10 mm Hg, consider the presence of COPD. During the general examination, signs of anemia (pale conjunctivae), cyanosis, and cirrhosis (spider angiomata, gynecomastia) should be sought. Examination of the chest should focus on symmetry of movement; percussion (dullness indicative of pleural effusion, hyper-resonance a sign of emphysema); and auscultation (wheezes, rales, rhonchi, prolonged expiratory phase, diminished breath sounds, which are clues to disorders of the airways, and interstitial edema or fibrosis). The cardiac examination should focus on signs of elevated right heart pressures (jugular venous distention, edema, accentuated pulmonic component to the second heart sound); left ventricular dysfunction (S3 and S4 gallops); and valvular disease (murmurs). When examining the abdomen with the patient in the supine position, it should be noted whether there is paradoxical movement of the abdomen (inward motion during inspiration), a sign of diaphragmatic weakness. Clubbing of the digits may be an indication of interstitial pulmonary fibrosis, and the presence of joint swelling or deformation as well as changes consistent with Raynaud's disease may be indicative of a collagen-vascular process that can be associated with pulmonary disease.

Patients with exertional dyspnea should be asked to walk under observation in order to reproduce the symptoms. The patient should be examined for new findings that were not present at rest and for oxygen saturation. A "picture" of the patient while symptomatic may be worth thousands of dollars in laboratory tests.

Following the history and physical examination, a *chest radiograph* should be obtained. The lung volumes should be assessed (hyperinflation indicates obstructive lung disease, low lung volumes suggest interstitial edema or fibrosis, diaphragmatic dysfunction, or impaired chest wall motion). The pulmonary parenchyma should be examined for evidence of interstitial disease and emphysema. Prominent pulmonary vasculature in the upper zones indicates pulmonary venous hypertension, while enlarged central pulmonary arteries suggest pulmonary artery hypertension. An enlarged cardiac silhouette suggests a dilated cardiomyopathy or valvular disease. Bilateral pleural effusions are typical of congestive heart failure and some forms of collagen vascular disease. Unilateral effusions raise the specter of carcinoma and pulmonary embolism but may also occur in heart failure. *Computed tomography* (CT) *of the chest* is generally reserved for further evaluation of the lung parenchyma (interstitial lung disease) and possible pulmonary embolism.

Laboratory studies should include an electrocardiogram to look for evidence of ventricular hypertrophy and prior myocardial infarction. Echocardiography is indicated in patients in whom systolic dysfunction, pulmonary hypertension, or valvular heart disease is suspected.

Distinguishing Cardiovascular from Respiratory System Dyspnea If a patient has evidence of both pulmonary and cardiac disease, a cardiopulmonary exercise test should be carried out to determine which system is responsible for the exercise limitation. If, at peak exercise, the patient achieves predicted maximal ventilation, demonstrates an increase in dead space or hypoxemia (oxygen saturation below 90%), or develops bronchospasm, the respiratory system is probably the cause of the problem. Alternatively, if the heart rate is >85% of the predicted maximum, if anaerobic threshold occurs early, if the blood pressure becomes excessively high or drops during exercise, if the O_2 pulse (O_2 consumption/heart rate, an indicator of stroke volume) falls, or if there are ischemic changes on the electrocardiogram, an abnormality of the cardiovascular system is likely the explanation for the breathing discomfort.

Rx DYSPNEA

The first goal is to correct the underlying problem responsible for the symptom. If this is not possible, one attempts to lessen the intensity of the symptom and its effect on the patient's quality of life. Supplemental O_2 should be administered if the resting O_2 saturation is ≤90% or if the pa-

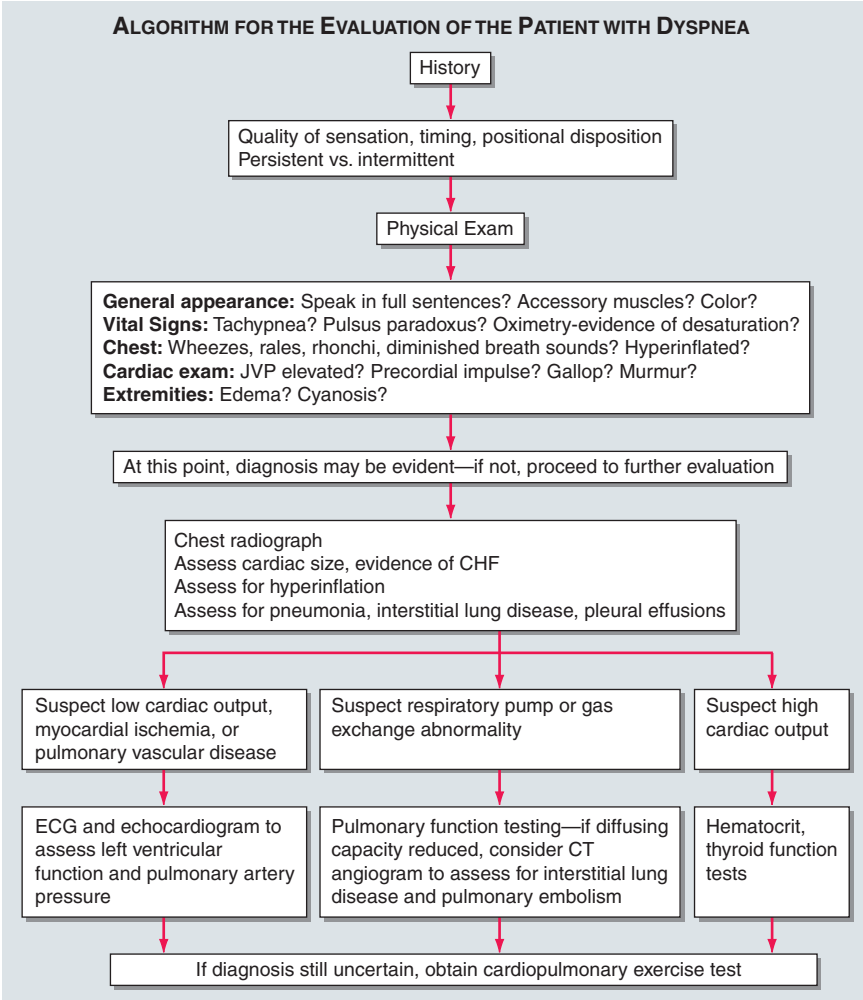

FIGURE 33-3 An algorithm for the evaluation of the patient with dyspnea. JVP, jugular venous pulse; CHF, congestive heart failure; ECG, electrocardiogram; CT, computed tomography. *(Adapted from Schwartzstein and Feller-Kopman.)*

tient's saturation drops to these levels with activity. For patients with COPD, pulmonary rehabilitation programs have demonstrated positive effects on dyspnea, exercise capacity, and rates of hospitalization. Studies of anxiolytics and antidepressants have not demonstrated consistent benefit. Experimental interventions—e.g., cold air on the face, chest wall vibration, and inhaled furosemide—to modulate the afferent information from receptors throughout the respiratory system are being studied.

PULMONARY EDEMA

MECHANISMS OF FLUID ACCUMULATION

The extent to which fluid accumulates in the interstitium of the lung depends on the balance of hydrostatic and oncotic forces within the pulmonary capillaries and in the surrounding tissue. Hydrostatic pressure favors movement of fluid from the capillary into the interstitium. The oncotic pressure, which is determined by the protein concentration in the blood, favors movement of fluid into the vessel. Albumin, the primary protein in the plasma, may be low in conditions such as cirrhosis and nephrotic syndrome. While hypoalbuminemia favors movement of fluid into the tissue for any given hydrostatic pressure in the capillary, it is usually not sufficient by itself to cause interstitial edema. In a healthy individual, the tight junctions of the capillary endothelium are impermeable to proteins, and the lymphatics in the tissue carry away the small amounts of protein that may leak out; together these factors result in an oncotic force that maintains fluid in the capillary. Disruption of the endothelial barrier, however, allows protein to escape the capillary bed and enhances the movement of fluid into the tissue of the lung.

Cardiogenic Pulmonary Edema (See also Chap. 266) Cardiac abnormalities that lead to an increase in pulmonary venous pressure shift the balance of forces between the capillary and the interstitium. Hydrostatic pressure is increased and fluid exits the capillary at an increased rate, resulting in interstitial and, in more severe cases, alveolar edema. The development of pleural effusions may further compromise respiratory system function and contribute to breathing discomfort.

Early signs of pulmonary edema include exertional dyspnea and orthopnea. Chest radiographs show peribronchial thickening, prominent vascular markings in the upper lung zones, and Kerley B lines. As the pulmonary edema worsens, alveoli fill with fluid; the chest radiograph shows patchy alveolar filling, typically in a perihilar distribution, which then progresses to diffuse alveolar infiltrates. Increasing airway edema is associated with rhonchi and wheezes.

Noncardiogenic Pulmonary Edema By definition, hydrostatic pressures are normal in noncardiogenic pulmonary edema. Lung water increases due to damage of the pulmonary capillary lining with leakage of proteins and other macromolecules into the tissue; fluid follows the protein as oncotic forces are shifted from the vessel to the surrounding lung tissue. This process is associated with dysfunction of the surfactant lining the alveoli, increased surface forces, and a propensity for the alveoli to collapse at low lung volumes. Physiologically, noncardiogenic pulmonary edema is characterized by intrapulmonary shunt with hypoxemia and decreased pulmonary compliance. Pathologically, hyaline membranes are evident in the alveoli, and inflammation leading to pulmonary fibrosis may be seen. Clinically, the picture ranges from mild dyspnea to respiratory failure. Auscultation of the lungs may be relatively normal despite chest radiographs that show diffuse alveolar infiltrates. CT scans demonstrate that the distribution of alveolar edema is more heterogeneous than was once thought.

It is useful to categorize the causes of noncardiogenic pulmonary edema in terms of whether the injury to the lung is likely to result from direct, indirect, or pulmonary vascular causes (Table 33-2). Direct inju-

TABLE 33-2 COMMON CAUSES OF NONCARDIOGENIC PULMONARY EDEMA

Direct Injury to Lung
Chest trauma, pulmonary contusion
Aspiration
Smoke inhalation
Pneumonia
Oxygen toxicity
Pulmonary embolism, reperfusion
Hematogenous Injury to Lung
Sepsis
Pancreatitis
Nonthoracic trauma

Intravenous drug use, e.g., heroin
Cardiopulmonary bypass
Possible Lung Injury Plus Elevated Hydrostatic Pressures
High altitude pulmonary edema
Neurogenic pulmonary edema
Reexpansion pulmonary edema

ries are mediated via the airways (e.g. aspiration) or as the consequence of blunt chest trauma. Indirect injury is the consequence of mediators that reach the lung via the blood stream. The third category includes conditions that may be the consequence of acute changes in pulmonary vascular pressures, possibly the result of sudden autonomic discharge in the case of neurogenic and high-altitude pulmonary edema, or sudden swings of pleural pressure, as well as transient damage to the pulmonary capillaries in the case of reexpansion pulmonary edema.

Distinguishing Cardiogenic from Noncardiogenic Pulmonary Edema The *history* is essential for assessing the likelihood of underlying cardiac disease as well as for identification of one of the conditions associated with noncardiogenic pulmonary edema. The *physical examination* in cardiogenic pulmonary edema is notable for evidence of increased intracardiac pressures (S3 gallop, elevated jugular venous pulse, peripheral edema), and rales and/or wheezes on auscultation of the chest. In contrast, the physical examination in noncardiogenic pulmonary edema is dominated by the findings of the precipitating condition; pulmonary findings may be relatively normal in the early stages. The *chest radiograph* in cardiogenic pulmonary edema typically shows an enlarged cardiac silhouette, vascular redistribution, interstitial thickening, and perihilar alveolar infiltrates; pleural effusions are common. In noncardiogenic pulmonary edema, heart size is normal, alveolar infiltrates are distributed more uniformly throughout the lungs, and pleural effusions are uncommon. Finally, the *hypoxemia* of cardiogenic pulmonary edema is due largely to ventilation-perfusion mismatch and responds to the administration of supplemental oxygen. In contrast, hypoxemia in noncardiogenic pulmonary edema is due primarily to intrapulmonary shunting and typically persists despite high concentrations of inhaled O_2.

34 Cough and Hemoptysis

Steven E. Weinberger, David A. Lipson

COUGH

Cough is an explosive expiration that provides a normal protective mechanism for clearing the tracheobronchial tree of secretions and foreign material. When excessive or bothersome, it is also one of the most common symptoms for which patients seek medical attention. Reasons for this include discomfort from the cough itself, interference with normal lifestyle, and concern for the cause of the cough, especially fear of cancer.

MECHANISM

Coughing may be initiated either voluntarily or reflexively. As a defensive reflex it has both afferent and efferent pathways. The *afferent limb* includes receptors within the sensory distribution of the trigeminal, glossopharyngeal, superior laryngeal, and vagus nerves. The *efferent limb* includes the recurrent laryngeal nerve and the spinal nerves. The cough starts with a deep inspiration followed by glottic closure, relaxation of the diaphragm, and muscle contraction against a closed glottis. The resulting markedly positive intrathoracic pressure causes narrowing of the trachea. Once the glottis opens, the large pressure differential between the airways and the atmosphere coupled with tracheal narrowing produces rapid flow rates through the trachea. The shearing forces that develop aid in the elimination of mucus and foreign materials.

ETIOLOGY

Cough can be initiated by a variety of irritant triggers either from an exogenous source (smoke, dust, fumes, foreign bodies) or from an endogenous origin (upper airway secretions, gastric contents). These stimuli may affect receptors in the upper airway (especially the pharynx and larynx) or in the lower respiratory tract, following access to the tracheobronchial tree by inhalation or aspiration. When cough is triggered by upper airway secretions (as with postnasal drip) or gastric contents (as with gastroesophageal reflux), the initiating factor can go unrecognized and the cough may persist. Additionally, prolonged exposure to such irritants may initiate airway inflammation, which can itself precipitate cough and sensitize the airway to other irritants. Cough associated with gastroesophageal reflux is due only in part to irritation of upper airway receptors or to aspiration of gastric contents, as a vagally mediated reflex mechanism secondary to acid in the distal esophagus may also contribute.

Any disorder resulting in inflammation, constriction, infiltration, or compression of airways can be associated with cough. Inflammation commonly results from airway infections, ranging from viral or bacterial bronchitis to bronchiectasis. In viral bronchitis, airway inflammation sometimes persists long after resolution of the typical acute symptoms, thereby producing a prolonged cough that may last for weeks. Pertussis infection is also a possible cause of persistent cough in adults; however, diagnosis is generally made on clinical grounds (Chap. 142). Asthma is a common cause of cough. Although the clinical setting commonly suggests when a cough is secondary to asthma, some patients present with cough in the absence of wheezing or dyspnea, thus making the diagnosis more subtle ("cough variant asthma"). A neoplasm infiltrating the airway wall, such as bronchogenic carcinoma or a carcinoid tumor, is commonly associated with cough. Airway infiltration with granulomas may also trigger a cough, as seen with endobronchial sarcoidosis or tuberculosis. Compression of airways results from extrinsic masses such as lymph nodes or mediastinal tumors, or rarely from an aortic aneurysm.

Examples of parenchymal lung disease potentially producing cough include interstitial lung disease, pneumonia, and lung abscess. Congestive heart failure may be associated with cough, probably as a consequence of interstitial as well as peribronchial edema. A nonproductive cough complicates the use of angiotensin-converting enzyme (ACE) inhibitors in 5–20% of patients taking these agents. Onset is usually within 1 week of starting the drug but can be delayed up to 6 months. Although the mechanism is not known with certainty, it may relate to accumulation of bradykinin or substance P, both of which are degraded by ACE. In contrast, angiotensin II receptor antagonists do not seem to increase cough, likely because these drugs do not significantly increase bradykinin levels.

The most common causes of cough can be categorized according to the duration of the cough. Acute cough (<3 weeks) is most often due to upper respiratory infection (especially the common cold, acute bacterial sinusitis, and pertussis), but more serious disorders, such as pneumonia, pulmonary embolus, and congestive heart failure, can also present in

this fashion. Subacute cough (between 3 and 8 weeks) is commonly post-infectious, resulting from persistent airway inflammation and/or postnasal drip following viral infection, pertussis, or infection with *Mycoplasma* or *Chlamydia*. In the patient with subacute cough that is not clearly post-infectious, the varied causes of chronic cough should be considered. Chronic cough (>8 weeks) in a smoker raises the possibilities of chronic obstructive lung disease or bronchogenic carcinoma. In a nonsmoker who has a normal chest radiograph and is not taking an ACE inhibitor, the most common causes of chronic cough are postnasal drip (sometimes termed the *upper airway cough syndrome*), asthma, and gastroesophageal reflux. Eosinophilic bronchitis in the absence of asthma has also been recognized as a potential cause of chronic cough.

APPROACH TO THE PATIENT: Cough

A detailed *history* frequently provides the most valuable clues for the etiology of the cough. Particularly important questions include:

1. Is the cough acute, subacute, or chronic?
2. At its onset, were there associated symptoms suggestive of a respiratory infection?
3. Is it seasonal or associated with wheezing?
4. Is it associated with symptoms suggestive of postnasal drip (nasal discharge, frequent throat clearing, a "tickle in the throat") or gastroesophageal reflux (heartburn or sensation of regurgitation)? However, the absence of such suggestive symptoms does not exclude either of these diagnoses.
5. Is it associated with fever or sputum? If sputum is present, what is its character?
6. Does the patient have any associated diseases or risk factors for disease (e.g., cigarette smoking, risk factors for infection with HIV, environmental exposures)?
7. Is the patient taking an ACE inhibitor?

The general *physical examination* may point to a systemic or nonpulmonary cause of cough, such as heart failure or primary nonpulmonary neoplasm. Examination of the oropharynx may provide suggestive evidence for postnasal drip, including oropharyngeal mucus or erythema, or a "cobblestone" appearance to the mucosa. Auscultation of the chest may demonstrate inspiratory stridor (indicative of upper airway disease), rhonchi or expiratory wheezing (indicative of lower airway disease), or inspiratory crackles (suggestive of a process involving the pulmonary parenchyma, such as interstitial lung disease, pneumonia, or pulmonary edema).

Chest radiography may be particularly helpful in suggesting or confirming the cause of the cough. Important potential findings include the presence of an intrathoracic mass lesion, localized pulmonary parenchymal opacification, or diffuse interstitial or alveolar disease. An area of honeycombing or cyst formation may suggest bronchiectasis, while symmetric bilateral hilar adenopathy may suggest sarcoidosis.

Pulmonary function testing (Chap. 246) is useful for assessing the functional abnormalities that accompany certain disorders producing cough. Measurement of forced expiratory flow rates can demonstrate reversible airflow obstruction characteristic of asthma. When asthma is considered but flow rates are normal, bronchoprovocation testing with methacholine or cold-air inhalation can demonstrate hyperreactivity of the airways to a bronchoconstrictive stimulus. Measurement of lung volumes and diffusing capacity is useful primarily for demonstration of a restrictive pattern, often seen with any of the diffuse interstitial lung diseases.

If *sputum* is produced, gross and microscopic examination may provide useful information. Purulent sputum suggests chronic bronchitis, bronchiectasis, pneumonia, or lung abscess. Blood in the sputum may be seen in the same disorders, but its presence also raises the question of an endobronchial tumor. Greater than 3% eosinophils seen on staining of induced sputum in a patient without asthma suggests the possibility of eosinophilic bronchitis. Gram and acid-fast stains and cultures may demonstrate a particular infectious pathogen, while sputum cytology may provide a diagnosis of a pulmonary malignancy.

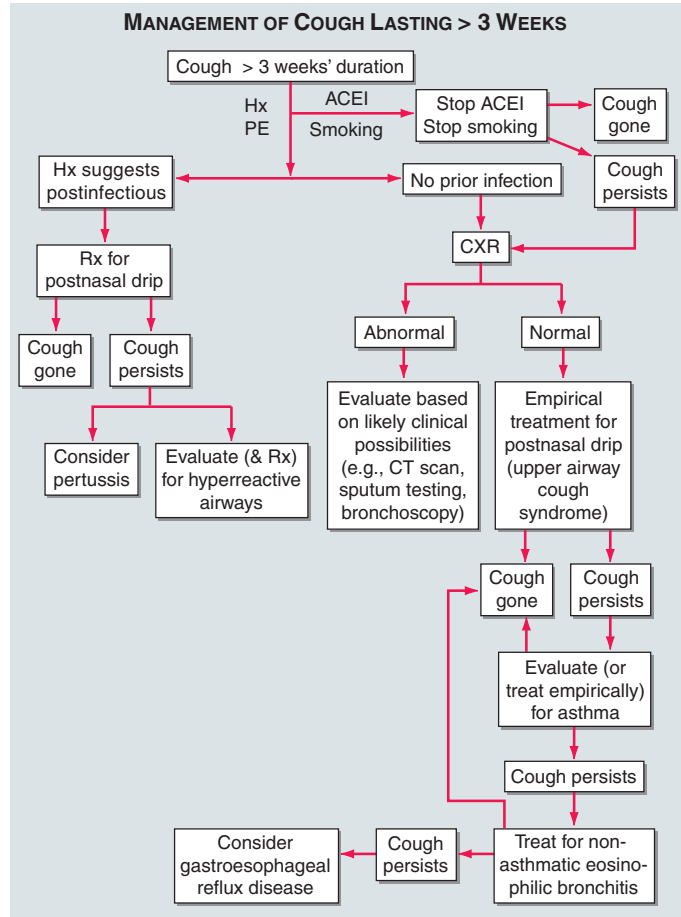

FIGURE 34-1 Algorithm for management of cough lasting >3 weeks. Cough between 3 and 8 weeks is considered subacute; cough >8 weeks is considered chronic. Hx, history; PE, physical examination; ACEI, angiotensin-converting enzyme inhibitor; Rx, treat; CXR, chest x-ray.

More specialized studies are helpful in specific circumstances. *Fiberoptic bronchoscopy* is the procedure of choice for visualizing an endobronchial tumor and collecting cytologic and histologic specimens. Inspection of the tracheobronchial mucosa can demonstrate endobronchial granulomas often seen in sarcoidosis, and endobronchial biopsy of such lesions or transbronchial biopsy of the lung interstitium can confirm the diagnosis. Inspection of the airway mucosa by bronchoscopy may also demonstrate the characteristic appearance of endobronchial Kaposi's sarcoma in patients with AIDS. *High-resolution computed tomography* (HRCT) can confirm the presence of interstitial lung disease and frequently suggests a diagnosis based on the specific abnormal pattern. It is the procedure of choice for demonstrating dilated airways and confirming the diagnosis of bronchiectasis.

A diagnostic algorithm for evaluation of subacute and chronic cough is presented in Fig. 34-1.

COMPLICATIONS

Common complications of coughing include chest and abdominal wall soreness, urinary incontinence, and exhaustion. On occasion, paroxysms of coughing may precipitate syncope (cough syncope; Chap. 21), consequent to markedly positive intrathoracic and alveolar pressures, diminished venous return, and decreased cardiac output. Although cough fractures of the ribs may occur in otherwise normal

patients, their occurrence should at least raise the possibility of pathologic fractures, which are seen with multiple myeloma, osteoporosis, and osteolytic metastases.

Rx COUGH

Definitive treatment of cough depends on determining the underlying cause and then initiating specific therapy. Elimination of an exogenous inciting agent (cigarette smoke, ACE inhibitors) or an endogenous trigger (postnasal drip, gastroesophageal reflux) is usually effective when such a precipitant can be identified. Other important management considerations are treatment of specific respiratory tract infections, bronchodilators for potentially reversible airflow obstruction, inhaled glucocorticoids for eosinophilic bronchitis, chest physiotherapy and other methods to enhance clearance of secretions in patients with bronchiectasis, and treatment of endobronchial tumors or interstitial lung disease when such therapy is available and appropriate. In patients with chronic, unexplained cough, an empirical approach to treatment is often used for both diagnostic and therapeutic purposes, starting with an antihistamine-decongestant combination, nasal glucocorticoids, or nasal ipratropium spray to treat unrecognized postnasal drip. If ineffective, this may be followed sequentially by empirical treatment for asthma, nonasthmatic eosinophilic bronchitis, and gastroesophageal reflux.

Symptomatic or nonspecific therapy of cough should be considered when: (1) the cause of the cough is not known or specific treatment is not possible, and (2) the cough performs no useful function or causes marked discomfort or sleep disturbance. An irritative, nonproductive cough may be suppressed by an antitussive agent, which increases the latency or threshold of the cough center. Such agents include codeine (15 mg qid) or nonnarcotics such as dextromethorphan (15 mg qid). These drugs provide symptomatic relief by interrupting prolonged, self-perpetuating paroxysms. However, a cough productive of significant quantities of sputum should usually not be suppressed, since retention of sputum in the tracheobronchial tree may interfere with the distribution of alveolar ventilation and the ability of the lung to resist infection.

HEMOPTYSIS

Hemoptysis is defined as the expectoration of blood from the respiratory tract, a spectrum that varies from blood-streaking of sputum to coughing up large amounts of pure blood. *Massive hemoptysis* is variably defined as the expectoration of >100–600 mL over a 24-h period, although the patient's estimation of the amount of blood is notoriously unreliable. Expectoration of even relatively small amounts of blood is a frightening symptom and may be a marker for potentially serious disease, such as bronchogenic carcinoma. Massive hemoptysis, on the other hand, can represent an acutely life-threatening problem. Blood can fill the airways and the alveolar spaces, not only seriously disturbing gas exchange but potentially causing asphyxiation.

ETIOLOGY

Because blood originating from the nasopharynx or the gastrointestinal tract can mimic blood coming from the lower respiratory tract, it is important to determine initially that the blood is not coming from one of these alternative sites. Clues that the blood is originating from the gastrointestinal tract include a dark red appearance and an acidic pH, in contrast to the typical bright red appearance and alkaline pH of true hemoptysis.

An etiologic classification of hemoptysis can be based on the site of origin within the lungs (Table 34-1). The most common site of bleeding is the tracheobronchial tree, which can be affected by inflammation (acute or chronic bronchitis, bronchiectasis) or by neoplasm (bronchogenic carcinoma, endobronchial metastatic carcinoma, or bronchial carcinoid tumor). The bronchial arteries, which originate either from the aorta or from intercostal arteries and are therefore part of the high-pressure systemic circulation, are the source of bleeding in bronchitis or bronchiectasis or with endobronchial tumors. Blood originating from the pulmonary parenchyma can be either from a localized source, such as an infection (pneumonia, lung abscess, tuberculosis), or from a process diffusely affecting the parenchyma (as with a coagulopathy or with an autoimmune process such as Goodpasture's syndrome). Disorders primarily affecting the pulmonary vasculature include pulmonary embolic disease and those conditions associated with elevated pulmonary venous and capillary pressures, such as mitral stenosis or left ventricular failure.

TABLE 34-1 DIFFERENTIAL DIAGNOSIS OF HEMOPTYSIS

Source other than the lower respiratory tract
Upper airway (nasopharyngeal) bleeding
Gastrointestinal bleeding
Tracheobronchial source
Neoplasm (bronchogenic carcinoma, endobronchial metastatic tumor, Kaposi's sarcoma, bronchial carcinoid)
Bronchitis (acute or chronic)
Bronchiectasis
Broncholithiasis
Airway trauma
Foreign body
Pulmonary parenchymal source
Lung abscess
Pneumonia
Tuberculosis
Mycetoma ("fungus ball")
Goodpasture's syndrome
Idiopathic pulmonary hemosiderosis
Wegener's granulomatosis
Lupus pneumonitis
Lung contusion
Primary vascular source
Arteriovenous malformation
Pulmonary embolism
Elevated pulmonary venous pressure (esp. mitral stenosis)
Pulmonary artery rupture secondary to balloon-tip pulmonary artery catheter manipulation
Miscellaneous/rare causes
Pulmonary endometriosis (catamenial hemoptysis)
Systemic coagulopathy or use of anticoagulants or thrombolytic agents

Adapted from SE Weinberger: *Principles of Pulmonary Medicine*, 4th ed. Philadelphia, Saunders, 2004, with permission.

Although the relative frequency of the different etiologies of hemoptysis varies from series to series, most recent studies indicate that bronchitis and bronchogenic carcinoma are the two most common causes in the United States. Despite the lower frequency of tuberculosis and bronchiectasis seen in recent compared to older series, these two disorders still represent the most common causes of massive hemoptysis in several series, especially worldwide. Even after extensive evaluation, a sizable proportion of patients (up to 30% in some series) have no identifiable etiology for their hemoptysis. These patients are classified as having idiopathic or cryptogenic hemoptysis, and subtle airway or parenchymal disease is presumably responsible for the bleeding.

APPROACH TO THE PATIENT: Hemoptysis

The *history* is extremely valuable. Hemoptysis that is described as blood-streaking of mucopurulent or purulent sputum often suggests bronchitis. Chronic production of sputum with a recent change in quantity or appearance favors an acute exacerbation of chronic bronchitis. Fever or chills accompanying blood-streaked purulent sputum suggests pneumonia, whereas a putrid smell to the sputum raises the possibility of lung abscess. When sputum production has been chronic and copious, the diagnosis of bronchiectasis should be considered. Hemoptysis following the acute onset of pleuritic chest pain and dyspnea is suggestive of pulmonary embolism.

A history of previous or coexisting disorders should be sought, such as renal disease (seen with Goodpasture's syndrome or Wegener's granulomatosis), lupus erythematosus (with associated pulmonary hemorrhage from lupus pneumonitis), or a previous malignancy (either recurrent lung cancer or endobronchial metastasis from a nonpulmonary primary tumor) or treatment for malignancy (with

recent chemotherapy or a bone marrow transplant). In a patient with AIDS, endobronchial or pulmonary parenchymal Kaposi's sarcoma should be considered. Risk factors for bronchogenic carcinoma, particularly smoking and asbestos exposure, should be sought. Patients should be questioned about previous bleeding disorders, treatment with anticoagulants, or use of drugs that can be associated with thrombocytopenia.

The *physical examination* may also provide helpful clues to the diagnosis. For example, examination of the lungs may demonstrate a pleural friction rub (pulmonary embolism), localized or diffuse crackles (parenchymal bleeding or an underlying parenchymal process associated with bleeding), evidence of airflow obstruction (chronic bronchitis), or prominent rhonchi, with or without wheezing or crackles (bronchiectasis). Cardiac examination may demonstrate findings of pulmonary arterial hypertension, mitral stenosis, or heart failure. Skin and mucosal examination may reveal Kaposi's sarcoma, arteriovenous malformations of Osler-Rendu-Weber disease, or lesions suggestive of systemic lupus erythematosus.

Diagnostic evaluation of hemoptysis starts with a chest radiograph (often followed by a CT scan) to look for a mass lesion, findings suggestive of bronchiectasis (Chap. 252), or focal or diffuse parenchymal disease (representing either focal or diffuse bleeding or a focal area of pneumonitis). Additional initial screening evaluation often includes a complete blood count, a coagulation profile, and assessment for renal disease with a urinalysis and measurement of blood urea nitrogen and creatinine levels. When sputum is present, examination by Gram and acid-fast stains (along with the corresponding cultures) is indicated.

Fiberoptic bronchoscopy is particularly useful for localizing the site of bleeding and for visualization of endobronchial lesions. When bleeding is massive, rigid bronchoscopy is often preferable to fiberoptic bronchoscopy because of better airway control and greater suction capability. In patients with suspected bronchiectasis, HRCT is the diagnostic procedure of choice.

A diagnostic algorithm for evaluation of nonmassive hemoptysis is presented in Fig. 34- 2.

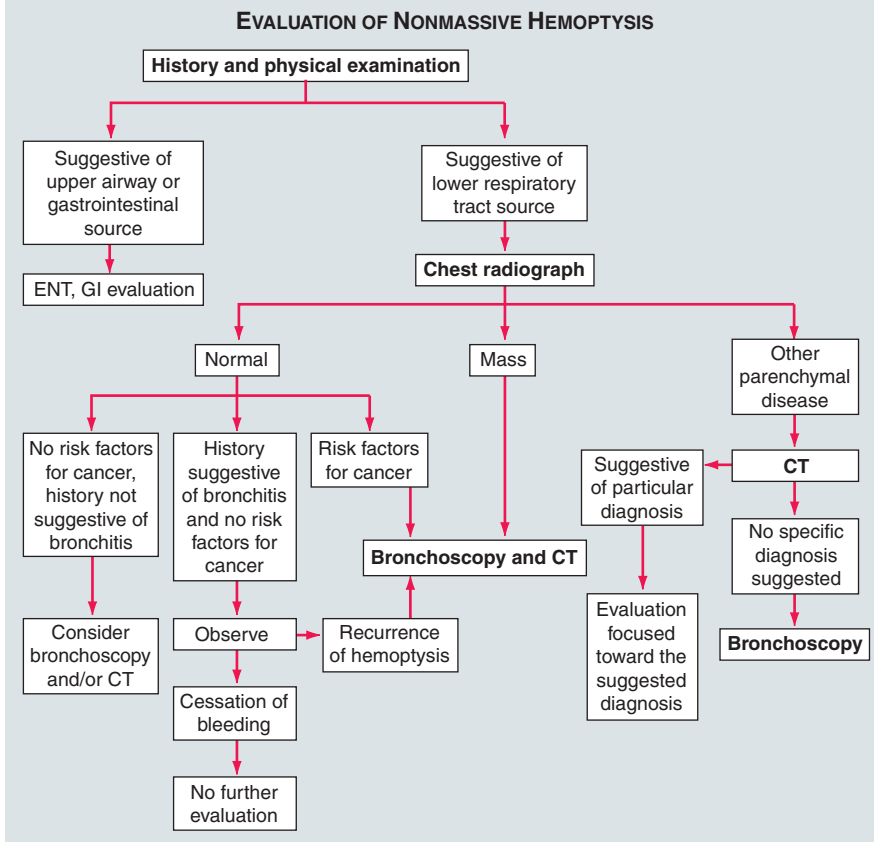

FIGURE 34-2 An algorithm for the evaluation of nonmassive hemoptysis. ENT, ear, nose, and throat; GI, gastrointestinal; CT, computed tomography.

HEMOPTYSIS

The rapidity of bleeding and its effect on gas exchange determine the urgency of management. When the bleeding is confined to either blood-streaking of sputum or production of small amounts of pure blood, gas exchange is usually preserved; establishing a diagnosis is the first priority. When hemoptysis is massive, maintaining adequate gas exchange, preventing blood from spilling into unaffected areas of lung, and avoiding asphyxiation are the highest priorities. Keeping the patient at rest and partially suppressing cough may help the bleeding to subside. If the origin of the blood is known and is limited to one lung, the bleeding lung should be placed in the dependent position, so that blood is not aspirated into the unaffected lung.

With massive bleeding, the need to control the airway and maintain adequate gas exchange may necessitate endotracheal intubation and mechanical ventilation. In patients in danger of flooding the lung contralateral to the side of hemorrhage despite proper positioning, isolation of the right and left mainstem bronchi from each other can be achieved by selectively intubating the nonbleeding lung (often with bronchoscopic guidance) or by using specially designed double-lumen endotracheal tubes. Another option involves inserting a balloon catheter through a bronchoscope by direct visualization and inflating the balloon to occlude the bronchus leading to the bleeding site. This technique not only prevents aspiration of blood into unaffected areas but also may promote tamponade of the bleeding site and cessation of bleeding.

Other available techniques for control of significant bleeding include laser phototherapy, electrocautery, bronchial artery embolization, and surgical resection of the involved area of lung. With bleeding from an endobronchial tumor, argon plasma coagulation or the neodymium:yttrium-aluminum-garnet (Nd:YAG) laser can often achieve at least temporary hemostasis by coagulating the bleeding site. Electrocautery, which uses an electric current for thermal destruction of tissue, can be used similarly for management of bleeding from an endobronchial tumor. Bronchial artery embolization involves an arteriographic procedure in which a vessel proximal to the bleeding site is cannulated, and a material such as Gelfoam is injected to occlude the bleeding vessel. Surgical resection is a therapeutic option either for the emergent therapy of life-threatening hemoptysis that fails to respond to other measures or for the elective but definitive management of localized disease subject to recurrent bleeding.

35 Hypoxia and Cyanosis

Eugene Braunwald

HYPOXIA

The fundamental task of the cardiorespiratory system is to deliver O_2 (and substrates) to the cells and to remove CO_2 (and other metabolic products) from them. Proper maintenance of this function depends on intact cardiovascular and respiratory systems, an adequate number of red blood cells and hemoglobin, and a supply of inspired gas containing adequate O_2.

EFFECTS

Decreased O_2 availability to cells results in an inhibition of the respiratory chain and increased anaerobic glycolysis. This switch from aerobic to anaerobic metabolism, Pasteur's effect, maintains some, albeit markedly reduced, adenosine triphosphate (ATP) production. In severe hypoxia, when ATP production is inadequate to meet the energy requirements of ionic and osmotic equilibrium, cell membrane depolarization leads to uncontrolled Ca^{2+} influx and activation of Ca^{2+}-dependent phospholipases and proteases. These events, in turn, cause cell swelling and ultimately cell necrosis.

The adaptations to hypoxia are mediated, in part, by the upregulation of genes encoding a variety of proteins, including glycolytic enzymes such as phosphoglycerate kinase and phosphofructokinase, as well as the glucose transporters Glut-1 and Glut-2; and by growth factors, such as vascular endothelial growth factor (VEGF) and erythropoietin, which enhance erythrocyte production.

During hypoxia systemic arterioles dilate, at least in part, by opening of K_{ATP} channels in vascular smooth-muscle cells due to the hypoxia-induced reduction in ATP concentration. By contrast, in pulmonary vascular smooth-muscle cells, inhibition of K^+ channels causes depolarization which, in turn, activates voltage-gated Ca^{2+} channels raising the cytosolic $[Ca^{2+}]$ and causing smooth-muscle cell contraction. Hypoxia-induced pulmonary arterial constriction shunts blood away from poorly ventilated toward better-ventilated portions of the lung; however, it also increases pulmonary vascular resistance and right ventricular afterload.

Effects on the Central Nervous System Changes in the central nervous system, particularly the higher centers, are especially important consequences of hypoxia. Acute hypoxia causes impaired judgment, motor incoordination, and a clinical picture resembling acute alcoholism. High-altitude illness is characterized by headache secondary to cerebral vasodilatation, and by gastrointestinal symptoms, dizziness, insomnia, and fatigue, or somnolence. Pulmonary arterial and sometimes venous constriction cause capillary leakage and high-altitude pulmonary edema (HAPE) (Chap. 33), which intensifies hypoxia and can initiate a vicious circle. Rarely, high-altitude cerebral edema (HACE) develops. This is manifest by severe headache and papilledema and can cause coma. As hypoxia becomes more severe, the centers of the brainstem are affected, and death usually results from respiratory failure.

CAUSES OF HYPOXIA

Respiratory Hypoxia When hypoxia occurs consequent to respiratory failure, Pa_{O_2} declines, and when respiratory failure is persistent, the hemoglobin-oxygen (Hb-O_2) dissociation curve (see Fig. 99-2) is displaced to the right, with greater quantities of O_2 released at any level of tissue P_{O_2}. Arterial hypoxemia, i.e., a reduction of O_2 saturation of arterial blood (Sa_{O_2}), and consequent cyanosis are likely to be more marked when such depression of Pa_{O_2} results from pulmonary disease than when the depression occurs as the result of a decline in the fraction of oxygen in inspired air (FI_{O_2}). In this latter situation, Pa_{CO_2} falls secondary to anoxia-induced hyperventilation and the Hb-O_2 dissociation curve is displaced to the left, limiting the decline in Sa_{O_2} at any level of Pa_{O_2}.

The most common cause of respiratory hypoxia is *ventilation-perfusion mismatch* resulting from perfusion of poorly ventilated alveoli. Respiratory hypoxemia may also be caused by *hypoventilation*, and it is then associated with an elevation of Pa_{CO_2} (Chap. 246). These two forms of respiratory hypoxia are usually correctable by inspiring 100% O_2 for several minutes. A third cause is shunting of blood across the lung from the pulmonary arterial to the venous bed (*intrapulmonary right-to-left shunting*) by perfusion of nonventilated portions of the lung, as in pulmonary atelectasis or through pulmonary arteriovenous connections. The low Pa_{O_2} in this situation is correctable only in part by an FI_{O_2} of 100%.

Hypoxia Secondary to High Altitude As one ascends rapidly to 3000 m (~10,000 ft), the reduction of the O_2 content of inspired air (FI_{O_2}) leads to a decrease in alveolar P_{O_2} to about 60 mmHg, and a condition termed *high-altitude illness* develops (see above). At higher altitudes, arterial saturation declines rapidly and symptoms become more serious; and at 5000 m, unacclimatized individuals usually cease to be able to function normally.

Hypoxia Secondary to Right-to-Left Extrapulmonary Shunting From a physiologic viewpoint, this cause of hypoxia resembles intrapulmonary right-to-left shunting but is caused by congenital cardiac malformations such as tetralogy of Fallot, transposition of the great arteries, and Eisenmenger's syndrome (Chap. 229). As in pulmonary right-to-left shunting, the Pa_{O_2} cannot be restored to normal with inspiration of 100% O_2.

Anemic Hypoxia A reduction in hemoglobin concentration of the blood is attended by a corresponding decline in the O_2-carrying capacity of the blood. Although the Pa_{O_2} is normal in anemic hypoxia, the absolute quantity of O_2 transported per unit volume of blood is diminished. As the anemic blood passes through the capillaries and the usual quantity of O_2 is removed from it, the P_{O_2} and saturation in the venous blood decline to a greater degree than normal.

Carbon Monoxide (CO) Intoxication (See also **Chap. e34**) Hemoglobin that is combined with CO (carboxyhemoglobin, COHb) is unavailable for O_2 transport. In addition, the presence of COHb shifts the Hb-O_2 dissociation curve to the left (see Fig. 99-2) so that O_2 is unloaded only at lower tensions, contributing further to tissue hypoxia.

Circulatory Hypoxia As in anemic hypoxia, the Pa_{O_2} is usually normal, but venous and tissue P_{O_2} values are reduced as a consequence of reduced tissue perfusion and greater tissue O_2 extraction. This pathophysiology leads to an increased arterial–mixed venous O_2 difference, or $(a - \bar{v})$ gradient. Generalized circulatory hypoxia occurs in heart failure (Chap. 227) and in most forms of shock (Chap. 264).

Specific Organ Hypoxia Localized circulatory hypoxia may occur consequent to decreased perfusion secondary to organic arterial obstruction, as in localized atherosclerosis in any vascular bed, or as a consequence of vasoconstriction, as observed in Raynaud's phenomenon (Chap. 243). Localized hypoxia may also result from venous obstruction and the resultant expansion of interstitial fluid causing arterial compression and, thereby, reduction of arterial inflow. Edema, which increases the distance through which O_2 must diffuse before it reaches cells, can also cause localized hypoxia. In an attempt to maintain adequate perfusion to more vital organs in patients with reduced cardiac output secondary to heart failure or hypovolemic shock, vasoconstriction may reduce perfusion in the limbs and skin, causing hypoxia of these regions.

Increased O_2 Requirements If the O_2 consumption of tissues is elevated without a corresponding increase in perfusion, tissue hypoxia ensues and the P_{O_2} in venous blood declines. Ordinarily, the clinical picture of patients with hypoxia due to an elevated metabolic rate, as in fever or thyrotoxicosis, is quite different from that in other types of hypoxia; the skin is warm and flushed owing to increased cutaneous blood flow that dissipates the excessive heat produced, and cyanosis is usually absent.

Exercise is a classic example of increased tissue O_2 requirements. These increased demands are normally met by several mechanisms operating si-

multaneously: (1) increasing the cardiac output and ventilation and, thus, O_2 delivery to the tissues; (2) preferentially directing the blood to the exercising muscles by changing vascular resistances in the circulatory beds of exercising tissues, directly and/or reflexly; (3) increasing O_2 extraction from the delivered blood and widening the arteriovenous O_2 difference; and (4) reducing the pH of the tissues and capillary blood, shifting the Hb-O_2 curve to the right (see Fig. 99-2) and unloading more O_2 from hemoglobin. If the capacity of these mechanisms is exceeded, then hypoxia, especially of the exercising muscles, will result.

Improper Oxygen Utilization Cyanide (**Chap. e35**) and several other similarly acting poisons cause cellular hypoxia. The tissues are unable to utilize O_2, and as a consequence, the venous blood tends to have a high O_2 tension. This condition has been termed *histotoxic hypoxia*.

ADAPTATION TO HYPOXIA

An important component of the respiratory response to hypoxia originates in special chemosensitive cells in the carotid and aortic bodies and in the respiratory center in the brainstem. The stimulation of these cells by hypoxia increases ventilation, with a loss of CO_2, and can lead to respiratory alkalosis. When combined with the metabolic acidosis resulting from the production of lactic acid, the serum bicarbonate level declines (Chap. 48).

With the reduction of Pa_{O_2}, cerebrovascular resistance decreases and cerebral blood flow increases in an attempt to maintain O_2 delivery to the brain. However, when the reduction of Pa_{O_2} is accompanied by hyperventilation and a reduction of Pa_{CO_2}, cerebrovascular resistance rises, cerebral blood flow falls, and hypoxia is intensified.

The diffuse, systemic vasodilation that occurs in generalized hypoxia raises the cardiac output. In patients with underlying heart disease, the requirements of peripheral tissues for an increase of cardiac output with hypoxia may precipitate congestive heart failure. In patients with ischemic heart disease, a reduced Pa_{O_2} may intensify myocardial ischemia and further impair left ventricular function.

One of the important mechanisms of compensation for chronic hypoxia is an increase in the hemoglobin concentration and in the number of red blood cells in the circulating blood, i.e., the development of polycythemia secondary to erythropoietin production (Chap. 103). In persons with chronic hypoxemia secondary to prolonged residence at a high altitude (>13,000 ft, 4200 m), a condition termed *chronic mountain sickness* develops. It is characterized by a blunted respiratory drive, reduced ventilation, erythrocytosis, cyanosis, weakness, right ventricular enlargement secondary to pulmonary hypertension, and even stupor.

CYANOSIS

Cyanosis refers to a bluish color of the skin and mucous membranes resulting from an increased quantity of reduced hemoglobin, or of hemoglobin derivatives, in the small blood vessels of those areas. It is usually most marked in the lips, nail beds, ears, and malar eminences. Cyanosis, especially if developed recently, is more commonly detected by a family member than the patient. The florid skin characteristic of polycythemia vera (Chap. 103) must be distinguished from the true cyanosis discussed here. A cherry-colored flush, rather than cyanosis, is caused by COHb (**Chap. e35**).

The degree of cyanosis is modified by the color of the cutaneous pigment and the thickness of the skin, as well as by the state of the cutaneous capillaries. The accurate clinical detection of the presence and degree of cyanosis is difficult, as proved by oximetric studies. In some instances, central cyanosis can be detected reliably when the Sa_{O_2} has fallen to 85%; in others, particularly in dark-skinned persons, it may not be detected until it has declined to 75%. In the latter case, examination of the mucous membranes in the oral cavity and the conjunctivae rather than examination of the skin is more helpful in the detection of cyanosis.

The increase in the quantity of reduced hemoglobin in the mucocutaneous vessels that produces cyanosis may be brought about either by an increase in the quantity of venous blood as a result of dilation of the venules and venous ends of the capillaries or by a reduction in the Sa_{O_2} in the capillary blood. In general, cyanosis becomes apparent when the concentration of reduced hemoglobin in capillary blood exceeds 40 g/L (4 g/dL).

It is the *absolute*, rather than the *relative*, quantity of reduced hemoglobin that is important in producing cyanosis. Thus, in a patient with severe anemia, the *relative* quantity of reduced hemoglobin in the venous blood may be very large when considered in relation to the total quantity of hemoglobin in the blood. However, since the concentration of the latter is markedly reduced, the *absolute* quantity of reduced hemoglobin may still be small, and, therefore, patients with severe anemia and even *marked* arterial desaturation may not display cyanosis. Conversely, the higher the total hemoglobin content, the greater is the tendency toward cyanosis; thus, patients with marked polycythemia tend to be cyanotic at higher levels of Sa_{O_2} than patients with normal hematocrit values. Likewise, local passive congestion, which causes an increase in the total quantity of reduced hemoglobin in the vessels in a given area, may cause cyanosis. Cyanosis is also observed when nonfunctional hemoglobin, such as methemoglobin or sulfhemoglobin (Chap. 99), is present in blood.

Cyanosis may be subdivided into central and peripheral types. In the *central* type, the Sa_{O_2} is reduced or an abnormal hemoglobin derivative is present, and the mucous membranes and skin are both affected. *Peripheral* cyanosis is due to a slowing of blood flow and abnormally great extraction of O_2 from normally saturated arterial blood. It results from vasoconstriction and diminished peripheral blood flow, such as occurs in cold exposure, shock, congestive failure, and peripheral vascular disease. Often in these conditions, the mucous membranes of the oral cavity or those beneath the tongue may be spared. Clinical differentiation between central and peripheral cyanosis may not always be simple, and in conditions such as cardiogenic shock with pulmonary edema there may be a mixture of both types.

DIFFERENTIAL DIAGNOSIS

Central Cyanosis (Table 35-1) Decreased Sa_{O_2} results from a marked reduction in the Pa_{O_2}. This reduction may be brought about by a decline in the FI_{O_2} without sufficient compensatory alveolar hyperventilation to maintain alveolar P_{O_2}. Cyanosis usually becomes manifest in an ascent to an altitude of 4000 m (13,000 ft).

Seriously *impaired pulmonary function*, through perfusion of unventilated or poorly ventilated areas of the lung or alveolar hypoventilation, is a common cause of central cyanosis (Chap. 246). This condition may occur acutely, as in extensive pneumonia or pulmonary edema, or chronically with chronic pulmonary diseases (e.g., emphysema). In the latter situation, secondary polycythemia is generally present and clubbing of the fingers (see below) may occur. Another cause of reduced

TABLE 35-1 CAUSES OF CYANOSIS

Central Cyanosis
Decreased arterial oxygen saturation
Decreased atmospheric pressure—high altitude
Impaired pulmonary function
Alveolar hypoventilation
Uneven relationships between pulmonary ventilation and perfusion (perfusion of hypoventilated alveoli)
Impaired oxygen diffusion
Anatomic shunts
Certain types of congenital heart disease
Pulmonary arteriovenous fistulas
Multiple small intrapulmonary shunts
Hemoglobin with low affinity for oxygen
Hemoglobin abnormalities
Methemoglobinemia—hereditary, acquired
Sulfhemoglobinema—acquired
Carboxyhemoglobinemia (not true cyanosis)
Peripheral Cyanosis
Reduced cardiac output
Cold exposure
Redistribution of blood flow from extremities
Arterial obstruction
Venous obstruction

Sa_{O_2} is *shunting of systemic venous blood into the arterial circuit*. Certain forms of congenital heart disease are associated with cyanosis on this basis (see above and Chap. 229).

Pulmonary arteriovenous fistulae may be congenital or acquired, solitary or multiple, microscopic or massive. The severity of cyanosis produced by these fistulae depends on their size and number. They occur with some frequency in hereditary hemorrhagic telangiectasia. Sa_{O_2} reduction and cyanosis may also occur in some patients with cirrhosis, presumably as a consequence of pulmonary arteriovenous fistulae or portal vein–pulmonary vein anastomoses.

In patients with cardiac or pulmonary right-to-left shunts, the presence and severity of cyanosis depend on the size of the shunt relative to the systemic flow as well as on the Hb-O_2 saturation of the venous blood. With increased extraction of O_2 from the blood by the exercising muscles, the venous blood returning to the right side of the heart is more unsaturated than at rest, and shunting of this blood intensifies the cyanosis. Secondary polycythemia occurs frequently in patients with arterial O_2 unsaturation and contributes to the cyanosis.

Cyanosis can be caused by small quantities of circulating methemoglobin and by even smaller quantities of sulfhemoglobin (Chap. 99). Although they are uncommon causes of cyanosis, these abnormal oxyhemoglobin derivatives should be sought by spectroscopy when cyanosis is not readily explained by malfunction of the circulatory or respiratory systems. Generally, digital clubbing does not occur with them.

Peripheral Cyanosis Probably the most common cause of peripheral cyanosis is the normal vasoconstriction resulting from exposure to cold air or water. When cardiac output is reduced, cutaneous vasoconstriction occurs as a compensatory mechanism so that blood is diverted from the skin to more vital areas such as the central nervous system and heart, and cyanosis of the extremities may result even though the arterial blood is normally saturated.

Arterial obstruction to an extremity, as with an embolus, or arteriolar constriction, as in cold-induced vasospasm (Raynaud's phenomenon, Chap. 243), generally results in pallor and coldness, and there may be associated cyanosis. Venous obstruction, as in thrombophlebitis, dilates the subpapillary venous plexuses and thereby intensifies cyanosis.

APPROACH TO THE PATIENT: Cyanosis

Certain features are important in arriving at the cause of cyanosis:

1. It is important to ascertain the time of onset of cyanosis. Cyanosis present since birth or infancy is usually due to congenital heart disease.
2. Central and peripheral cyanosis must be differentiated. Evidence of disorders of the respiratory or cardiovascular systems are helpful. Massage or gentle warming of a cyanotic extremity will increase peripheral blood flow and abolish peripheral, but not central, cyanosis.
3. The presence or absence of clubbing of the digits (see below) should be ascertained. The combination of cyanosis and clubbing is frequent in patients with congenital heart disease and right-to-left shunting, and is seen occasionally in patients with pulmonary disease such as lung abscess or pulmonary arteriovenous fistulae. In contrast, peripheral cyanosis or acutely developing central cyanosis is *not* associated with clubbed digits.
4. Pa_{O_2} and Sa_{O_2} should be determined, and in patients with cyanosis in whom the mechanism is obscure, spectroscopic examination of the blood performed to look for abnormal types of hemoglobin (critical in the differential diagnosis of cyanosis).

CLUBBING

The selective bullous enlargement of the distal segments of the fingers and toes due to proliferation of connective tissue, particularly on the dorsal surface, is termed *clubbing*; there is also increased sponginess of the soft tissue at the base of the nail. Clubbing may be hereditary, idiopathic, or acquired and associated with a variety of disorders, including cyanotic congenital heart disease (see above), infective endocarditis, and a variety of pulmonary conditions (among them primary and metastatic lung cancer, bronchiectasis, lung abscess, cystic fibrosis, and mesothelioma), as well as with some gastrointestinal diseases (including inflammatory bowel disease and hepatic cirrhosis). In some instances it is occupational, e.g., in jackhammer operators.

Clubbing in patients with primary and metastatic lung cancer, mesothelioma, bronchiectasis, and hepatic cirrhosis may be associated with *hypertrophic osteoarthropathy*. In this condition, the subperiosteal formation of new bone in the distal diaphyses of the long bones of the extremities causes pain and symmetric arthritis-like changes in the shoulders, knees, ankles, wrists, and elbows. The diagnosis of hypertrophic osteoarthropathy may be confirmed by bone radiographs. Although the mechanism of clubbing is unclear, it appears to be secondary to a humoral substance that causes dilation of the vessels of the fingertip.

36 Edema

Eugene Braunwald, Joseph Loscalzo

Edema is defined as a clinically apparent increase in the interstitial fluid volume, which may expand by several liters before the abnormality is evident. Therefore, a weight gain of several kilograms usually precedes overt manifestations of edema, and a similar weight loss from diuresis can be induced in a slightly edematous patient before "dry weight" is achieved. *Anasarca* refers to gross, generalized edema. *Ascites* (Chap. 44) and *hydrothorax* refer to accumulation of excess fluid in the peritoneal and pleural cavities, respectively, and are considered to be special forms of edema.

Depending on its cause and mechanism, edema may be localized or have a generalized distribution; it is recognized in its generalized form by puffiness of the face, which is most readily apparent in the periorbital areas, and by the persistence of an indentation of the skin following pressure; this is known as "pitting" edema. In its more subtle form, edema may be detected by noting that after the stethoscope is removed from the chest wall, the rim of the bell leaves an indentation on the skin of the chest for a few minutes. When the ring on a finger fits more snugly than in the past or when a patient complains of difficulty in putting on shoes, particularly in the evening, edema may be present.

About one-third of total-body water is confined to the extracellular space. Approximately 75% of the latter, in turn, is interstitial fluid and the remainder is the plasma.

Starling Forces The forces that regulate the disposition of fluid between these two components of the extracellular compartment are frequently referred to as the *Starling forces*. The hydrostatic pressure within the vascular system and the colloid oncotic pressure in the interstitial fluid tend to promote movement of fluid from the vascular to the extravascular space. On the other hand, the colloid oncotic pressure contributed by plasma proteins and the hydrostatic pressure within the interstitial fluid, referred to as the *tissue tension*, promote the movement of fluid into the vascular compartment.

As a consequence of these forces, there is a movement of water and diffusible solutes from the vascular space at the arteriolar end of the capillaries. Fluid is returned from the interstitial space into the vascular system at the venous end of the capillaries and by way of the lymphatics. Unless these channels are obstructed, lymph flow rises with increases in net movement of fluid from the vascular compartment to the interstitium. These flows are usually balanced so that a steady state exists in the sizes of the intravascular and interstitial compartments, and, yet, a large exchange between them occurs. However, should either the hydrostatic or oncotic pressure gradient be altered significantly, a further net movement of fluid between the two components of the extracellular space will take place. The development of edema, then, depends on one or more alterations in the Starling forces so that there is increased flow of fluid from the vascular system into the interstitium or into a body cavity.

Edema due to an increase in capillary pressure may result from an elevation of venous pressure due to obstruction to venous and/or lymphatic drainage. An increase in capillary pressure may be generalized, as occurs in congestive heart failure (see below). The Starling forces may also be imbalanced when the colloid oncotic pressure of the plasma is reduced, owing to any factor that may induce hypoalbuminemia, such as severe malnutrition, liver disease, loss of protein into the urine or into the gastrointestinal tract, or a severe catabolic state. Edema may be localized to one extremity when venous pressure is elevated due to unilateral thrombophlebitis (see below).

Capillary Damage Edema may also result from damage to the capillary endothelium, which increases its permeability and permits the transfer of protein into the interstitial compartment. Injury to the capillary wall can result from drugs, viral or bacterial agents, and thermal or mechanical trauma. Increased capillary permeability may also be a consequence of a hypersensitivity reaction and is characteristic of immune injury. Damage to the capillary endothelium is presumably responsible for inflammatory edema, which is usually nonpitting, localized, and accompanied by other signs of inflammation—redness, heat, and tenderness.

Reduction of Effective Arterial Volume In many forms of edema, the effective arterial blood volume, a parameter that represents the filling of the arterial tree, is reduced. Underfilling of the arterial tree may be caused by a reduction of cardiac output and/or systemic vascular resistance. As a consequence of underfilling, a series of physiologic responses designed to restore the effective arterial volume to normal are set into motion. A key element of these responses is the retention of salt and, therefore, of water, ultimately leading to edema.

Renal Factors and the Renin-Angiotensin-Aldosterone (RAA) System (See also Chap. 336) In the final analysis, renal retention of Na^+ is central to the development of generalized edema. The diminished renal blood flow characteristic of states in which the effective arterial blood volume is reduced is translated by the renal juxtaglomerular cells (specialized myoepithelial cells surrounding the afferent arteriole) into a signal for increased renin release (Chap. 336). Renin is an enzyme with a molecular mass of about 40,000 Da that acts on its substrate, angiotensinogen, an α_2-globulin synthesized by the liver, to release angiotensin I, a decapeptide, which is broken down to angiotensin II (AII), an octapeptide. AII has generalized vasoconstrictor properties; it is especially active on the efferent arterioles. This efferent arteriolar constriction reduces the hydrostatic pressure in the peritubular capillaries, while the increased filtration fraction raises the colloid osmotic pressure in these vessels, thereby enhancing salt and water reabsorption in the proximal tubule as well as in the ascending limb of the loop of Henle.

The RAA system has long been recognized as a hormonal system; however, it also operates locally. Intrarenally produced AII contributes to glomerular efferent arteriolar constriction, and this "tubuloglomerular feedback" causes salt and water retention. These renal effects of AII are mediated by activation of AII type 1 receptors, which can be blocked by specific antagonists [angiotensin receptor blockers (ARBs)].

The mechanisms responsible for the increased release of renin when renal blood flow is reduced include: (1) a baroreceptor response in which reduced renal perfusion results in incomplete filling of the renal arterioles and diminished stretch of the juxtaglomerular cells, a signal that increases the elaboration and/or release of renin; (2) reduced glomerular filtration, which lowers the NaCl load reaching the distal renal tubules and the macula densa, cells in the distal convoluted tubules that act as chemoreceptors and that signal the neighboring juxtaglomerular cells to secrete renin; and (3) activation of the β-adrenergic receptors in the juxtaglomerular cells by the sympathetic nervous system and by circulating catecholamines, which also stimulates renin release. These three mechanisms generally act in concert to enhance Na^+ retention and, thereby, contribute to the formation of edema.

AII that enters the systemic circulation stimulates the production of aldosterone by the zona glomerulosa of the adrenal cortex. Aldosterone, in turn, enhances Na^+ reabsorption (and K^+ excretion) by the collecting tubule. In patients with heart failure, not only is aldosterone secretion elevated but the biologic half-life of aldosterone is prolonged, which increases further the plasma level of the hormone. A depression of hepatic blood flow, especially during exercise, is responsible for reduced hepatic catabolism of aldosterone. The activation of the RAA system is most striking in the early phase of acute, severe heart failure and is less intense in patients with chronic, stable, compensated heart failure.

Increased quantities of aldosterone are secreted in heart failure and in other edematous states, and blockade of the action of aldosterone by spironolactone (an aldosterone antagonist) or amiloride (a blocker of epithelial Na^+ channels) often induces a moderate diuresis in edematous states. Yet, persistently augmented levels of aldosterone (or other mineralocorticoids) alone do not always promote accumulation of edema, as witnessed by the lack of striking fluid retention in most instances of primary aldosteronism (Chap. 336). Furthermore, although normal individuals retain some NaCl and water with the administration of potent mineralocorticoids, such as deoxycorticosterone acetate or fludrocortisone, this accumulation is self-limiting, despite continued exposure to the steroid, a phenomenon known as *mineralocorticoid escape*. The failure of normal individuals who receive large doses of mineralocorticoids to accumulate large quantities of extracellular fluid and to develop edema is probably a consequence of an increase in glomerular filtration rate (pressure natriuresis) and the action of natriuretic substance(s) (see below). The continued secretion of aldosterone may be more important in the accumulation of fluid in edematous states because patients with edema secondary to heart failure, nephrotic syndrome, and hepatic cirrhosis are generally unable to repair the deficit in effective arterial blood volume. As a consequence, they do not develop pressure natriuresis.

Arginine Vasopressin (AVP) (See also Chap. 334) The secretion of AVP occurs in response to increased intracellular osmolar concentration, and by stimulating V_2 receptors, AVP increases the reabsorption of free water in the renal distal tubule and collecting duct, thereby increasing total-body water. Circulating AVP is elevated in many patients with heart failure secondary to a nonosmotic stimulus associated with decreased effective arterial volume. Such patients fail to show the normal reduction of AVP with a reduction of osmolality, contributing to edema formation and hyponatremia.

Endothelin This potent peptide vasoconstrictor is released by endothelial cells; its concentration is elevated in heart failure and contributes to renal vasoconstriction, Na^+ retention, and edema in heart failure.

Natriuretic Peptides Atrial distention and/or a Na^+ load cause release into the circulation of atrial natriuretic peptide (ANP), a polypeptide; a high-molecular-weight precursor of ANP is stored in secretory granules within atrial myocytes. Release of ANP causes (1) excretion of sodium and water by augmenting glomerular filtration rate, inhibiting sodium reabsorption in the proximal tubule, and inhibiting release of renin and aldosterone; and (2) arteriolar and venous dilation by antagonizing the vasoconstrictor actions of AII, AVP, and sympathetic stimulation. Thus, ANP has the capacity to oppose Na^+ retention and arterial pressure elevation in hypervolemic states.

The closely related brain natriuretic peptide (BNP) is stored primarily in ventricular myocardium and is released when ventricular diastolic pressure rises. Its actions are similar to those of ANP. Circulating levels of ANP and BNP are elevated in congestive heart failure and in cirrhosis with ascites, but obviously not sufficiently to prevent edema formation. In addition, in edematous states there is abnormal resistance to the actions of natriuretic peptides.

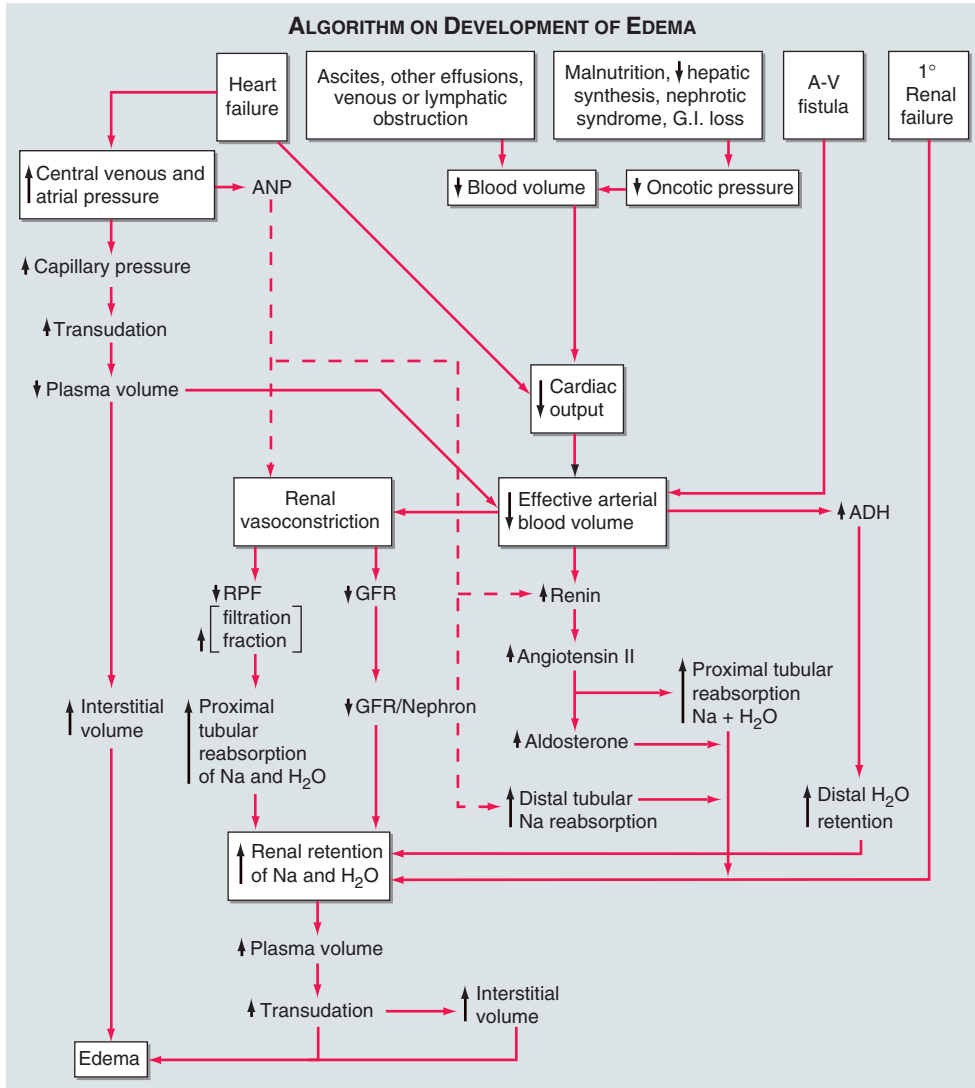

FIGURE 36-1 Sequence of events leading to the formation and retention of salt and water and the development of edema. ANP, atrial natriuretic peptide; RPF, renal plasma flow; GFR, glomerular filtration rate; ADH, antidiuretic hormone. Inhibitory influences are shown by broken lines.

CLINICAL CAUSES OF EDEMA

Obstruction of Venous (and Lymphatic) Drainage of a Limb In this condition the hydrostatic pressure in the capillary bed upstream (proximal) to the obstruction increases so that an abnormal quantity of fluid is transferred from the vascular to the interstitial space. Since the alternative route (i.e., the lymphatic channels) may also be obstructed or maximally filled, an increased volume of interstitial fluid in the limb develops, i.e., there is trapping of fluid in the extremity. Tissue tension rises in the affected limb until it counterbalances the primary alterations in the Starling forces, at which time no further fluid accumulates. The net effect is a local increase in the volume of interstitial fluid, causing local edema. The displacement of fluid into a limb may occur at the expense of the blood volume in the remainder of the body, thereby reducing effective arterial blood volume and leading to the retention of NaCl and H_2O until the deficit in plasma volume has been corrected. This same sequence occurs in ascites and hydrothorax, in which fluid is trapped or accumulates in the cavitary space, depleting the intravascular volume and leading to secondary salt and fluid retention.

Congestive Heart Failure (See also Chap. 227) In this disorder the impaired systolic emptying of the ventricle(s) and/or the impairment of ventricular relaxation promotes an accumulation of blood in the venous circulation at the expense of the effective arterial volume, and the aforementioned sequence of events (Fig. 36-1) is initiated. In mild heart failure, a small increment of total blood volume may repair the deficit of arterial volume and establish a new steady state. Through the operation of Starling's law of the heart, an increase in ventricular diastolic volume promotes a more forceful contraction and may thereby restore the cardiac output. However, if the cardiac disorder is more severe, fluid retention continues, and the increment in blood volume accumulates in the venous circulation. With reduction in cardiac output, a decrease in baroreflex-mediated inhibition of the vasomotor center activates renal vasoconstrictor nerves and the RAA system, causing Na^+ and H_2O retention.

Incomplete ventricular emptying (systolic heart failure) and/or inadequate ventricular relaxation (diastolic heart failure) both lead to an elevation of ventricular diastolic pressure. If the impairment of cardiac function primarily involves the right ventricle, pressures in the systemic veins and capillaries rise, augmenting the transudation of fluid into the interstitial space and enhancing the likelihood of peripheral edema. The elevated systemic venous pressure is transmitted to the thoracic duct with consequent reduction of lymph drainage, further increasing the accumulation of edema.

If the impairment of cardiac function (incomplete ventricular emptying and/or inadequate relaxation) involves the left ventricle primarily, then pulmonary venous and capillary pressures rise. Pulmonary artery pressure rises and this, in turn, interferes with the emptying of the right ventricle, leading to an elevation of right ventricular diastolic and of central and systemic venous pressures, thereby enhancing the likelihood of the formation of peripheral edema. The elevation of pulmonary capillary pressure may cause pulmonary edema, which im-

pairs gas exchange. The resultant hypoxemia may impair cardiac function further, sometimes causing a vicious circle.

Nephrotic Syndrome and Other Hypoalbuminemic States (See also Chap. 277) The primary alteration in this disorder is a diminished colloid oncotic pressure due to losses of large quantities of protein into the urine. With severe hypoalbuminemia and the consequent reduced colloid osmotic pressure, the NaCl and H_2O that are retained cannot be restrained within the vascular compartment, and total and effective arterial blood volumes decline. This process initiates the edema-forming sequence of events described above, including activation of the RAA system. Impaired renal function contributes further to the formation of edema. A similar sequence of events occurs in other conditions that lead to *severe* hypoalbuminemia, including (1) severe nutritional deficiency states; (2) severe, chronic liver disease (see below); and (3) protein-losing enteropathy.

Cirrhosis (See also Chaps. 44 and 302) This condition is characterized by hepatic venous outflow blockade, which, in turn, expands the splanchnic blood volume and increases hepatic lymph formation. Intrahepatic hypertension acts as a potent stimulus for renal Na^+ retention and a reduction of effective arterial blood volume. These alterations are frequently complicated by hypoalbuminemia secondary to reduced hepatic synthesis, as well as systemic vasodilation, which reduce the effective arterial blood volume further, leading to activation of the RAA system, of renal sympathetic nerves, and of other NaCl- and H_2O-retaining mechanisms. The concentration of circulating aldosterone is often elevated by the liver's failure to metabolize this hormone. Initially, the excess interstitial fluid is localized preferentially proximal (upstream) to the congested portal venous system and obstructed hepatic lymphatics, i.e., in the peritoneal cavity (ascites, Chap. 44). In later stages, particularly when there is severe hypoalbuminemia, peripheral edema may develop. The excess production of prostaglandins (PGE_2 and PGI_2) in cirrhosis attenuates renal Na^+ retention. When the synthesis of these substances is inhibited by nonsteroidal anti-inflammatory drugs (NSAIDs), renal function deteriorates and Na^+ retention increases.

Drug-Induced Edema A large number of widely used drugs can cause edema (Table 36-1). Mechanisms include renal vasoconstriction (NSAIDs and cyclosporine), arteriolar dilatation (vasodilators), augmented renal Na^+ reabsorption (steroid hormones), and capillary damage (interleukin 2).

Idiopathic Edema This syndrome, which occurs almost exclusively in women, is characterized by periodic episodes of edema (unrelated to the menstrual cycle), frequently accompanied by abdominal distention. Diurnal alterations in weight occur with orthostatic retention of NaCl and H_2O, so that the patient may weigh several pounds more after having been in the upright posture for several hours. Such large diurnal weight changes suggest an increase in capillary permeability that appears to fluctuate in severity and to be aggravated by hot weather. There is some evidence that a reduction in plasma volume occurs in this condition with secondary activation of the RAA system and impaired suppression of AVP release.

Idiopathic edema should be distinguished from cyclical or premenstrual edema, in which the NaCl and H_2O retention may be secondary to excessive estrogen stimulation. There are also some cases in which the edema appears to be diuretic-induced. It has been postulated that in these patients chronic diuretic administration leads to mild blood volume depletion, which causes chronic hyperreninemia and juxtaglomerular hyperplasia. Salt-retaining mechanisms appear to overcompensate for the direct effects of the diuretics. *Acute* withdrawal of diuretics can then leave the Na^+-retaining forces unopposed, leading to fluid retention and edema. Decreased dopaminergic activity and reduced urinary kallikrein and kinin excretion have been reported in this condition and may also be of pathogenetic importance.

TABLE 36-1 DRUGS ASSOCIATED WITH EDEMA FORMATION

- Nonsteroidal anti-inflammatory drugs
- Antihypertensive agents
  - Direct arterial/arteriolar vasodilators
    - Hydralazine
    - Clonidine
    - Methyldopa
    - Guanethidine
    - Minoxidil
  - Calcium channel antagonists
  - α-Adrenergic antagonists
  - Thiazolidinediones
- Steroid hormones
  - Glucocorticoids
  - Anabolic steroids
  - Estrogens
  - Progestins
- Cyclosporine
- Growth hormone
- Immunotherapies
  - Interleukin 2
  - OKT3 monoclonal antibody

Rx IDIOPATHIC EDEMA

The treatment of idiopathic cyclic edema includes a reduction in NaCl intake, rest in the supine position for several hours each day, and the wearing of elastic stockings (which should be put on before arising in the morning). A variety of pharmacologic agents, including angiotensin-converting enzyme inhibitors, progesterone, the dopamine receptor agonist bromocriptine, and the sympathomimetic amine dextroamphetamine, have all been reported to be useful when administered to patients who do not respond to simpler measures. Diuretics may be helpful initially but may lose their effectiveness with continuous administration; accordingly, they should be employed sparingly, if at all. Discontinuation of diuretics paradoxically leads to diuresis in diuretic-induced edema, described above.

DIFFERENTIAL DIAGNOSIS

LOCALIZED EDEMA

(See also Chap. 243) Edema originating from inflammation or hypersensitivity is usually readily identified. Localized edema due to venous or lymphatic obstruction may be caused by thrombophlebitis, chronic lymphangitis, resection of regional lymph nodes, filariasis, etc. Lymphedema is particularly intractable because restriction of lymphatic flow results in increased protein concentration in the interstitial fluid, a circumstance that aggravates retention of fluid.

GENERALIZED EDEMA

The differences among the three major causes of generalized edema are shown in Table 36-2.

The great majority of patients with generalized edema suffer from advanced cardiac, renal, hepatic, or nutritional disorders. Consequently, the differential diagnosis of generalized edema should be directed toward identifying or excluding these several conditions.

Edema of Heart Failure (See also Chap. 227) The presence of heart disease, as manifested by cardiac enlargement and a gallop rhythm, together with evidence of cardiac failure, such as dyspnea, basilar rales, venous distention, and hepatomegaly, usually indicate that edema results from heart failure. Noninvasive tests, such as echocardiography, may be helpful in establishing the diagnosis of heart disease. The edema of heart failure typically occurs in the dependent portions of the body.

Edema of the Nephrotic Syndrome (See also Chap. 277) Marked proteinuria (>3.5 g/d), hypoalbuminemia (<35 g/L), and, in some instances, hypercholesterolemia are present. This syndrome may occur during the course of a variety of kidney diseases, which include glo-

TABLE 36-2 PRINCIPAL CAUSES OF GENERALIZED EDEMA: HISTORY, PHYSICAL EXAMINATION, AND LABORATORY FINDINGS

Organ System	History	Physical Examination	Laboratory Findings
Cardiac	Dyspnea with exertion prominent—often associated with orthopnea—or paroxysmal nocturnal dyspnea	Elevated jugular venous pressure, ventricular (S_3) gallop; occasionally with displaced or dyskinetic apical pulse; peripheral cyanosis, cool extremities, small pulse pressure when severe	Elevated urea nitrogen-to-creatinine ratio common; elevated uric acid; serum sodium often diminished; liver enzymes occasionally elevated with hepatic congestion
Hepatic	Dyspnea infrequent, except if associated with significant degree of ascites; most often a history of ethanol abuse	Frequently associated with ascites; jugular venous pressure normal or low; blood pressure lower than in renal or cardiac disease; one or more additional signs of chronic liver disease (jaundice, palmar erythema, Dupuytren's contracture, spider angiomata, male gynecomastia; asterixis and other signs of encephalopathy) may be present	If severe, reductions in serum albumin, cholesterol, other hepatic proteins (transferrin, fibrinogen); liver enzymes elevated, depending on the cause and acuity of liver injury; tendency toward hypokalemia, respiratory alkalosis; macrocytosis from folate deficiency
Renal	Usually chronic: may be associated with uremic signs and symptoms, including decreased appetite, altered (metallic or fishy) taste, altered sleep pattern, difficulty concentrating, restless legs or myoclonus; dyspnea can be present, but generally less prominent than in heart failure	Blood pressure may be elevated; hypertensive or diabetic retinopathy in selected cases; nitrogenous fetor; periorbital edema may predominate; pericardial friction rub in advanced cases with uremia	Albuminuria, hypoalbuminemia; sometimes, elevation of serum creatinine and urea nitrogen; hyperkalemia, metabolic acidosis, hyperphosphatemia, hypocalcemia, anemia (usually normocytic)

Source: From Chertow.

merulonephritis, diabetic glomerulosclerosis, and hypersensitivity reactions. A history of previous renal disease may or may not be elicited.

Edema of Acute Glomerulonephritis and Other Forms of Renal Failure (See also Chap. 277) The edema occurring during the acute phases of glomerulonephritis is characteristically associated with hematuria, proteinuria, and hypertension. Although some evidence supports the view that the fluid retention is due to increased capillary permeability, in most instances the edema results from primary retention of NaCl and H_2O by the kidneys owing to renal insufficiency. This state differs from congestive heart failure in that it is characterized by a normal (or sometimes even increased) cardiac output and a normal arterial–mixed venous oxygen difference. Patients with edema due to renal failure commonly have evidence of arterial hypertension as well as pulmonary congestion on chest roentgenograms even without cardiac enlargement, but they may not develop orthopnea. Patients with *chronic* renal failure may also develop edema due to primary renal retention of NaCl and H_2O.

Edema of Cirrhosis (See also Chap. 302) Ascites and biochemical and clinical evidence of hepatic disease (collateral venous channels, jaundice, and spider angiomas) characterize edema of hepatic origin. The ascites (Chap. 44) is frequently refractory to treatment because it collects as a result of a combination of obstruction of hepatic lymphatic drainage, portal hypertension, and hypoalbuminemia. A sizable accumulation of ascitic fluid may increase intraabdominal pressure and impede venous return from the lower extremities; hence, it tends to promote accumulation of edema in this region as well.

Edema of Nutritional Origin A diet grossly deficient in protein over a prolonged period may produce hypoproteinemia and edema. The latter may be intensified by the development of beriberi heart disease, also of nutritional origin, in which multiple peripheral arteriovenous fistulae result in reduced effective systemic perfusion and effective arterial blood volume, thereby enhancing edema formation (Chap. 71). Edema may actually become intensified when famished subjects are first provided with an adequate diet. The ingestion of more food may increase the quantity of NaCl ingested, which is then retained along with H_2O. So-called refeeding edema may also be linked to increased release of insulin, which directly increases tubular Na^+ reabsorption. In addition to hypoalbuminemia, hypokalemia and caloric deficits may be involved in the edema of starvation.

Other Causes of Edema These include hypothyroidism, in which the edema (myxedema) is located typically in the pretibial region and which may also be associated with periorbital puffiness; exogenous hyperadrenocortism; pregnancy; and administration of estrogens and vasodilators, particularly dihydropyridines such as nifedipine.

DISTRIBUTION OF EDEMA

The distribution of edema is an important guide to its cause. Thus, edema limited to one leg or to one or both arms is usually the result of venous and/or lymphatic obstruction. Edema resulting from hypoproteinemia characteristically is generalized, but it is especially evident in the very soft tissues of the eyelids and face and tends to be most pronounced in the morning because of the recumbent posture assumed during the night. Less common causes of facial edema include trichinosis, allergic reactions, and myxedema. Edema associated with heart failure, by contrast, tends to be more extensive in the legs and to be accentuated in the evening, a feature also determined largely by posture. When patients with heart failure have been confined to bed, edema may be most prominent in the presacral region. Paralysis reduces lymphatic and venous drainage on the affected side and may be responsible for unilateral edema.

ADDITIONAL FACTORS IN DIAGNOSIS

The color, thickness, and sensitivity of the skin are significant. Local tenderness and warmth suggest inflammation. Local cyanosis may signify venous obstruction. In individuals who have had repeated episodes of prolonged edema, the skin over the involved areas may be thickened, indurated, and often red.

Estimation of the venous pressure is of importance in evaluating edema. Ordinarily, a significant generalized increase in venous pressure can be recognized by the level at which cervical veins collapse (Chap. 220). In patients with obstruction of the superior vena cava, edema is confined to the face, neck, and upper extremities, in which the venous pressure is elevated compared with that in the lower extremities. Severe heart failure may cause ascites that may be distinguished from the ascites caused by hepatic cirrhosis by the jugular venous pressure, which is usually elevated in heart failure and normal in cirrhosis.

Determination of the concentration of serum albumin aids importantly in identifying those patients in whom edema is due, at least in part, to diminished intravascular colloid oncotic pressure. The presence of proteinuria also affords useful clues. The absence of proteinuria excludes nephrotic syndrome but cannot exclude nonproteinuric causes of renal failure. Slight to moderate proteinuria is the rule in patients with heart failure.

APPROACH TO THE PATIENT: Edema

An important first question is whether the edema is localized or generalized. If it is localized, those local phenomena that may be responsible should be considered. If the edema is generalized, it should be determined, first, if there is serious hypoalbuminemia, e.g., serum albumin <25 g/L. If so, the history, physical examination, urinalysis, and other laboratory data will help evaluate the question of cirrhosis, severe malnutrition, or the nephrotic syndrome as the underlying disorder. If hypoalbuminemia is not present, it should be determined if there is evidence of congestive heart failure of a severity to promote generalized edema. Finally, it should be determined whether the patient has an adequate urine output, or if there is significant oliguria or anuria. **These abnormalities are discussed in Chaps. 45, 273, and 274.**

37 Palpitations

Joseph Loscalzo

Palpitations are extremely common among patients who present to their caregiver and can best be defined as an intermittent "thumping," "pounding," or "fluttering" sensation in the chest. This sensation can be either intermittent or sustained, and either regular or irregular. Most patients interpret palpitations as an unusual awareness of the heart beat and become especially concerned when they sense that they have had "skipped" or "missing" heart beats. Palpitations are often noted when the patient is quietly resting, during which time other stimuli are minimal. Palpitations that are positional may reflect a structural process within (e.g., atrial myxoma) or adjacent to (e.g., mediastinal mass) the heart.

Palpitations are brought about by cardiac (43%), psychiatric (31%), miscellaneous (10%), and unknown (16%) causes, according to one large series. Cardiac causes include premature atrial and ventricular contractions, supraventricular and ventricular arrhythmias, mitral valve prolapse, aortic regurgitation, and atrial myxoma. Intermittent palpitations are commonly caused by premature atrial or ventricular contractions: the postextrasystolic beat is sensed by the patient owing to the increase in ventricular end-diastolic dimension following the pause in the cardiac cycle and the increased strength of contraction (*postextrasystolic potentiation*) of that beat. Regular, sustained palpitations can be caused by regular supraventricular and ventricular tachycardias (Chap. 226). Irregular, sustained palpitations can be caused by atrial fibrillation.

It is important to note that most arrhythmias are not associated with palpitations. In those that are, it is often useful either to ask the patient to "tap out" the rhythm of the palpitations or to take his or her pulse while palpitations are occurring. In general, hyperdynamic cardiovascular states caused by catecholaminergic stimulation from exercise, stress, or pheochromocytoma can lead to palpitations. In addition, the enlarged ventricle of aortic regurgitation and accompanying hyperdynamic precordium frequently lead to the sensation of palpitations. Other factors that enhance the strength of myocardial contraction, including tobacco, caffeine, aminophylline, atropine, thyroxine, cocaine, and amphetamines, can cause palpitations.

Psychiatric causes of palpitations include panic attack or disorder, anxiety states, and somatization, alone or in combination. Patients with psychiatric causes for palpitations more commonly report a longer duration of the sensation (>15 min) and other accompanying symptoms than do patients with other causes. Among the miscellaneous causes of palpitations are included thyrotoxicosis, drugs (see above) and ethanol, spontaneous skeletal muscle contractions of the chest wall, pheochromocytoma, and systemic mastocytosis.

APPROACH TO THE PATIENT: Palpitations

The principal goal in assessing patients with palpitations is to determine if the symptom is caused by a life-threatening arrhythmia. Patients with preexisting coronary artery disease (CAD) or risk factors for CAD are at greatest risk for ventricular arrhythmias as a cause for palpitations. In addition, the association of palpitations with other symptoms suggesting hemodynamic compromise, including syncope or lightheadedness, supports this diagnosis. Palpitations caused by sustained tachyarrhythmias in patients with CAD can be accompanied by angina pectoris or dyspnea. In patients with ventricular dysfunction (systolic or diastolic), aortic stenosis, hypertrophic cardiomyopathy, or mitral stenosis, with or without CAD, palpitations can be accompanied by dyspnea from increased left atrial and pulmonary capillary wedge pressure.

Key features of the physical examination that will help confirm or refute the presence of an arrhythmia as a cause for the palpitations and its adverse hemodynamic consequences include measurement of the vital signs, assessment of the jugular venous pressure and pulse, and auscultation of the chest and precordium. A resting electrocardiogram can be used to document the arrhythmia. If exertion is known to induce the arrhythmia and accompanying palpitations, exercise electrocardiography can be used to make the diagnosis. If the arrhythmia is sufficiently infrequent, other methods must be used, including continuous electrocardiographic (Holter) monitoring; telephonic monitoring, through which the patient can transmit an electrocardiographic tracing during a sensed episode; and loop recordings (external or implantable), which can capture the electrocardiographic event for later review.

Most patients with palpitations do not have serious arrhythmias or underlying structural heart disease. Occasional benign atrial or ventricular premature contractions can often be managed with beta blocker therapy if sufficiently troubling to the patient. Palpitations incited by alcohol, tobacco, or illicit drugs need to be managed by abstention, while those caused by pharmacologic agents should be addressed by considering alternative therapies. Psychiatric causes of palpitations may benefit from cognitive or pharmacotherapies. The physician should note that palpitations are at the very least bothersome and, on occasion, frightening to the patient. Once serious causes for the symptom have been excluded, the patient should be reassured the palpitations will not adversely affect his or her prognosis.

e8 Approach to the Patient with a Heart Murmur

Patrick T. O'Gara, Eugene Braunwald

The differential diagnosis of a heart murmur begins with a careful assessment of its major attributes and response to bedside maneuvers. The history, clinical context, and associated findings provide additional clues by which the significance of a heart murmur is established. Following completion of these initial steps, noninvasive testing can be pursued to clarify any remaining ambiguity and to provide additional anatomic and physiologic information that will impact patient management. Accurate bedside identification of a heart murmur can also inform decisions regarding referral to a cardiovascular specialist, the indications for antibiotic or rheumatic fever prophylaxis, and the need to restrict various forms of physical activity.

Heart murmurs are caused by audible vibrations that are due to increased turbulence from accelerated blood flow through normal or abnormal orifices; flow through a narrowed or irregular orifice into a dilated vessel or chamber; or backward flow through an incompetent valve, ventricular septal defect, or patent ductus arteriosus. They are traditionally defined in terms of their timing within the cardiac cycle (Fig. e8-1). *Systolic murmurs* begin with or after the first heart sound (S_1) and terminate at or before the component (A_2 or P_2) of the second heart sound (S_2) that corresponds to their side of origin (left or right, respectively). *Diastolic murmurs* begin with or after the associated component of S_2 and end at or before the subsequent S_1. *Continuous murmurs* are not confined to either phase of the cardiac cycle, but rather begin in early systole and proceed through S_2 into all or part of diastole. The accurate timing of heart murmurs is the first step in their identification. The distinction between S_1 and S_2, and therefore systole and diastole, is usually a straightforward process, but can be difficult in the setting of a tachyarrhythmia, in which case the heart sounds can be distinguished by simultaneous palpation of the carotid arterial pulse. The upstroke should closely follow S_1.

Duration The duration of a heart murmur depends on the length of time in the cardiac cycle over which a pressure difference exists between two cardiac chambers, the left ventricle and the aorta, the right ventricle and the pulmonary artery, or the great vessels. The magnitude and variability of this pressure difference dictate the velocity of flow; the degree of turbulence; and the resulting frequency, configuration, and intensity of the murmur. The diastolic murmur of chronic aortic regurgitation (AR) is a blowing, high-frequency event, whereas the murmur of mitral stenosis (MS), indicative of the left atrial–left ventricular diastolic pressure gradient, is a low-frequency event, heard as a rumbling sound with the bell of the stethoscope. The frequency components of a heart murmur may vary at different sites of auscultation. The coarse systolic murmur of aortic stenosis (AS) may sound higher-pitched and more acoustically pure at the apex, a phenomenon eponymously referred to as the *Gallavardin effect*. Some murmurs may have a distinct or unusual quality, such as the "honking" sound appreciated in some patients with mitral regurgitation (MR) due to mitral valve prolapse (MVP).

The configuration of a heart murmur may be crescendo, decrescendo, crescendo-decrescendo, or plateau. The decrescendo configuration of the murmur of chronic AR (Fig. e8-1*E*) can be understood in terms of the progressive decline in the diastolic pressure gradient between the aorta and the left ventricle. The crescendo-decrescendo configuration of the murmur of AS reflects the changes in the systolic pressure gradient between the left ventricle and the aorta as ejection occurs, whereas the plateau configuration of the murmur of chronic rheumatic MR (Fig. e8-1*B*) is consistent with the large and nearly constant pressure difference between the left ventricle and the left atrium.

Intensity The intensity of a heart murmur is graded on a scale of 1–6 (or I–VI). A grade 1 murmur is very soft and is heard with great effort.

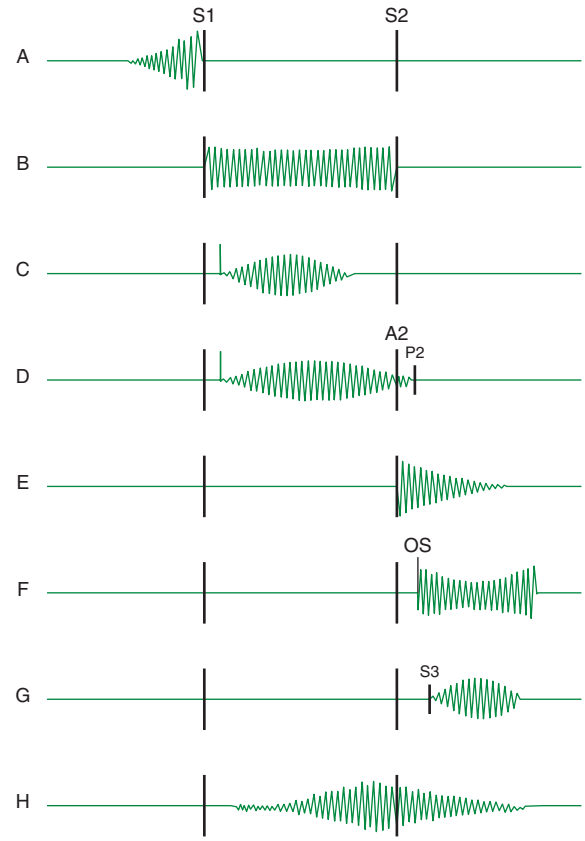

FIGURE e8-1 Diagram depicting principal heart murmurs. ***A.*** Presystolic murmur of mitral or tricuspid stenosis. ***B.*** Holosystolic (pansystolic) murmur of mitral or tricuspid regurgitation or of ventricular septal defect. ***C.*** Aortic ejection murmur beginning with an ejection click and fading before the second heart sound. ***D.*** Systolic murmur in pulmonic stenosis spilling through the aortic second sound, pulmonic valve closure being delayed. ***E.*** Aortic or pulmonary diastolic murmur. ***F.*** Long diastolic murmur of mitral stenosis following the opening snap. ***G.*** Short mid-diastolic inflow murmur following a third heart sound. ***H.*** Continuous murmur of patent ductus arteriosus. *(Adapted from P Wood, Diseases of the Heart and Circulation, London, Eyre & Spottiswood, Ltd.,1968.)*

A grade 2 murmur is easily heard, but not particularly loud. A grade 3 murmur is loud, but is not accompanied by a palpable thrill over the site of maximal intensity. A grade 4 murmur is very loud and accompanied by a thrill. A grade 5 murmur is loud enough to be heard with only the edge of the stethoscope touching the chest, whereas a grade 6 murmur is loud enough to be heard with the stethoscope slightly off the chest. Murmurs of grade 3 or greater intensity usually signify important structural heart disease and indicate high blood flow velocity at the site of murmur production. Small ventricular septal defects (VSDs), for example, are accompanied by loud, usually grade 4 or greater, systolic murmurs as blood is ejected at high velocity from the left to the right ventricle. Low velocity events, such as left-to-right shunting across an atrial septal defect (ASD), are usually silent. The intensity of a heart murmur may also be diminished by any process that increases the distance between the intracardiac source and the stethoscope on the chest wall, such as obesity, obstructive lung disease, and a large pericardial effusion. The intensity of a murmur may also be misleadingly soft when cardiac output is significantly reduced.

Location and Radiation Recognition of the location and radiation of the murmur helps facilitate its accurate identification (Fig. e8-2). Adventitious sounds, such as a systolic click or diastolic snap, or abnormalities of S_1 or S_2, may provide additional clues. Careful attention to the characteristics of the murmur and other heart sounds during the

respiratory cycle and the performance of simple bedside maneuvers when indicated complete the auscultatory examination. These features, and recommendations for further testing, are discussed below in the context of specific systolic, diastolic, and continuous heart murmurs (Table e8-1).

SYSTOLIC HEART MURMURS

Early Systolic Murmurs Early systolic murmurs begin with S_1 and extend for a variable period of time, ending well before S_2. Their causes are relatively few in number. *Acute severe MR* into a normal-sized, relatively noncompliant left atrium results in an early, decrescendo systolic murmur best heard at or just medial to the apical impulse. These characteristics reflect the progressive attenuation of the pressure gradient between the left ventricle and the left atrium during systole due to the rapid rise in left atrial pressure caused by the sudden volume load into an unprepared chamber, and contrast sharply with the auscultatory features of chronic MR. Clinical settings in which acute, severe MR occur include: (1) papillary muscle rupture complicating acute myocardial infarction (MI) (Chap. 239), (2) rupture of chordae tendineae in the setting of myxomatous mitral valve disease (MVP, Chap. 230), (3) infective endocarditis (Chap. 118), and (4) blunt chest wall trauma.

Acute, severe MR from papillary muscle rupture usually accompanies an inferior, posterior, or lateral MI and occurs 2–7 days after presentation. It is often signaled by chest pain, hypotension, and pulmonary edema, but a murmur may be absent in up to 50% of cases. The posteromedial papillary muscle is involved six to ten times more frequently than the anterolateral papillary muscle. The murmur is to be distinguished from that associated with post-MI ventricular septal rupture, which is accompanied by a systolic thrill at the left sternal border in nearly all patients and is holosystolic in duration. A new heart murmur following MI is an indication for transthoracic echocardiography (TTE) (Chap. 222), which allows bedside delineation of its etiology and pathophysiologic significance. The distinction between acute MR and ventricular septal rupture can also be achieved with right heart catheterization, sequential determination of oxygen saturations, and analysis of the pressure waveforms (tall *v* wave in the pulmonary artery wedge pressure in MR). Post-MI mechanical complications of this nature mandate aggressive medical stabilization and prompt referral for surgical repair.

Spontaneous chordal rupture can complicate the course of myxomatous mitral valve disease (MVP) and result in new-onset or "acute on chronic" severe MR. MVP may occur as an isolated phenomenon or the lesion may be part of a more generalized connective tissue disorder as seen, for example, in patients with Marfan syndrome. Acute severe MR as a consequence of infective endocarditis results from destruction of leaflet tissue, chordal rupture, or both. Blunt chest wall trauma is usually self-evident, but may be disarmingly trivial. It can result in papillary muscle contusion and rupture, chordal detachment,

TABLE e8-1 PRINCIPAL CAUSES OF HEART MURMURS

Systolic Murmurs

- Early systolic
  - Mitral
    - Acute MR
  - VSD
    - Muscular
    - Nonrestrictive with pulmonary hypertension
  - Tricuspid
    - TR with normal pulmonary artery pressure
- Mid-systolic
  - Aortic
    - Obstructive
      - Supravalvular—supravalvular aortic stenosis, coarctation of the aorta
      - Valvular—AS and aortic sclerosis
      - Subvalvular—discrete, tunnel or HOCM
    - Increased flow, hyperkinetic states, AR, complete heart block
    - Dilatation of ascending aorta, atheroma, aortitis
  - Pulmonary
    - Obstructive
      - Supravalvular—pulmonary artery stenosis
      - Valvular–pulmonic valve stenosis
      - Subvalvular–infundibular stenosis (dynamic)
    - Increased flow, hyperkinetic states, left-to-right shunt (e.g., ASD)
    - Dilatation of pulmonary artery
- Late systolic
  - Mitral
    - MVP, acute myocardial ischemia
  - Tricuspid
    - TVP
- Holosystolic
  - Atrioventricular valve regurgitation (MR, TR)
  - Left-to-right shunt at ventricular level (VSD)

Early Diastolic Murmurs

- Aortic regurgitation
  - Valvular: congenital (bicuspid valve), rheumatic deformity, endocarditis, prolapse, trauma, post-valvulotomy
  - Dilatation of valve ring: aorta dissection, annulo-aortic ectasia, cystic medial degeneration, hypertension, ankylosing spondylitis
  - Widening of commissures: syphilis
- Pulmonic regurgitation
  - Valvular: post-valvulotomy, endocarditis, rheumatic fever, carcinoid
  - Dilatation of valve ring: pulmonary hypertension; Marfan syndrome
  - Congenital: isolated or associated with tetralogy of Fallot, VSD, pulmonic stenosis

Mid-Diastolic Murmurs

- Mitral
  - Mitral stenosis
  - Carey-Coombs murmur (mid-diastolic apical murmur in acute rheumatic fever)
  - Increased flow across nonstenotic mitral valve (e.g., MR, VSD, PDA, high-output states, and complete heart block)
- Tricuspid
  - Tricuspid stenosis
  - Increased flow across nonstenotic tricuspid valve (e.g., TR, ASD, and anomalous pulmonary venous return)
- Left and right atrial tumors (myxoma)
- Severe AR (Austin Flint murmur)

Continuous Murmurs

- Patent ductus arteriosus
- Coronary AV fistula
- Ruptured sinus of Valsalva aneurysm
- Aortic septal defect
- Cervical venous hum
- Anomalous left coronary artery
- Proximal coronary artery stenosis
- Mammary souffle of pregnancy
- Pulmonary artery branch stenosis
- Bronchial collateral circulation
- Small (restrictive) ASD with MS
- Intercostal AV fistula

Note: AR, aortic regurgitation; AS, aortic stenosis; ASD, atrial septal defect; AV, arteriovenous; HOCM, hypertrophic obstructive cardiomyopathy; MR, mitral regurgitation; MS, mitral stenosis; MVP, mitral valve prolapse; PDA, patent ductus arteriosus; TR, tricuspid regurgitation; TVP, tricuspid valve prolapse; VSD, ventricular septal defect.

or leaflet avulsion. TTE is indicated in all cases of suspected acute severe MR to define its mechanism and severity, delineate left ventricular size and systolic function, and provide an assessment of suitability for primary valve repair.

A congenital, small muscular VSD (Chap. 229) may be associated with an early systolic murmur. The defect closes progressively during septal contraction and thus the murmur is confined to early systole. It is localized to the left sternal border (Fig. e8-2) and is usually of grade 4 or 5 intensity. Signs of pulmonary hypertension or left ventricular volume overload are absent. Anatomically large and uncorrected VSDs, which usually involve the membranous portion of the septum, may lead to pulmonary hypertension. The murmur associated with the left-to-right shunt, which may earlier have been holosystolic, becomes limited to the first portion of systole as the elevated pulmonary vascular resistance leads to an abrupt rise in right ventricular pressure and an attenuation of the interventricular pressure gradient during the remainder of the cardiac cycle. In such instances, signs of pulmonary hypertension (right ventricular lift, loud and single or closely split S_2) may predominate. The murmur is best heard along the left sternal border but is softer. Suspicion of a VSD is an indication for TTE.

Tricuspid regurgitation (TR) with normal pulmonary artery pressures, as may occur with infective endocarditis, may produce an early systolic murmur. The murmur is soft (grade 1 or 2), best heard at the lower left sternal border, and may increase in intensity with inspiration (Carvallo's sign). Regurgitant "*c-v*" waves may be visible in the jugular venous pulse. TR in this setting is not associated with signs of right heart failure.

Mid-Systolic Murmurs Mid-systolic murmurs begin at a short interval following S_1, end before S_2 (Fig. e8-1*C*), and are usually crescendo-decrescendo in configuration. Aortic stenosis is the most common cause of a mid-systolic murmur in an adult. The murmur of AS is usually loudest to the right of the sternum in the second intercostal space (aortic area, Fig. e8-2) and radiates into the carotids. Transmission of the mid-systolic murmur to the apex, where it becomes higher pitched, is common (Gallavardin effect, see above).

Differentiation of this apical systolic murmur from MR can be difficult. The murmur of AS will increase in intensity, or become louder, in the beat following a premature beat, whereas the murmur of MR will remain of constant intensity from beat to beat. The intensity of the AS murmur also varies directly with the cardiac output. With a normal cardiac output, a systolic thrill and grade 4 or higher murmur suggest severe AS. The murmur is softer in the setting of heart failure and low cardiac output. Other auscultatory findings of severe AS include a soft or absent A_2, paradoxical splitting of S_2, an apical S_4, and a late-peaking systolic murmur. In children, adolescents, and young adults with congenital valvular AS, an early ejection sound (click) is usually audible, more often along the left sternal border than at the base. Its presence signifies a flexible, noncalcified bicuspid valve (or one of its variants) and localizes the left ventricular outflow obstruction to the valvular (rather than sub- or supravalvular) level.

Assessment of the volume and rate of rise of the carotid pulse can provide additional information. A small and delayed upstroke (*parvus et tardus*) is consistent with severe AS. The carotid pulse examination is less discriminatory, however, in older patients with stiffened arteries. The electrocardiogram (ECG) shows signs of left ventricular hypertrophy (LVH) as the severity of the stenosis increases. TTE is indicated to assess the anatomic features of the aortic valve, the severity of the stenosis, left ventricular size, wall thickness and function, and the size and contour of the aortic root and proximal ascending aorta.

The obstructive form of hypertrophic cardiomyopathy (HOCM) is associated with a mid-systolic murmur that is usually loudest along the left sternal border or between the left lower sternal border and the apex (Chap. 231, Fig. e8-2). The murmur is produced by both dynamic left ventricular outflow tract obstruction and MR, and thus its configuration is a hybrid between ejection and regurgitant phenomena. The intensity of the murmur may vary from beat to beat, and following provocative maneuvers, but usually does not exceed grade 3. The murmur will classically increase in intensity with maneuvers that result in increasing degrees of outflow tract obstruction, such as a reduction in preload or afterload (Valsalva, standing, vasodilators) or to an augmentation of contractility (inotropic stimulation). Maneuvers that increase preload (squatting, passive leg raising, volume administration) or afterload (squatting, vasopressors) or that reduce contractility (β-adrenoreceptor blockers) decrease the intensity of the murmur. In rare patients, there may be reversed splitting of S_2. A sustained left ventricular apical impulse and an S_4 may be appreciated. In contrast to AS, the carotid upstroke is rapid and of normal volume. Rarely, it is bisferiens or bifid in contour (see Fig. 220-2*D*) due to mid-systolic closure of the aortic valve. LVH is present on the ECG and the diagnosis is confirmed by TTE. Although the systolic murmur associated with MVP behaves similarly to that due to HOCM in response to the Valsalva maneuver and to standing/squatting (Fig. e8-3), these two lesions can be distinguished on the basis of their associated findings, such as the presence of LVH in HOCM or a non-ejection click in MVP.

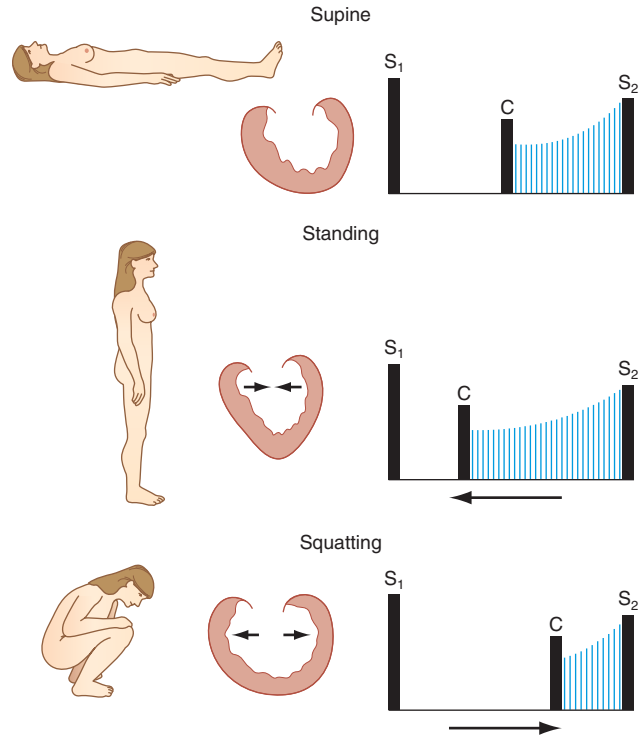

FIGURE e8-3 A mid-systolic nonejection sound (C) occurs in mitral valve prolapse and is followed by a late systolic murmur that crescendos to the second heart sound (S_2). Standing decreases venous return; the heart becomes smaller; C moves closer to the first heart sound (S_1) and the mitral regurgitant murmur has an earlier onset. With prompt squatting, venous return increases; the heart becomes larger; C moves toward S_2, and the duration of the murmur shortens. *(From JA Shaver, JJ Leonard, DF Leon, Examination of the Heart, Part IV, Auscultation of the Heart. Dallas, American Heart Association, 1990, p 13. Copyright, American Heart Association.)*

The mid-systolic, crescendo-decrescendo murmur of congenital pulmonic stenosis (PS, Chap. 229), is best appreciated in the second and third left intercostal spaces (pulmonic area) (Figs. e8-2 and e8-4). The duration of the murmur lengthens and the intensity of P_2 diminishes with increasing degrees of valvular stenosis (Fig. e8-1*D*). An early ejection sound, the intensity of which decreases with inspiration, is heard in younger patients. A parasternal lift and ECG evidence of right ventricular hypertrophy indicate severe pressure overload. If obtained, the chest x-ray may show poststenotic dilatation of the main pulmonary artery. TTE is recommended for complete characterization.

Significant left-to-right intracardiac shunting due to an ASD (Chap. 229) leads to an increase in pulmonary blood flow and a grade 2–3 mid-systolic murmur at the mid to upper left sternal border with fixed

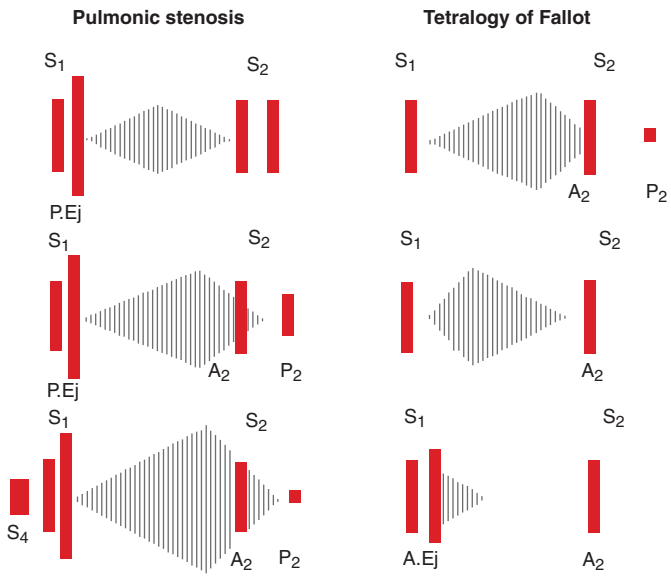

FIGURE e8-4 ***Left.*** In valvular pulmonic stenosis with intact ventricular septum, right ventricular systolic ejection becomes progressively longer, with increasing obstruction to flow. As a result, the murmur becomes longer and louder, enveloping the aortic component of the second heart sound (A_2). The pulmonic component (P_2) occurs later, and splitting becomes wider but more difficult to hear because A_2 is lost in the murmur and P_2 becomes progressively fainter and lower pitched. As the pulmonic gradient increases, isometric contraction shortens until the pulmonary valvular ejection sound fuses with the first heart sound (S_1). In severe pulmonic stenosis with concentric hypertrophy and decreasing right ventricular compliance, a fourth heart sound appears. ***Right.*** In tetralogy of Fallot with increasing obstruction at pulmonic infundibular area, an increasing amount of right ventricular blood is shunted across the silent ventricular septal defect and flow across the obstructed outflow tract decreases. Therefore, with increasing obstruction the murmur becomes shorter, earlier, and fainter. P_2 is absent in severe tetralogy of Fallot. A large aortic root receives almost all cardiac output from both ventricular chambers, and the aorta dilates and is accompanied by a root ejection sound that does not vary with respiration. *(From JA Shaver, JJ Leonard, DF Leon, Examination of the Heart, Part IV, Auscultation of the Heart. Dallas, American Heart Association, 1990, p 45. Copyright, American Heart Association.)*

splitting of S_2. Ostium secundum ASDs are most common. Features suggestive of a primum ASD include the coexistence of MR due to a cleft anterior mitral valve leaflet and left axis deviation of the QRS complex on ECG. With sinus venosus ASDs, the left-to-right shunt is usually not large enough to result in a systolic murmur, though the ECG may show abnormalities of sinus node function. A grade 2 or 3 mid-systolic murmur may also be heard best at the upper left sternal border in patients with idiopathic dilatation of the pulmonary artery. A pulmonary ejection sound is present. TTE is indicated to evaluate a grade 2 or 3 mid-systolic murmur when there are other signs of cardiac disease.

An isolated grade 1 or 2 midsystolic murmur, heard in the absence of symptoms or signs of heart disease, is most often a benign finding for which no further evaluation, including TTE, is necessary. The most common example of a murmur of this type in an older adult patient is the crescendo-decrescendo murmur of aortic valve sclerosis, heard at the second right interspace (Fig. e8-2). Aortic sclerosis is defined as focal thickening and calcification of the aortic valve to a degree that does not interfere with leaflet opening. The carotid upstrokes are normal and electrocardiographic LVH is not present. A grade 1 or 2 mid-systolic murmur can often be heard at the left sternal border with pregnancy, hyperthyroidism, or anemia, physiologic states that are associated with accelerated blood flow. *Still's murmur* refers to a benign grade 2, vibratory mid-systolic murmur at the lower left sternal border in normal children and adolescents (Fig. e8-2).

Late Systolic Murmurs A late systolic murmur that is best heard at the left ventricular apex is often due to MVP (Chap. 230). Often, this murmur is introduced by one or more nonejection clicks. The radiation of the murmur can help identify the specific mitral leaflet involved in the process of prolapse or flail. The term *flail* refers to the movement made by an unsupported portion of the leaflet after loss of its chordal attachment(s). With posterior leaflet prolapse or flail, the resultant jet of MR is directed anteriorly and medially, as a result of which the murmur radiates to the base of the heart and masquerades as AS. Anterior leaflet prolapse or flail results in a posteriorly directed MR jet that radiates to the axilla or left infrascapular region. Leaflet flail is associated with a murmur of grade 3 or 4 intensity that can be heard throughout the precordium in thin-chested patients. The presence of an S_3 or a short, rumbling mid-diastolic murmur, signifies severe MR.

Bedside maneuvers that decrease left ventricular preload, such as standing, will cause the click and murmur of MVP to move closer to the first heart sound, as leaflet prolapse occurs earlier in systole. Standing also causes the murmur to become louder and longer. With squatting, left ventricular preload and afterload are increased abruptly, and the click and murmur move away from the first heart sound, as leaflet prolapse is delayed. The murmur becomes softer and shorter in duration (Fig. e8-3). As noted above, these responses to standing and squatting are similar to those observed in patients with HOCM.

A late, apical systolic murmur indicative of MR may be heard transiently in the setting of acute myocardial ischemia. It is due to apical tethering and malcoaptation of the leaflets in response to structural and functional changes of the ventricle and mitral annulus. The intensity of the murmur varies as a function of left ventricular afterload and will increase in the setting of hypertension. TTE is recommended for assessment of late systolic murmurs.

Holosystolic Murmurs (Figs. e8-1*B* and e8-5) Holosystolic murmurs begin with S_1 and continue through systole to S_2. They are usually indicative of chronic mitral or tricuspid valve regurgitation or a VSD, and warrant TTE for further characterization. The holosystolic murmur of chronic MR is best heard at the left ventricular apex and radiates to the axilla (Fig. e8-2). It is usually high pitched and plateau in configuration because of the wide difference between left ventricular and left atrial pressure throughout systole. In contrast to acute MR, left atrial compliance is normal or even increased in chronic MR. As a result, there is only a small increase in left atrial pressure for any increase in regurgitant volume.

There are several conditions associated with chronic MR and an apical holosystolic murmur, including rheumatic scarring of the leaflets, mitral annular calcification, and severe left ventricular chamber enlargement. The circumference of the mitral annulus increases as the left ventricle enlarges and leads to failure of leaflet coaptation with central MR in patients with dilated cardiomyopathy (Chap. 231). The severity of the MR is worsened by any contribution from apical displacement of the papillary muscles and leaflet tethering. Because the mitral annulus is contiguous with the left atrial endocardium, gradual enlargement of the left atrium from chronic MR will result in further stretching of the annulus and more MR and thus, "MR begets MR." Chronic severe MR results in enlargement and leftward displacement of the left ventricular apex beat and, in some patients, a diastolic filling complex as described previously.

The holosystolic murmur of chronic TR is generally softer than that of MR, is loudest at the left lower sternal border, and usually increases in intensity with inspiration (Carvallo's sign). Associated signs include "*c-v*" waves in the jugular venous pulse, an enlarged and pulsatile liver, ascites, and peripheral edema. The abnormal jugular venous wave forms are the predominant finding and are very often seen in the absence of an audible murmur, despite Doppler echocardiographic verification of TR. Causes of primary TR include myxomatous disease

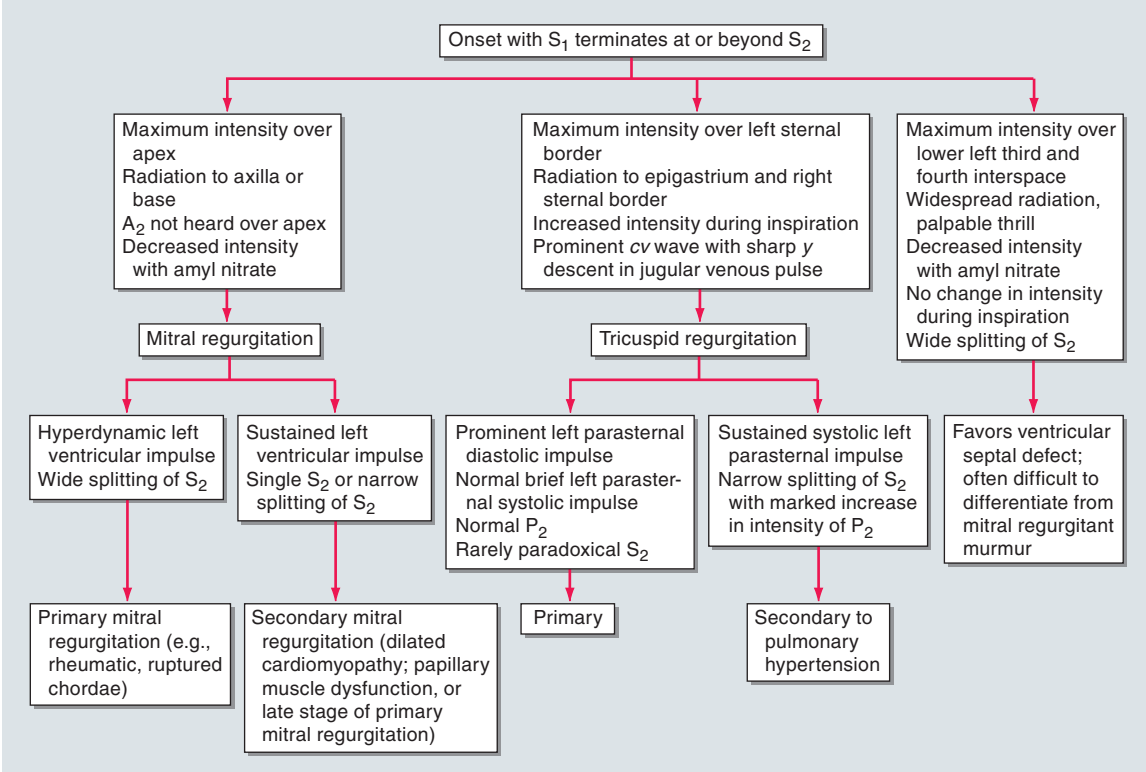

FIGURE e8-5 Differential diagnosis of a holosystolic murmur. S_1, first heart sound; S_2, second heart sound; A_2, aortic component of the second heart sound; P_2, pulmonic component of the second heart sound. *[From C Chatterjee, in K Chatterjee et al (eds): Cardiology: An illustrated Text/Reference, Philadelphia, Lippincott, 1991, with permission.]*

(prolapse), endocarditis, rheumatic disease, carcinoid, Ebstein's anomaly, and chordal detachment following the performance of right ventricular endomyocardial biopsy. TR is more commonly a passive process that results secondarily from chronic elevations of pulmonary artery and right ventricular pressures, leading to right ventricular enlargement, annular dilatation, papillary muscle displacement, and failure of leaflet coaptation.

The holosystolic murmur of a VSD is loudest at the mid- to lower left sternal border (Fig. e8-2) and radiates widely. A thrill is present at the site of maximal intensity in the majority of patients. There is no change in the intensity of the murmur with inspiration. The intensity of the murmur varies as a function of the anatomic size of the defect. Small, restrictive VSDs, as exemplified by the *maladie de Roger*, create a very loud murmur due to the significant and sustained systolic pressure gradient between the left and right ventricles. With large defects, the ventricular pressures tend to equalize, shunt flow is balanced, and a murmur is not appreciated. The distinction between post-MI ventricular septal rupture and MR has been reviewed previously.

DIASTOLIC HEART MURMURS

Early Diastolic Murmurs (Fig. e8-1*E*) Chronic AR results in a high-pitched, blowing, decrescendo, early to mid-diastolic murmur that begins following the aortic component of S_2 (A_2) and is best heard at the second right interspace (Fig. e8-6). The murmur may be soft and difficult to hear, unless auscultation is performed with the patient leaning forward at end-expiration. This maneuver brings the aortic root closer to the anterior chest wall. Radiation of the murmur may provide a clue as to the cause of the AR. With primary valve disease, such as that due to congenital bicuspid disease, prolapse, or endocarditis, the diastolic murmur tends to radiate along the left sternal border. When AR is caused by aortic root disease, the diastolic murmur may radiate along the right sternal border. Diseases of the aortic root cause dilatation or distortion of the aortic annulus and failure of leaflet coaptation. Causes include Marfan syndrome with aneurysm formation, annulo-aortic ectasia, ankylosing spondylitis, and aortic dissection.

Chronic, severe AR may also produce a lower pitched mid- to late, grade 1 or 2 diastolic murmur at the apex (Austin Flint murmur), which is thought to reflect turbulence at the mitral inflow area from the admixture of regurgitant (aortic) and forward (mitral) blood flow (Fig. e8-1*G*). This lower pitched apical diastolic murmur can be distinguished from that due to MS by the absence of an opening snap and the response of the murmur to a vasodilator challenge. Lowering afterload with an agent such as amyl nitrite will decrease the duration and magnitude of the aortic–left ventricular diastolic pressure gradient, and thus the Austin Flint murmur of severe AR will become shorter and softer. The intensity of the diastolic murmur of mitral stenosis (Fig. e8-7) may either remain constant or increase with afterload reduction because of the reflex increase in cardiac output and mitral valve flow.

Although AS and AR may coexist, a grade 2 or 3 crescendo-decrescendo mid-systolic murmur is frequently heard at the base of the heart in patients with isolated severe AR, and is due to an increased volume and rate of systolic flow. Accurate bedside identification of coexistent AS can be difficult, unless the carotid pulse examination is abnormal or the mid-systolic murmur is of grade 4 or greater intensity. In the absence of heart failure, chronic severe AR is accompanied by several peripheral signs of significant diastolic run-off, including a wide pulse pressure, a water-hammer carotid upstroke (Corrigan's pulse), and Quincke's pulsations of the nail beds. The diastolic murmur of *acute severe AR* (Fig. e8-6) is notably shorter in duration and lower pitched than the murmur of chronic AR. It can be very difficult to appreciate in the presence of a rapid heart rate. These attributes reflect the abrupt rate of rise of diastolic pressure within the unprepared and noncompliant left ventricle, and the correspondingly rapid decline in the aortic–left ventricular diastolic pressure gradient. Left ventricular diastolic pressure may increase sufficiently to result in premature closure of the mitral valve and a soft first heart sound. Peripheral signs of significant diastolic run-off are absent.

Pulmonic regurgitation (PR) results in a decrescendo, early to mid-diastolic murmur (*Graham Steell murmur*) that begins after the pul-

Copyright © 2008 The McGraw-Hill Companies. All rights reserved.

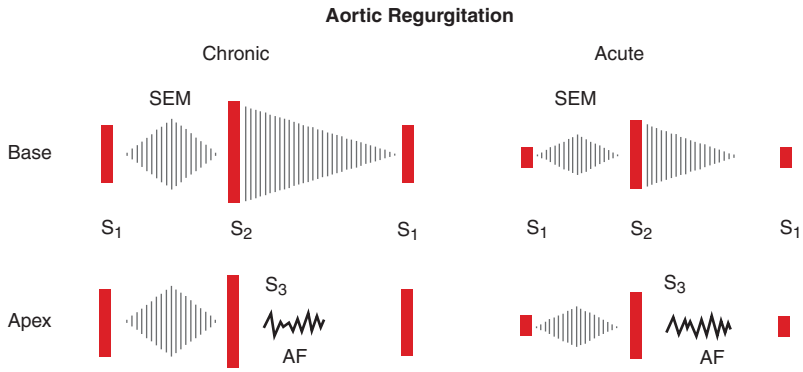

FIGURE e8-6 Contrast between the auscultatory findings in chronic and acute aortic regurgitation. In chronic aortic regurgitation, a prominent systolic ejection murmur resulting from the large forward stroke volume is heard at the base and the apex and ends well before the second heart sound (S_2). The aortic diastolic regurgitant murmur begins with S_2 and continues in a decrescendo fashion, terminating before the first heart sound (S_1). At the apex, the mid-diastolic component of Austin Flint murmur (AF) is introduced by a prominent third heart sound (S_3). A pre-systolic component of the AF is also heard. In acute aortic regurgitation there is a significant decrease in the intensity of the systolic ejection murmur compared with that of chronic aortic regurgitation because of the decreased forward stroke volume. S_1 is markedly decreased in intensity because of premature closure of the mitral valve, and at the apex the presystolic component of the AF murmur is absent. The early diastolic murmur at the base ends well before S_1 because of equilibration of the left ventricle and aortic end-diastolic pressure. Significant tachycardia is usually present. *(From JA Shaver: Heart Dis Stroke 2:100, 1994.)*

monic component of S_2 (P_2), is best heard at the second left interspace, and radiates along the left sternal border. The intensity of the murmur may increase with inspiration. PR is most commonly due to dilatation of the valve annulus from chronic elevation of the pulmonary artery pressure. Signs of pulmonary hypertension, including a right ventricular lift and a loud, single or narrowly split S_2, are present. These features also help distinguish PR from AR as the cause of a decrescendo diastolic murmur heard along the left sternal border. PR in the absence of pulmonary hypertension can occur with endocarditis or a congenitally deformed valve. It is usually present following repair of tetralogy of Fallot in childhood. When pulmonary hypertension is not present, the diastolic murmur is softer and lower pitched than the classic Graham Steell murmur, and the examiner can be misled as to the severity of the PR.

TTE is indicated for the further evaluation of the patient with an early to mid-diastolic murmur. Longitudinal assessment of the severity of the valve lesion and ventricular size and systolic function help guide the decision for surgical management. TTE can also provide anatomic information regarding the root and proximal ascending aorta, though computed tomographic or magnetic resonance angiography may be indicated for more precise characterization (Chap. 222).

Mid-Diastolic Murmurs (Figs. e8-1*G* and e8-1*H*) Mid-diastolic murmurs result from obstruction and/or augmented flow at the level of the mitral or tricuspid valve. Rheumatic fever is the most common cause of MS (Fig. e8-7). In younger patients with pliable valves, S_1 is loud and the murmur begins after an opening snap, which is a high-pitched sound that occurs shortly after S_2. The distance between the pulmonic component of the second heart sound (P_2) and the opening snap is inversely related to the magnitude of the left atrial to left ventricular pressure gradient. The murmur of MS is low pitched and thus is best heard with the bell of the stethoscope. It is loudest at the left ventricular apex and often only appreciated when the patient is turned in the left lateral decubitus position. It is usually of grade 1 or 2 intensity, but may be absent when the cardiac output is severely reduced despite significant obstruction. The intensity of the murmur increases during maneuvers that increase cardiac output and mitral valve flow, such as exercise. The duration of the murmur reflects the length of time over which left atrial pressure exceeds left ventricular pressure. An increase in the intensity of the murmur just before S_1, a phenomenon known as *pre-systolic accentuation* (Figs. e8-1*A*, e8-7), occurs in patients in sinus rhythm and is due to a late increase in transmitral flow with atrial contraction. Pre-systolic accentuation does not occur in patients with atrial fibrillation.

The mid-diastolic murmur associated with tricuspid stenosis is best heard at the lower left sternal border and increases in intensity with inspiration. A prolonged *y* descent may be visible in the jugular venous wave form. This murmur is very difficult to hear and often obscured by left-sided acoustical events.

There are several other causes of mid-diastolic murmurs. Large left atrial myxomas may prolapse across the mitral valve and cause variable degrees of obstruction to left ventricular inflow (Chap. 233). The murmur associated with an atrial myxoma may change in duration and intensity with changes in body position. An opening snap is not present and there is no pre-systolic accentuation. Augmented mitral diastolic flow can occur with isolated severe MR or with a large left-to-right shunt at the ventricular or great vessel level and produce a soft, rapid filling sound (S_3) followed by a short, low-pitched mid-diastolic apical murmur. The Austin Flint murmur of severe, chronic AR has already been described.

A short mid-diastolic murmur is rarely heard during an episode of acute rheumatic fever (Carey-Coombs murmur) and is due to enhanced flow through an edematous mitral valve. An opening snap is not present in the acute phase and the murmur dissipates with resolution of the acute attack. Complete heart block with dyssynchronous atrial and ventricular activation may be associated with intermittent mid- to-late diastolic murmurs if atrial contraction occurs when the mitral valve is partially closed. Mid-diastolic murmurs indicative of increased tricuspid valve flow can occur with severe, isolated TR and with large ASDs and significant left-to-right shunting. Other signs

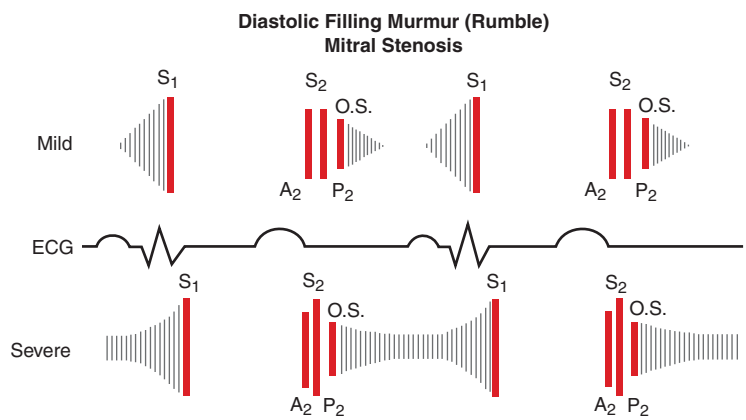

FIGURE e8-7 Diastolic filling murmur (rumble) in mitral stenosis. In mild mitral stenosis, the diastolic gradient across the valve is limited to the two phases of rapid ventricular filling in early diastole and pre-systole. The rumble may occur during either or both periods. As the stenotic process becomes severe, a large pressure gradient exists across the valve during the entire diastolic filling period, and the rumble persists throughout diastole. As the left atrial pressure becomes greater, the interval between A_2 and the opening snap shortens. In severe mitral stenosis, secondary pulmonary hypertension develops and results in a loud P_2 and the splitting interval usually narrows. ECG, electrocardiogram. *(From JA Shaver, JJ Leonard, DF Leon, Examination of the Heart, Part IV, Auscultation of the Heart. Dallas, American Heart Association, 1990, p 55. Copyright, American Heart Association.)*

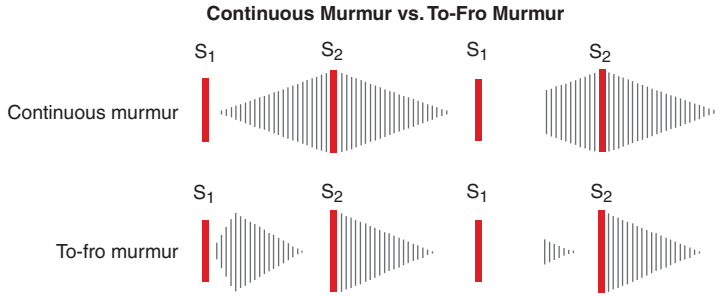

FIGURE e8-8 Comparison of the continuous murmur and the to-fro murmur. During abnormal communication between high-pressure and low-pressure systems, a large pressure gradient exists throughout the cardiac cycle, producing a continuous murmur. A classic example is patent ductus arteriosus. At times, this type of murmur can be confused with a to-fro murmur, which is a combination of systolic ejection murmur and a murmur of semilunar valve incompetence. A classic example of a to-fro murmur is aortic stenosis and regurgitation. A continuous murmur crescendos to around the second heart sound (S_2), whereas a to-fro murmur has two components. The mid-systolic ejection component decrescendos and disappears as it approaches S_2. *(From JA Shaver, JJ Leonard, DF Leon, Examination of the Heart, Part IV, Auscultation of the Heart. Dallas, American Heart Association, 1990, p 55. Copyright, American Heart Association.)*

of an ASD are present (Chap. 229), including fixed-splitting of S_2 and a mid-systolic murmur at the mid- to upper left sternal border. TTE is indicated for evaluation of the patient with a mid- to late diastolic murmur. Findings specific to the diseases discussed above will help guide management.

CONTINUOUS MURMURS

(Figs. e8-1*H* and e8-8) Continuous murmurs begin in systole, peak near the second heart sound, and continue into all or part of diastole. Their presence throughout the cardiac cycle implies a pressure gradient between two chambers or vessels during both systole and diastole. The continuous murmur associated with a patent ductus arteriosus is best heard at the upper left sternal border. Large, uncorrected shunts may lead to pulmonary hypertension, attenuation or obliteration of the diastolic component of the murmur, reversal of shunt flow, and differential cyanosis of the lower extremities. A ruptured sinus of Valsalva aneurysm creates a continuous murmur of abrupt onset at the upper right sternal border. Rupture typically occurs into a right heart chamber, and the murmur is indicative of a continuous pressure difference between the aorta and either the right ventricle or right atrium. A continuous murmur may also be audible along the left sternal border with a coronary arteriovenous fistula and at the site of an arteriovenous fistula used for hemodialysis access. Enhanced flow through enlarged intercostal collateral arteries in patients with aortic coarctation may produce a continuous murmur along the course of one or more ribs. A cervical bruit with both systolic and diastolic components (a to-fro murmur, Fig. e8-8) usually indicates a high-grade carotid artery stenosis.

Not all continuous murmurs are pathologic. A continuous venous hum can be heard in healthy children and young adults, especially during pregnancy. It is best appreciated in the right supraclavicular fossa and can be obliterated by pressure over the right internal jugular vein or by having the patient turn his/her head toward the examiner. The continuous mammary souffle of pregnancy is created by enhanced arterial flow through engorged breasts and usually appears during the late third trimester or early puerperium. The murmur is louder in systole. Firm pressure with the diaphragm of the stethoscope can eliminate the diastolic portion of the murmur.

DYNAMIC AUSCULTATION

(Tables e8-2 and 220-1) Careful attention to the behavior of heart murmurs during simple maneuvers that alter cardiac hemodynamics can provide important clues as to their cause and significance.

TABLE e8-2 DYNAMIC AUSCULTATION: BEDSIDE MANEUVERS THAT CAN BE USED TO CHANGE THE INTENSITY OF CARDIAC MURMURS (SEE TEXT)

1. Respiration
2. Isometric exercise (handgrip)
3. Transient arterial occlusion
4. Pharmacologic manipulation of preload and/or afterload
5. Valsalva maneuver
6. Rapid standing/squatting
7. Post-premature beat

Respiration Auscultation should be performed during quiet respiration or with a modest increase in inspiratory effort, as more forceful movement of the chest tends to obscure the heart sounds. Left-sided murmurs may be best heard at end-expiration, when lung volumes are minimized and the heart and great vessels are brought closer to the chest wall. This phenomenon is characteristic of the murmur of AR. Murmurs of right-sided origin, such as tricuspid or pulmonic regurgitation, increase in intensity during inspiration. The intensity of left-sided murmurs either remains constant or decreases with inspiration.

Bedside assessment should also account for the behavior of S_2 with respiration and the dynamic relationship between the aortic and pulmonic components (Fig. e8-9). Reversed splitting can be a feature of severe AS, HOCM, left bundle branch block, right ventricular apical pacing, or acute myocardial ischemia. Fixed splitting of S_2 in the presence of a grade 2 or 3 mid-systolic murmur at the mid- or upper left sternal border indicates an ASD. Physiologic but wide splitting during the respiratory cycle implies either premature aortic

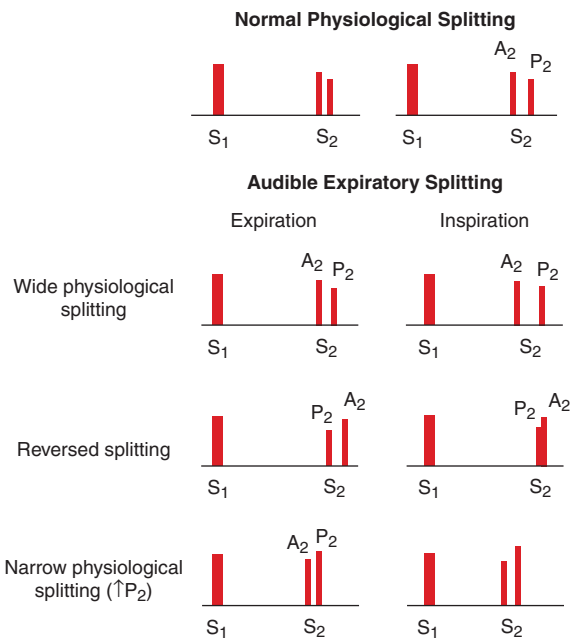

FIGURE e8-9 ***Top.*** Normal physiologic splitting. During expiration, the aortic (A_2) and pulmonic (P_2) components of the second heart sound are separated by <30 ms and are appreciated as a single sound. During inspiration, the splitting interval widens, and A_2 and P_2 are clearly separated into two distinct sounds. ***Bottom.*** Audible expiratory splitting. Wide physiologic splitting is caused by a delay in P_2. Reversed splitting is caused by a delay in A_2, resulting in paradoxical movement; i.e., with inspiration P_2 moves towards A_2, and the splitting interval narrows. Narrow physiologic splitting occurs in pulmonary hypertension, and both A_2 and P_2 are heard during expiration at a narrow splitting interval because of the increased intensity and high-frequency composition of P_2. *(From JA Shaver, JJ Leonard, DF Leon, Examination of the Heart, Part IV, Auscultation of the Heart. Dallas, American Heart Association, 1990, p 17. Copyright, American Heart Association.)*

valve closure, as can occur with severe MR, or delayed pulmonic valve closure due to PS or right bundle branch block.

Alterations of Systemic Vascular Resistance Murmurs can change characteristics following maneuvers that alter systemic vascular resistance and left ventricular afterload. The systolic murmurs of MR and VSD become louder during sustained handgrip, simultaneous inflation of blood pressure cuffs on both upper extremities to pressures 20–40 mmHg above systolic pressure for 20 s, or infusion of a vasopressor agent. The murmurs associated with AS or HOCM will either become softer or remain unchanged with these maneuvers. The diastolic murmur of AR becomes louder in response to interventions that raise systemic vascular resistance.

Opposite changes in systolic and diastolic murmurs may occur with the use of pharmacologic agents that lower systemic vascular resistance. Inhaled amyl nitrite is now rarely used for this purpose but can help to distinguish the murmur of AS or HOCM from that of either MR or VSD. The former two murmurs increase in intensity, whereas the latter two become softer after exposure to amyl nitrite. As noted previously, the Austin Flint murmur of severe AR becomes softer, but the mid-diastolic rumble of MS becomes louder, in response to the abrupt lowering of systemic vascular resistance with amyl nitrite.

Changes in Venous Return The Valsalva maneuver results in an increase in intrathoracic pressure, followed by a decrease in venous return, ventricular filling, and cardiac output. The majority of murmurs decrease in intensity during the strain phase of the maneuver. Two notable exceptions are the murmurs associated with MVP and obstructive HOCM, both of which become louder during the Valsalva maneuver. The murmur of MVP may also become longer as leaflet prolapse occurs earlier in systole at smaller ventricular volumes. These murmurs behave in a similar and parallel fashion with standing. Both the click and the murmur of MVP move closer in timing to S_1 on rapid standing (Fig. e8-3). The increase in the intensity of the murmur of HOCM is predicated on the augmentation of the dynamic left ventricular outflow tract gradient that occurs with reduced ventricular filling. Squatting results in abrupt increases in both venous return and left ventricular afterload, changes that predictably cause a decrease in the intensity and duration of the murmurs associated with MVP and HOCM. The click and murmur of MVP move away from S_1 with squatting.

Post-Premature Ventricular Contraction A change in the intensity of a systolic murmur in the first beat after a premature beat, or in the beat after a long cycle length in patients with atrial fibrillation, can help distinguish AS from MR, particularly in an older patient in whom the murmur of AS is well transmitted to the apex. Systolic murmurs due to left ventricular outflow obstruction, including that due to AS, increase in intensity in the beat following a premature beat because of the combined effects of enhanced left ventricular filling and post-extrasystolic potentiation of contractile function. Forward flow accelerates, causing an increase in the gradient and a louder murmur. The intensity of the murmur of MR does not change in the post-premature beat as there is relatively little further increase in mitral valve flow or change in the left ventricular to left atrial gradient.

THE CLINICAL CONTEXT

Additional clues as to the etiology and importance of a heart murmur can be gleaned from the history and other physical examination findings. Symptoms suggestive of cardiovascular, neurologic, or pulmonary disease should help focus the differential diagnosis, as should findings relevant to the jugular venous pressure and wave forms, the arterial pulses, other heart sounds, the lungs, abdomen, skin, and extremities. In many instances, laboratory studies, an ECG, and/or a chest x-ray may have been obtained earlier and may contain valuable information. A patient with suspected infective endocarditis, for example, may have a murmur in the setting of fever, chills, anorexia, fatigue, dyspnea, splenomegaly, petechiae, and positive blood cultures. A new systolic murmur in a patient with a marked fall in blood pressure after a recent MI suggests myocardial rupture. On the other hand, an isolated grade 1 or 2 mid-systolic murmur at the left sternal border in a healthy, active, and asymptomatic young adult is most likely a benign finding for which no further evaluation is indicated. The context in which the murmur is appreciated often dictates the need for further testing.

ECHOCARDIOGRAPHY

(See Fig. e8-10, Chaps. 220 and 222) Echocardiography with color flow and spectral Doppler is a valuable tool for the assessment of cardiac murmurs. Information regarding valve structure and function, chamber size, wall thickness, ventricular function, estimated pulmonary artery pressures, intracardiac shunt flow, pulmonary and hepatic vein flow, and aortic flow can be readily ascertained. It is important to note that Doppler signals of trace or mild valvular regurgitation of no clinical consequence can be detected with structurally normal tricuspid, pulmonic, and mitral valves. Such signals are not likely to generate enough turbulence to create a murmur.

Echocardiography is indicated for the evaluation of patients with early, late, or holosystolic murmurs, and for patients with grade 3 or louder mid-systolic murmurs. Patients with grade 1 or 2 mid-systolic murmurs, but other symptoms or signs of cardiovascular disease, including those from ECG or chest x-ray, should also undergo echocardiography. Echocardiography is indicated for the evaluation of any patient with a diastolic murmur and for patients with continuous murmurs not due to a venous hum or mammary souffle. Echocardiography should also be considered when there is a clinical need to verify normal cardiac structure and function in a patient whose symptoms and signs are likely noncardiac in origin. The performance of serial echocardiography to follow the course of asymptomatic individuals with valvular heart disease is a central feature of their longitudinal assessment and provides valuable information that may impact on decisions regarding the timing of surgery. Routine echocardiography is *not* recommended for asymptomatic patients with a grade 1 or 2 mid-systolic murmur without other signs of heart disease. For this category of patients, referral to a cardiovascular specialist should be considered if doubt exists regarding the significance of the murmur after the initial examination.

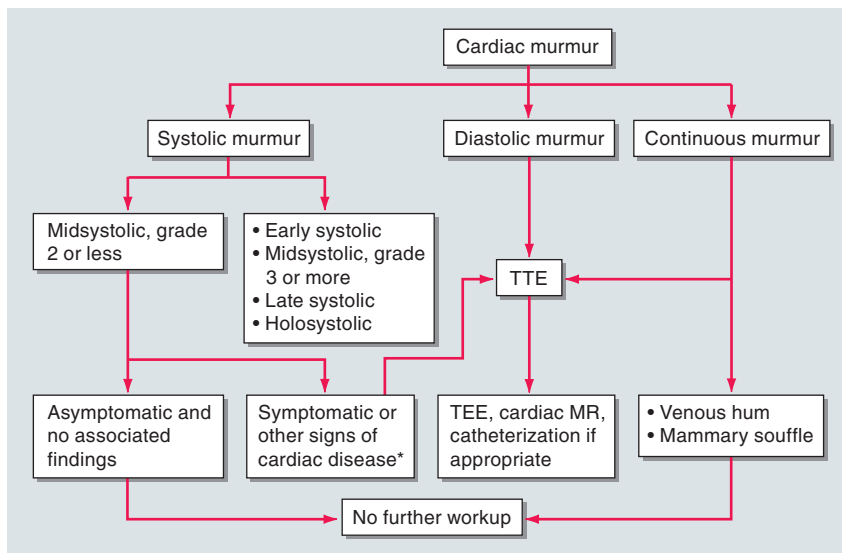

FIGURE e8-10 Strategy for evaluating heart murmurs. *If an electrocardiogram or chest x-ray has been obtained and is abnormal, echocardiography is indicated. TTE, transthoracic echocardiography; TEE, transesophageal echocardiography; MR, magnetic resonance. *(Adapted from Bonow et al.)*

The selective use of echocardiography outlined above has not been subjected to rigorous cost-effective analysis. At least one study has suggested that initial referral of pediatric patients with heart murmurs to a specialist results in modest cost savings. For some clinicians, handheld or miniaturized cardiac ultrasound devices have replaced the stethoscope. Although several reports attest to the improved sensitivity of such devices for the detection of valvular heart disease, accuracy is highly operator dependent and incremental cost considerations have not been adequately addressed. The use of electronic or digital stethoscopes with spectral display capabilities has also been proposed as a method to improve the characterization of heart murmurs and the teaching of cardiac auscultation.

OTHER CARDIAC TESTING

(Chap. 222, Fig. e8-10) In relatively few patients, clinical assessment and TTE do not adequately characterize the origin and significance of a heart murmur. Transesophageal echocardiography (TEE) can be considered for further evaluation, especially when the TTE windows are limited by body size, chest configuration, or intrathoracic pathology. TEE offers enhanced sensitivity for the detection of a wide range of structural cardiac disorders. Electrocardiographically gated cardiac magnetic resonance (CMR) imaging, although limited in its ability to display valvular morphology, can provide quantitative information regarding valvular function, stenosis severity, regurgitant fraction, shunt flow, chamber and great vessel size, ventricular function, and myocardial perfusion. CMR has greater capability than cardiac computed tomography (CCT) in this regard and has largely supplanted the need for cardiac catheterization and invasive hemodynamic assessment when there is a discrepancy between the clinical and echocardiographic findings. Coronary angiography is performed routinely in most adult patients prior to valve surgery, especially when there is a suspicion of coronary artery disease predicated on symptoms, risk factors, and/or age.

INTEGRATED APPROACH

The accurate identification of a heart murmur begins with a systematic approach to cardiac auscultation. Characterization of its major attributes, as reviewed above, allows the examiner to construct a preliminary differential diagnosis, which is then refined by integration of information available from the history, associated cardiac findings, the general physical examination, and the clinical context. The need for and urgency of further testing follow sequentially. Correlation of the findings on auscultation with the noninvasive data provides an educational feedback loop and an opportunity for improving physical examination skills. Cost constraints mandate that noninvasive imaging be justified on the basis of its incremental contribution to diagnosis, treatment, and outcome. Additional study is required to assess the cost-effective application of newer imaging technology.

SECTION 6 ALTERATIONS IN GASTROINTESTINAL FUNCTION

38 Dysphagia

Raj K. Goyal

Dysphagia is defined as a sensation of "sticking" or obstruction of the passage of food through the mouth, pharynx, or esophagus. However, it is often used as an umbrella term to include other symptoms related to swallowing difficulty. *Aphagia* signifies complete esophageal obstruction, which is usually due to bolus impaction and represents a medical emergency. *Difficulty in initiating a swallow* occurs in disorders of the voluntary phase of swallowing. However, once initiated, swallowing is completed normally. *Odynophagia* means painful swallowing. Frequently, odynophagia and dysphagia occur together. *Globus pharyngeus* is the sensation of a lump lodged in the throat. However, no difficulty is encountered when swallowing is performed. *Misdirection of food*, resulting in nasal regurgitation and laryngeal and pulmonary aspiration during swallowing, is characteristic of oropharyngeal dysphagia. *Phagophobia*, meaning fear of swallowing, and *refusal to swallow* may occur in hysteria, rabies, tetanus, and pharyngeal paralysis due to fear of aspiration. Painful inflammatory lesions that cause odynophagia may also cause refusal to swallow. Some patients may feel the food as it goes down the esophagus. This esophageal sensitivity is not associated with either food sticking or obstruction.

PHYSIOLOGY OF SWALLOWING

The process of swallowing begins with a voluntary (oral) phase that includes a preparatory phase during which a food bolus suitable for swallowing is prepared and a transfer phase during which the bolus is pushed into the pharynx by contraction of the tongue. The bolus then activates oropharyngeal sensory receptors that initiate the deglutition reflex. The deglutition reflex is centrally mediated and involves a complex series of events. It serves both to propel food through the pharynx and the esophagus and to prevent its entry into the airway. When the bolus is propelled backward by the tongue, the larynx moves forward and the upper esophageal sphincter (UES) opens. As the bolus moves into the pharynx, contraction of the superior pharyngeal constrictor against the contracted soft palate initiates a peristaltic contraction that proceeds rapidly downward to move the bolus through the pharynx and the esophagus. The lower esophageal sphincter (LES) opens as the food enters the esophagus and remains open until the peristaltic contraction has swept the bolus into the stomach. Peristaltic contraction in response to a swallow is called *primary peristalsis*. It involves inhibition followed by sequential contraction of muscles along the entire swallowing passage. The inhibition that precedes the peristaltic contraction is called *deglutitive inhibition*. Local distention of the esophagus from residual food activates *secondary peristalsis*.

Muscles of the oral cavity, pharynx, UES, and cervical esophagus are striated and are directly innervated by the lower motor neurons carried in the cranial nerves. Oral cavity muscles are innervated by the Vth and the VIIth cranial nerves and the tongue muscles by the XIIth cranial nerve. Pharyngeal muscles are innervated by the IXth and the Xth cranial nerves.

The UES consists of constrictor and dilator muscles. The constrictor muscles include the cricopharyngeus and inferior pharyngeal constrictor muscles. The dilator muscles include a number of suprahyoid muscles including the geniohyoid muscle. The constrictor muscles are innervated by the Xth cranial nerves and the dilator muscles are innervated by the XIIth and also the Vth and the VIIth cranial nerves. The UES remains closed owing to the elastic properties of its wall and to neurogenic tonic contraction of the cricopharyngeus muscle. Inhibition of the vagal excitatory activity in the central nervous system relaxes the cricopharyngeus, and contraction of the dilator muscles opens the UES by causing upward and forward displacement of the larynx.

The neuromuscular apparatus for peristalsis is different in cervical and thoracic parts of the esophagus. The cervical esophagus, like the pharyngeal muscles, is composed of striated muscles and is innervated by lower motor neurons in the vagus (Xth cranial) nerve. Peristalsis in the cervical esophagus is due to sequential activation of the vagal motor neurons in the nucleus ambiguus.

In contrast, the thoracic esophagus and LES are composed of smooth-muscle fibers and are innervated by excitatory and inhibitory neurons within the esophageal myenteric plexus. Neurotransmitters of the excitatory nerves are acetylcholine and substance P, and of the inhibitory nerves are vasoactive intestinal peptide (VIP) and nitric oxide. Separate groups of parasympathetic preganglionic nerve fibers in the Xth cranial nerve arising from its dorsal motor nucleus project onto the inhibitory and excitatory postganglionic myenteric neurons. Patterned activation of inhibitory followed by excitatory vagal pathways is responsible for peristalsis, which consists of a sequence of inhibition (deglutitive inhibition) followed by contraction. The LES relaxes, with deglutitive inhibition, at the onset of esophageal peristalsis.

The LES is closed at rest because of its intrinsic myogenic tone, influenced by excitatory and inhibitory nerves. The function of the LES is supplemented by the striated muscle of the diaphragmatic crura, which surrounds the LES and acts as an external LES.

PATHOPHYSIOLOGY OF DYSPHAGIA

Based on anatomic site of involvement, dysphagia may be divided into oral, pharyngeal, and esophageal dysphagia. Normal transport of an ingested bolus through the swallowing passage depends on the size of the ingested bolus and size of the lumen, the force of peristaltic contraction, and deglutitive inhibition, including normal relaxation of UES and LES during swallowing. Dysphagia caused by a large bolus or a narrow lumen is called *mechanical dysphagia*, whereas dysphagia due to weakness of peristaltic contractions or to impaired deglutitive inhibition causing nonperistaltic contractions and impaired sphincter relaxation is called *motor dysphagia*.

Oral and Pharyngeal (Oropharyngeal) Dysphagia Oral-phase dysphagia is associated with poor bolus formation and control, so that food may either drool out of the mouth or overstay in the mouth or the patient may experience difficulty in initiating the swallowing reflex. Poor bolus control may also lead to premature spillage of food into the pharynx and aspiration into the unguarded larynx and/or nasal cavity. Pharyngeal-phase dysphagia is associated with stasis of food in the pharynx due to poor pharyngeal propulsion and obstruction at the UES. Pharyngeal stasis leads to nasal regurgitation and laryngeal aspiration during or after a swallow. Nasal regurgitation and laryngeal aspiration during the process of swallowing are hallmarks of oropharyngeal dysphagia.

Oropharyngeal dysphagia may be due to mechanical causes, including a variety of developmental abnormalities, head and neck tumors, radiation therapy, and inflammatory processes (Table 38-1).

TABLE 38-1 OROPHARYNGEAL DYSPHAGIA

Oropharyngeal Mechanical Dysphagia

I. Wall defects
- A. Congenital
  - 1. Cleft lip, cleft palate
  - 2. Laryngeal clefts
- B. Post surgical

II. Intrinsic narrowing
- A. Inflammatory
  - 1. Viral (herpes simplex, varicella-zoster, cytomegalovirus)
  - 2. Bacterial (peritonsillar abscess)
  - 3. Fungal *(Candida)*
  - 4. Mucocutaneous bullous diseases
  - 5. Caustic, chemical, thermal injury
- B. Web
  - 1. Plummer-Vinson syndrome
- C. Strictures
  - 1. Congenital microganthia
  - 2. Caustic ingestion
  - 3. Post-radiation
- D. Tumors
  - 1. Benign
  - 2. Malignant

III. Extrinsic compression
- A. Retropharyngeal abscess, mass
- B. Zenker's diverticulum
- C. Thyroid disorders
- D. Vertebral osteophytes

Oropharyngeal Motor Dysphagia

I. Diseases of cerebral cortex and brainstem
- A. With altered consciousness or dementia
  - 1. Dementias including Alzheimer's disease
  - 2. Altered consciousness, metabolic encephalopathy, encephalitis, meningitis, cerebrovascular accident, brain injury
- B. With normal cognitive functions
  - 1. Brain injury
  - 2. Cerebral palsy
  - 3. Rabies, tetanus, neurosyphilis
  - 4. Cerebrovascular disease
  - 5. Parkinson's disease and other extrapyramidal lesions
  - 6. Multiple sclerosis (bulbar and pseudobulbar palsy)
  - 7. Amyotrophic lateral sclerosis (motor neuron disease)
  - 8. Poliomyelitis and post-poliomyelitis syndrome

II. Diseases of cranial nerves (V, VII, IX, X, XII)
- A. Basilar meningitis (chronic inflammatory, neoplastic)
- B. Nerve injury
- C. Neuropathy (Guillain-Barré syndrome, familial dysautonomia, sarcoid, diabetic and other causes)

III. Neuromuscular
- A. Myasthenia gravis
- B. Eaton-Lambert syndrome
- C. Botulinum toxin
- D. Aminoglycoside and other drugs

IV. Muscle disorders
- A. Myositis (polymyositis, dermatomyositis, sarcoidosis)
- B. Metabolic myopathy (mitochondrial myopathy, thyroid myopathy)
- C. Primary myopathies (myotonic dystrophy, oculopharyngeal myopathy)

Oropharyngeal motor dysphagia results from impairment of the voluntary effort required in bolus preparation or neuromuscular disorders affecting bolus preparation, initiation of the swallowing reflex, timely passage of food through the pharynx, and prevention of entry of food into the nasal and the laryngeal opening. Paralysis of the suprahyoid muscles leads to loss of opening of the UES and severe dysphagia. Because each side of the pharynx is innervated by ipsilateral nerves, a unilateral lesion of motor neurons leads to unilateral pharyngeal paralysis.

Neuromuscular disorders causing dysphagia are listed in Table 38-1. They include a variety of cortical and suprabulbar disorders, lesions of the cranial nerves in their nuclei in the brain stem or their course to the muscles, defects of neurotransmission at the motor end plates, and muscular diseases. Some of these disorders also involve laryngeal muscles and vocal cords, causing hoarseness.

Since the oropharyngeal phase of swallowing lasts no more than a second, rapid-sequence videofluoroscopy is necessary to permit detection and analysis of abnormalities of oral and pharyngeal function. However, such studies can only be performed in a fully conscious and cooperative patient. A videofluoroscopic swallowing study (VFSS) using barium of different consistencies may reveal difficulties in the oral phase of swallowing. The pharynx is examined to detect stasis of barium in the valleculae and pyriform sinuses and regurgitation of barium into the nose and tracheobronchial tree. Pharyngeal contraction waves and opening of UES with a swallow are carefully monitored. Manometric studies may demonstrate reduced amplitude of pharyngeal contractions and reduced UES pressure without further fall in pressure on swallowing (see Fig. 286-3). General treatment consists of maneuvers to reduce pharyngeal stasis and to enhance airway protection under the direction of a trained swallow therapist. Feeding by a naso-gastric tube or an endoscopically placed gastrostomy tube may be necessary for nutritional support; however, these maneuvers do not provide protection against aspiration of salivary secretions. Gastrostomy tube feeding may actually increase gastroesophageal reflux and lead to more aspiration. Jejunostomy tube feeding may lessen reflux.

Dysphagia resulting from a cerebrovascular accident usually improves with time, although often not completely. Patients with myasthenia gravis (Chap. 381) and polymyositis (Chap. 383) may respond to treatment of the primary disease. Cricopharyngeal myotomy is usually not helpful. Extensive operative procedures to prevent aspiration are rarely needed. Death is often due to pulmonary complications.

A cricopharyngeal bar results from failure of the cricopharyngeus to relax but with normal activity of the suprahyoid muscles on swallowing. Barium swallow shows a prominent projection on the posterior wall of the pharynx at the level of the lower part of the cricoid cartilage (see Fig. 286-1). A transient cricopharyngeal bar is seen in up to 5% of individuals without dysphagia undergoing upper gastrointestinal studies; it can be produced in normal individuals during a Valsalva maneuver. A persistent cricopharyngeal bar may be caused by fibrosis in the cricopharyngeus. Cricopharyngeal myotomy may be helpful in severely symptomatic case with functional evidence of obstruction by the cricopharyngeus muscle, but is contraindicated in the presence of gastroesophageal reflux because it may lead to pharyngeal and pulmonary aspiration. Globus pharyngeus mainly occurs in individuals with emotional disorders, particularly in women. Results of barium studies and manometry are normal. Treatment consists primarily of reassurance. Some patients with globus pharyngeus have associated reflux esophagitis, and they may respond to treatment of the esophagitis.

Esophageal Dysphagia In an adult, the esophageal lumen can distend up to 4 cm in diameter. When the esophagus cannot dilate beyond 2.5 cm in diameter, dysphagia to normal solid food can occur. Dysphagia is always present when the esophagus cannot distend beyond 1.3 cm. Circumferential lesions produce dysphagia more consistently than do lesions that involve only a portion of circumferences of the esophageal wall, as uninvolved segments retain their distensibility. The esophageal causes of mechanical dysphagia are listed in Table 38-2. Common causes include carcinoma, peptic and other benign strictures, and lower esophageal ring. Esophageal motor dysphagia may result from abnormalities in peristalsis and deglutitive inhibition due to diseases of the esophageal striated or smooth muscle.

Diseases of the striated muscle often also involve the cervical part of the esophagus, in addition to affecting the oropharyngeal muscles. Clinical manifestations of the cervical esophageal involvement are usually overshadowed by those of the oropharyngeal dysphagia.

Diseases of the smooth-muscle segment involve the thoracic part of the esophagus and the LES. Dysphagia occurs when the peristaltic contractions are weak or absent or when the contractions are nonperistaltic. Loss of peristalsis may be associated with failure of LES relaxation. Weakness of contractile power occurs due to muscle weakness, as in scleroderma or impaired cholinergic effect. Nonperistaltic contractions and failure of LES relaxation occur due to impaired inhibitory innervation. In diffuse esophageal spasm (DES), inhibitory innervation only to the esophageal body is impaired, whereas in achalasia inhibitory innervation to both the esophageal body and LES is impaired. Dysphagia due to esophageal muscle

TABLE 38-2 ESOPHAGEAL DYSPHAGIA

Esophageal Mechanical Dysphagia

I. Wall defects
  A. Congenital
  B. Tracheoesophageal fistula
II. Intrinsic narrowing
  A. Inflammatory esophagitis
    1. Viral (herpes simplex, varicella-zoster, cytomegalovirus)
    2. Bacterial
    3. Fungal *(Candida)*
    4. Mucocutaneous bullous diseases
    5. Caustic, chemical, thermal injury
    6. Eosinophilic esophagitis
  B. Webs and rings
    1. Esophageal (congenital, inflammatory)
    2. Lower esophageal mucosal ring (Schatzki's ring)
    3. Eosinophilic esophagitis
    4. Host-versus-graft disease, mucocutaneous disorders
  C. Benign strictures
    1. Peptic
    2. Caustic
    3. Pill-induced
    4. Inflammatory (Crohn's disease, *Candida*, mucocutaneous lesions)
    5. Ischemic
    6. Postoperative
    7. Post-radiation
    8. Congenital
  D. Tumors
    1. Benign
    2. Malignant
III. Extrinsic compression
  A. Vascular compression (dysphagia lusoria, aberrant right subclavian artery, right-sided aorta, left atrial enlargement, aortic aneurysm)
  B. Posterior mediastinal mass
  C. Postvagotomy hematoma and fibrosis

Esophageal Motor Dysphagia

I. Disorders of cervical esophagus
  (see oropharyngeal motor disorders, Table 38-1)
II. Disorders of thoracic esophagus
  A. Diseases of smooth muscle or excitatory nerves
    1. Weak muscle contraction or LES tone
      a. Idiopathic
      b. Scleroderma and related collagen vascular diseases
      c. Hollow visceral myopathy
      d. Myotonic dystrophy
      e. Metabolic neuromyopathy (amyloid, alcohol?, diabetes?)
      f. Drugs: anticholinergics, smooth muscle relaxants
    2. Enhanced muscle contraction
      a. Hypertensive peristalsis (nutcracker esophagus)
      b. Hypertensive LES, hypercontracting LES
  B. Disorders of inhibitory innervation
    1. Diffuse esophageal spasm
    2. Achalasia
      a. Primary
      b. Secondary (Chagas' disease, carcinoma, lymphoma, neuropathic intestinal pseudo-obstruction syndrome)
    3. Contractile (muscular) lower esophageal ring

Note: LES, lower esophageal sphincter.

weakness is often associated with symptoms of gastroesophageal reflux disease (GERD). Dysphagia due to loss of the inhibitory innervation is typically not associated with GERD but may be associated with chest pain.

The causes of esophageal motor dysphagia are also listed in Table 38-2; they include scleroderma of the esophagus, achalasia, DES, and other motor disorders.

APPROACH TO THE PATIENT: Dysphagia

Figure 38-1 shows an algorithm of approach to a patient with dysphagia.

HISTORY The history can provide a presumptive diagnosis in >80% of patients. The site of dysphagia described by the patient helps to determine the site of esophageal obstruction; the lesion is at or below the perceived location of dysphagia.

Associated symptoms provide important diagnostic clues. Nasal regurgitation and tracheobronchial aspiration with swallowing are hallmarks of pharyngeal paralysis or a tracheoesophageal fistula. Tracheobronchial aspiration unrelated to swallowing may be due to achalasia, Zenker's diverticulum, or gastroesophageal reflux.

Association of laryngeal symptoms and dysphagia occurs in various neuromuscular disorders. The presence of hoarseness may be an important diagnostic clue. When hoarseness precedes dysphagia, the primary lesion is usually in the larynx; hoarseness following dysphagia may suggest involvement of the recurrent laryngeal nerve by extension of esophageal carcinoma. Sometimes hoarseness may be due to laryngitis secondary to gastroesophageal reflux. Hiccups may rarely occur with a lesion in the distal portion of the esophagus. Unilateral wheezing with dysphagia may indicate a mediastinal mass involving the esophagus and a large bronchus.

The type of food causing dysphagia provides useful information. Difficulty only with solids implies mechanical dysphagia with a lumen that is not severely narrowed. In advanced obstruction, dysphagia occurs with liquids as well as solids. In contrast, motor dysphagia due to achalasia and DES is equally affected by solids and liquids from the very onset. Patients with scleroderma have dysphagia to solids that is unrelated to posture and to liquids while recumbent but not upright. When peptic stricture develops in patients with scleroderma, dysphagia becomes more persistent.

The duration and course of dysphagia are helpful in diagnosis. Transient dysphagia may be due to an inflammatory process. Progressive dysphagia lasting a few weeks to a few months is suggestive of carcinoma of the esophagus. Episodic dysphagia to solids lasting several years indicates a benign disease characteristic of a lower esophageal ring.

Severe weight loss that is out of proportion to the degree of dysphagia is highly suggestive of carcinoma.

Chest pain with dysphagia occurs in DES and related motor disorders. Chest pain resembling DES may occur in esophageal obstruction due to a large bolus. A prolonged history of heartburn and reflux preceding dysphagia indicates peptic stricture. A history of prolonged nasogastric intubation, ingestion of caustic agents, ingestion of pills without water, previous radiation therapy, or associated mucocutaneous diseases may provide the cause of esophageal stricture. If odynophagia is present, candidal, herpes, or pill-induced esophagitis should be suspected.

In patients with AIDS or other immunocompromised states, esophagitis due to opportunistic infections such as *Candida*, herpes simplex virus, or cytomegalovirus and to tumors such as Kaposi's sarcoma and lymphoma should be considered.

PHYSICAL EXAMINATION Physical examination is important in oral and pharyngeal motor dysphagia. Signs of bulbar or pseudobulbar palsy, including dysarthria, dysphonia, ptosis, tongue atrophy, and hyperactive jaw jerk, in addition to evidence of generalized neuromuscular disease, should be sought. The neck should be examined for thyromegaly or a spinal abnormality. A careful inspection of the mouth and pharynx should disclose lesions that may interfere with passage of food. Pulmonary complications such as acute or chronic aspiration pneumonia may be present.

Physical examination is often unrevealing in esophageal dysphagia. Changes in the skin and extremities may suggest a diagnosis of scleroderma and other collagen vascular diseases or mucocutaneous diseases such as pemphigoid or epidermolysis bullosa, which may involve the esophagus. Cancer spread to lymph nodes and liver may be evident.

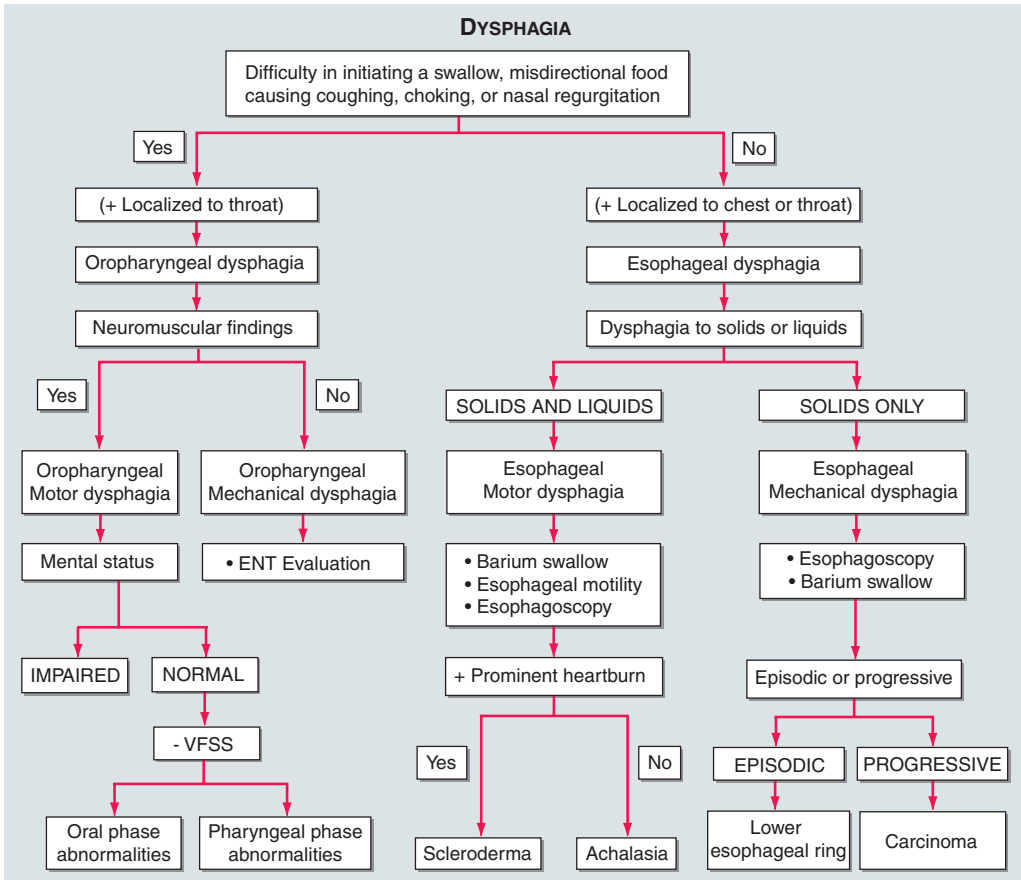

FIGURE 38-1 Approach to the patient with dysphagia. ENT, ear, nose, and throat; VFSS, videofluoroscopic swallowing study.

DIAGNOSTIC PROCEDURES Dysphagia is usually a symptom of organic disease rather than a functional complaint. If oral or pharyngeal dysphagia is suspected, VFSS by both a radiologist and a swallow therapist is the procedure of choice. Videoendoscopy is currently performed only in specialized centers. Otolaryngoscopic and neurologic evaluation are also usually required.

If esophageal mechanical dysphagia is suspected on clinical history, barium swallow and esophagogastroscopy with or without mucosal biopsies are the diagnostic procedures of choice. In some cases, CT examination and endoscopic ultrasound may be useful. For motor esophageal dysphagia, barium swallow, esophageal manometry, esophageal pH, and impedance testing are useful diagnostic tests. Esophagogastroscopy is also often performed in patients with motor dysphagia to exclude an associated structural abnormality (Chap. 286).

39 Nausea, Vomiting, and Indigestion

William L. Hasler

Nausea is the subjective feeling of a need to vomit. *Vomiting* (emesis) is the oral expulsion of gastrointestinal contents resulting from contractions of gut and thoracoabdominal wall musculature. Vomiting is contrasted with *regurgitation*, the effortless passage of gastric contents into the mouth. *Rumination* is the repeated regurgitation of stomach contents, which may be rechewed and reswallowed. In contrast to vomiting, these phenomena often exhibit volitional control. *Indigestion* is a nonspecific term that encompasses a variety of upper abdominal complaints including nausea, vomiting, heartburn, regurgitation, and dyspepsia (the presence of symptoms thought to originate in the gastroduodenal region). Some individuals with dyspepsia report predominantly epigastric burning, gnawing discomfort, or pain. Others with dyspepsia experience a constellation of symptoms including postprandial fullness, early satiety (an inability to complete a meal due to premature fullness), bloating, eructation (belching), and anorexia.

NAUSEA AND VOMITING

MECHANISMS

Vomiting is coordinated by the brain stem and is effected by neuromuscular responses in the gut, pharynx, and thoracoabdominal wall. The mechanisms underlying nausea are poorly understood but likely involve the cerebral cortex, as nausea requires conscious perception. This is supported by electroencephalographic studies showing activation of temporofrontal cortical regions during nausea.

Coordination of Emesis Several brain stem nuclei—including the nucleus tractus solitarius, dorsal vagal and phrenic nuclei, medullary nuclei that regulate respiration, and nuclei that control pharyngeal, facial, and tongue movements—coordinate the initiation of emesis. Neurotransmitters involved in this coordination are uncertain; however, roles for neurokinin NK_1, serotonin 5-HT_3, and vasopressin pathways are postulated.

Somatic and visceral muscles exhibit stereotypic responses during emesis. Inspiratory thoracic and abdominal wall muscles contract, producing high intrathoracic and intraabdominal pressures that facilitate expulsion of gastric contents. The gastric cardia herniates across the diaphragm and the larynx moves upward to promote oral propulsion of the vomitus. Under normal conditions, distally migrating gut contractions are regulated by an electrical phenomenon, the slow wave, which cycles at 3 cycles/min in the stomach and 11 cycles/min in the duodenum. With emesis, there is slow-wave abolition and initiation of orally propagating spike activity, which evokes retrograde contractions that assist in oral expulsion of intestinal contents.

Activators of Emesis Emetic stimuli act at several sites. Emesis provoked by unpleasant thoughts or smells originates in the cerebral cortex, whereas cranial nerves mediate vomiting after gag reflex activation. Mo-

tion sickness and inner ear disorders act on the labyrinthine apparatus, whereas gastric irritants and cytotoxic agents such as cisplatin stimulate gastroduodenal vagal afferent nerves. Nongastric visceral afferents are activated by intestinal and colonic obstruction and mesenteric ischemia. The area postrema, a medullary nucleus, responds to bloodborne emetic stimuli and is termed the *chemoreceptor trigger zone*. Many emetogenic drugs act on the area postrema, as do bacterial toxins and metabolic factors produced during uremia, hypoxia, and ketoacidosis.

Neurotransmitters that mediate induction of vomiting are selective for these anatomic sites. Labyrinthine disorders stimulate vestibular cholinergic muscarinic M_1 and histaminergic H_1 receptors, whereas gastroduodenal vagal afferent stimuli activate serotonin 5-HT_3 receptors. The area postrema is richly served by nerve fibers acting on 5-HT_3, M_1, H_1, and dopamine D_2 receptor subtypes. Transmitter mediators in the cerebral cortex are poorly understood, although cortical cannabinoid CB_1 pathways have been characterized. Optimal pharmacologic management of vomiting requires understanding of these pathways.

TABLE 39-1 CAUSES OF NAUSEA AND VOMITING

Intraperitoneal	Extraperitoneal	Medications/Metabolic Disorders
Obstructing disorders	Cardiopulmonary disease	Drugs
Pyloric obstruction	Cardiomyopathy	Cancer chemotherapy
Small bowel obstruction	Myocardial infarction	Antibiotics
Colonic obstruction	Labyrinthine disease	Cardiac antiarrhythmics
Superior mesenteric artery syndrome	Motion sickness	Digoxin
Enteric infections	Labyrinthitis	Oral hypoglycemics
Viral	Malignancy	Oral contraceptives
Bacterial	Intracerebral disorders	Endocrine/metabolic disease
Inflammatory diseases	Malignancy	Pregnancy
Cholecystitis	Hemorrhage	Uremia
Pancreatitis	Abscess	Ketoacidosis
Appendicitis	Hydrocephalus	Thyroid and parathyroid disease
Hepatitis	Psychiatric illness	Adrenal insufficiency
Altered sensorimotor function	Anorexia and bulimia nervosa	Toxins
Gastroparesis	Depression	Liver failure
Intestinal pseudoobstruction	Postoperative vomiting	Ethanol
Functional dyspepsia		
Gastroesophageal reflux		
Chronic idiopathic nausea		
Functional vomiting		
Cyclic vomiting syndrome		
Biliary colic		
Abdominal irradiation		

DIFFERENTIAL DIAGNOSIS

Nausea and vomiting are caused by conditions within and outside the gut as well as by drugs and circulating toxins (Table 39-1).

Intraperitoneal Disorders Visceral obstruction and inflammation of hollow and solid viscera may produce vomiting as the main symptom. Gastric obstruction results from ulcer disease and malignancy, while small-bowel and colonic obstruction occur because of adhesions, benign or malignant tumors, volvulus, intussusception, or inflammatory diseases such as Crohn's disease. The superior mesenteric artery syndrome, occurring after weight loss or prolonged bed rest, results when the duodenum is compressed by the overlying superior mesenteric artery. Abdominal irradiation impairs intestinal contractile function and induces strictures. Biliary colic causes nausea via action on visceral afferent nerves. Vomiting with pancreatitis, cholecystitis, and appendicitis is due to localized visceral irritation and induction of ileus. Enteric infections with viruses or bacteria such as *Staphylococcus aureus* and *Bacillus cereus* are common causes of acute vomiting, especially in children. Opportunistic infections such as cytomegalovirus or herpes simplex virus induce emesis in immunocompromised individuals.

Disordered gut sensorimotor function also commonly causes nausea and vomiting. *Gastroparesis* is defined as a delay in emptying of food from the stomach and occurs after vagotomy, with pancreatic adenocarcinoma, with mesenteric vascular insufficiency, or in systemic diseases such as diabetes, scleroderma, and amyloidosis. Idiopathic gastroparesis occurring in the absence of systemic illness may follow a viral prodrome, suggesting an infectious etiology. Intestinal pseudoobstruction is characterized by disrupted intestinal and colonic motor activity and leads to retention of food residue and secretions, bacterial overgrowth, nutrient malabsorption, and symptoms of nausea, vomiting, bloating, pain, and altered defecation. *Intestinal pseudoobstruction* may be idiopathic or inherited as a familial visceral myopathy or neuropathy, or it may result from systemic disease or as a paraneoplastic complication of a malignancy such as small cell lung carcinoma. Patients with gastroesophageal reflux may report nausea and vomiting, as do some individuals with functional dyspepsia and irritable bowel syndrome.

Three other functional disorders without organic abnormalities have been characterized in adults. *Chronic idiopathic nausea* is defined as nausea without vomiting occurring several times weekly, whereas *functional vomiting* is defined as one or more vomiting episodes weekly in the absence of an eating disorder or psychiatric disease. *Cyclic vomiting syndrome* is a rare disorder of unknown etiology that produces periodic discrete episodes of relentless nausea and vomiting. The syndrome shows a strong association with migraine headaches, suggesting that some cases may be migraine variants. Cyclic vomiting is most common in children, although adult cases have been described in association with rapid gastric emptying and with chronic cannabis use.

Extraperitoneal Disorders Myocardial infarction and congestive heart failure are cardiac causes of nausea and vomiting. Postoperative emesis occurs after 25% of surgeries, most commonly laparotomy and orthopedic surgery, and is more prevalent in women. Increased intracranial pressure from tumors, bleeding, abscess, or obstruction to cerebrospinal fluid outflow produces prominent vomiting with or without nausea. Motion sickness, labyrinthitis, and Ménière's disease evoke symptoms via labyrinthine pathways. Patients with psychiatric illnesses including anorexia nervosa, bulimia nervosa, anxiety, and depression may report significant nausea that may be associated with delayed gastric emptying.

Medications and Metabolic Disorders Drugs evoke vomiting by action on the stomach (analgesics, erythromycin) or area postrema (digoxin, opiates, anti-Parkinsonian drugs). Emetogenic agents include antibiotics, cardiac antiarrhythmics, antihypertensives, oral hypoglycemics, and contraceptives. Cancer chemotherapy causes vomiting that is acute (within hours of administration), delayed (after 1 or more days), or anticipatory. Acute emesis resulting from highly emetogenic agents such as cisplatin is mediated by 5-HT_3 pathways, whereas delayed emesis is 5-HT_3-independent. Anticipatory nausea often responds better to anxiolytic therapy than to antiemetics.

Several metabolic disorders elicit nausea and vomiting. Pregnancy is the most prevalent endocrinologic cause of nausea, occurring in 70% of women in the first trimester. Hyperemesis gravidarum is a severe form of nausea of pregnancy which can produce significant fluid loss and electrolyte disturbances. Uremia, ketoacidosis, and adrenal insufficiency, as well as parathyroid and thyroid disease, are other metabolic causes of emesis.

Circulating toxins evoke symptoms via effects on the area postrema. Endogenous toxins are generated in fulminant liver failure, whereas exogenous enterotoxins may be produced by enteric bacterial infection. Ethanol intoxication is a common toxic etiology of nausea and vomiting.

APPROACH TO THE PATIENT: Nausea and Vomiting

HISTORY AND PHYSICAL EXAMINATION The history helps define the etiology of unexplained nausea and vomiting. Drugs, toxins, and gastrointestinal infections commonly cause acute symptoms, whereas established illnesses evoke chronic complaints. Pyloric obstruction and gastroparesis produce vomiting within 1 h of eating, whereas emesis from intestinal obstruction occurs later. In severe cases of gastroparesis, the vomitus may contain food residue ingested hours or days previously. Hematemesis raises suspicion of an ulcer, malignancy, or Mallory-Weiss tear, whereas feculent emesis is noted with distal intestinal or colonic obstruction. Bilious vomiting excludes gastric obstruction, while emesis of undigested food is consistent with a Zenker's diverticulum or achalasia. Relief of abdominal pain by emesis characterizes small-bowel obstruction, whereas vomiting has no effect on pancreatitis or cholecystitis pain. Pronounced weight loss raises concern about malignancy or obstruction. Fevers suggest inflammation; an intracranial source is considered if there are headaches or visual field changes. Vertigo or tinnitus indicates labyrinthine disease.

The physical examination complements information obtained in the history. Demonstration of orthostatic hypotension and reduced skin turgor indicate intravascular fluid loss. Pulmonary abnormalities raise concern for aspiration of vomitus. Abdominal auscultation may reveal absent bowel sounds with ileus. High-pitched rushes suggest bowel obstruction, while a succussion splash upon abrupt lateral movement of the patient is found with gastroparesis or pyloric obstruction. Tenderness or involuntary guarding raises suspicion of inflammation, whereas fecal blood suggests mucosal injury from ulcer, ischemia, or tumor. Neurologic etiologies present with papilledema, visual field loss, or focal neural abnormalities. Neoplasm is suggested by palpation of masses or adenopathy.

DIAGNOSTIC TESTING For intractable symptoms or an elusive diagnosis, selected diagnostic tests can direct clinical management. Electrolyte replenishment is indicated for hypokalemia or metabolic alkalosis. Detection of iron-deficiency anemia mandates a search for mucosal injury. Pancreaticobiliary disease is indicated by abnormal pancreatic enzymes or liver biochemistries, whereas endocrinologic, rheumatologic, or paraneoplastic etiologies are suggested by specific hormone or serologic testing. If luminal obstruction is suspected, supine and upright abdominal radiographs may show intestinal air-fluid levels with reduced colonic air. Ileus is characterized by diffusely dilated air-filled bowel loops.

Anatomic studies may be indicated if initial testing is nondiagnostic. Upper endoscopy detects ulcers or malignancy, while small-bowel barium radiography diagnoses partial small-bowel obstruction. Colonoscopy or contrast enema radiography can detect colonic obstruction. Abdominal ultrasound or computed tomography (CT) defines intraperitoneal inflammatory processes, while CT or magnetic resonance imaging (MRI) of the head can delineate intracranial disease. Mesenteric angiography or MRI is useful when ischemia is considered.

Gastrointestinal motility testing may detect a motor disorder that contributes to symptoms when anatomic abnormalities are absent. Gastroparesis commonly is diagnosed using gastric scintigraphy, by which emptying of a radiolabeled meal is measured. Isotopic breath tests and telemetry capsule methods also have been validated. Electrogastrography, a noninvasive test of gastric slow-wave activity using cutaneous electrodes placed over the stomach, has been proposed as an alternate means of diagnosing gastroparesis. The diagnosis of intestinal pseudoobstruction often is suggested by abnormal barium transit and luminal dilation on small-bowel contrast radiography. Small-intestinal manometry can confirm the diagnosis and further characterize the motor abnormality as neuropathic or myopathic based on contractile patterns. Such investigation can obviate the need for open intestinal biopsy to evaluate for smooth muscle or neuronal degeneration.

℞ NAUSEA AND VOMITING

GENERAL PRINCIPLES Therapy of vomiting is tailored to correction of medically or surgically remediable abnormalities if possible. Hospitalization is considered for severe dehydration especially if oral fluid replenishment cannot be sustained. Once oral intake is tolerated, nutrients are restarted with liquids that are low in fat, as lipids delay gastric emptying. Foods high in indigestible residues are avoided as these also prolong gastric retention.

ANTIEMETIC MEDICATIONS The most commonly used antiemetic agents act on sites within the central nervous system **(Table 39-2)**. Antihistamines such as meclizine and dimenhydrinate and anticholinergic drugs like scopolamine act on labyrinthine-activated pathways and are useful in motion sickness and inner ear disorders. Dopamine D_2 antagonists treat emesis evoked by area postrema stimuli and are useful for medication, toxic, and metabolic etiologies. Dopamine antagonists freely cross the blood-brain barrier and cause anxiety, dystonic reactions, hyperprolactinemic effects (galactorrhea and sexual dysfunction), and irreversible tardive dyskinesia.

Other drug classes exhibit antiemetic properties. Serotonin 5-HT_3 antagonists such as ondansetron and granisetron exhibit utility in postoperative vomiting, after radiation therapy, and in the prevention of cancer chemotherapy–induced emesis. The usefulness of 5-HT_3 antagonists for other causes of emesis is less well established. Low-dose tricyclic antidepressant agents provide symptomatic benefit in patients with chronic idiopathic nausea and functional vomiting as well as in diabetic patients with nausea and vomiting whose disease is of long standing.

GASTROINTESTINAL MOTOR STIMULANTS Drugs that stimulate gastric emptying are indicated for gastroparesis (Table 39-2). Metoclopramide, a combined 5-HT_4 agonist and D_2 antagonist, exhibits efficacy in gastroparesis, but antidopaminergic side effects limit its use in 25% of patients. Erythromycin, a macrolide antibiotic, increases gastroduodenal motility by action on receptors for motilin, an endogenous stimulant of fasting motor activity. Intravenous erythromycin is useful for inpatients with refractory gastroparesis; however, oral forms also have some utility. Domperidone, a D_2 antagonist not available in the United States, exhibits prokinetic and antiemetic effects but does not cross into most other brain regions; thus, anxiety and dystonic reactions are rare. The main side effects of domperidone relate to induction of hyperprolactinemia via effects on pituitary regions served by a porous blood-brain barrier. The 5-HT_4 agonist tegaserod potently stimulates gastric emptying in patients with gastroparesis; however, its effects on symptoms of gastric retention are unproven.

Patients with refractory upper gut motility disorders pose significant challenges. Liquid suspensions of prokinetic drugs may be beneficial, as liquids empty from the stomach more rapidly than pills. Metoclopramide can be administered subcutaneously in patients unresponsive to oral drugs. Intestinal pseudoobstruction may respond to the somatostatin analogue octreotide, which induces propagative small intestinal motor complexes. Pyloric injections of botulinum toxin are reported in uncontrolled studies to benefit patients with gastroparesis. Placement of a feeding jejunostomy reduces hospitalizations and improves overall health in some patients with gastroparesis who do not respond to drug therapy. Surgical options are limited for refractory cases, but postvagotomy gastroparesis may improve with near-total resection of the stomach. Implanted gastric electrical stimulators may reduce symptoms, enhance nutrition, improve quality of life, and decrease health care expenditures in patients with medication-refractory gastroparesis.

SELECTED CLINICAL SETTINGS Cancer chemotherapeutic agents such as cisplatin are intensely emetogenic (Chap. 77). Given prophylactically, 5-HT_3 antagonists prevent chemotherapy-induced acute vomiting in most cases (Table 39-2). Optimal antiemetic effects often are obtained with a 5-HT_3 antagonist combined with a glucocorticoid. High-dose metoclopramide also exhibits efficacy in chemotherapy-evoked emesis, while benzodiazepines such as lorazepam are useful in reducing anticipatory nausea and vomiting. Therapy of delayed emesis 1–5 days after chemotherapy is less successful. Neurokinin NK_1 antagonists (e.g., aprepitant) exhibit antiemetic and antinausea effects during both the acute and delayed periods after chemotherapy. Cannabinoids such as tetrahydrocannabinol, long advocated for cancer-associated emesis, produce significant side effects and exhibit no

TABLE 39-2 TREATMENT OF NAUSEA AND VOMITING

Treatment	Mechanism	Examples	Clinical Indications
Antiemetic agents	Antihistaminergic	Dimenhydrinate, meclizine	Motion sickness, inner ear disease
	Anticholinergic	Scopolamine	Motion sickness, inner ear disease
	Antidopaminergic	Prochlorperazine, thiethylperazine	Medication-, toxin-, or metabolic-induced emesis
	5-HT_3 antagonist	Ondansetron, granisetron	Chemotherapy- and radiation-induced emesis, postoperative emesis
	NK_1 antagonist	Aprepitant	Chemotherapy-induced nausea and vomiting
	Tricyclic antidepressant	Amitriptyline, nortriptyline	Chronic idiopathic nausea, functional vomiting, cyclic vomiting syndrome
Prokinetic agents	5-HT_4 agonist and antidopaminergic	Metoclopramide	Gastroparesis
	Motilin agonist	Erythromycin	Gastroparesis, ?intestinal pseudoobstruction
	Peripheral antidopaminergic	Domperidone	Gastroparesis
	5-HT_4 agonist	Tegaserod	?Gastroparesis, ?intestinal pseudoobstruction
	Somatostatin analogue	Octreotide	Intestinal pseudoobstruction
Special settings	Benzodiazepines	Lorazepam	Anticipatory nausea and vomiting with chemotherapy
	Glucocorticoids	Methylprednisolone, dexamethasone	Chemotherapy-induced emesis
	Cannabinoids	Tetrahydrocannabinol	?Chemotherapy-induced emesis

more efficacy than antidopaminergic agents. Most current drug regimens produce greater reductions in vomiting than in nausea.

The clinician should exercise caution in managing the pregnant patient with nausea. Studies of the teratogenic effects of available antiemetic agents provide conflicting results. Few controlled trials have been performed in nausea of pregnancy, although antihistamines such as meclizine and antidopaminergics such as prochlorperazine demonstrate efficacy greater than placebo. Some obstetricians offer alternative therapies such as pyridoxine, acupressure, or ginger.

Controlling emesis in cyclic vomiting syndrome is a challenge. In many individuals, prophylactic treatment with tricyclic antidepressants, cyproheptadine, or β-adrenoceptor antagonists can reduce the frequency of attacks. Intravenous 5-HT_3 antagonists combined with the sedating effects of a benzodiazepine such as lorazepam are a mainstay of treatment of acute symptom flares. Small studies report benefits with antimigraine therapies, including the serotonin 5-HT_1 agonist sumatriptan as well as certain newer anticonvulsant drugs.

INDIGESTION

MECHANISMS

The most common causes of indigestion are gastroesophageal acid reflux and functional dyspepsia. Other cases are a consequence of a more serious organic illness.

Gastroesophageal Acid Reflux Acid reflux can result from a variety of physiologic defects. Reduced lower esophageal sphincter (LES) tone is an important cause of reflux in scleroderma and pregnancy; it may also be a factor in patients without other systemic conditions. Many individuals exhibit frequent transient LES relaxations during which acid bathes the esophagus. Overeating and aerophagia can transiently override the barrier function of the LES, whereas impaired esophageal body motility and reduced salivary secretion prolong acid exposure. The role of hiatal hernias is controversial—although most reflux patients exhibit hiatal hernias, most individuals with hiatal hernias do not have excess heartburn.

Gastric Motor Dysfunction Disturbed gastric motility is purported to cause acid reflux in some cases of indigestion. Delayed gastric emptying is also found in 25–50% of functional dyspeptics. The relation of these defects to symptom induction is uncertain; many studies show poor correlation between symptom severity and the degree of motor dysfunction. Impaired gastric fundus relaxation after eating may underlie selected dyspeptic symptoms like bloating, nausea, and early satiety.

Visceral Afferent Hypersensitivity Disturbed gastric sensory function is proposed as a pathogenic factor in functional dyspepsia. Visceral afferent hypersensitivity was first demonstrated in patients with irritable bowel syndrome who had heightened perception of rectal balloon inflation without changes in rectal compliance. Similarly, dyspeptic patients experience discomfort with fundic distention to lower pressures than healthy controls. Some patients with heartburn exhibit normal esophageal acid exposure. These individuals with functional heartburn are believed to have heightened perception of normal esophageal pH.

Other Factors *Helicobacter pylori* has a clear etiologic role in peptic ulcer disease, but ulcers cause a minority of cases of dyspepsia. Infection with *H. pylori* is considered to be a minor factor in the genesis of functional dyspepsia. In contrast, functional dyspepsia is associated with a reduced sense of physical and mental well-being and is exacerbated by stress, suggesting an important role for psychological factors. Analgesics cause dyspepsia, while nitrates, calcium channel blockers, theophylline, and progesterone promote acid reflux. Other exogenous stimuli that induce acid reflux include ethanol, tobacco, and caffeine via LES relaxation. Genetic factors may contribute to development of acid reflux.

DIFFERENTIAL DIAGNOSIS

Gastroesophageal Reflux Disease Gastroesophageal reflux disease (GERD) is prevalent in Western society. Heartburn is reported once monthly by 40% of Americans and daily by 7–10%. Most cases of heartburn occur because of excess acid reflux; however, approximately 10% of patients with functional heartburn exhibit normal degrees of esophageal acid exposure.

Functional Dyspepsia Nearly 25% of the populace has dyspeptic symptoms at least six times yearly, but only 10–20% of these individuals present to physicians. Functional dyspepsia, the cause of symptoms in 60% of dyspeptic patients, is defined as ≥3 months of bothersome postprandial fullness, early satiety, epigastric pain, or epigastric burning with symptom onset at least 6 months before diagnosis in the absence of organic cause. Most patients follow a benign course, but a small number with *H. pylori* infection or on nonsteroidal anti-inflammatory drugs (NSAIDs) progress to ulcer formation. As with idiopathic gastroparesis, some cases of functional dyspepsia result from prior gastrointestinal infection.

Ulcer Disease In most cases of GERD, there is no destruction of the esophagus. However, 5% of patients develop esophageal ulcers, and some form strictures. Symptoms do not reliably distinguish nonerosive from erosive or ulcerative esophagitis. Some 15–25% of cases of dyspepsia stem from ulcers of the stomach or duodenum. The most common causes of ulcer disease are gastric infection with *H. pylori* and use of NSAIDs. Other rare causes of gastroduodenal ulcer include Crohn's disease (Chap. 289) and Zollinger-Ellison syndrome (Chap. 287), a condition resulting from gastrin overproduction by an endocrine tumor.

Malignancy Dyspeptic patients often seek care because of fear of cancer. However, <2% of cases result from gastroesophageal malignancy. Esophageal squamous cell carcinoma occurs most often in those with histories

of tobacco or ethanol intake. Other risk factors include prior caustic ingestion, achalasia, and the hereditary disorder tylosis. Esophageal adenocarcinoma usually complicates long-standing acid reflux. Between 8 and 20% of GERD patients exhibit intestinal metaplasia of the esophagus, termed *Barrett's metaplasia*. This condition predisposes to esophageal adenocarcinoma (Chap. 87). Gastric malignancies include adenocarcinoma, which is prevalent in certain Asian societies, and lymphoma.

Other Causes Alkaline reflux esophagitis produces GERD-like symptoms in patients who have had surgery for peptic ulcer disease. Opportunistic fungal or viral esophageal infections may produce heartburn or chest discomfort but more often cause odynophagia. Other causes of esophageal inflammation include eosinophilic esophagitis and pill esophagitis. Biliary colic is in the differential diagnosis of dyspepsia, but most patients with true biliary colic report discrete episodes of right upper quadrant or epigastric pain rather than chronic burning discomfort, nausea, and bloating. Intestinal lactase deficiency produces gas, bloating, discomfort, and diarrhea after lactose ingestion. Lactase deficiency occurs in 15–25% of Caucasians of northern European descent but is more common in African Americans and Asians. Intolerance of other carbohydrates (e.g., fructose, sorbitol) produces similar symptoms. Small-intestinal bacterial overgrowth may produce dyspepsia, often with bowel dysfunction, distention, and malabsorption. Pancreatic disease (chronic pancreatitis and malignancy), hepatocellular carcinoma, celiac disease, Ménétrier's disease, infiltrative diseases (sarcoidosis and eosinophilic gastroenteritis), mesenteric ischemia, thyroid and parathyroid disease, and abdominal wall strain cause dyspepsia. Extraperitoneal etiologies of indigestion include congestive heart failure and tuberculosis.

APPROACH TO THE PATIENT: Indigestion

HISTORY AND PHYSICAL EXAMINATION Care of the patient with indigestion requires a thorough interview. GERD classically produces heartburn, a substernal warmth in the epigastrium that moves toward the neck. Heartburn often is exacerbated by meals and may awaken the patient. Associated symptoms include regurgitation of acid and water brash, the reflex release of salty salivary secretions into the mouth. Atypical symptoms include pharyngitis, asthma, cough, bronchitis, hoarseness, and chest pain that mimics angina. Some patients with acid reflux on esophageal pH testing do not report heartburn and note abdominal pain or other symptoms.

Some individuals with dyspepsia report a predominance of epigastric pain or burning that is intermittent and not generalized or localized to other regions. Others experience a postprandial distress syndrome characterized by fullness occurring after normal-sized meals and early satiety that prevents completion of regular meals several times weekly, with associated bloating, belching, or nausea. Functional dyspepsia overlaps with other functional bowel disorders such as irritable bowel syndrome.

The physical exam with GERD and functional dyspepsia usually is normal. In atypical GERD, pharyngeal erythema and wheezing may be noted. Poor dentition may be seen with prolonged acid regurgitation. Functional dyspeptics may exhibit epigastric tenderness or abdominal distention.

Discrimination between functional and organic causes of indigestion mandates exclusion of selected historic and examination features. Odynophagia suggests esophageal infection, while dysphagia is worrisome for a benign or malignant esophageal blockage. Other alarming features include unexplained weight loss, recurrent vomiting, occult or gross gastrointestinal bleeding, jaundice, a palpable mass or adenopathy, and a family history of gastrointestinal malignancy.

DIAGNOSTIC TESTING As indigestion is prevalent and because most cases result from GERD or functional dyspepsia, a general principle is to perform only limited and directed diagnostic testing of selected individuals.

TABLE 39-3 ALARM SYMPTOMS IN GERD

Odynophagia
Unexplained weight loss
Recurrent vomiting
Occult or gross gastrointestinal bleeding
Jaundice
Palpable mass or adenopathy
Family history of gastrointestinal malignancy

Once alarm factors are excluded (Table 39-3), patients with typical GERD do not need further evaluation and are treated empirically. Upper endoscopy is indicated to exclude mucosal injury in cases with atypical symptoms, symptoms unresponsive to acid suppressing drugs, or alarm factors. For heartburn >5 years in duration, especially in patients >50 years old, endoscopy is recommended to screen for Barrett's metaplasia. However, the clinical benefits and cost-effectiveness of this approach have not been validated in controlled studies. Ambulatory esophageal pH testing using a catheter method or an implanted esophageal capsule device is considered for drug-refractory symptoms and atypical symptoms like unexplained chest pain. Esophageal manometry most commonly is ordered when surgical treatment of GERD is considered. A low LES pressure may predict failure of drug therapy and helps select patients who may require surgery. Demonstration of disordered esophageal body peristalsis may affect the decision to operate or modify the type of operation chosen. Manometry with provocative testing may clarify the diagnosis in patients with atypical symptoms. Blind perfusion of saline and then acid into the esophagus, known as the *Bernstein test*, can delineate whether unexplained chest discomfort results from acid reflux.

Upper endoscopy is performed as the initial diagnostic test in patients with unexplained dyspepsia who are >55 years old or have alarm factors because of the elevated risks of malignancy and ulcer in these groups. The management approach to patients <55 years old without alarm factors is dependent on the prevalence of *H. pylori* infection in the local population. For individuals who reside in regions with low *H. pylori* prevalence (<10%), a 4-week trial of a potent acid-suppressing medication such as a proton pump inhibitor is recommended. If this fails, a "test and treat" approach is most commonly applied. *H. pylori* status is determined with urea breath testing, stool antigen measurement, or blood serology testing. Those who are *H. pylori* positive are given therapy to eradicate the infection. If symptoms resolve on either of these regimens, no further intervention is required. For patients in areas with high *H. pylori* prevalence (>10%), an initial test and treat approach is advocated, with a subsequent trial of an acid-suppressing regimen offered for those who fail *H. pylori* treatment or for those who are negative for the infection. In each of these patient subsets, upper endoscopy is reserved for those who fail to respond to therapy.

Further testing is indicated if other factors are present. If bleeding is reported, a blood count is obtained to exclude anemia. Thyroid chemistries or calcium levels screen for metabolic disease, whereas specific serologies may suggest celiac disease. For suspected pancreaticobiliary causes, pancreatic and liver chemistries are obtained. If abnormalities are found, abdominal ultrasound or CT may give important information. Gastric emptying scintigraphy is considered to exclude gastroparesis in patients whose dyspeptic symptoms resemble postprandial distress when drug treatment fails. Gastric scintigraphy also assesses for gastroparesis in patients with GERD, especially if surgical intervention is being considered. Breath testing after carbohydrate ingestion may detect lactase deficiency, intolerance to other dietary carbohydrates, or small-intestinal bacterial overgrowth.

Rx INDIGESTION

GENERAL PRINCIPLES For mild indigestion, reassurance that a careful evaluation revealed no serious organic disease may be the only intervention needed. Drugs that cause acid reflux or dyspepsia should be

stopped if possible. Patients with GERD should limit ethanol, caffeine, chocolate, and tobacco use because of their effects on the LES. Other measures in GERD include ingesting a low-fat diet, avoiding snacks before bedtime, and elevating the head of the bed.

Specific therapies for organic disease should be offered when possible. Surgery is appropriate in disorders like biliary colic, while diet changes are indicated for lactase deficiency or celiac disease. Some illnesses such as peptic ulcer disease may be cured by specific medical regimens. However, as most indigestion is caused by GERD or functional dyspepsia, medications that reduce gastric acid, stimulate motility, or blunt gastric sensitivity are indicated.

ACID-SUPPRESSING OR NEUTRALIZING MEDICATIONS Drugs that reduce or neutralize gastric acid are most often prescribed for GERD. Histamine H_2 antagonists such as cimetidine, ranitidine, famotidine, and nizatidine are useful in mild to moderate GERD. For severe symptoms or many cases of erosive or ulcerative esophagitis, proton pump inhibitors such as omeprazole, lansoprazole, rabeprazole, pantoprazole, or esomeprazole are needed. These drugs, which inhibit gastric H^+, K^+-ATPase activity, are more potent than H_2 antagonists. Acid suppressants may be taken continuously or on demand depending on symptom severity. Many patients initially started on a proton pump inhibitor can be stepped down to an H_2 antagonist. Combination therapy with a proton pump inhibitor and an H_2 antagonist has been proposed for some refractory cases.

Acid-suppressing drugs are also effective in appropriately selected patients with functional dyspepsia. Meta-analysis of eight controlled trials calculated a risk ratio of 0.86, with a 95% confidence interval of 0.78–0.95, favoring proton pump inhibitor therapy over placebo. The benefits of less potent acid reducing therapies such as H_2 antagonists are unproven.

Liquid antacids are useful for short-term control of mild GERD but are less effective for severe disease unless given at high doses that elicit side effects (diarrhea and constipation with magnesium- and aluminum-containing agents, respectively). Alginic acid in combination with antacids may form a floating barrier to acid reflux in individuals with upright symptoms. Sucralfate is a salt of aluminum hydroxide and sucrose octasulfate that buffers acid and binds pepsin and bile salts. Its efficacy in GERD is felt to be comparable to that of H_2 antagonists.

***HELICOBACTER PYLORI* ERADICATION** *H. pylori* eradication is clearly indicated only for peptic ulcer and mucosa-associated lymphoid tissue gastric lymphoma. The utility of eradication therapy in functional dyspepsia is less well established, but <15% of cases relate to this infection. Meta-analysis of 13 controlled trials calculated a risk ratio of 0.91, with a 95% confidence interval of 0.87–0.96, favoring *H. pylori* eradication therapy over placebo. Several drug combinations show efficacy in eliminating the infection (Chap. 287); most include 10–14 days of a proton pump inhibitor or bismuth subsalicylate in concert with two antibiotics. *H. pylori* infection is associated with reduced prevalence of GERD, especially in the elderly. However, eradication of the infection does not worsen GERD symptoms. To date, no consensus recommendations regarding *H. pylori* eradication in GERD patients have been offered.

GASTROINTESTINAL MOTOR STIMULANTS Motor stimulants (also known as prokinetics) such as metoclopramide, erythromycin, domperidone, and tegaserod have limited utility in GERD. The γ-aminobutyric acid B (GABA-B) agonist baclofen reduces esophageal acid exposure by inhibiting transient LES relaxations; the clinical benefits of this drug are yet to be defined in large trials. Several studies have evaluated the effectiveness of motor-stimulating drugs in functional dyspepsia; however, convincing evidence of their benefits has not been found. Some clinicians suggest that patients with symptoms resembling postprandial distress may respond preferentially to prokinetic drugs.

OTHER OPTIONS Antireflux surgery (fundoplication) is offered to GERD patients who are young and may require lifelong therapy, have typical heartburn and regurgitation, and are responsive to proton pump inhibitors. Individuals who may respond less well to operative therapy include those with atypical symptoms, those with poor response to proton pump inhibitors, and those who have esophageal motor disturbances. Fundoplications are performed laparoscopically when possible and include the Nissen and Toupet procedures in which the proximal stomach is partly or completely wrapped around the distal esophagus to increase LES pressure. Dysphagia, gas-bloat syndrome, and gastroparesis may be long-term complications of these procedures. Endoscopic therapies for increasing the barrier function of the gastroesophageal junction, including radiofrequency energy delivery, suturing, biopolymer implantation, and gastroplication, have been investigated in patients with refractory GERD with variable results and some adverse consequences.

Some patients with functional heartburn and functional dyspepsia refractory to standard therapies may respond to low-dose tricyclic antidepressants. Their mechanism of action is unknown but may involve blunting of visceral pain processing in the brain. Gas and bloating are among the most troubling symptoms in some patients with indigestion and can be difficult to treat. Dietary exclusion of gas-producing foods such as legumes and use of simethicone or activated charcoal provide symptom benefits in some patients. Therapies that modify gut flora, including antibiotics and probiotic preparations containing active bacterial cultures, are useful for cases of bacterial overgrowth and functional lower gastrointestinal disorders, but their utility in functional dyspepsia is unproven. Psychological treatments may be offered for refractory functional dyspepsia, but no convincing data suggest their efficacy.

40 Diarrhea and Constipation

Michael Camilleri, Joseph A. Murray

Diarrhea and constipation are exceedingly common and together exact an enormous toll in terms of mortality, morbidity, social inconvenience, loss of work productivity, and consumption of medical resources. Worldwide, >1 billion individuals suffer one or more episodes of acute diarrhea each year. Among the 100 million persons affected annually by acute diarrhea in the United States, nearly half must restrict activities, 10% consult physicians, ~250,000 require hospitalization, and ~5000 die (primarily the elderly). The annual economic burden to society may exceed $20 billion. Acute infectious diarrhea remains one of the most common causes of mortality in developing countries, particularly among children, accounting for 2–3 million deaths per year. Constipation, by contrast, is rarely associated with mortality and is exceedingly common in developed countries, leading to frequent self-medication and, in a third of those, to medical consultation. Population statistics on chronic diarrhea and constipation are more uncertain, perhaps due to variable definitions and reporting, but the frequency of these conditions is also high. United States popula-

tion surveys put prevalence rates for chronic diarrhea at 2–7% and for chronic constipation at 12–19%, with women being affected twice as often as men. Diarrhea and constipation are among the most common patient complaints faced by internists and primary care physicians, and they account for nearly 50% of referrals to gastroenterologists.

Although diarrhea and constipation may present as mere nuisance symptoms at one extreme, they can be severe or life-threatening at the other. Even mild symptoms may signal a serious underlying gastrointestinal lesion, such as colorectal cancer, or systemic disorder, such as thyroid disease. Given the heterogeneous causes and potential severity of these common complaints, it is imperative for clinicians to appreciate the pathophysiology, etiologic classification, diagnostic strategies, and principles of management of diarrhea and constipation, so that rational and cost-effective care can be delivered.

NORMAL PHYSIOLOGY

While the primary function of the small intestine is the digestion and assimilation of nutrients from food, the small intestine and colon together perform important functions that regulate the secretion and absorption of water and electrolytes, the storage and subsequent transport of intraluminal contents aborally, and the salvage of some nutrients after bacterial metabolism of carbohydrate that are not absorbed in the small intestine. The main motor functions are summarized in Table 40-1. Alterations in fluid and electrolyte handling contribute significantly to diarrhea. Alterations in motor and sensory functions of the colon result in highly prevalent syndromes such as irritable bowel syndrome (IBS), chronic diarrhea, and chronic constipation.

NEURAL CONTROL

The small intestine and colon have intrinsic and extrinsic innervation. The *intrinsic innervation*, also called the enteric nervous system, comprises myenteric, submucosal, and mucosal neuronal layers. The function of these layers is modulated by interneurons through the actions of neurotransmitter amines or peptides, including acetylcholine, vasoactive intestinal peptide (VIP), opioids, norepinephrine, serotonin, ATP, and nitric oxide. The myenteric plexus regulates smooth-muscle function, and the submucosal plexus affects secretion, absorption, and mucosal blood flow.

The *extrinsic innervations* of the small intestine and colon are part of the autonomic nervous system and also modulate motor and secretory functions. The parasympathetic nerves convey visceral sensory and excitatory pathways to the colon. Parasympathetic fibers via the vagus nerve reach the small intestine and proximal colon along the branches of the superior mesenteric artery. The distal colon is supplied by sacral parasympathetic nerves ($S_{2–4}$) via the pelvic plexus; these fibers course through the wall of the colon as ascending intracolonic fibers as far as, and in some instances including, the proximal colon. The chief excitatory neurotransmitters controlling motor function are acetylcholine and the tachykinins, such as substance P. The sympathetic nerve supply modulates motor functions and reaches the small intestine and colon alongside their arterial vessels. Sympathetic input to the gut is generally excitatory to sphincters and inhibitory to nonsphincteric muscle. Visceral afferents convey sensation from the gut to the central nervous system; initially, they course along sympathetic fibers, but as they approach the spinal cord they separate, have cell bodies in the dorsal root ganglion, and enter the dorsal horn of the spinal cord. Afferent signals are conveyed to the brain along the lateral spinothalamic tract and the nociceptive dorsal column pathway and are then projected beyond the thalamus and brainstem to the insula and cerebral cortex to be perceived. Other afferent fibers synapse in the prevertebral ganglia and reflexly modulate intestinal motility.

TABLE 40-1 NORMAL GASTROINTESTINAL MOTILITY: FUNCTIONS AT DIFFERENT ANATOMIC LEVELS

Stomach and small bowel
Synchronized MMCs in fasting
Accommodation, trituration, mixing, transit
Stomach ~3 h
Small bowel ~3 h
Ileal reservoir empties boluses
Colon: irregular mixing, fermentation, absorption, transit
Ascending, transverse: reservoirs
Descending: conduit
Sigmoid/rectum: volitional reservoir

Note: MMC, migrating motor complex.

INTESTINAL FLUID ABSORPTION AND SECRETION

On an average day, 9 L of fluid enter the gastrointestinal (GI) tract; ~1 L of residual fluid reaches the colon; the stool excretion of fluid constitutes about 0.2 L/d. The colon has a large capacitance and functional reserve and may recover up to four times its usual volume of 0.8 L/d, provided the rate of flow permits reabsorption to occur. Thus, the colon can partially compensate for excess fluid delivery to the colon because of intestinal absorptive or secretory disorders.

In the colon, sodium absorption is predominantly electrogenic, and uptake takes place at the apical membrane; it is compensated for by the export functions of the basolateral sodium pump. A variety of neural and non-neural mediators regulate colonic fluid and electrolyte balance, including cholinergic, adrenergic, and serotonergic mediators. Angiotensin and aldosterone also influence colonic absorption, reflecting the common embryologic development of the distal colonic epithelium and the renal tubules.

SMALL-INTESTINAL MOTILITY

During fasting, the motility of the small intestine is characterized by a cyclical event called the migrating motor complex (MMC), which serves to clear nondigestible residue from the small intestine (the intestinal "housekeeper"). This organized, propagated series of contractions lasts on average 4 min, occurs every 60–90 min, and usually involves the entire small intestine. After food ingestion, the small intestine produces irregular, mixing contractions of relatively low amplitude, except in the distal ileum where more powerful contractions occur intermittently and empty the ileum by bolus transfers.

ILEOCOLONIC STORAGE AND SALVAGE

The distal ileum acts as a reservoir, emptying intermittently by bolus movements. This action allows time for salvage of fluids, electrolytes, and nutrients. Segmentation by haustra compartmentalizes the colon and facilitates mixing, retention of residue, and formation of solid stools. There is increased appreciation of the intimate interaction between the colonic function and the luminal ecology. The resident bacteria in the colon are necessary for the digestion of unabsorbed carbohydrates that reach the colon even in health, thereby providing a vital source of nutrients to the mucosa. Normal colonic flora also keeps pathogens at bay by a variety of mechanisms. In health, the ascending and transverse regions of colon function as reservoirs (average transit, 15 h), and the descending colon acts as a conduit (average transit, 3 h). The colon is efficient at conserving sodium and water, a function that is particularly important in sodium-depleted patients in whom the small intestine alone is unable to maintain sodium balance. Diarrhea or constipation may result from alteration in the reservoir function of the proximal colon or the propulsive function of the left colon. Constipation may also result from disturbances of the rectal or sigmoid reservoir, typically as a result of dysfunction of the pelvic floor or the coordination of defecation.

COLONIC MOTILITY AND TONE

The small intestinal MMC only rarely continues into the colon. However, short duration or phasic contractions mix colonic contents, and high-amplitude (>75 mmHg) propagated contractions (HAPCs) are sometimes associated with mass movements through the colon and normally occur approximately five times per day, usually on awakening in the morning and postprandially. Increased frequency of HAPCs may result in diarrhea or urgency. The predominant phasic contractions in the colon are irregular and nonpropagated and serve a "mixing" function.

Colonic tone refers to the background contractility upon which phasic contractile activity (typically contractions lasting <15 s) is superimposed. It is an important cofactor in the colon's capacitance (volume accommodation) and sensation.

COLONIC MOTILITY AFTER MEAL INGESTION

After meal ingestion, colonic phasic and tonic contractility increase for a period of ~2 h. The initial phase (~10 min) is mediated by the vagus nerve in response to mechanical distention of the stomach. The subsequent response of the colon requires caloric stimulation and is mediated at least in part by hormones, e.g., gastrin and serotonin.

DEFECATION

Tonic contraction of the puborectalis muscle, which forms a sling around the rectoanal junction, is important to maintain continence; during defecation, sacral parasympathetic nerves relax this muscle, facilitating the straightening of the rectoanal angle (Fig. 40-1). Distention of the rectum results in transient relaxation of the internal anal sphincter via intrinsic and reflex sympathetic innervation. As sigmoid and rectal contractions increase the pressure within the rectum, the rectosigmoid angle opens by >15°. Voluntary relaxation of the external anal sphincter (striated muscle innervated by the pudendal nerve) in response to the sensation produced by distention permits the evacuation of feces; this evacuation process can be augmented by an increase in intra-abdominal pressure created by the Valsalva maneuver. Defecation can also be delayed voluntarily by contraction of the external anal sphincter.

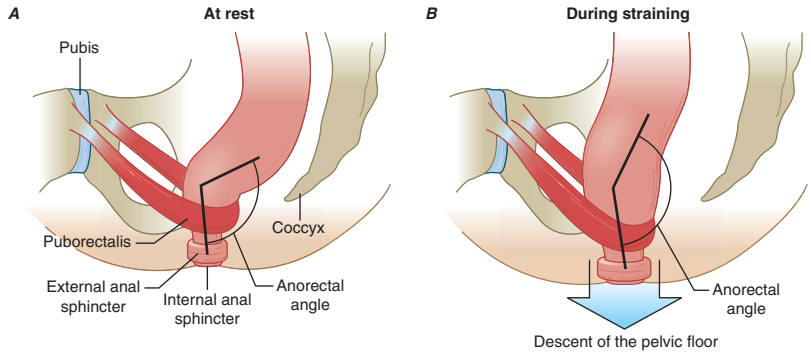

FIGURE 40-1 Sagittal view of the anorectum (*A*) at rest and (*B*) during straining to defecate. Continence is maintained by normal rectal sensation and tonic contraction of the internal anal sphincter and the puborectalis muscle, which wraps around the anorectum, maintaining an anorectal angle between 80° and 110°. During defecation, the pelvic floor muscles (including the puborectalis) relax, allowing the anorectal angle to straighten by at least 15°, and the perineum descends by 1.0–3.5 cm. The external anal sphincter also relaxes and reduces pressure on the anal canal. *(Reproduced with permission from Lembo and Camilleri.)*

DIARRHEA

DEFINITION

Diarrhea is loosely defined as passage of abnormally liquid or unformed stools at an increased frequency. For adults on a typical Western diet, stool weight >200 g/d can generally be considered diarrheal. Diarrhea may be further defined as *acute* if <2 weeks, *persistent* if 2–4 weeks, and *chronic* if >4 weeks in duration.

Two common conditions, usually associated with the passage of stool totaling <200 g/d, must be distinguished from diarrhea, as diagnostic and therapeutic algorithms differ. *Pseudodiarrhea*, or the frequent passage of small volumes of stool, is often associated with rectal urgency and accompanies IBS or proctitis. *Fecal incontinence* is the involuntary discharge of rectal contents and is most often caused by neuromuscular disorders or structural anorectal problems. Diarrhea and urgency, especially if severe, may aggravate or cause incontinence. Pseudodiarrhea and fecal incontinence occur at prevalence rates comparable to or higher than that of chronic diarrhea and should always be considered in patients complaining of "diarrhea." Overflow diarrhea may occur in nursing home patients due to fecal impaction that is readily detectable by rectal examination. A careful history and physical examination generally allow these conditions to be discriminated from true diarrhea.

ACUTE DIARRHEA

More than 90% of cases of acute diarrhea are caused by infectious agents; these cases are often accompanied by vomiting, fever, and abdominal pain. The remaining 10% or so are caused by medications, toxic ingestions, ischemia, and other conditions.

Infectious Agents Most infectious diarrheas are acquired by fecal-oral transmission or, more commonly, via ingestion of food or water contaminated with pathogens from human or animal feces. In the immunocompetent person, the resident fecal microflora, containing >500 taxonomically distinct species, are rarely the source of diarrhea and may actually play a role in suppressing the growth of ingested pathogens. Disturbances of flora by antibiotics can lead to diarrhea by reducing the digestive function or by allowing the overgrowth of pathogens, such as *Clostridium difficile* (Chap. 123). Acute infection or injury occurs when the ingested agent overwhelms the host's mucosal immune and nonimmune (gastric acid, digestive enzymes, mucus secretion, peristalsis, and suppressive resident flora) defenses. Established clinical associations with specific enteropathogens may offer diagnostic clues.

In the United States, five high-risk groups are recognized:

1. *Travelers.* Nearly 40% of tourists to endemic regions of Latin America, Africa, and Asia develop so-called traveler's diarrhea, most commonly due to enterotoxigenic or enteroaggregative *Escherichia coli* as well as to *Campylobacter*, *Shigella*, *Aeromonas*, norovirus, *Coronavirus* and *Salmonella*. Visitors to Russia (especially St. Petersburg) may have increased risk of *Giardia*-associated diarrhea; visitors to Nepal may acquire *Cyclospora*. Campers, backpackers, and swimmers in wilderness areas may become infected with *Giardia*. Cruise ships may be affected by outbreaks of gastroenteritis caused by agents such as Norwalk virus.
2. *Consumers of certain foods.* Diarrhea closely following food consumption at a picnic, banquet, or restaurant may suggest infection with *Salmonella*, *Campylobacter*, or *Shigella* from chicken; enterohemorrhagic *E. coli* (O157:H7) from undercooked hamburger; *Bacillus cereus* from fried rice; *Staphylococcus aureus* or *Salmonella* from mayonnaise or creams; *Salmonella* from eggs; and *Vibrio* species, *Salmonella*, or acute hepatitis A from seafood, especially if raw.
3. *Immunodeficient persons.* Individuals at risk for diarrhea include those with either primary immunodeficiency (e.g., IgA deficiency, common variable hypogammaglobulinemia, chronic granulomatous disease) or the much more common secondary immunodeficiency states (e.g., AIDS, senescence, pharmacologic suppression). Common enteric pathogens often cause a more severe and protracted diarrheal illness, and, particularly in persons with AIDS, opportunistic infections, such as by *Mycobacterium* species, certain viruses (cytomegalovirus, adenovirus, and herpes simplex), and protozoa (*Cryptosporidium*, *Isospora belli*, Microsporida, and *Blastocystis hominis*) may also play a role (Chap. 182). In patients with AIDS, agents transmitted venereally per rectum (e.g., *Neisseria gonorrhoeae*, *Treponema pallidum*, *Chlamydia*) may contribute to proctocolitis. Persons with hemochromatosis are especially prone to invasive, even fatal, enteric infections with *Vibrio* species and *Yersinia* infections and should avoid raw fish.
4. *Daycare attendees and their family members.* Infections with *Shigella*, *Giardia*, *Cryptosporidium*, rotavirus, and other agents are very common and should be considered.
5. *Institutionalized persons.* Infectious diarrhea is one of the most frequent categories of nosocomial infections in many hospitals and long-term care facilities; the causes are a variety of microorganisms but most commonly *C. difficile*.

The pathophysiology underlying acute diarrhea by infectious agents produces specific clinical features that may also be helpful in diagnosis (Table 40-2). Profuse watery diarrhea secondary to small bowel hypersecretion occurs with ingestion of preformed bacterial toxins, enterotoxin-producing bacteria, and enteroadherent pathogens. Diarrhea associated with marked vomiting and minimal or no fever may occur abruptly within a few hours after ingestion of the former two types; vomiting is usually less, and abdominal cramping or bloating is greater; fever is higher with the latter. Cytotoxin-producing and invasive microorganisms all cause high fever and abdominal pain. Invasive bacteria and *Entamoeba histolytica* often cause bloody diarrhea (referred to as *dysentery*). *Yersinia* invades the terminal ileal and proximal colon mucosa and may cause especially severe abdominal pain with tenderness mimicking acute appendicitis.

Finally, infectious diarrhea may be associated with systemic manifestations. Reiter's syndrome (arthritis, urethritis, and conjunctivitis) may accompany or follow infections by *Salmonella*, *Campylobacter*, *Shigella*, and *Yersinia*. Yersiniosis may also lead to an autoimmune-type thyroiditis, pericarditis, and glomerulonephritis. Both enterohemorrhagic *E. coli* (O157:H7) and *Shigella* can lead to the *hemolytic-uremic syndrome* with an attendant high mortality rate. The syndrome of postinfectious IBS has now been recognized as a complication of infectious diarrhea. Acute diarrhea can also be a major symptom of several systemic infections including *viral hepatitis*, *listeriosis*, *legionellosis*, and *toxic shock syndrome*.

TABLE 40-2 ASSOCIATION BETWEEN PATHOBIOLOGY OF CAUSATIVE AGENTS AND CLINICAL FEATURES IN ACUTE INFECTIOUS DIARRHEA

Pathobiology/Agents	Incubation Period	Vomiting	Abdominal Pain	Fever	Diarrhea
Toxin producers					
Preformed toxin					
Bacillus cereus, *Staphylococcus aureus*,	1–8 h	3–4+	1–2+	0–1+	3–4+, watery
Clostridium perfringens	8–24 h				
Enterotoxin					
Vibrio cholerae, enterotoxigenic *Escherichia coli*, *Klebsiella pneumoniae*, *Aeromonas* species	8–72 h	2–4+	1–2+	0–1+	3–4+, watery
Enteroadherent					
Enteropathogenic and enteroadherent *E. coli*, *Giardia* organisms, cryptosporidiosis, helminths	1–8 d	0–1+	1–3+	0–2+	1–2+, watery, mushy
Cytotoxin-producers					
Clostridium difficile	1–3 d	0–1+	3–4+	1–2+	1–3+, usually watery, occasionally bloody
Hemorrhagic *E. coli*	12–72 h	0–1+	3–4+	1–2+	1–3+, initially watery, quickly bloody
Invasive organisms					
Minimal inflammation					
Rotavirus and Norwalk agent	1–3 d	1–3+	2–3+	3–4+	1–3+, watery
Variable inflammation					
Salmonella, *Campylobacter*, and *Aeromonas* species, *Vibrio parahaemolyticus*, *Yersinia*	12 h–11 d	0–3+	2–4+	3–4+	1–4+, watery or bloody
Severe inflammation					
Shigella species, enteroinvasive *E. coli*, *Entamoeba histolytica*	12 h–8 d	0–1+	3–4+	3–4+	1–2+, bloody

Source: Adapted from DW Powell, in T Yamada (ed): *Textbook of Gastroenterology and Hepatology*, 4th ed. Philadelphia, Lippincott Williams & Wilkins, 2003; and DR Syndman, in SL Gorbach (ed): *Infectious Diarrhea*. London, Blackwell, 1986.

Other Causes Side effects from medications are probably the most common noninfectious cause of acute diarrhea, and etiology may be suggested by a temporal association between use and symptom onset. Although innumerable medications may produce diarrhea, some of the more frequently incriminated include antibiotics, cardiac antidysrhythmics, antihypertensives, nonsteroidal anti-inflammatory drugs (NSAIDs), certain antidepressants, chemotherapeutic agents, bronchodilators, antacids, and laxatives. Occlusive or nonocclusive *ischemic colitis* typically occurs in persons >50 years; often presents as acute lower abdominal pain preceding watery, then bloody diarrhea; and generally results in acute inflammatory changes in the sigmoid or left colon while sparing the rectum. Acute diarrhea may accompany colonic *diverticulitis* and *graft-versus-host disease*. Acute diarrhea, often associated with systemic compromise, can follow ingestion of toxins including organophosphate insecticides, amanita and other mushrooms, arsenic, and preformed environmental toxins in seafood, such as ciguatera and scombroid. Conditions causing chronic diarrhea can also be confused with acute diarrhea early in their course. This confusion may occur with inflammatory bowel disease (IBD) and some of the other inflammatory chronic diarrheas that may have an abrupt rather than insidious onset and exhibit features that mimic infection.

APPROACH TO THE PATIENT: Acute Diarrhea

The decision to evaluate acute diarrhea depends on its severity and duration and on various host factors (Fig. 40-2). Most episodes of acute diarrhea are mild and self-limited and do not justify the cost and potential morbidity of diagnostic or pharmacologic interventions. Indications for evaluation include profuse diarrhea with dehydration, grossly bloody stools, fever ≥ 38.5° C, duration > 48 h without improvement, recent antibiotic use, new community outbreaks, associated severe abdominal pain in patients >50 years, and elderly (≥70 years) or immunocompromised patients. In some cases of moderately severe febrile diarrhea associated with fecal leukocytes (or increased fecal levels of the leukocyte proteins) or with gross blood, a diagnostic evaluation might be avoided in favor of an empirical antibiotic trial (see below).

The cornerstone of diagnosis in those suspected of severe acute infectious diarrhea is microbiologic analysis of the stool. Workup includes cultures for bacterial and viral pathogens, direct inspection for ova and parasites, and immunoassays for certain bacterial toxins (*C. difficile*), viral antigens (rotavirus), and protozoal antigens (*Giardia*, *E. histolytica*). The aforementioned clinical and epidemiologic associations may assist in focusing the evaluation. If a particular pathogen or set of possible pathogens is so implicated, then either the whole panel of routine studies may not be necessary or, in some instances, special cultures may be appropriate as for enterohemorrhagic and other types of *E. coli*, *Vibrio* species, and *Yersinia*. Molecular diagnosis of pathogens in stool can be made by identification of unique DNA sequences; and evolving microarray technologies could lead to a more rapid, sensitive, specific, and cost-effective diagnostic approach in the future.

Persistent diarrhea is commonly due to *Giardia* (Chap. 202), but additional causative organisms that should be considered include *C. difficile* (especially if antibiotics had been administered), *E. his-*

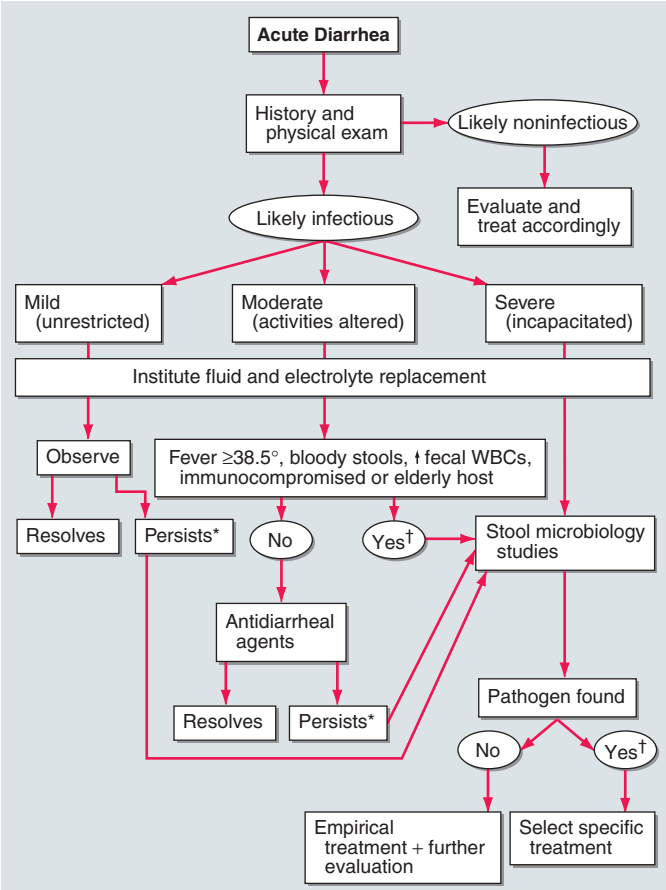

FIGURE 40-2 Algorithm for the management of acute diarrhea. Consider empirical Rx before evaluation with (*) metronidazole and with (†) quinolone. WBCs, white blood cells.

tolytica, *Cryptosporidium*, *Campylobacter*, and others. If stool studies are unrevealing, then flexible sigmoidoscopy with biopsies and upper endoscopy with duodenal aspirates and biopsies may be indicated. Brainerd diarrhea is an increasingly recognized entity characterized by an abrupt-onset diarrhea that persists for at least 4 weeks, but may last 1–3 years, and is thought to be of infectious origin. It may be associated with subtle inflammation of the distal small intestine or proximal colon.

Structural examination by sigmoidoscopy, colonoscopy, or abdominal CT scanning (or other imaging approaches) may be appropriate in patients with uncharacterized persistent diarrhea to exclude IBD, or as an initial approach in patients with suspected noninfectious acute diarrhea such as might be caused by ischemic colitis, diverticulitis, or partial bowel obstruction.

℞ ACUTE DIARRHEA

Fluid and electrolyte replacement are of central importance to all forms of acute diarrhea. Fluid replacement alone may suffice for mild cases. Oral sugar-electrolyte solutions (sport drinks or designed formulations) should be instituted promptly with severe diarrhea to limit dehydration, which is the major cause of death. Profoundly dehydrated patients, especially infants and the elderly, require IV rehydration.

In moderately severe nonfebrile and nonbloody diarrhea, antimotility and antisecretory agents such as loperamide can be useful adjuncts to control symptoms. Such agents should be avoided with febrile dysentery, which may be exacerbated or prolonged by them. Bismuth subsalicylate may reduce symptoms of vomiting and diarrhea but should not be used to treat immunocompromised patients or those with renal impairment because of the risk of bismuth encephalopathy.

Judicious use of antibiotics is appropriate in selected instances of acute diarrhea and may reduce its severity and duration (Fig. 40-2). Many physicians treat moderately to severely ill patients with febrile dysentery empirically without diagnostic evaluation using a quinolone, such as ciprofloxacin (500 mg bid for 3–5 d). Empirical treatment can also be considered for suspected giardiasis with metronidazole (250 mg qid for 7 d). Selection of antibiotics and dosage regimens are otherwise dictated by specific pathogens, geographic patterns of resistance, and conditions found (Chaps. 122, 143, and 146–152). Antibiotic coverage is indicated whether or not a causative organism is discovered in patients who are immunocompromised, have mechanical heart valves or recent vascular grafts, or are elderly. Antibiotic prophylaxis is indicated for certain patients traveling to high-risk countries in whom the likelihood or seriousness of acquired diarrhea would be especially high, including those with immunocompromise, IBD, hemochromatosis, or gastric achlorhydria. Use of trimethoprim/sulfamethoxazole, ciprofloxacin, or rifaximin may reduce bacterial diarrhea in such travelers by 90%, though rifaximin may not be suitable for invasive disease. Finally, physicians should be vigilant to identify if an outbreak of diarrheal illness is occurring and to alert the public health authorities promptly. This may reduce the ultimate size of the affected population.

CHRONIC DIARRHEA

Diarrhea lasting >4 weeks warrants evaluation to exclude serious underlying pathology. In contrast to acute diarrhea, most of the causes of chronic diarrhea are noninfectious. The classification of chronic diarrhea by pathophysiologic mechanism facilitates a rational approach to management, though many diseases cause diarrhea by more than one mechanism (Table 40-3).

Secretory Causes Secretory diarrheas are due to derangements in fluid and electrolyte transport across the enterocolonic mucosa. They are characterized clinically by watery, large-volume fecal outputs that are typically painless and persist with fasting. Because there is no malab-

TABLE 40-3 MAJOR CAUSES OF CHRONIC DIARRHEA ACCORDING TO PREDOMINANT PATHOPHYSIOLOGIC MECHANISM

Secretory causes
- Exogenous stimulant laxatives
- Chronic ethanol ingestion
- Other drugs and toxins
- Endogenous laxatives (dihydroxy bile acids)
- Idiopathic secretory diarrhea
- Certain bacterial infections
- Bowel resection, disease, or fistula (↓ absorption)
- Partial bowel obstruction or fecal impaction
- Hormone-producing tumors (carcinoid, VIPoma, medullary cancer of thyroid, mastocytosis, gastrinoma, colorectal villous adenoma)
- Addison's disease
- Congenital electrolyte absorption defects

Osmotic causes
- Osmotic laxatives (Mg^{2+}, PO_4^{-3}, SO_4^{-2})
- Lactase and other disaccharide deficiencies
- Nonabsorbable carbohydrates (sorbitol, lactulose, polyethylene glycol)

Steatorrheal causes
- Intraluminal maldigestion (pancreatic exocrine insufficiency, bacterial overgrowth, bariatric surgery, liver disease)
- Mucosal malabsorption (celiac sprue, Whipple's disease, infections, abetalipoproteinemia, ischemia)
- Post-mucosal obstruction (1° or 2° lymphatic obstruction)

Inflammatory causes
- Idiopathic inflammatory bowel disease (Crohn's, chronic ulcerative colitis)
- Lymphocytic and collagenous colitis
- Immune-related mucosal disease (1° or 2° immunodeficiencies, food allergy, eosinophilic gastroenteritis, graft-vs-host disease)
- Infections (invasive bacteria, viruses, and parasites, Brainerd diarrhea)
- Radiation injury
- Gastrointestinal malignancies

Dysmotile causes
- Irritable bowel syndrome (including post-infectious IBS)
- Visceral neuromyopathies
- Hyperthyroidism
- Drugs (prokinetic agents)
- Postvagotomy

Factitial causes
- Munchausen
- Eating disorders

Iatrogenic causes
- Cholecystectomy
- Ileal resection
- Bariatric surgery
- Vagotomy, fundoplication

sorbed solute, stool osmolality is accounted for by normal endogenous electrolytes with no fecal osmotic gap.

MEDICATIONS Side effects from regular ingestion of drugs and toxins are the most common secretory causes of chronic diarrhea. Hundreds of prescription and over-the-counter medications (see "Other Causes of Acute Diarrhea," above) may produce unwanted diarrhea. Surreptitious or habitual use of stimulant laxatives [e.g., senna, cascara, bisacodyl, ricinoleic acid (castor oil)] must also be considered. Chronic ethanol consumption may cause a secretory-type diarrhea due to enterocyte injury with impaired sodium and water absorption as well as rapid transit and other alterations. Inadvertent ingestion of certain environmental toxins (e.g., arsenic) may lead to chronic rather than acute forms of diarrhea. Certain bacterial infections may occasionally persist and be associated with a secretory-type diarrhea.

BOWEL RESECTION, MUCOSAL DISEASE, OR ENTEROCOLIC FISTULA These conditions may result in a secretory-type diarrhea because of inadequate surface for reabsorption of secreted fluids and electrolytes. Unlike other secretory diarrheas, this subset of conditions tends to worsen with eating. With disease (e.g., Crohn's ileitis) or resection of <100 cm of terminal ileum, dihydroxy bile acids may escape absorption and stimulate colonic secretion (cholorrheic diarrhea). This mechanism may contribute to so-called *idiopathic secretory diarrhea*, in which bile acids are functionally malabsorbed from a normal-appearing terminal ileum. Partial bowel obstruction, ostomy stricture, or fecal impaction may paradoxically lead to increased fecal output due to fluid hypersecretion.

HORMONES Although uncommon, the classic examples of secretory diarrhea are those mediated by hormones. *Metastatic gastrointestinal carcinoid tumors* or, rarely, *primary bronchial carcinoids* may produce watery diarrhea alone or as part of the carcinoid syndrome that comprises episodic flushing, wheezing, dyspnea, and right-sided valvular heart disease. Diarrhea is due to the release into the circulation of potent intestinal secretagogues including serotonin, histamine, prostaglandins, and various kinins. Pellagra-like skin lesions may rarely occur as the result of serotonin overproduction with niacin depletion. *Gastrinoma*, one of the most common neuroendocrine tumors, most typically presents with refractory peptic ulcers, but diarrhea occurs in up to one-third of cases and may be the only clinical manifestation in 10%. While other secretagogues released with gastrin may play a role, the diarrhea most often results from fat maldigestion owing to pancreatic enzyme inactivation by low intraduodenal pH. The watery diarrhea hypokalemia achlorhydria syndrome, also called *pancreatic cholera*, is due to a non-β cell pancreatic adenoma, referred to as a *VIPoma*, that secretes VIP and a host of other peptide hormones including pancreatic polypeptide, secretin, gastrin, gastrin-inhibitory polypeptide (also called glucose-dependent insulinotropic peptide), neurotensin, calcitonin, and prostaglandins. The secretory diarrhea is often massive with stool volumes >3 L/d; daily volumes as high as 20 L have been reported. Life-threatening dehydration; neuromuscular dysfunction from associated hypokalemia, hypomagnesemia, or hypercalcemia; flushing; and hyperglycemia may accompany a VIPoma. *Medullary carcinoma of the thyroid* may present with watery diarrhea caused by calcitonin, other secretory peptides, or prostaglandins. This tumor occurs sporadically or, in 25–50% of cases, as a feature of multiple endocrine neoplasia type 2a with pheochromocytomas and hyperparathyroidism. Prominent diarrhea is often associated with metastatic disease and poor prognosis. *Systemic mastocytosis*, which may be associated with the skin lesion urticaria pigmentosa, may cause diarrhea that is either secretory, and mediated by histamine, or inflammatory due to intestinal infiltration by mast cells. Large *colorectal villous adenomas* may rarely be associated with a secretory diarrhea that may cause hypokalemia, can be inhibited by NSAIDs, and is apparently mediated by prostaglandins.

CONGENITAL DEFECTS IN ION ABSORPTION Rarely, defects in specific carriers associated with ion absorption cause watery diarrhea from birth, and these disorders include defective Cl^-/HCO_3^- exchange (*congenital chloridorrhea*) with alkalosis and defective Na^+/H^+ exchange with acidosis. Some hormone deficiencies may be associated with watery diarrhea, such as occurs with adrenocortical insufficiency (Addison's disease) that may be accompanied by skin hyperpigmentation.

Osmotic Causes Osmotic diarrhea occurs when ingested, poorly absorbable, osmotically active solutes draw enough fluid into the lumen to exceed the reabsorptive capacity of the colon. Fecal water output increases in proportion to such a solute load. Osmotic diarrhea characteristically ceases with fasting or with discontinuation of the causative agent.

OSMOTIC LAXATIVES Ingestion of magnesium-containing antacids, health supplements, or laxatives may induce osmotic diarrhea typified by a stool osmotic gap (>50 mosmol/L): serum osmolarity (typically 290 mosmol/kg)[2 × (fecal sodium + potassium concentration)]. Measurement of fecal osmolarity is no longer recommended since, even when measured immediately after evacuation, it may be erroneous, as carbohydrates are metabolized by colonic bacteria, causing an increase in osmolarity.

CARBOHYDRATE MALABSORPTION Carbohydrate malabsorption due to acquired or congenital defects in brush-border disaccharidases and other enzymes leads to osmotic diarrhea with a low pH. One of the most common causes of chronic diarrhea in adults is *lactase deficiency*, which affects three-fourths of non-Caucasians worldwide and 5–30% of persons in the United States; the total lactose load at any one time influences the symptoms experienced. Most patients learn to avoid milk products without requiring treatment with enzyme supplements. Some sugars, such as sorbitol, lactulose, or fructose, are frequently malabsorbed, and diarrhea ensues with ingestion of medications, gum, or candies sweetened with these poorly or incompletely absorbed sugars.

Steatorrheal Causes Fat malabsorption may lead to greasy, foul-smelling, difficult-to-flush diarrhea often associated with weight loss and nutritional deficiencies due to concomitant malabsorption of amino acids and vitamins. Increased fecal output is caused by the osmotic effects of fatty acids, especially after bacterial hydroxylation, and, to a lesser extent, by the neutral fat. Quantitatively, steatorrhea is defined as stool fat exceeding the normal 7 g/d; rapid-transit diarrhea may result in fecal fat up to 14 g/d; daily fecal fat averages 15–25 g with small intestinal diseases and is often >32 g with pancreatic exocrine insufficiency. Intraluminal maldigestion, mucosal malabsorption, or lymphatic obstruction may produce steatorrhea.

INTRALUMINAL MALDIGESTION This condition most commonly results from pancreatic exocrine insufficiency, which occurs when >90% of pancreatic secretory function is lost. *Chronic pancreatitis*, usually a sequel of ethanol abuse, most frequently causes pancreatic insufficiency. Other causes include *cystic fibrosis*, *pancreatic duct obstruction*, and rarely, *somatostatinoma*. Bacterial overgrowth in the small intestine may deconjugate bile acids and alter micelle formation, impairing fat digestion; it occurs with stasis from a blind-loop, small bowel diverticulum or dysmotility and is especially likely in the elderly. Finally, cirrhosis or biliary obstruction may lead to mild steatorrhea due to deficient intraluminal bile acid concentration.

MUCOSAL MALABSORPTION Mucosal malabsorption occurs from a variety of enteropathies, but most commonly from *celiac disease*. This gluten-sensitive enteropathy affects all ages and is characterized by villous atrophy and crypt hyperplasia in the proximal small bowel and can present with fatty diarrhea associated with multiple nutritional deficiencies of varying severity. Celiac disease is much more frequent than previously thought; it affects ~1% of the population, frequently presents without steatorrhea, can mimic IBS, and has many other GI and extraintestinal manifestations. *Tropical sprue* may produce a similar histologic and clinical syndrome but occurs in residents of or travelers

to tropical climates; abrupt onset and response to antibiotics suggest an infectious etiology. *Whipple's disease*, due to the bacillus *Tropheryma whipplei* and histiocytic infiltration of the small-bowel mucosa, is a less common cause of steatorrhea that most typically occurs in young or middle-aged men; it is frequently associated with arthralgias, fever, lymphadenopathy, and extreme fatigue and may affect the central nervous system and endocardium. A similar clinical and histologic picture results from *Mycobacterium avium-intracellulare* infection in patients with AIDS. *Abetalipoproteinemia* is a rare defect of chylomicron formation and fat malabsorption in children, associated with acanthocytic erythrocytes, ataxia, and retinitis pigmentosa. Several other conditions may cause mucosal malabsorption including infections, especially with protozoa such as *Giardia*, numerous medications (e.g., colchicine, cholestyramine, neomycin), and chronic ischemia.

POSTMUCOSAL LYMPHATIC OBSTRUCTION The pathophysiology of this condition, which is due to the rare *congenital intestinal lymphangiectasia* or to *acquired lymphatic obstruction* secondary to trauma, tumor, or infection, leads to the unique constellation of fat malabsorption with enteric losses of protein (often causing edema) and lymphocytopenia. Carbohydrate and amino acid absorption are preserved.

Inflammatory Causes Inflammatory diarrheas are generally accompanied by pain, fever, bleeding, or other manifestations of inflammation. The mechanism of diarrhea may not only be exudation but, depending on lesion site, may include fat malabsorption, disrupted fluid/electrolyte absorption, and hypersecretion or hypermotility from release of cytokines and other inflammatory mediators. The unifying feature on stool analysis is the presence of leukocytes or leukocyte-derived proteins such as calprotectin. With severe inflammation, exudative protein loss can lead to anasarca (generalized edema). Any middle-aged or older person with chronic inflammatory-type diarrhea, especially with blood, should be carefully evaluated to exclude a colorectal tumor.

IDIOPATHIC INFLAMMATORY BOWEL DISEASE The illnesses in this category, which include *Crohn's disease* and *chronic ulcerative colitis*, are among the most common organic causes of chronic diarrhea in adults and range in severity from mild to fulminant and life-threatening. They may be associated with uveitis, polyarthralgias, cholestatic liver disease (primary sclerosing cholangitis), and skin lesions (erythema nodosum, pyoderma gangrenosum). *Microscopic colitis*, including both lymphocytic and *collagenous colitis*, is an increasingly recognized cause of chronic watery diarrhea, especially in middle-aged women and those on NSAIDS; biopsy of a normal-appearing colon is required for histologic diagnosis. It may coexist with symptoms suggesting IBS or with celiac sprue. It typically responds well to anti-inflammatory drugs (e.g., bismuth), to the opioid agonist loperamide, or to budesonide.

PRIMARY OR SECONDARY FORMS OF IMMUNODEFICIENCY Immunodeficiency may lead to prolonged infectious diarrhea. With common variable *hypogammaglobulinemia*, diarrhea is particularly prevalent and often the result of giardiasis.

EOSINOPHILIC GASTROENTERITIS Eosinophil infiltration of the mucosa, muscularis, or serosa at any level of the GI tract may cause diarrhea, pain, vomiting, or ascites. Affected patients often have an atopic history, Charcot-Leyden crystals due to extruded eosinophil contents may be seen on microscopic inspection of stool, and peripheral eosinophilia is present in 50–75% of patients. While hypersensitivity to certain foods occurs in adults, true food allergy causing chronic diarrhea is rare.

OTHER CAUSES Chronic inflammatory diarrhea may be caused by *radiation enterocolitis*, *chronic graft-versus-host disease*, *Behçet's syndrome*, and *Cronkite-Canada syndrome*, among others.

Dysmotility Causes Rapid transit may accompany many diarrheas as a secondary or contributing phenomenon, but primary dysmotility is an unusual etiology of true diarrhea. Stool features often suggest a secretory diarrhea, but mild steatorrhea of up to 14 g of fat per day can be produced by maldigestion from rapid transit alone. *Hyperthyroidism*, *carcinoid syndrome*, and certain drugs (e.g., prostaglandins, prokinetic agents) may produce hypermotility with resultant diarrhea. Primary visceral neuromyopathies or idiopathic acquired intestinal pseudoobstruction may lead to stasis with secondary bacterial overgrowth causing diarrhea. *Diabetic diarrhea*, often accompanied by peripheral and generalized autonomic neuropathies, may occur in part because of intestinal dysmotility.

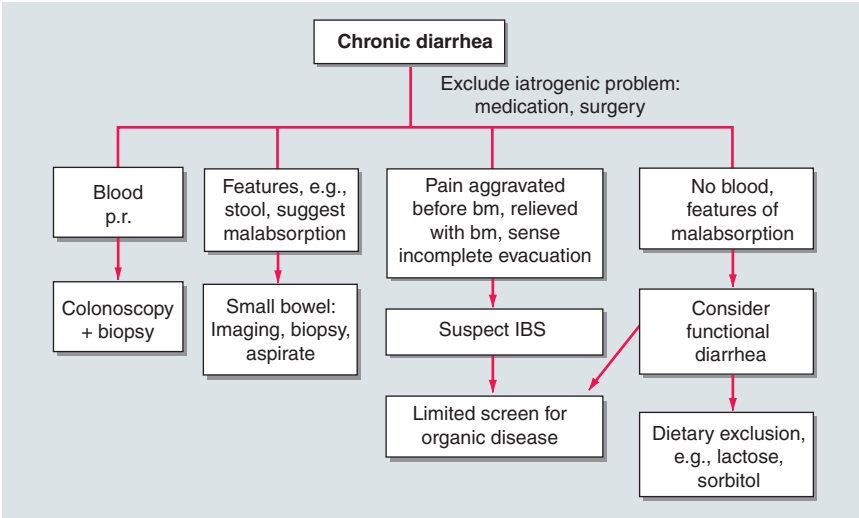
The exceedingly common *irritable bowel syndrome* (10% point prevalence, 1–2% per year incidence) is characterized by disturbed intestinal and colonic motor and sensory responses to various stimuli. Symptoms of stool frequency typically cease at night, alternate with periods of constipation, are accompanied by abdominal pain relieved with defecation, and rarely result in weight loss or true diarrhea.

Factitial Causes Factitial diarrhea accounts for up to 15% of unexplained diarrheas referred to tertiary care centers. Either as a form of *Munchausen syndrome* (deception or self-injury for secondary gain) or *eating disorders*, some patients covertly self-administer laxatives alone or in combination with other medications (e.g., diuretics) or surreptitiously add water or urine to stool sent for analysis. Such patients are typically women, often with histories of psychiatric illness and disproportionately from careers in health care. Hypotension and hypokalemia are common co-presenting features. The evaluation of such patients may be difficult: contamination of the stool with water or urine is suggested by very low or high stool osmolarity, respectively. Such patients often deny this possibility when confronted, but they do benefit from psychiatric counseling when they acknowledge their behavior.

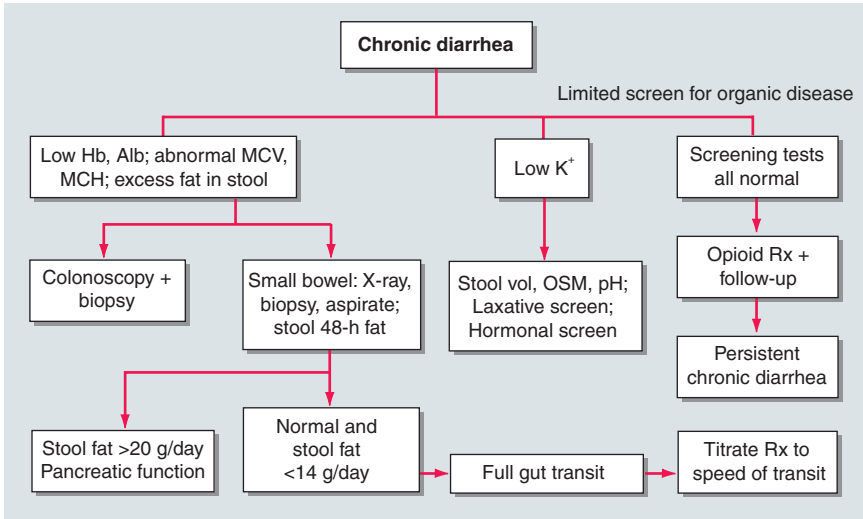
APPROACH TO THE PATIENT: Chronic Diarrhea

The laboratory tools available to evaluate the very common problem of chronic diarrhea are extensive, and many are costly and invasive. As such, the diagnostic evaluation must be rationally directed by a careful history and physical examination (Fig. 40-3*A*). When this strategy is unrevealing, simple triage tests are often warranted to direct the choice of more complex investigations (Fig. 40-3*B*). The history, physical examination (Table 40-4), and routine blood studies should attempt to characterize the mechanism of diarrhea, identify diagnostically helpful associations, and assess the patient's fluid/electrolyte and nutritional status. Patients should be questioned about the onset, duration, pattern, aggravating (especially diet) and relieving factors, and stool characteristics of their diarrhea. The presence or absence of fecal incontinence, fever, weight loss, pain, certain exposures (travel, medications, contacts with diarrhea), and common extraintestinal manifestations (skin changes, arthralgias, oral aphthous ulcers) should be noted. A family history of IBD or sprue may indicate those possibilities. Physical findings may offer clues such as a thyroid mass, wheezing, heart murmurs, edema, hepatomegaly, abdominal masses, lymphadenopathy, mucocutaneous abnormalities, perianal fistulae, or anal sphincter laxity. Peripheral blood leukocytosis, elevated sedimentation rate, or C-reactive protein suggests inflammation; anemia reflects blood loss or nutritional deficiencies; or eosinophilia may occur with parasitoses, neoplasia, collagen-vascular disease, allergy, or eosinophilic gastroenteritis. Blood chemistries may demonstrate electrolyte, hepatic, or other metabolic disturbances. Measuring tissue transglutaminase antibodies may help detect celiac disease.

A therapeutic trial is often appropriate, definitive, and highly cost effective when a specific diagnosis is suggested on the initial physician encounter. For example, chronic watery diarrhea, which ceases with fasting in an otherwise healthy young adult, may justify a trial of a lactose-restricted diet; bloating and diarrhea persisting since a mountain backpacking trip may warrant a trial of metronidazole for likely giardiasis; and postprandial diarrhea persisting



A



B

FIGURE 40-3 Chronic diarrhea. *A.* Initial management based on accompanying symptoms or features. ***B.*** Evaluation based on findings from a limited age appropriate screen for organic disease. p.r., per rectum; bm, bowel movement; IBS, irritable bowel syndrome; Hb, hemoglobin; Alb, albumin; MCV, mean corpuscular volume; MCH, mean corpuscular hemoglobin; OSM, osmolality. *(Reprinted from M Camilleri: Clin Gastroenterol Hepatol. 2:198, 2004.)*

since an ileal resection might be due to bile acid malabsorption and be treated with cholestyramine before further evaluation. Persistent symptoms require additional investigation.

Certain diagnoses may be suggested on the initial encounter, e.g., idiopathic IBD; however, additional focused evaluations may be necessary to confirm the diagnosis and characterize the severity or extent of disease so that treatment can be best guided. Patients suspected of having IBS should be initially evaluated with flexible sigmoidoscopy with colorectal biopsies; those with normal findings might be reassured and, as indicated, treated empirically with antispasmodics, antidiarrheals, bulk agents, anxiolytics, or antidepressants. Any patient who presents with chronic diarrhea and hematochezia should be evaluated with stool microbiologic studies and colonoscopy.

In an estimated two-thirds of cases, the cause for chronic diarrhea remains unclear after the initial encounter, and further testing is required. Quantitative stool collection and analyses can yield important objective data that may establish a diagnosis or characterize the type of diarrhea as a triage for focused additional studies (Fig. 40-3*B*). If stool weight is >200 g/d, additional stool analyses should be performed that might include electrolyte concentration, pH, occult blood testing, leukocyte inspection (or leukocyte protein assay), fat quantitation, and laxative screens.

For secretory diarrheas (watery, normal osmotic gap), possible medication-related side effects or surreptitious laxative use should be reconsidered. Microbiologic studies should be done including fecal bacterial cultures (including media for *Aeromonas* and *Pleisiomonas*), inspection for ova and parasites, and *Giardia* antigen assay (the most sensitive test for giardiasis). Small-bowel bacterial overgrowth can be excluded by intestinal aspirates with quantitative cultures or with glucose or lactulose breath tests involving measurement of breath hydrogen, methane, or other metabolite (e.g., $^{14}CO_2$). However, interpretation of these breath tests may be confounded by disturbances of intestinal transit. When suggested by history or other findings, screens for peptide hormones should be pursued (e.g., serum gastrin, VIP, calcitonin, and thyroid hormone/thyroid-stimulating hormone, or urinary 5-hydroxyindolacetic acid and histamine). Upper endoscopy and colonoscopy with biopsies and small-bowel barium x-rays are helpful to rule out structural or occult inflammatory disease.

Further evaluation of osmotic diarrhea should include tests for lactose intolerance and magnesium ingestion, the two most common causes. Low fecal pH suggests carbohydrate malabsorption; lactose malabsorption can be confirmed by lactose breath testing or by a therapeutic trial with lactose exclusion and observation of the effect of lactose challenge (e.g., a liter of milk). Lactase determination on small-bowel biopsy is generally not available. If fecal magnesium or laxative levels are elevated, then inadvertent or surreptitious ingestion should be considered and psychiatric help should be sought.

For those with proven fatty diarrhea, endoscopy with small-bowel biopsy (including aspiration for *Giardia* and quantitative cultures) should be performed; if this procedure is unrevealing, a small-bowel radiograph is often an appropriate next step. If small-bowel studies are negative or if pancreatic disease is suspected, pancreatic exocrine insufficiency should be excluded with direct tests, such as the secretin-cholecystokinin stimulation test or a variation that could be performed endoscopically. In general, indirect tests such as assay of fecal chymotrypsin activity or a bentiromide test have fallen out of favor because of low sensitivity and specificity.

TABLE 40-4 PHYSICAL EXAMINATION IN PATIENTS WITH CHRONIC DIARRHEA

1. Are there general features to suggest malabsorption or inflammatory bowel disease (IBD) such as anemia, dermatitis herpetiformis, edema, or clubbing?
2. Are there features to suggest underlying autonomic neuropathy or collagen-vascular disease in the pupils, orthostasis, skin, hands, or joints?
3. Is there an abdominal mass or tenderness?
4. Are there any abnormalities of rectal mucosa, rectal defects, or altered anal sphincter functions?
5. Are there any mucocutaneous manifestations of systemic disease such as dermatitis herpetiformis (celiac disease), erythema nodosum (ulcerative colitis), flushing (carcinoid), or oral ulcers for IBD or celiac disease?

Chronic inflammatory-type diarrheas should be suspected by the presence of blood or leukocytes in the stool. Such findings warrant stool cultures, inspection for ova and parasites, *C. difficile* toxin assay, colonoscopy with biopsies, and, if indicated, small-bowel contrast studies.

℞ CHRONIC DIARRHEA

Treatment of chronic diarrhea depends on the specific etiology and may be curative, suppressive, or empirical. If the cause can be eradicated, treatment is curative as with resection of a colorectal cancer, antibiotic administration for Whipple's disease, or discontinuation of a drug. For many chronic conditions, diarrhea can be controlled by suppression of the underlying mechanism. Examples include elimination of dietary lactose for lactase deficiency or gluten for celiac sprue, use of glucocorticoids or other anti-inflammatory agents for idiopathic IBDs, adsorptive agents such as cholestyramine for ileal bile acid malabsorption, proton pump inhibitors such as omeprazole for the gastric hypersecretion of gastrinomas, somatostatin analogues such as octreotide for malignant carcinoid syndrome, prostaglandin inhibitors such as indomethacin for medullary carcinoma of the thyroid, and pancreatic enzyme replacement for pancreatic insufficiency. When the specific cause or mechanism of chronic diarrhea evades diagnosis, empirical therapy may be beneficial. Mild opiates, such as diphenoxylate or loperamide, are often helpful in mild or moderate watery diarrhea. For those with more severe diarrhea, codeine or tincture of opium may be beneficial. Such antimotility agents should be avoided with IBD, as toxic megacolon may be precipitated. Clonidine, an α_2-adrenergic agonist, may allow control of diabetic diarrhea. For all patients with chronic diarrhea, fluid and electrolyte repletion is an important component of management (see "Acute Diarrhea," above). Replacement of fat-soluble vitamins may also be necessary in patients with chronic steatorrhea.

CONSTIPATION

DEFINITION

Constipation is a common complaint in clinical practice and usually refers to persistent, difficult, infrequent, or seemingly incomplete defecation. Because of the wide range of normal bowel habits, constipation is difficult to define precisely. Most persons have at least three bowel movements per week; however, low stool frequency alone is not the sole criterion for the diagnosis of constipation. Many constipated patients have a normal frequency of defecation but complain of excessive straining, hard stools, lower abdominal fullness, or a sense of incomplete evacuation. The individual patient's symptoms must be analyzed in detail to ascertain what is meant by "constipation" or "difficulty" with defecation.

Stool form and consistency are well correlated with the time elapsed from the preceding defecation. Hard, pellety stools occur with slow transit, while loose watery stools are associated with rapid transit. Both small pellety or very large stools are more difficult to expel than normal stools.

The perception of hard stools or excessive straining is more difficult to assess objectively, and the need for enemas or digital disimpaction is a clinically useful way to corroborate the patient's perceptions of difficult defecation.

Psychosocial or cultural factors may also be important. A person whose parents attached great importance to daily defecation will become greatly concerned when he or she misses a daily bowel movement; some children withhold stool to gain attention or because of fear of pain from anal irritation; and some adults habitually ignore or delay the call to have a bowel movement.

CAUSES

Pathophysiologically, chronic constipation generally results from inadequate fiber or fluid intake or from disordered colonic transit or anorectal function. These result from neurogastroenterologic disturbance, certain drugs, advancing age, or in association with a large number of systemic diseases that affect the gastrointestinal tract (Table 40-5). Constipation of recent onset may be a symptom of significant organic disease such as tumor or stricture. In *idiopathic constipation*, a subset of patients exhibit delayed emptying of the ascending and transverse colon with prolongation of transit (often in the proximal colon) and a reduced frequency of propulsive HAPCs. *Outlet obstruction to defecation* (also called *evacuation disorders*) may cause delayed colonic transit, which is usually corrected by biofeedback retraining of the disordered defecation. Constipation of any cause may be exacerbated by hospitalization or chronic illnesses that lead to physical or mental impairment and result in inactivity or physical immobility.

TABLE 40-5 CAUSES OF CONSTIPATION IN ADULTS

Types of Constipation and Causes	Examples
Recent onset	
Colonic obstruction	Neoplasm; stricture: ischemic, diverticular, inflammatory
Anal sphincter spasm	Anal fissure, painful hemorrhoids
Medications	
Chronic	
Irritable bowel syndrome	Constipation-predominant, alternating
Medications	Ca^{2+} blockers, antidepressants
Colonic pseudo-obstruction	Slow-transit constipation, megacolon (rare Hirschsprung's, Chagas)
Disorders of rectal evacuation	Pelvic floor dysfunction; anismus; descending perineum syndrome; rectal mucosal prolapse; rectocele
Endocrinopathies	Hypothyroidism, hypercalcemia, pregnancy
Psychiatric disorders	Depression, eating disorders, drugs
Neurologic disease	Parkinsonism, multiple sclerosis, spinal cord injury
Generalized muscle disease	Progressive systemic sclerosis

APPROACH TO THE PATIENT: Constipation

A careful history should explore the patient's symptoms and confirm whether he or she is indeed constipated based on frequency (e.g., fewer than three bowel movements per week), consistency (lumpy/hard), excessive straining, prolonged defecation time, or need to support the perineum or digitate the anorectum. In the vast majority of cases (probably >90%), there is no underlying cause (e.g., cancer, depression, or hypothyroidism), and constipation responds to ample hydration, exercise, and supplementation of dietary fiber (15–25 g/d). A good diet and medication history and attention to psychosocial issues are key. Physical examination and, particularly, a rectal examination should exclude fecal impaction and most of the important diseases that present with constipation and possibly indicate features suggesting an evacuation disorder (e.g., high anal sphincter tone).

The presence of weight loss, rectal bleeding, or anemia with constipation mandates either flexible sigmoidoscopy plus barium enema or colonoscopy alone, particularly in patients >40 years, to exclude structural diseases such as cancer or strictures. Colonoscopy alone is most cost effective in this setting since it provides an opportunity to biopsy mucosal lesions, perform polypectomy, or dilate strictures. Barium enema has advantages over colonoscopy in the patient with isolated constipation, since it is less costly and identifies colonic dilatation and all significant mucosal lesions or strictures that are likely to present with constipation. Melanosis coli, or pigmentation of the colon mucosa, indicates the use of anthraquinone laxatives such as cascara or senna; however, this is usually apparent from a careful history. An unexpected disorder such as megacolon or cathartic colon may also be detected by colonic radiographs. Measurement of serum calcium, potassium, and thyroid-stimulating hormone levels will identify rare patients with metabolic disorders.

Patients with more troublesome constipation may not respond to fiber alone and may be helped by a bowel training regimen: tak-

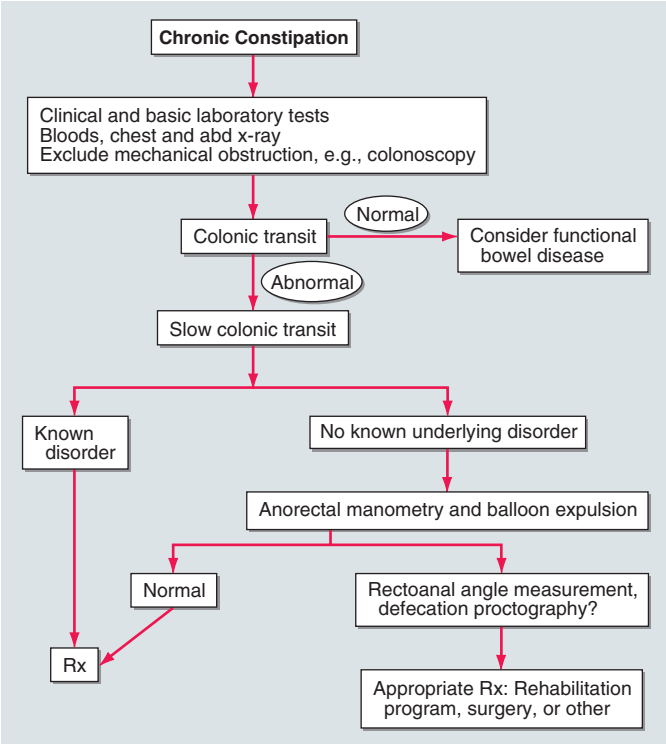


FIGURE 40-4 Algorithm for the management of constipation.

ing an osmotic laxative (lactulose, sorbitol, polyethylene glycol) and evacuating with enema or glycerine suppository as needed. After breakfast, a distraction-free 15–20 min on the toilet without straining is encouraged. Excessive straining may lead to development of hemorrhoids, and, if there is weakness of the pelvic floor or injury to the pudendal nerve, may result in obstructed defecation from descending perineum syndrome several years later. Those few who do not benefit from the simple measures delineated above or require long-term treatment with potent laxatives with the attendant risk of developing laxative abuse syndrome are assumed to have severe or intractable constipation and should have further investigation (Fig. 40-4). Novel agents that induce secretion (e.g., lubiprostone, a chloride channel activator) are also available.

INVESTIGATION OF SEVERE CONSTIPATION

A small minority (probably <5%) of patients have severe or "intractable" constipation. These are the patients most likely to be seen by gastroenterologists or in referral centers. Further observation of the patient may occasionally reveal a previously unrecognized cause, such as an evacuation disorder, laxative abuse, malingering, or psychological disorder. In these patients, evaluations of the physiologic function of the colon and pelvic floor and of psychological status aid in the rational choice of treatment. Even among these highly selected patients with severe constipation, a cause can be identified in only about two-thirds of tertiary referral patients (see below).

Measurement of Colonic Transit Radiopaque marker transit tests are easy, repeatable, generally safe, inexpensive, reliable, and highly applicable in evaluating constipated patients in clinical practice. Several validated methods are very simple. For example, radiopaque markers are ingested; an abdominal flat film taken 5 days later should indicate passage of 80% of the markers out of the colon without the use of laxatives or enemas. This test does not provide useful information about the transit profile of the stomach and small bowel.

Radioscintigraphy with a delayed-release capsule containing radiolabeled particles has been used to noninvasively characterize normal, accelerated, or delayed colonic function over 24–48 h with low radiation exposure. This approach simultaneously assesses gastric, small bowel (which may be important in ~20% of patients with delayed colonic transit since they reflect a more generalized GI motility disorder), and colonic transit. The disadvantages are the greater cost and the need for specific materials prepared in a nuclear medicine laboratory.

Anorectal and Pelvic Floor Tests Pelvic floor dysfunction is suggested by the inability to evacuate the rectum, a feeling of persistent rectal fullness, rectal pain, the need to extract stool from the rectum digitally, application of pressure on the posterior wall of the vagina, support of the perineum during straining, and excessive straining. These significant symptoms should be contrasted with the sense of incomplete rectal evacuation, which is common in IBS.

Formal psychological evaluation may identify eating disorders, "control issues," depression, or post-trauma stress disorders that may respond to cognitive or other intervention and may be important in restoring quality of life to patients who might present with chronic constipation.

A simple clinical test in the office to document a nonrelaxing puborectalis muscle is to have the patient strain to expel the index finger during a digital rectal examination. Motion of the puborectalis posteriorly during straining indicates proper coordination of the pelvic floor muscles.

Measurement of perineal descent is relatively easy to gauge clinically by placing the patient in the left decubitus position and watching the perineum to detect inadequate descent (<1.5 cm, a sign of pelvic floor dysfunction) or perineal ballooning during straining relative to bony landmarks (>4 cm, suggesting excessive perineal descent).

A useful overall test of evacuation is the balloon expulsion test. A balloon-tipped urinary catheter is placed and inflated with 50 mL of water. Normally, a patient can expel it while seated on a toilet or in the left lateral decubitus position. In the lateral position, the weight needed to facilitate expulsion of the balloon is determined; normally expulsion occurs with <200 g added.

Anorectal manometry when used in the evaluation of patients with severe constipation may find an excessively high resting (>80 mmHg) or squeeze anal sphincter tone, suggesting anismus (anal sphincter spasm). This test also identifies rare syndromes, such as adult Hirschsprung's disease, by the absence of the rectoanal inhibitory reflex.

Defecography (a dynamic barium enema including lateral views obtained during barium expulsion) reveals "soft abnormalities" in many patients; the most relevant findings are the measured changes in rectoanal angle, anatomic defects of the rectum such as internal mucosal prolapse, and enteroceles or rectoceles. Surgically remediable conditions are identified in only a few patients. These include severe, whole-thickness intussusception with complete outlet obstruction due to funnel-shaped plugging at the anal canal or an extremely large rectocele that fills preferentially during attempts at defecation instead of expulsion of the barium through the anus. In summary, defecography requires an interested and experienced radiologist, and abnormalities are not pathognomonic for pelvic floor dysfunction. The most common cause of outlet obstruction is failure of the puborectalis muscle to relax; this is not identified by defecography but requires a dynamic study such as proctography. MRI is being developed as an alternative and provides more information about the structure and function of the pelvic floor, distal colorectum, and anal sphincters.

Dynamic imaging studies such as proctography during defecation or scintigraphic expulsion of artificial stool help measure perineal descent and the rectoanal angle during rest, squeezing, and straining, and scintigraphic expulsion quantitates the amount of "artificial stool" emptied. Lack of straightening of the rectoanal angle by at least 15° during defecation confirms pelvic floor dysfunction.

Neurologic testing (electromyography) is more helpful in the evaluation of patients with incontinence than of those with symptoms suggesting obstructed defecation. The absence of neurologic signs in the lower extremities suggests that any documented denervation of the puborectalis results from pelvic (e.g., obstetric) injury or from stretching of the pudendal nerve by chronic, long-standing straining. Constipation is common among patients with spinal cord injuries, neurologic diseases such as Parkinson's disease, multiple sclerosis, and diabetic neuropathy.

Spinal-evoked responses during electrical rectal stimulation or stimulation of external anal sphincter contraction by applying magnetic stimulation over the lumbosacral cord identify patients with limited sacral neuropathies with sufficient residual nerve conduction to attempt biofeedback training.

In summary, a balloon expulsion test is an important screening test for anorectal dysfunction. If positive, an anatomic evaluation of the rectum or anal sphincters and an assessment of pelvic floor relaxation are the tools for evaluating patients in whom obstructed defecation is suspected.

℞ CONSTIPATION

After the cause of constipation is characterized, a treatment decision can be made. Slow-transit constipation requires aggressive medical or surgical treatment; anismus or pelvic floor dysfunction usually responds to biofeedback management (Fig. 40-4). However, only ~60% of patients with severe constipation are found to have such a physiologic disorder (half with colonic transit delay and half with evacuation disorder). Patients with spinal cord injuries or other neurologic disorders require a dedicated bowel regime that often includes rectal stimulation, enema therapy, and carefully timed laxative therapy.

Patients with slow-transit constipation are treated with bulk, osmotic, prokinetic, secretory, and stimulant laxatives including fiber, psyllium, milk of magnesia, lactulose, polyethylene glycol (colonic lavage solution), lubiprostone, and bisacodyl. Newer treatment aimed at enhancing motility and secretion may have application in circumstances such as constipation-predominant IBS in females or severe constipation. If a 3- to 6-month trial of medical therapy fails and patients continue to have documented slow-transit constipation unassociated with obstructed defecation, the patients should be considered for laparoscopic colectomy with ileorectostomy; however, this should not be undertaken if there is continued evidence of an evacuation disorder or a generalized GI dysmotility. Referral to a specialized center for further tests of colonic motor function is warranted. The decision to resort to surgery is facilitated in the presence of megacolon and megarectum. The complications after surgery include small-bowel obstruction (11%) and fecal soiling, particularly at night during the first postoperative year. Frequency of defecation is 3–8 per day during the first year, dropping to 1–3 per day from the second year after surgery.

Patients who have a combined (evacuation and transit/motility) disorder should pursue pelvic floor retraining (biofeedback and muscle relaxation), psychological counseling, and dietetic advice first, followed by colectomy and ileorectosomy if colonic transit studies do not normalize and symptoms are intractable despite biofeedback and optimized medical therapy. In patients with pelvic floor dysfunction alone, biofeedback training has a 70–80% success rate, measured by the acquisition of comfortable stool habits. Attempts to manage pelvic floor dysfunction with operations (internal anal sphincter or puborectalis muscle division) have achieved only mediocre success and have been largely abandoned.

41 Weight Loss

Carol M. Reife

Significant unintentional weight loss in a previously healthy individual is often a harbinger of underlying systemic disease. During the routine medical examination, changes in weight should always be assessed; loss of 5% of body weight over 6–12 months should prompt further evaluation.

PHYSIOLOGY OF WEIGHT REGULATION

The normal individual maintains body weight at a remarkably stable "set point," given the wide variation in daily caloric intake and level of activity. Because of the physiologic importance of maintaining energy stores, voluntary weight loss is difficult to achieve and sustain.

Appetite and metabolism are regulated by an intricate network of neural and hormonal factors. The hypothalamic feeding and satiety centers play a central role in these processes (Chap. 74). Neuropeptides such as corticotropin-releasing hormone (CRH), α-melanocyte-stimulating hormone (α-MSH), and cocaine- and amphetamine-related transcript (CART) induce anorexia by acting centrally on satiety centers. The gastrointestinal peptides ghrelin, glucagon, somatostatin, and cholecystokinin signal satiety and thus decrease food intake. Hypoglycemia suppresses insulin, reducing glucose utilization and inhibiting the satiety center.

Leptin is produced by adipose tissue, and it plays a central role in the long-term maintenance of weight homeostasis by acting on the hypothalamus to decrease food intake and increase energy expenditure (Chap. 74). Leptin suppresses expression of hypothalamic neuropeptide Y, a potent appetite stimulatory peptide, and it increases the expression of α-MSH, which acts through the MC4R melanocortin receptor to decrease appetite. Thus, leptin activates a series of downstream neural pathways that alter food-seeking behavior and metabolism. Leptin deficiency, which occurs in conjunction with the loss of adipose tissue, stimulates appetite and induces adaptive responses including inhibition of hypothalamic thyrotropin-releasing hormone (TRH) and gonadotropin-releasing hormone (GnRH).

A variety of cytokines, including tumor necrosis factor α (TNF-α), interleukin (IL) 6 (IL-6), IL-1, interferon γ (IFN-γ), ciliary neurotrophic factor (CNTF), and leukemia inhibitory factor (LIF), can induce cachexia (Chap. 17). In addition to causing anorexia, these factors may stimulate fever, depress myocardial function, modulate immune and inflammatory responses, and induce a variety of specific metabolic alterations. TNF-α, for example, preferentially mobilizes fat but spares skeletal muscle. Levels of these cytokines may be increased in patients with cancer, sepsis, chronic inflammatory conditions, AIDS, or congestive heart failure.

Weight loss occurs when energy expenditure exceeds calories available for energy utilization (Chap. 72). In most individuals, approximately half of food energy is utilized for basal processes such as maintenance of body temperature. In a 70-kg person, basal activity consumes ~1800 kcal/d. About 40% of caloric intake is used for physical activity, although athletes may use >50% during vigorous exercise. About 10% of caloric intake is used for dietary thermogenesis, the energy expended for digestion, absorption, and metabolism of food.

Mechanisms of weight loss include decreased food intake, malabsorption, loss of calories, and increased energy requirements (Fig. 41-1). Changes in weight may involve loss of tissue mass or body fluid content. A deficit of 3500 kcal generally correlates with the loss of 0.45 kg (1 lb) of body fat, but one must also consider water weight [1 kg/L (2.2 lb/L)] gained or lost. Weight loss that persists over weeks to months reflects the loss of tissue mass.

Food intake may be influenced by a wide variety of visual, olfactory, and gustatory stimuli as well as by genetic, psychological, and social fac-

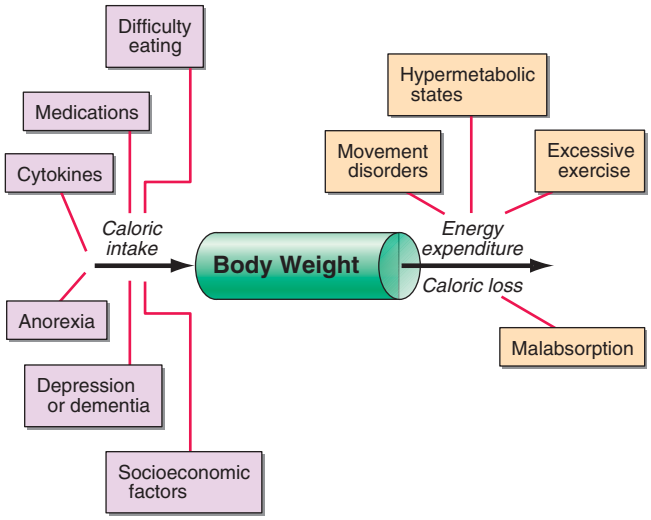

FIGURE 41-1 Energy balance and pathophysiology of weight loss.

tors. Absorption may be impaired because of pancreatic insufficiency, cholestasis, celiac sprue, intestinal tumors, radiation injury, inflammatory bowel disease, infection, or medication effect. These disease processes may be manifest as changes in stool frequency and consistency. Calories may also be lost due to vomiting or diarrhea, glucosuria in diabetes mellitus, or fistulous drainage. Resting energy expenditure decreases with age and can be affected by thyroid status. Beginning at about age 60, body weight declines by an average of 0.5% per year. Body composition is also affected by aging; adipose tissue increases and lean muscle mass decreases with age.

SIGNIFICANCE OF WEIGHT LOSS

Unintentional weight loss, especially in the elderly, is relatively common and is associated with increased morbidity and mortality rates, even after comorbid conditions have been taken into account. Prospective studies indicate that significant involuntary weight loss is associated with a mortality rate of 25% over the next 18 months. Retrospective studies of significant weight loss in the elderly document mortality rates of 9–38% over a 2- to 3-year period.

Cancer patients with weight loss have decreased performance status, impaired responses to chemotherapy, and reduced median survival (Chap. 77). Marked weight loss also predisposes to infection. Patients undergoing elective surgery, who have lost >4.5 kg (>10 lb) in 6 months, have higher surgical mortality rates. Vitamin and nutrient deficiencies may also accompany significant weight loss (Chap. 71).

CAUSES OF WEIGHT LOSS

The list of possible causes of weight loss is extensive (Table 41-1). In the elderly, the most common causes of weight loss are depression, cancer, and benign gastrointestinal disease. Lung and gastrointestinal cancer are the most common malignancies in patients presenting with weight loss. In younger individuals, diabetes mellitus, hyperthyroidism, psychiatric disturbances including eating disorders, and infection, especially with HIV, should be considered.

The cause of involuntary weight loss is rarely occult. Careful history and physical examination, in association with directed diagnostic testing, will identify the cause of weight loss in 75% of patients. The etiology of weight loss may not be found in the remaining patients, despite extensive testing. Patients with negative evaluations tend to have lower mortality rates than those found to have organic disease.

Patients with medical causes of weight loss usually have signs or symptoms that suggest involvement of a particular organ system. Gastrointestinal tumors, including those of the pancreas and liver, may affect food intake early in the course of illness, causing weight loss before other symptoms are apparent. Lung cancer may present with post-obstructive pneumonia, dyspnea, or cough and hemoptysis; however, it may be silent and should be considered even in those without a history of cigarette smoking. Depression and isolation can cause profound weight loss, especially in the elderly. Chronic pulmonary disease and congestive heart failure can produce anorexia, and they also increase resting energy expenditure. Weight loss may be the presenting sign of infectious diseases such as HIV infection, tuberculosis, endocarditis, and fungal or parasitic infections. Hyperthyroidism or pheochromocytoma increases metabolism. Elderly patients with apathetic hyperthyroidism may present with weight loss and weakness, with few other manifestations of thyrotoxicosis. New-onset diabetes mellitus is often accompanied by weight loss, reflecting glucosuria and loss of the anabolic actions of insulin. Adrenal insufficiency may be suggested by increased pigmentation, hyponatremia, and hyperkalemia.

APPROACH TO THE PATIENT: Weight Loss

Before extensive evaluation is undertaken, it is important to confirm weight loss and to determine the time interval over which it has occurred. Almost half of patients who claim significant weight loss have no actual change when body weight is measured objectively. In the absence of documentation, changes in belt notch position or the fit of clothing may be confirmatory. Not infrequently, patients who have actually sustained significant weight loss are unaware that it has occurred. Routine documentation of weight during office visits is therefore important.

The review of systems should focus on signs or symptoms that are associated with disorders that commonly cause weight loss. These include fever, pain, shortness of breath or cough, palpitations, and evidence of neurologic disease. Gastrointestinal isturbances, including difficulty eating, dysphagia, anorexia, nausea, and change in bowel habits, should be sought. Travel history, use of cigarettes and alcohol, and all medications should be reviewed, and patients should be questioned about previous illness or surgery as well as diseases in family members. Risk factors for HIV infection should be assessed. Signs of depression, evidence of dementia, and social factors, including financial issues that might affect food intake, should be considered.

Physical examination should begin with weight determination and documentation of vital signs. The skin should be examined for pallor, jaundice, turgor, scars from prior surgery, and stigmata of systemic disease. The search for oral thrush or dental disease, thyroid gland enlarge-

ment, adenopathy, and respiratory or cardiac abnormalities and a detailed examination of the abdomen often lead to clues for further evaluation. Rectal examination, including prostate examination, should be performed in men; and all women should have a pelvic examination, even if they have had a hysterectomy. Neurologic examination should include mental status assessment and screening for depression.

Laboratory testing should confirm or exclude possible diagnoses elicited from the history and physical examination (Table 41-2). An initial phase of testing should include a complete blood count with differential, serum chemistry tests including glucose, electrolytes, renal and liver tests, calcium, thyroid-stimulating hormone (TSH), urinalysis, and chest x-ray. Patients at risk for HIV infection should have HIV antibody testing. In all cases, recommended cancer screening tests appropriate for the gender and age group, such as mammograms and colonoscopies, should be updated (Chap. 78).

TABLE 41-2 SCREENING TESTS FOR EVALUATION OF INVOLUNTARY WEIGHT LOSS

Initial testing	Additional testing
CBC	HIV test
Electrolytes, calcium, glucose	Upper and/or lower gastrointestinal endoscopy
Renal and liver function tests	Abdominal CT scan or MRI
Urinalysis	Chest CT scan
TSH	
Chest x-ray	
Recommended cancer screening	

If gastrointestinal signs or symptoms are present, upper and/or lower endoscopy and abdominal imaging with either CT or MRI have a relatively high yield, consistent with the high prevalence of gastrointestinal disorders in patients with weight loss. If an etiology of weight loss is not found, careful clinical follow-up, rather than persistent undirected testing, is reasonable.

42 Gastrointestinal Bleeding

Loren Laine

Bleeding from the gastrointestinal (GI) tract may present in five ways. *Hematemesis* is vomitus of red blood or "coffee-grounds" material. *Melena* is black, tarry, foul-smelling stool. *Hematochezia* is the passage of bright red or maroon blood from the rectum. *Occult GI bleeding* (GIB) may be identified in the absence of overt bleeding by a fecal occult blood test or the presence of iron deficiency. Finally, patients may present only with *symptoms of blood loss or anemia* such as lightheadedness, syncope, angina, or dyspnea.

SOURCES OF GASTROINTESTINAL BLEEDING

Upper Gastrointestinal Sources of Bleeding (Table 42-1) The annual incidence of hospital admissions for upper GIB (UGIB) in the United States and Europe is ~0.1%, with a mortality rate of ~5–10%. Patients rarely die from exsanguination; rather, they die due to decompensation from other underlying illnesses. The mortality rate for patients <60 years in the absence of major concurrent illness is <1%. Independent predictors of rebleeding and death in patients hospitalized with UGIB include increasing age, comorbidities, and hemodynamic compromise (tachycardia or hypotension).

Peptic ulcers are the most common cause of UGIB, accounting for up to ~50% of cases; an increasing proportion is due to nonsteroidal anti-inflammatory drugs (NSAIDs), with the prevalence of *Helicobacter pylori* decreasing. Mallory-Weiss tears account for ~5–10 or 15% of cases. The proportion of patients bleeding from varices varies widely from ~5 to 30%, depending on the population. Hemorrhagic or erosive gastropathy (e.g., due to NSAIDs or alcohol) and erosive esophagitis often cause mild UGIB, but major bleeding is rare.

PEPTIC ULCERS In addition to clinical features, characteristics of an ulcer at endoscopy provide important prognostic information. One-third of patients with active bleeding or a nonbleeding visible vessel have further bleeding that requires urgent surgery if they are treated conservatively. These patients clearly benefit from endoscopic therapy with bipolar electrocoagulation, heater probe, injection therapy (e.g., absolute alcohol, 1:10,000 epinephrine), and/or clips with reductions in bleeding, hospital stay, mortality rate, and costs. In contrast, patients with clean-based ulcers have rates of recurrent bleeding approaching zero. If there is no other reason for hospitalization, such patients may be discharged on the first hospital day, following stabilization. Patients without clean-based ulcers should usually remain in the hospital for 3 days, as most episodes of recurrent bleeding occur within 3 days.

Randomized controlled trials document that a high-dose constant-infusion IV proton pump inhibitor (PPI) (e.g., omeprazole 80-mg bolus and 8-mg/h infusion), designed to sustain intragastric pH > 6 and enhance clot stability, decreases further bleeding (but not mortality), in patients with high-risk ulcers (active bleeding, nonbleeding visible vessel, adherent clot), even after appropriate endoscopic therapy. Institution of therapy at presentation in all patients with UGIB does not significantly improve outcomes such as further bleeding, transfusions, or mortality as compared to initiating therapy only when high-risk ulcers are identified at the time of endoscopy.

One-third of patients with a bleeding ulcer will rebleed within the next 1–2 years. Prevention of recurrent bleeding focuses on the three main factors in ulcer pathogenesis, *H. pylori*, NSAIDs, and acid. Eradi-

TABLE 42-1 SOURCES OF BLEEDING IN PATIENTS HOSPITALIZED FOR UPPER GI BLEEDING IN YEARS 2000–2002

Sources of Bleeding	Proportion of Patients, %
Ulcers	31–59
Varices	7–20
Mallory-Weiss tears	4–8
Gastroduodenal erosions	2–7
Erosive esophagitis	1–13
Neoplasm	2–7
Vascular ectasias	0–6
No source identified	8–14

cation of *H. pylori* in patients with bleeding ulcers decreases rates of rebleeding to <5%. If a bleeding ulcer develops in a patient taking NSAIDs, the NSAIDs should be discontinued, if possible. If NSAIDs must be continued, initial treatment should be with a PPI. Long-term preventive strategies to decrease NSAID-associated ulcers include use of a cyclooxygenase 2 (COX-2) selective inhibitor (coxib) or addition of GI co-therapy to a traditional NSAID. PPIs and misoprostol are effective co-therapies, but PPIs are more commonly used due to less frequent dosing (once daily) and fewer side effects (e.g., diarrhea). However, either PPI co-therapy alone or use of a coxib alone is associated with an annual rebleeding rate of ~10% in high-risk patients (i.e., a recent bleeding ulcer). Combination of a coxib and PPI provides a further significant decrease in ulcers and recurrent bleeding and should be employed in very high-risk patients. Patients with bleeding ulcers unrelated to *H. pylori* or NSAIDs should remain on full-dose antisecretory therapy indefinitely. **Peptic ulcers are discussed in Chap. 287.**

MALLORY-WEISS TEARS The classic history is vomiting, retching, or coughing preceding hematemesis, especially in an alcoholic patient. Bleeding from these tears, which are usually on the gastric side of the gastroesophageal junction, stops spontaneously in 80–90% of patients and recurs in only 0–7%. Endoscopic therapy is indicated for actively bleeding Mallory-Weiss tears. Angiographic therapy with embolization and operative therapy with oversewing of the tear are rarely required. **Mallory-Weiss tears are discussed in Chap. 286.**

ESOPHAGEAL VARICES Patients with variceal hemorrhage have poorer outcomes than patients with other sources of UGIB. Endoscopic therapy for acute bleeding and repeated sessions of endoscopic therapy to eradicate esophageal varices significantly reduce rebleeding and mortality. Ligation is the endoscopic therapy of choice for esophageal varices because it has less rebleeding, a lower mortality rate, fewer local complications, and requires fewer treatment sessions to achieve variceal eradication than sclerotherapy.

Octreotide (50-μg bolus and 50-μg/h IV infusion for 2–5 days) further helps in the control of acute bleeding when used in combination with endoscopic therapy. Other vasoactive agents such as somatostatin and terlipressin, available outside the United States, are also effective. Antibiotic therapy (e.g., quinolones) is also recommended for patients with cirrhosis presenting with UGIB, as antibiotics decrease bacterial infections and mortality in this population. Over the long term, treatment with nonselective beta blockers decreases recurrent bleeding from esophageal varices. Chronic therapy with beta blockers plus endoscopic ligation is recommended for prevention of recurrent esophageal variceal bleeding.

In patients who have persistent or recurrent bleeding despite endoscopic and medical therapy, more invasive therapy is warranted. Transjugular intrahepatic portosystemic shunt (TIPS) decreases rebleeding more effectively than endoscopic therapy, although hepatic encephalopathy is more common and the mortality rates are comparable. Most patients with TIPS have shunt stenosis within 1–2 years and require reintervention to maintain shunt patency, although the use of coated stents appears to markedly decrease shunt dysfunction, at least in the first year. A randomized comparison of TIPS and distal splenorenal shunt in Child-Pugh class A or B cirrhotic patients with refractory variceal bleeding revealed no significant difference in rebleeding, encephalopathy, or survival, but a much higher rate of reintervention with TIPS (82% vs. 11%). Therefore, TIPS is most appropriate in patients with more severe liver disease and those in whom transplant is anticipated. Patients with milder, well-compensated cirrhosis should require fewer re-interventions with decompressive surgery, although the higher initial risks of surgery must also be considered.

Portal hypertension is also responsible for bleeding from gastric varices, varices in the small and large intestine, and portal hypertensive gastropathy and enterocolopathy.

HEMORRHAGIC AND EROSIVE GASTROPATHY ("GASTRITIS") Hemorrhagic and erosive gastropathy, often labeled gastritis, refers to endoscopically visualized subepithelial hemorrhages and erosions. These are mucosal lesions and thus do not cause major bleeding. They develop in various clinical settings, the most important of which are NSAID use, alcohol intake, and stress. Half of patients who chronically ingest NSAIDs have erosions (15–30% have ulcers), while up to 20% of actively drinking alcoholic patients with symptoms of UGIB have evidence of subepithelial hemorrhages or erosions.

Stress-related gastric mucosal injury occurs only in extremely sick patients: those who have experienced serious trauma, major surgery, burns covering more than one-third of the body surface area, major intracranial disease, and severe medical illness (i.e., ventilator dependence, coagulopathy). Significant bleeding probably does not develop unless ulceration occurs. The mortality rate in these patients is quite high because of their serious underlying illnesses.

The incidence of bleeding from stress-related gastric mucosal injury or ulceration has decreased dramatically in recent years, most likely due to better care of critically ill patients. Pharmacologic prophylaxis for bleeding may be considered in the high-risk patients mentioned above. Multiple trials document the efficacy of intravenous H_2-receptor antagonist therapy, which is more effective than sucralfate but not superior to a PPI immediate-release suspension given via nasogastric tube. Prophylactic therapy decreases bleeding but does not lower the mortality rate.

OTHER CAUSES Other, less frequent causes of UGIB include erosive duodenitis, neoplasms, aortoenteric fistulas, vascular lesions [including hereditary hemorrhagic telangiectasias (Osler-Weber-Rendu) and gastric antral vascular ectasia ("watermelon stomach")], Dieulafoy's lesion (in which an aberrant vessel in the mucosa bleeds from a pinpoint mucosal defect), prolapse gastropathy (prolapse of proximal stomach into esophagus with retching, especially in alcoholics), and hemobilia and hemosuccus pancreaticus (bleeding from the bile duct or pancreatic duct).

Small-Intestinal Sources of Bleeding Small-intestinal sources of bleeding (bleeding from sites beyond the reach of the standard upper endoscope) are difficult to diagnose and are responsible for the majority of cases of obscure GIB. Fortunately, small-intestinal bleeding is uncommon. The most common causes are vascular ectasias and tumors (e.g., adenocarcinoma, leiomyoma, lymphoma, benign polyps, carcinoid, metastases, and lipoma). Other less common causes include Crohn's disease, infection, ischemia, vasculitis, small-bowel varices, diverticula, Meckel's diverticulum, duplication cysts, and intussusception. NSAIDs induce small-intestinal erosions and ulcers and may be a relatively common cause of chronic, obscure GIB; coxibs induce less small-intestinal injury than traditional NSAIDs.

Meckel's diverticulum is the most common cause of significant lower GIB (LGIB) in children, decreasing in frequency as a cause of bleeding with age. In adults <40–50 years, small-bowel tumors often account for obscure GIB; in patients >50–60 years, vascular ectasias are usually responsible.

Vascular ectasias should be treated with endoscopic therapy if possible. Surgical therapy can be used for vascular ectasias isolated to a segment of the small intestine when endoscopic therapy is unsuccessful. Although estrogen/progesterone compounds have been used for vascular ectasias, a double-blind trial found no benefit in prevention of recurrent bleeding. Isolated lesions, such as tumors, diverticula, or duplications, are generally treated with surgical resection.

Colonic Sources of Bleeding The incidence of hospitalizations for LGIB is about one-fifth that for UGIB. Hemorrhoids are probably the most common cause of LGIB; anal fissures also cause minor bleeding and pain. If these local anal processes, which rarely require hospitalization, are excluded, the most common causes of LGIB in adults are diverticula, vascular ectasias (especially in the proximal colon of patients >70 years), neoplasms (primarily adenocarcinoma), and colitis—most commonly infectious or idiopathic inflammatory bowel disease, but occasionally ischemic or radiation-induced. Uncommon causes include post-polypectomy bleeding, solitary rectal ulcer

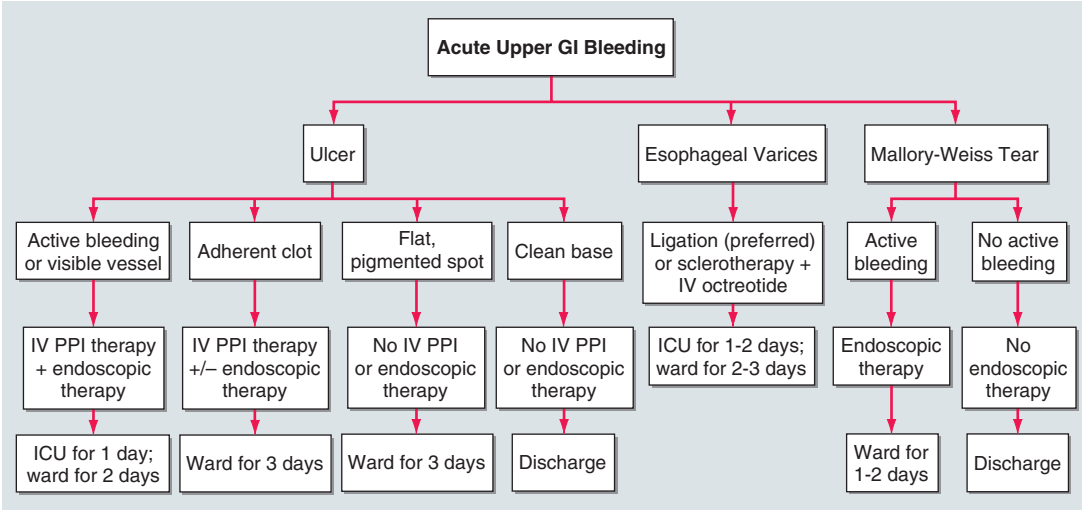

FIGURE 42-1 Suggested algorithm for patients with acute upper gastrointestinal bleeding. Recommendations on level of care and time of discharge assume patient is stabilized without further bleeding or other concomitant medical problems. PPI, proton pump inhibitor; ICU, intensive care unit.

syndrome, NSAID-induced ulcers or colitis, trauma, varices (most commonly rectal), lymphoid nodular hyperplasia, vasculitis, and aortocolic fistulas. In children and adolescents, the most common colonic causes of significant GIB are inflammatory bowel disease and juvenile polyps.

Diverticular bleeding is abrupt in onset, usually painless, sometimes massive, and often from the right colon; minor and occult bleeding is not characteristic. Clinical reports suggest that bleeding colonic diverticula stop bleeding spontaneously in ~80% of patients and rebleed in about 20–25% of patients. Intraarterial vasopressin or embolization by superselective technique should stop bleeding in a majority of patients. If bleeding persists or recurs, segmental surgical resection is indicated.

Bleeding from right colonic vascular ectasias in the elderly may be overt or occult; it tends to be chronic and only occasionally is hemodynamically significant. Endoscopic hemostatic therapy may be useful in the treatment of vascular ectasias, as well as discrete bleeding ulcers and post-polypectomy bleeding, while endoscopic polypectomy, if possible, is used for bleeding colonic polyps. Surgical therapy is generally required for major, persistent, or recurrent bleeding from the wide variety of colonic sources of GIB that cannot be treated medically, angiographically, or endoscopically.

APPROACH TO THE PATIENT: Gastrointestinal Bleeding

Measurement of the heart rate and blood pressure is the best way to assess a patient with GIB. Clinically significant bleeding leads to postural changes in heart rate or blood pressure, tachycardia, and, finally, recumbent hypotension. In contrast, the hemoglobin does not fall immediately with acute GIB, due to proportionate reductions in plasma and red cell volumes (i.e., "people bleed whole blood"). Thus, hemoglobin may be normal or only minimally decreased at the initial presentation of a severe bleeding episode. As extravascular fluid enters the vascular space to restore volume, the hemoglobin falls, but this process may take up to 72 h. Patients with slow, chronic GIB may have very low hemoglobin values despite normal blood pressure and heart rate. With the development of iron-deficiency anemia, the mean corpuscular volume will be low and red blood cell distribution width will be increased.

DIFFERENTIATION OF UPPER FROM LOWER GIB Hematemesis indicates an upper GI source of bleeding (above the ligament of Treitz). Melena indicates that blood has been present in the GI tract for at least 14 h. Thus, the more proximal the bleeding site, the more likely melena will occur. Hematochezia usually represents a lower GI source of bleeding, although an upper GI lesion may bleed so briskly that blood does not remain in the bowel long enough for melena to develop. When hematochezia is the presenting symptom of UGIB, it is associated with hemodynamic instability and dropping hemoglobin. Bleeding lesions of the small bowel may present as melena or hematochezia. Other clues to UGIB include hyperactive bowel sounds and an elevated blood urea nitrogen level (due to volume depletion and blood proteins absorbed in the small intestine).

A nonbloody nasogastric aspirate may be seen in up to 18% of patients with UGIB—usually from a duodenal source. Even a bile-stained appearance does not exclude a bleeding postpyloric lesion since reports of bile in the aspirate are incorrect in ~50% of cases. Testing of aspirates that are not grossly bloody for occult blood is not useful.

DIAGNOSTIC EVALUATION OF THE PATIENT WITH GIB **Upper GIB** (Fig. 42-1) History and physical examination are not usually diagnostic of the source of GIB. Upper endoscopy is the test of choice in patients with UGIB and should be performed urgently in patients with hemodynamic instability (hypotension, tachycardia, or postural changes in heart rate or blood pressure). Early endoscopy is also beneficial in cases of milder bleeding for management decisions. Patients with major bleeding and high-risk endoscopic findings (e.g., varices, ulcers with active bleeding or a visible vessel) benefit from endoscopic hemostatic therapy, while patients with low-risk lesions (e.g., clean-based ulcers, nonbleeding Mallory-Weiss tears, erosive or hemorrhagic gastropathy) who have stable vital signs and hemoglobin, and no other medical problems, can be discharged home.

Lower GIB (Fig. 42-2) Patients with hematochezia and hemodynamic instability should have upper endoscopy to rule out an upper GI source before evaluation of the lower GI tract. Patients with presumed LGIB may undergo early sigmoidoscopy for the detection of obvious, low-lying lesions. However, the procedure is difficult with brisk bleeding, and it is usually not possible to identify the area of bleeding. Sigmoidoscopy is useful primarily in patients <40 years with minor bleeding.

Colonoscopy after an oral lavage solution is the procedure of choice in patients admitted with LGIB unless bleeding is too massive or unless sigmoidoscopy has disclosed an obvious actively bleeding lesion. ^{99m}Tc-labeled red cell scan allows repeated imaging for up to 24 h and may identify the general location of bleeding. However, radionuclide scans should be interpreted with caution

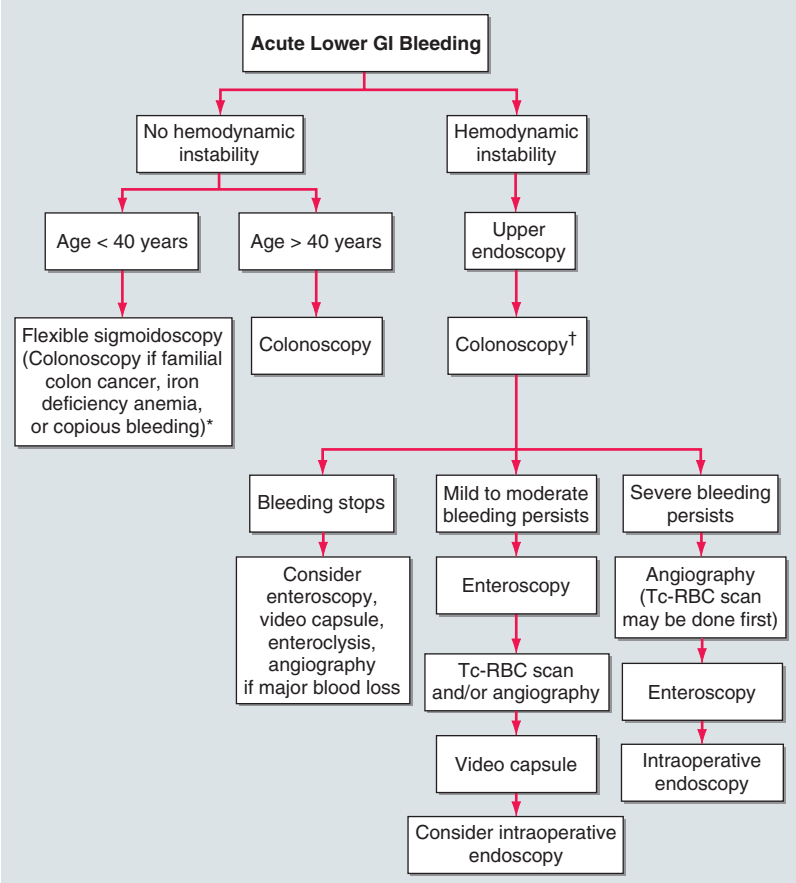

FIGURE 42-2 Suggested algorithm for patients with acute lower gastrointestinal bleeding. Sequential recommendations under "Hemodynamic instability" assume a test is found to be nondiagnostic before next test is performed. *Some suggest colonoscopy for any degree of rectal bleeding in patients <40 years as well. †If massive bleeding does not allow time for colonic lavage, proceed to angiography. Tc-RBC, ^{99m}technetium-labeled red blood cell.

because results, especially from later images, are highly variable. In active LGIB, angiography can detect the site of bleeding (extravasation of contrast into the gut) and permits treatment with intraarterial infusion of vasopressin or embolization. Even after bleeding has stopped, angiography may identify lesions with abnormal vasculature, such as vascular ectasias or tumors.

GIB of Obscure Origin Obscure GIB is defined as persistent or recurrent bleeding for which no source has been identified by routine endoscopic and contrast x-ray studies; it may be overt (e.g., melena, hematochezia) or occult. Push enteroscopy, with a specially designed enteroscope or a pediatric colonoscope to inspect the entire duodenum and part of the jejunum, is generally the next step. Push enteroscopy may identify probable bleeding sites in 20–40% of patients with obscure GIB. Video capsule endoscopy, which allows endoscopic examination of the entire small intestine, increases diagnostic yield in obscure GIB: a systematic review of 14 trials comparing push enteroscopy to capsule revealed "clinically significant findings" in 26% and 56% of patients, respectively. However, lack of control of the capsule prevents its manipulation and full visualization of the intestine; in addition, tissue cannot be sampled and therapy cannot be applied. A new endoscopic technique, double-balloon enteroscopy, allows the endoscopist to potentially examine and provide therapy to much or all of the small intestine. If enteroscopy and video capsule endoscopy are negative or unavailable, a specialized radiographic examination of the small bowel (e.g., enteroclysis) should be performed. Newer imaging techniques being investigated include CT and MR enterography.

Patients with continued obscure GIB who require transfusions or repeated hospitalizations warrant further investigations. ^{99m}Tc-labeled red blood cell scintigraphy should be employed. Angiography is useful even if bleeding has subsided, since it may disclose vascular anomalies or tumor vessels. ^{99m}Tc-pertechnetate scintigraphy for diagnosis of Meckel's diverticulum should be done, especially in the evaluation of young patients. When all tests are unrevealing, intraoperative endoscopy is indicated in patients with severe recurrent or persistent bleeding requiring repeated transfusions.

Occult GIB Occult GIB is manifested by a positive test for fecal occult blood or iron-deficiency anemia. Evaluation of a positive test for fecal occult blood generally should begin with colonoscopy, particularly in patients >40 years. If evaluation of the colon is negative, many perform upper endoscopy only if iron-deficiency anemia or upper GI symptoms are present, while others recommend upper endoscopy in all patients since up to 25–40% of these patients may have some abnormality noted on upper endoscopy. If standard endoscopic tests are unrevealing, enteroscopy, video capsule endoscopy, and/or enteroclysis may be considered in patients with iron-deficiency anemia.

43 Jaundice

Daniel S. Pratt, Marshall M. Kaplan

Jaundice, or icterus, is a yellowish discoloration of tissue resulting from the deposition of bilirubin. Tissue deposition of bilirubin occurs only in the presence of serum hyperbilirubinemia and is a sign of either liver disease or, less often, a hemolytic disorder. The degree of serum bilirubin elevation can be estimated by physical examination. Slight increases in serum bilirubin are best detected by examining the sclerae, which have a particular affinity for bilirubin due to their high elastin content. The presence of scleral icterus indicates a serum bilirubin of at least 51 μmol/L (3.0 mg/dL). The ability to detect scleral icterus is made more difficult if the examining room has fluorescent lighting. If the examiner suspects scleral icterus, a second place to examine is underneath the tongue. As serum bilirubin levels rise, the skin will eventually become yellow in light-skinned patients and even green if the process is long-standing; the green color is produced by oxidation of bilirubin to biliverdin.

The differential diagnosis for yellowing of the skin is limited. In addition to jaundice, it includes carotenoderma, the use of the drug quinacrine, and excessive exposure to phenols. Carotenoderma is the yellow color imparted to the skin by the presence of carotene; it occurs in healthy individuals who ingest excessive amounts of vegetables and fruits that contain carotene, such as carrots, leafy vegetables, squash, peaches, and oranges. Unlike jaundice, where the yellow coloration of the skin is uniformly distributed over the body, in carotenoderma the pigment is concentrated on the palms, soles, forehead, and nasolabial folds. Carotenoderma can be distinguished from jaundice by the sparing of the sclerae. Quinacrine causes a yellow discoloration of the skin in 4–37% of patients treated with it. Unlike carotene, quinacrine can cause discoloration of the sclerae.

Another sensitive indicator of increased serum bilirubin is darkening of the urine, which is due to the renal excretion of conjugated bilirubin. Patients often describe their urine as tea or cola colored. Bilirubinuria indicates an elevation of the direct serum bilirubin fraction and therefore the presence of liver disease.

Increased serum bilirubin levels occur when an imbalance exists between bilirubin production and clearance. A logical evaluation of the patient who is jaundiced requires an understanding of bilirubin production and metabolism.

PRODUCTION AND METABOLISM OF BILIRUBIN

(See also Chap. 297) Bilirubin, a tetrapyrrole pigment, is a breakdown product of heme (ferroprotoporphyrin IX). About 70–80% of the 250–300 mg of bilirubin produced each day is derived from the breakdown of hemoglobin in senescent red blood cells. The remainder comes from prematurely destroyed erythroid cells in bone marrow and from the turnover of hemoproteins such as myoglobin and cytochromes found in tissues throughout the body.

The formation of bilirubin occurs in reticuloendothelial cells, primarily in the spleen and liver. The first reaction, catalyzed by the microsomal enzyme heme oxygenase, oxidatively cleaves the α bridge of the porphyrin group and opens the heme ring. The end products of this reaction are biliverdin, carbon monoxide, and iron. The second reaction, catalyzed by the cytosolic enzyme biliverdin reductase, reduces the central methylene bridge of biliverdin and converts it to bilirubin. Bilirubin formed in the reticuloendothelial cells is virtually insoluble in water. This is due to tight internal hydrogen bonding between the water-soluble moieties of bilirubin, proprionic acid carboxyl groups of one dipyrrolic half of the molecule with the imino and lactam groups of the opposite half. This configuration blocks solvent access to the polar residues of bilirubin and places the hydrophobic residues on the outside. To be transported in blood, bilirubin must be solubilized. This is accomplished by its reversible, noncovalent binding to albumin. Unconjugated bilirubin bound to albumin is transported to the liver, where it, but not the albumin, is taken up by hepatocytes via a process that at least partly involves carrier-mediated membrane transport. No specific bilirubin transporter has yet been identified (Chap. 297, Fig. 297-1).

After entering the hepatocyte, unconjugated bilirubin is bound to the cytosolic protein ligandin, or glutathione S-transferase B. Whereas ligandin was initially thought to be a transport protein, responsible for delivering unconjugated bilirubin from the plasma membrane to the endoplasmic reticulum, it now appears that its role may in fact be to reduce bilirubin efflux back into the plasma. Studies suggest that unconjugated bilirubin may well rapidly diffuse unaided through the aqueous cytosol between membranes. In the endoplasmic reticulum, bilirubin is solubilized by conjugation to glucuronic acid, a process that disrupts the internal hydrogen bonds and yields bilirubin monoglucuronide and diglucuronide. The conjugation of glucuronic acid to bilirubin is catalyzed by bilirubin uridine diphosphate-glucuronosyl transferase (UDPGT). The now hydrophilic bilirubin conjugates diffuse from the endoplasmic reticulum to the canalicular membrane, where bilirubin monoglucuronide and diglucuronide are actively transported into canalicular bile by an energy-dependent mechanism involving the multiple drug resistance protein 2.

The conjugated bilirubin excreted into bile drains into the duodenum and passes unchanged through the proximal small bowel. Conjugated bilirubin is not taken up by the intestinal mucosa. When the conjugated bilirubin reaches the distal ileum and colon, it is hydrolyzed to unconjugated bilirubin by bacterial β-glucuronidases. The unconjugated bilirubin is reduced by normal gut bacteria to form a group of colorless tetrapyrroles called urobilinogens. About 80–90% of these products are excreted in feces, either unchanged or oxidized to orange derivatives called urobilins. The remaining 10–20% of the urobilinogens are passively absorbed, enter the portal venous blood, and are reexcreted by the liver. A small fraction (usually <3 mg/dL) escapes hepatic uptake, filters across the renal glomerulus, and is excreted in urine.

MEASUREMENT OF SERUM BILIRUBIN

The terms direct- and indirect-reacting bilirubin are based on the original van den Bergh reaction. This assay, or a variation of it, is still used in most clinical chemistry laboratories to determine the serum bilirubin level. In this assay, bilirubin is exposed to diazotized sulfanilic acid, splitting into two relatively stable dipyrrylmethene azopigments that absorb maximally at 540 nm, allowing for photometric analysis. The direct fraction is that which reacts with diazotized sulfanilic acid in the absence of an accelerator substance such as alcohol. The direct fraction provides an approximate determination of the conjugated bilirubin in serum. The total serum bilirubin is the amount that reacts after the addition of alcohol. The indirect fraction is the difference between the total and the direct bilirubin and provides an estimate of the unconjugated bilirubin in serum.

With the van den Bergh method, the normal serum bilirubin concentration usually is 17 μmol/L (<1 mg/dL). Up to 30%, or 5.1 μmol/L (0.3 mg/dL), of the total may be direct-reacting (conjugated) bilirubin. Total serum bilirubin concentrations are between 3.4 and 15.4 μmol/L (0.2 and 0.9 mg/dL) in 95% of a normal population.

Several new techniques, although less convenient to perform, have added considerably to our understanding of bilirubin metabolism. First, they demonstrate that in normal persons or those with Gilbert's syndrome, almost 100% of the serum bilirubin is unconjugated; <3% is monoconjugated bilirubin. Second, in jaundiced patients with hepatobiliary disease, the total serum bilirubin concentration measured by these new, more accurate methods is lower than the values found with diazo methods. This suggests that there are diazo-positive compounds distinct from bilirubin in the serum of patients with hepatobiliary disease. Third, these studies indicate that in jaundiced patients with hepatobiliary disease, monoglucuronides of bilirubin predominate over the diglucuronides. Fourth, part of the direct-reacting bilirubin fraction includes conjugated bilirubin that is covalently linked to albumin. This albumin-linked bilirubin fraction (*delta fraction,* or *biliprotein*) represents an important fraction of total serum bilirubin in patients with cholestasis and hepatobiliary disorders. Albumin-bound conjugated bilirubin is formed in serum when hepatic excretion of bilirubin glucuronides is impaired and the glucuronides are present in serum in increasing amounts. By virtue of its tight binding to albumin, the clearance rate of albumin-bound bilirubin from serum approximates the half-life of albumin, 12–14 days, rather than the short half-life of bilirubin, about 4 h.

The prolonged half-life of albumin-bound conjugated bilirubin explains two previously unexplained enigmas in jaundiced patients with liver disease: (1) that some patients with conjugated hyperbilirubinemia do not exhibit bilirubinuria during the recovery phase of their disease because the bilirubin is covalently bound to albumin and therefore not filtered by the renal glomeruli, and (2) that the elevated serum bilirubin level declines more slowly than expected in some patients who otherwise appear to be recovering satisfactorily. Late in the recovery phase of hepatobiliary disorders, all the conjugated bilirubin may be in the albumin-linked form. Its value in serum falls slowly because of the long half-life of albumin.

MEASUREMENT OF URINE BILIRUBIN

Unconjugated bilirubin is always bound to albumin in the serum, is not filtered by the kidney, and is not found in the urine. Conjugated bilirubin is filtered at the glomerulus and the majority is reabsorbed by the proximal tubules; a small fraction is excreted in the urine. Any bilirubin found in the urine is conjugated bilirubin. The presence of bilirubinuria implies the presence of liver disease. A urine dipstick test (Ictotest) gives the same information as fractionation of the serum bilirubin. This test is very accurate. A false-negative test is possible in patients with prolonged cholestasis due to the predominance of conjugated bilirubin covalently bound to albumin.

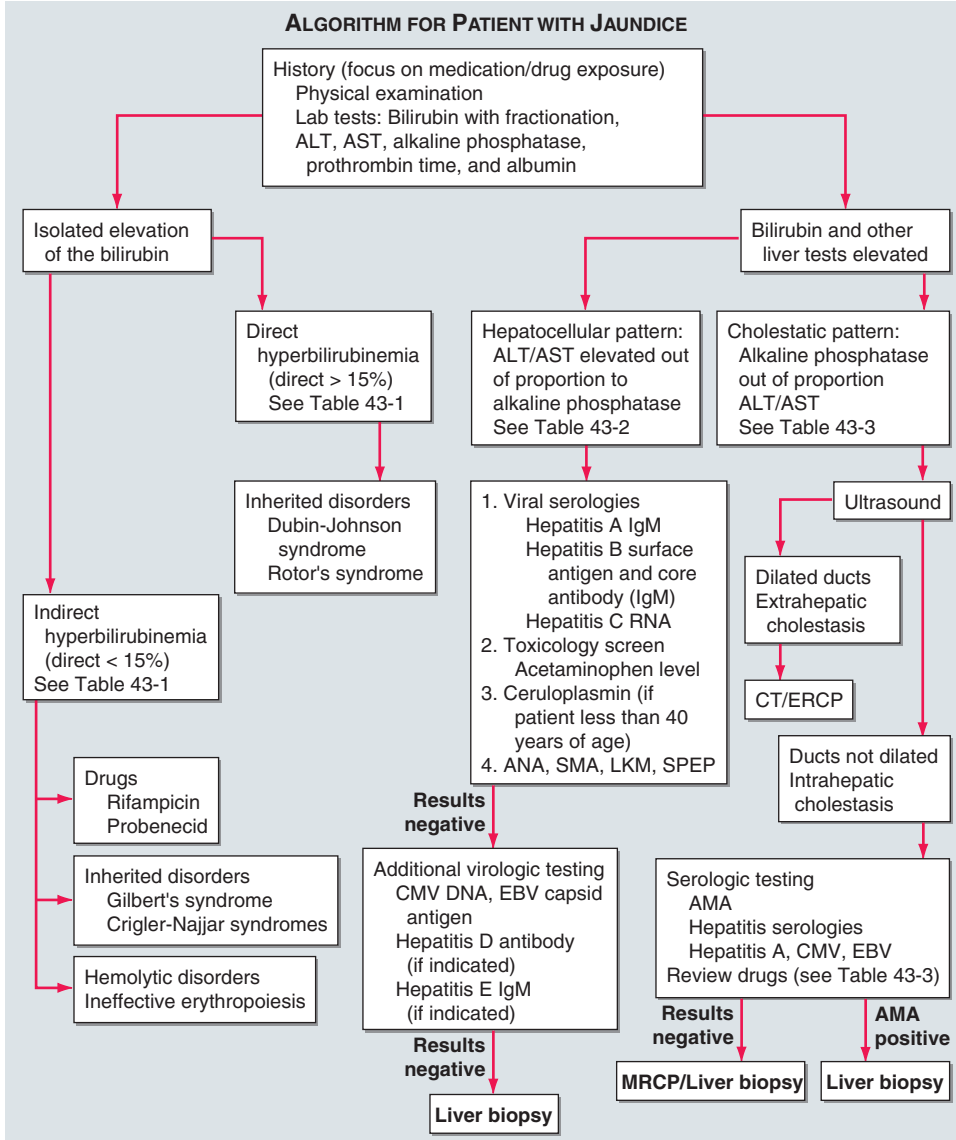

FIGURE 43-1 Evaluation of the patient with jaundice. MRCP, magnetic resonance cholangiopancreatography; ALT, alanine aminotransferase; AST, aspartate aminotransferase; SMA, smooth-muscle antibody; AMA, antimitochondrial antibody; LKM, liver-kidney microsomal antibody; SPEP, serum protein electrophoresis; CMV, cytomegalovirus; EBV, Epstein-Barr virus.

APPROACH TO THE PATIENT: Bilirubin

The bilirubin present in serum represents a balance between input from production of bilirubin and hepatic/biliary removal of the pigment. Hyperbilirubinemia may result from (1) overproduction of bilirubin; (2) impaired uptake, conjugation, or excretion of bilirubin; or (3) regurgitation of unconjugated or conjugated bilirubin from damaged hepatocytes or bile ducts. An increase in unconjugated bilirubin in serum results from either overproduction, impairment of uptake, or conjugation of bilirubin. An increase in conjugated bilirubin is due to decreased excretion into the bile ductules or backward leakage of the pigment. The initial steps in evaluating the patient with jaundice are to determine (1) whether the hyperbilirubinemia is predominantly conjugated or unconjugated in nature, and (2) whether other biochemical liver tests are abnormal. The thoughtful interpretation of limited data will allow for a rational evaluation of the patient (Fig. 43-1). This discussion will focus solely on the evaluation of the adult patient with jaundice.

ISOLATED ELEVATION OF SERUM BILIRUBIN **Unconjugated Hyperbilirubinemia** The differential diagnosis of an isolated unconjugated hyperbilirubinemia is limited (Table 43-1). The critical determination is whether the patient is suffering from a hemolytic process resulting in an overproduction of bilirubin (hemolytic disorders and ineffective erythropoiesis) or from impaired hepatic uptake/conjugation of bilirubin (drug effect or genetic disorders).

Hemolytic disorders that cause excessive heme production may be either inherited or acquired. Inherited disorders include spherocytosis, sickle cell anemia, thalassemia, and deficiency of red cell enzymes such as pyruvate kinase and glucose-6-phosphate dehydrogenase. In these conditions, the serum bilirubin rarely exceeds 86 µmol/L (5 mg/dL). Higher levels may occur when there is coexistent renal or hepatocellular dysfunction or in acute hemolysis such as a sickle cell crisis. In evaluating jaundice in patients with chronic hemolysis, it is important to remember the high incidence of pigmented (calcium bilirubinate) gallstones found in these patients, which increases the likelihood of choledocholithiasis as an alternative explanation for hyperbilirubinemia.

Acquired hemolytic disorders include microangiopathic hemolytic anemia (e.g., hemolytic-uremic syndrome), paroxysmal nocturnal hemoglobinuria, spur cell anemia, and immune hemolysis. Ineffective erythropoiesis occurs in cobalamin, folate, and iron deficiencies.

In the absence of hemolysis, the physician should consider a problem with the hepatic uptake or conjugation of bilirubin. Certain drugs, including rifampicin and probenecid, may cause unconjugated hyperbilirubinemia by diminishing hepatic uptake of

TABLE 43-1 CAUSES OF ISOLATED HYPERBILIRUBINEMIA

I. Indirect hyperbilirubinemia

    2. Rotor's syndrome

bilirubin. Impaired bilirubin conjugation occurs in three genetic conditions: Crigler-Najjar syndrome, types I and II, and Gilbert's syndrome. *Crigler-Najjar type I* is an exceptionally rare condition found in neonates and characterized by severe jaundice [bilirubin > 342 µmol/L (>20 mg/dL)] and neurologic impairment due to kernicterus, frequently leading to death in infancy or childhood. These patients have a complete absence of bilirubin UDPGT activity, usually due to mutations in the critical 3′ domain of the *UDPGT* gene, and are totally unable to conjugate, hence cannot excrete bilirubin. The only effective treatment is orthotopic liver transplantation. Use of gene therapy and allogeneic hepatocyte infusion are experimental approaches of future promise for this devastating disease.

Crigler-Najjar type II is somewhat more common than type I. Patients live into adulthood with serum bilirubin levels that range from 103–428 µmol/L (6–25 mg/dL). In these patients, mutations in the bilirubin *UDPGT* gene cause reduced but not completely absent activity of the enzyme. Bilirubin *UDPGT* activity can be induced by the administration of phenobarbital, which can reduce serum bilirubin levels in these patients. Despite marked jaundice, these patients usually survive into adulthood, although they may be susceptible to kernicterus under the stress of intercurrent illness or surgery.

Gilbert's syndrome is also marked by the impaired conjugation of bilirubin due to reduced bilirubin UDPGT activity. Patients with Gilbert's syndrome have a mild unconjugated hyperbilirubinemia with serum levels almost always <103 µmol/L (6 mg/dL). The serum levels may fluctuate, and jaundice is often identified only during periods of fasting. One molecular defect that has been identified in patients with Gilbert's syndrome is in the TATAA element in the 5′ promoter region of the bilirubin *UDPGT* gene upstream of exon 1. This defect alone is not necessarily sufficient for producing the clinical syndrome of Gilbert's as there are patients who are homozygous for this defect yet do not have the levels of hyperbilirubinemia typically seen in Gilbert's syndrome. An enhancer polymorphism that lowers transcriptional activity has recently been identified. The decrease in transcription caused by both mutations together may be critical for producing the syndrome. Unlike both Crigler-Najjar syndromes, Gilbert's syndrome is very common. The reported incidence is 3–7% of the population with males predominating over females by a ratio of 2–7:1.

Conjugated Hyperbilirubinemia Elevated conjugated hyperbilirubinemia is found in two rare inherited conditions: *Dubin-Johnson syndrome* and *Rotor's syndrome* (Table 43-1). Patients with both conditions present with asymptomatic jaundice, typically in the second generation of life. The defect in Dubin-Johnson syndrome is mutations in the gene for multiple drug resistance protein 2. These patients have altered excretion of bilirubin into the bile ducts. Rotor's syndrome seems to be a problem with the hepatic storage of bilirubin. Differentiating between these syndromes is possible, but clinically unnecessary, due to their benign nature.

ELEVATION OF SERUM BILIRUBIN WITH OTHER LIVER TEST ABNORMALITIES

The remainder of this chapter will focus on the evaluation of the patient with a conjugated hyperbilirubinemia in the setting of other liver test abnormalities. This group of patients can be divided into those with a primary hepatocellular process and those with intra- or extrahepatic cholestasis. Being able to make this differentiation will guide the physician's evaluation (Fig. 43-1). This differentiation is made on the basis of the history and physical examination as well as the pattern of liver test abnormalities.

History A complete medical history is perhaps the single most important part of the evaluation of the patient with unexplained jaundice. Important considerations include the use of or exposure to any chemical or medication, either physician-prescribed, over-the-counter, complementary or alternative medicines such as herbal and vitamin preparations, or other drugs such as anabolic steroids. The patient should be carefully questioned about possible parenteral exposures, including transfusions, IV and intranasal drug use, tattoos, and sexual activity. Other important questions include recent travel history, exposure to people with jaundice, exposure to possibly contaminated foods, occupational exposure to hepatotoxins, alcohol consumption, the duration of jaundice, and the presence of any accompanying symptoms such as arthralgias, myalgias, rash, anorexia, weight loss, abdominal pain, fever, pruritus, and changes in the urine and stool. While none of these latter symptoms are specific for any one condition, they can suggest a particular diagnosis. A history of arthralgias and myalgias predating jaundice suggests hepatitis, either viral or drug-related. Jaundice associated with the sudden onset of severe right upper quadrant pain and shaking chills suggests choledocholithiasis and ascending cholangitis.

Physical Examination The general assessment should include assessment of the patient's nutritional status. Temporal and proximal muscle wasting suggests long-standing diseases such as pancreatic cancer or cirrhosis. Stigmata of chronic liver disease, including spider nevi, palmar erythema, gynecomastia, caput medusae, Dupuytren's contractures, parotid gland enlargement, and testicular atrophy are commonly seen in advanced alcoholic (Laennec's) cirrhosis and occasionally in other types of cirrhosis. An enlarged left supraclavicular node (Virchow's node) or periumbilical nodule (Sister Mary Joseph's nodule) suggests an abdominal malignancy. Jugular venous distention, a sign of right-sided heart failure, suggests hepatic congestion. Right pleural effusion, in the absence of clinically apparent ascites, may be seen in advanced cirrhosis.

The abdominal examination should focus on the size and consistency of the liver, whether the spleen is palpable and hence enlarged, and whether there is ascites present. Patients with cirrhosis may have an enlarged left lobe of the liver, which is felt below the xiphoid, and an enlarged spleen. A grossly enlarged nodular liver or an obvious abdominal mass suggests malignancy. An enlarged tender liver could be viral or alcoholic hepatitis, an infiltrative process such as amyloid, or, less often, an acutely congested liver secondary to right-sided heart failure. Severe right upper quadrant tenderness with respiratory arrest on inspiration (Murphy's sign) suggests cholecystitis or, occasionally, ascending cholangitis. Ascites in the presence of jaundice suggests either cirrhosis or malignancy with peritoneal spread.

Laboratory Tests When the physician encounters a patient with unexplained jaundice, there is a battery of tests that are helpful in the initial evaluation. These include total and direct serum bilirubin with fractionation, aminotransferases, alkaline phosphatase, albumin, and prothrombin time tests. Enzyme tests [alanine aminotransferase (ALT), aspartate aminotransferase (AST), and alkaline phosphatase] are helpful in differentiating between a hepatocellular process and a cholestatic process (Table 296-1; Fig. 43-1), a critical step in determin-

ing what additional workup is indicated. Patients with a hepatocellular process generally have a disproportionate rise in the aminotransferases compared to the alkaline phosphatase. Patients with a cholestatic process have a disproportionate rise in the alkaline phosphatase compared to the aminotransferases. The bilirubin can be prominently elevated in both hepatocellular and cholestatic conditions and therefore is not necessarily helpful in differentiating between the two.

In addition to the enzyme tests, all jaundiced patients should have additional blood tests, specifically an albumin level and a prothrombin time, to assess liver function. A low albumin suggests a chronic process such as cirrhosis or cancer. A normal albumin is suggestive of a more acute process such as viral hepatitis or choledocholithiasis. An elevated prothrombin time indicates either vitamin K deficiency due to prolonged jaundice and malabsorption of vitamin K or significant hepatocellular dysfunction. The failure of the prothrombin time to correct with parenteral administration of vitamin K indicates severe hepatocellular injury.

The results of the bilirubin, enzyme tests, albumin, and prothrombin time tests will usually indicate whether a jaundiced patient has a hepatocellular or a cholestatic disease, as well as some indication of the duration and severity of the disease. The causes and evaluation of hepatocellular and cholestatic diseases are quite different.

Hepatocellular Conditions Hepatocellular diseases that can cause jaundice include viral hepatitis, drug or environmental toxicity, alcohol, and end-stage cirrhosis from any cause (Table 43-2). Wilson's disease, once believed to occur primarily in young adults, should be considered in all adults if no other cause of jaundice is found. Autoimmune hepatitis is typically seen in young to middle-aged women but may affect men and women of any age. Alcoholic hepatitis can be differentiated from viral and toxin-related hepatitis by the pattern of the aminotransferases. Patients with alcoholic hepatitis typically have an AST:ALT ratio of at least 2:1. The AST rarely exceeds 300 U/L. Patients with acute viral hepatitis and toxin-related injury severe enough to produce jaundice typically have aminotransferases > 500 U/L, with the ALT greater than or equal to the AST. The degree of aminotransferase elevation can occasionally help in differentiating between hepatocellular and cholestatic processes. While ALT and AST values less than 8 times normal may be seen in either hepatocellular or cholestatic liver disease, values 25 times normal or higher are seen primarily in acute hepatocellular diseases. Patients with jaundice from cirrhosis can have normal or only slight elevations of the aminotransferases.

When the physician determines that the patient has a hepatocellular disease, appropriate testing for acute viral hepatitis includes a hepatitis A IgM antibody, a hepatitis B surface antigen and core IgM antibody, and a hepatitis C viral RNA test. It can take many weeks for the hepatitis C antibody to become detectable, making it an unreliable test if acute hepatitis C is suspected. Depending on circumstances, studies for hepatitis D, E, Epstein-Barr virus (EBV), and cytomegalovirus (CMV) may be indicated. Ceruloplasmin is the initial screening test for Wilson's disease. Testing for autoimmune hepatitis usually includes an antinuclear antibody and measurement of specific immunoglobulins.

Drug-induced hepatocellular injury can be classified either as predictable or unpredictable. Predictable drug reactions are dose-dependent and affect all patients who ingest a toxic dose of the drug in question. The classic example is acetaminophen hepatotoxicity. Unpredictable or idiosyncratic drug reactions are not dose-dependent and occur in a minority of patients. A great number of drugs can cause idiosyncratic hepatic injury. Environmental toxins are also an important cause of hepatocellular injury. Examples include industrial chemicals such as vinyl chloride, herbal preparations containing pyrrolizidine alkaloids (Jamaica bush tea) and Kava Kava, and the mushrooms *Amanita phalloides* or *A. verna* that contain highly hepatotoxic amatoxins.

Cholestatic Conditions When the pattern of the liver tests suggests a cholestatic disorder, the next step is to determine whether it is intra- or extrahepatic cholestasis (Fig. 43-1). Distinguishing intrahepatic from extrahepatic cholestasis may be difficult. History, physical examination, and laboratory tests are often not helpful. The next appropriate test is an ultrasound. The ultrasound is inexpensive, does not expose the patient to ionizing radiation, and can detect dilation of the intra- and extrahepatic biliary tree with a high degree of sensitivity and specificity. The absence of biliary dilatation suggests intrahepatic cholestasis, while the presence of biliary dilatation indicates extrahepatic cholestasis. False-negative results occur in patients with partial obstruction of the common bile duct or in patients with cirrhosis or primary sclerosing cholangitis (PSC) where scarring prevents the intrahepatic ducts from dilating.

Although ultrasonography may indicate extrahepatic cholestasis, it rarely identifies the site or cause of obstruction. The distal common bile duct is a particularly difficult area to visualize by ultrasound because of overlying bowel gas. Appropriate next tests include CT, magnetic resonance cholangiography (MRCP), and endoscopic retrograde cholangiopancreatography (ERCP). CT scanning and MRCP are better than ultrasonography for assessing the head of the pancreas and for identifying choledocholithiasis in the distal common bile duct, particularly when the ducts are not dilated. ERCP is the "gold standard" for identifying choledocholithiasis. It is performed by introducing a side-viewing endoscope perorally into the duodenum. The ampulla of Vater is visualized and a catheter is advanced through the ampulla. Injection of dye allows for the visualization of the common bile duct and the pancreatic duct. The success rate for cannulation of the common bile duct ranges from 80–95%, depending on the operator's experience. Beyond its diagnostic capabilities, ERCP allows for therapeutic interventions, including the removal of common bile duct stones and the placement of stents. In patients in whom ERCP is unsuccessful and there is a high likelihood of the need for a therapeutic intervention, transhepatic cholangiography can provide the same information and allow for intervention. MRCP is a now widely available, noninvasive technique for imaging the bile and pancreatic ducts; it has replaced ERCP as the initial diagnostic test in cases where the need for intervention is felt to be small.

In patients with apparent *intrahepatic cholestasis*, the diagnosis is often made by serologic testing in combination with percutaneous liver biopsy. The list of possible causes of intrahepatic cholestasis is long and varied (Table 43-3). A number of conditions that typically cause a hepatocellular pattern of injury can also present as a cholestatic variant. Both hepatitis B and C can cause a cholestatic hepatitis (fibrosing cholestatic hepatitis). This disease variant has been reported in patients who have undergone solid organ transplantation. Hepatitis A, alcoholic hepatitis, EBV, and CMV may also present as cholestatic liver disease.

Drugs may cause intrahepatic cholestasis, a variant of drug-induced hepatitis. Drug-induced cholestasis is usually reversible after eliminating the offending drug, although it may take many

months for cholestasis to resolve. Drugs most commonly associated with cholestasis are the anabolic and contraceptive steroids. Cholestatic hepatitis has been reported with chlorpromazine, imipramine, tolbutamide, sulindac, cimetidine, and erythromycin estolate. It also occurs in patients taking trimethoprim, sulfamethoxazole, and penicillin-based antibiotics such as ampicillin, dicloxacillin, and clavulinic acid. Rarely, cholestasis may be chronic and associated with progressive fibrosis despite early discontinuation of the drug. Chronic cholestasis has been associated with chlorpromazine and prochlorperazine.

Primary biliary cirrhosis is an autoimmune disease predominantly of middle-aged women in which there is a progressive destruction of interlobular bile ducts. The diagnosis is made by the presence of the antimitochondrial antibody that is found in 95% of patients. *Primary sclerosing cholangitis* is characterized by the destruction and fibrosis of larger bile ducts. The disease may involve only the intrahepatic ducts and present as intrahepatic cholestasis. However, in 95% of patients with PSC, both intra- and extrahepatic ducts are involved. The diagnosis of PSC is made by imaging the biliary tree. The pathognomonic findings are multiple strictures of bile ducts with dilatations proximal to the strictures. Approximately 75% of patients with PSC have inflammatory bowel disease.

The *vanishing bile duct syndrome* and *adult bile ductopenia* are rare conditions in which there are a decreased number of bile ducts seen in liver biopsy specimens. The histologic picture is similar to that found in primary biliary cirrhosis. This picture is seen in patients who develop chronic rejection after liver transplantation and in those who develop graft-versus-host disease after bone marrow transplantation. Vanishing bile duct syndrome also occurs in rare cases of sarcoidosis, in patients taking certain drugs including chlorpromazine, and idiopathically.

There are also familial forms of intrahepatic cholestasis. The familial intrahepatic cholestatic syndromes include *progressive familial intrahepatic cholestasis* (PFIC) *types 1–3,* and *benign recurrent cholestasis* (BRC). PFIC1 and BRC are autosomal recessive diseases that result from mutations in the *ATP8B1* gene that encodes a protein belonging to the subfamily of P-type ATPases; the exact function of this protein remains poorly defined. While PFIC1 is a progressive condition that manifests in childhood, BRC presents later than PFIC1 and is marked by recurrent episodes of jaundice and pruritus; the episodes are self-limited but can be debilitating. PFIC2 is caused by mutations in the *ABCB11* gene, which encodes the bile salt export pump, and PFIC3 is caused by mutations in the multidrug-resistant P-glycoprotein 3. *Cholestasis of pregnancy* occurs in the second and third trimesters and resolves after delivery. Its cause is unknown, but the condition is probably inherited and cholestasis can be triggered by estrogen administration.

Other causes of intrahepatic cholestasis include total parenteral nutrition (TPN), nonhepatobiliary sepsis, benign postoperative cholestasis, and a paraneoplastic syndrome associated with a number of different malignancies, including Hodgkin's disease, medullary thyroid cancer, renal cell cancer, renal sarcoma, T cell lymphoma, prostate cancer, and several gastrointestinal malignancies. The term *Stauffer's syndrome* has been used for intrahepatic cholestasis specifically associated with renal cell cancer. In patients developing cholestasis in the intensive care unit, the major considerations should be sepsis, shock liver, and TPN jaundice. Jaundice occurring after bone marrow transplantation is most likely due to venoocclusive disease or graft-versus-host disease.

Causes of *extrahepatic cholestasis* can be split into malignant and benign (Table 43-3). Malignant causes include pancreatic, gallbladder, ampullary, and cholangiocarcinoma. The latter is most commonly associated with PSC and is exceptionally difficult to diagnose because its appearance is often identical to that of PSC. Pancreatic and gallbladder tumors, as well as cholangiocarcinoma, are rarely resectable and have poor prognoses. Ampullary carcinoma has the highest surgical cure rate of all the tumors that present as painless jaundice. Hilar lymphadenopathy due to metastases from other cancers may cause obstruction of the extrahepatic biliary tree.

Choledocholithiasis is the most common cause of extrahepatic cholestasis. The clinical presentation can range from mild right upper quadrant discomfort with only minimal elevations of the enzyme tests to ascending cholangitis with jaundice, sepsis, and circulatory collapse. PSC may occur with clinically important strictures limited to the extrahepatic biliary tree. In cases where there is a dominant stricture, patients can be effectively managed with serial endoscopic dilatations. Chronic pancreatitis rarely causes strictures of the distal common bile duct, where it passes through the head of the pancreas. AIDS cholangiopathy is a condition, usually due to infection of the bile duct epithelium with CMV or cryptosporidia, which has a cholangiographic appearance similar to that of PSC. These patients usually present with greatly elevated serum alkaline phosphatase levels (mean, 800 IU/L), but the bilirubin is often near normal. These patients do not typically present with jaundice.

SUMMARY

The goal of this chapter is not to provide an encyclopedic review of all of the conditions that can cause jaundice. Rather, it is intended to provide a framework that helps a physician to evaluate the patient with jaundice in a logical way (Fig. 43-1).

Simply stated, the initial step is to obtain appropriate blood tests to determine if the patient has an isolated elevation of serum bilirubin. If so, is the bilirubin elevation due to an increased unconjugated or con-

jugated fraction? If the hyperbilirubinemia is accompanied by other liver test abnormalities, is the disorder hepatocellular or cholestatic? If cholestatic, is it intra- or extrahepatic? All of these questions can be answered with a thoughtful history, physical examination, and interpretation of laboratory and radiologic tests and procedures.

ABDOMINAL SWELLING

Abdominal swelling or distention is a common problem in clinical medicine and may be the initial manifestation of a systemic disease or of otherwise unsuspected abdominal disease. *Subjective* abdominal enlargement, often described as a sensation of fullness or bloating, is usually transient and is often related to a functional gastrointestinal disorder when it is not accompanied by objective physical findings of increased abdominal girth or local swelling. *Obesity* and lumbar lordosis, which may be associated with prominence of the abdomen, may usually be distinguished from true increases in the volume of the peritoneal cavity by history and careful physical examination.

CLINICAL HISTORY

Abdominal swelling may first be noticed by the patient because of a progressive increase in belt or clothing size, the appearance of abdominal or inguinal hernias, or the development of a localized swelling. Often, considerable abdominal enlargement has gone unnoticed for weeks or months, either because of coexistent obesity or because the ascites formation has been insidious, without pain or localizing symptoms. Progressive abdominal distention may be associated with a sensation of "pulling" or "stretching" of the flanks or groins and vague low back pain. Localized pain usually results from involvement of an abdominal organ (e.g., a passively congested liver, large spleen, or colonic tumor). Pain is uncommon in cirrhosis with ascites, and when it is present, pancreatitis, hepatocellular carcinoma, or peritonitis should be considered. Tense ascites or abdominal tumors may produce increased intraabdominal pressure, resulting in indigestion and heartburn due to gastroesophageal reflux or dyspnea, abdominal wall hernias (inguinal and umbilical), orthopnea, and tachypnea from elevation of the diaphragm. A coexistent pleural effusion, more commonly on the right, presumably due to leakage of ascitic fluid through lymphatic channels in the diaphragm, may also contribute to respiratory embarrassment. A large pleural effusion, obscuring most of the lung, is known as a *hepatic hydrothorax*. The patient with diffuse abdominal swelling should be questioned about increased alcohol intake, a prior episode of jaundice or hematuria, or a change in bowel habits. Such historic information may provide the clues that will lead one to suspect an occult cirrhosis, a colonic tumor with peritoneal seeding, congestive heart failure, or nephrosis.

PHYSICAL EXAMINATION

A carefully executed general physical examination can yield valuable clues concerning the etiology of abdominal swelling. Thus palmar erythema and spider angiomas suggest an underlying cirrhosis, while supraclavicular adenopathy (Virchow's node) should raise the question of an underlying gastrointestinal malignancy.

Inspection of the abdomen is important. By noting the abdominal contour, one may be able to distinguish localized from generalized swelling. The tensely distended abdomen with tightly stretched skin, bulging flanks, and everted umbilicus is characteristic of ascites. A prominent abdominal venous pattern with the direction of flow away from the umbilicus is often a reflection of portal hypertension; venous collaterals with flow from the lower part of the abdomen toward the umbilicus suggest obstruction of the inferior vena cava; flow downward toward the umbilicus suggests superior vena cava obstruction. "Doming" of the abdomen with visible ridges from underlying intestinal loops is usually due to intestinal obstruction or distention. An epigastric mass, with evident peristalsis proceeding from left to right, usually indicates underlying pyloric obstruction. A liver with metastatic deposits may be visible as a nodular right upper quadrant mass moving with respiration.

Auscultation may reveal the high-pitched, rushing sounds of early intestinal obstruction or a succussion sound due to increased fluid and gas in a dilated hollow viscus. Careful auscultation over an enlarged liver occasionally reveals a harsh bruit signifying a vascular tumor (especially a hepatocellular carcinoma) or alcoholic hepatitis, or the leathery friction rub of a surface nodule. A venous hum at the umbilicus may signify portal hypertension and an increased collateral blood flow around the liver. A fluid wave and flank dullness that shifts with change in position of the patient are important signs that indicate the presence of peritoneal fluid, although a minimum of 1500 mL of fluid is usually required to produce these findings. In obese patients, small amounts of fluid may be difficult to demonstrate and often can only be detected by ultrasound examination of the abdomen, which can detect as little as 100 mL of fluid. Careful percussion should serve to distinguish generalized abdominal enlargement from localized swelling due to an enlarged uterus, ovarian cyst, or distended bladder. Percussion can also outline an abnormally small or large liver. Loss of normal liver dullness may result from massive hepatic necrosis; it also may be a clue to free gas in the peritoneal cavity, as from perforation of a hollow viscus.

Palpation is often difficult with massive ascites, and ballottement of overlying fluid may be the only method of palpating the liver or spleen. A slightly enlarged spleen in association with ascites may be the only evidence of an occult cirrhosis. When there is evidence of portal hypertension, a soft liver suggests that obstruction to portal flow is extrahepatic; a firm liver suggests cirrhosis as the likely cause of the portal hypertension. A very hard or nodular liver is a clue that the liver is infiltrated with tumor, and when accompanied by ascites, it suggests that the latter is due to peritoneal seeding. The presence of a hard periumbilical nodule (Sister Mary Joseph's nodule) suggests metastatic disease from a pelvic or gastrointestinal primary tumor. A pulsatile liver and ascites may be found in tricuspid insufficiency.

An attempt should be made to determine whether a mass is solid or cystic, smooth or irregular, and whether it moves with respiration. The liver, spleen, and gallbladder should descend with respiration unless they are fixed by adhesions or extension of tumor beyond the organ. A fixed mass not descending with respiration may indicate that it is retroperitoneal. Tenderness, especially if localized, may indicate an inflammatory process such as an abscess; it also may be due to stretching of the visceral peritoneum or tumor necrosis. Rectal and pelvic examinations are mandatory; they may reveal otherwise undetected masses due to tumor or infection.

Radiographic and laboratory examinations are essential for confirming or extending the impressions gained on physical examination. Upright and recumbent films of the abdomen may demonstrate the dilated loops of intestine with fluid levels characteristic of intestinal obstruction or the diffuse abdominal haziness and loss of psoas margins suggestive of ascites. Ultrasonography is often of value in detecting ascites, determining the presence of a mass, or evaluating the size of the liver and

TABLE 44-1 CHARACTERISTICS OF ASCITIC FLUID IN VARIOUS DISEASE STATES

Condition	Gross Appearance	Protein, g/L	Serum-Ascites Albumin Gradient, g/dL	Cell Count		Other Tests
				Red Blood Cells, >10,000/μL	White Blood Cells, per μL	
Cirrhosis	Straw-colored or bile-stained	<25 (95%)	>1.1	1%	<250 (90%)[a]; predominantly mesothelial	
Neoplasm	Straw-colored, hemorrhagic, mucinous, or chylous	>25 (75%)	<1.1	20%	>1000 (50%); variable cell types	Cytology, cell block, peritoneal biopsy
Tuberculous peritonitis	Clear, turbid, hemorrhagic, chylous	>25 (50%)	<1.1	7%	>1000 (70%); usually >70% lymphocytes	Peritoneal biopsy, stain and culture for acid-fast bacilli
Pyogenic peritonitis	Turbid or purulent	If purulent, >25	<1.1	Unusual	Predominantly polymorphonuclear leukocytes	Positive Gram's stain, culture
Congestive heart failure	Straw-colored	Variable, 15–53	>1.1	10%	<1000 (90%); usually mesothelial, mononuclear	
Nephrosis	Straw-colored or chylous	<25 (100%)	<1.1	Unusual	<250; mesothelial, mononuclear	If chylous, ether extraction, Sudan staining
Pancreatic ascites (pancreatitis, pseudocyst)	Turbid, hemorrhagic, or chylous	Variable, often >25	<1.1	Variable, may be blood-stained	Variable	Increased amylase in ascitic fluid and serum

[a]Because the conditions of examining fluid and selecting patients were not identical in each series, the percentage figures (in parentheses) should be taken as an indication of the order of magnitude rather than as the precise incidence of any abnormal finding.

spleen. CT scanning provides similar information and is often necessary to visualize the retroperitoneum, pancreas, and lymph nodes. A plain film of the abdomen may reveal the distended colon of otherwise unsuspected ulcerative colitis and give valuable information as to the size of the liver and spleen. An irregular and elevated right side of the diaphragm may be a clue to a liver abscess or hepatocellular carcinoma. Studies of the gastrointestinal tract with barium or other contrast media are usually necessary in the search for a primary tumor.

Laboratory abnormalities that are highly suggestive of cirrhosis as the cause of ascites include unexplained thrombocytopenia, decreased albumin, and a prolonged prothrombin time.

ASCITES

The evaluation of a patient with ascites requires that the cause of the ascites be established. In most cases ascites appears as part of a well-recognized illness, i.e., cirrhosis, congestive heart failure, nephrosis, or disseminated carcinomatosis. In these situations, the physician should determine that the development of ascites is indeed a consequence of the basic underlying disease and not due to the presence of a separate or related disease process. This distinction is necessary even when the cause of ascites seems obvious. For example, when the patient with compensated cirrhosis and minimal ascites develops progressive ascites that is increasingly difficult to control with sodium restriction or diuretics, the temptation is to attribute the worsening of the clinical picture to progressive liver disease. However, an occult hepatocellular carcinoma, portal vein thrombosis, spontaneous bacterial peritonitis, alcoholic hepatitis, viral infection, or even tuberculosis may be responsible for the decompensation. The disappointingly low success in diagnosing tuberculous peritonitis or hepatocellular carcinoma in the patient with cirrhosis and ascites reflects the too-low index of suspicion for the development of such superimposed conditions. Similarly, the patient with congestive heart failure may develop ascites from a disseminated carcinoma with peritoneal seeding. It is important to note, however, that while there are many different causes of ascites, in the United States >80% of cases are due to cirrhosis. Risk factors for the development of cirrhosis include alcoholism, viral hepatitis, nonalcoholic steatohepatitis, and a family history of liver disease.

Diagnostic paracentesis (50–100 mL) should be part of the routine evaluation of the patient with ascites, and does not routinely require the prior administration of platelets or fresh-frozen plasma unless disseminated intravascular coagulation is suspected. The fluid should be examined for its gross appearance; protein content, albumin level, cell count, and differential cell count should be determined; and Gram's and acid-fast stains and culture should be performed. Cytologic and cell-block examination may disclose an otherwise unsuspected carcinoma. A serum ascites–albumin gradient (SAAG) should be calculated to determine if the fluid has the features of a transudate or an exudate. The gradient correlates directly with portal pressure. A gradient >1.1 g/dL (high gradient) is characteristic of uncomplicated cirrhotic ascites and differentiates ascites due to portal hypertension from ascites not due to portal hypertension >97% of the time. Other etiologies of high-gradient ascites include alcoholic hepatitis, congestive heart failure, hepatic metastases, constrictive pericarditis, and Budd-Chiari syndrome. A gradient <1.1 g/dL (low gradient) suggests that the ascites is not due to portal hypertension with >97% accuracy and mandates a search for other causes such as peritoneal carcinomatosis, tuberculous peritonitis, pancreatitis, serositis, pyogenic peritonitis, and nephrotic syndrome (Table 44-1). Table 44-1 presents some of the disease states that produce high-SAAG and low-SAAG ascites. Although there is variability of the ascitic fluid in any given disease state, some features are sufficiently characteristic to suggest certain diagnostic possibilities. For example, blood-stained fluid with >25 g/L protein is unusual in uncomplicated cirrhosis but is consistent with tuberculous peritonitis or neoplasm. Cloudy fluid with a predominance of polymorphonuclear cells (>250/μL) and a positive Gram's stain are characteristic of bacterial peritonitis, which requires antibiotic therapy; if most cells are lymphocytes, tuberculosis should be suspected. The complete examination of each fluid is most important, for occasionally only one finding may be abnormal. For example, if the fluid is a typical transudate but contains >250 white blood cells per microliter, the finding should be recognized as atypical for cirrhosis and should warrant a search for tumor or infection. This is especially true in the evaluation of cirrhotic ascites where occult peritoneal infection may be present with only minor elevations in the white blood cell count of the peritoneal fluid (300–500/μL). Since Gram's stain of the fluid may be negative in a high proportion of such cases, careful culture of the peritoneal fluid is mandatory. Bedside inoculation of blood culture flasks with ascitic fluid results in a dramatically increased incidence of positive cultures when bacterial infection is present (90 vs. 40% positivity with conventional cultures done by the laboratory). Direct visualization of the peritoneum (laparoscopy) may disclose peritoneal deposits of tumor, tuberculosis, or metastatic disease of the liver. Biopsies are taken under direct vision, often adding to the diagnostic accuracy of the procedure.

Chylous ascites refers to a turbid, milky, or creamy peritoneal fluid due to the presence of thoracic or intestinal lymph. Such a fluid shows Sudan-staining fat globules microscopically and an increased triglyceride content by chemical examination. Opaque milky fluid usually has a triglyceride concentration of >11.3 mmol/L (>1000 mg/dL), but a triglyceride concentration of >2.3 mmol/L (>200 mg/dL) is sufficient for the diagnosis. A turbid fluid due to leukocytes or tumor cells may be confused with chylous fluid (pseudochylous), and it is often helpful to carry out alkalinization and ether extraction of the specimen. Alkali tend to dissolve cellular proteins and thereby reduce turbidity; ether extraction leads to clearing if the turbidity of the fluid is due to lipid. Chylous ascites is most often the result of lymphatic disruption or obstruction from cirrhosis, tumor, trauma, tuberculosis, filariasis (Chap. 211), or congenital abnormalities. It may also be seen in the nephrotic syndrome.

Rarely, ascitic fluid may be *mucinous* in character, suggesting either pseudomyxoma peritonei (Chap. 291) or rarely a colloid carcinoma of the stomach or colon with peritoneal implants.

On occasion, ascites may develop as a seemingly isolated finding in the absence of a clinically evident underlying disease. Then, a careful analysis of ascitic fluid may indicate the direction the evaluation should take. A useful framework for the workup starts with an analysis of whether the fluid is classified as a high (transudate) or low (exudate) gradient fluid. *High-gradient (transudative) ascites* of unclear etiology is most often due to occult cirrhosis, right-sided venous hypertension raising hepatic sinusoidal pressure, Budd-Chiari syndrome, or massive hepatic metastases. Cirrhosis with well-preserved liver function (normal albumin) resulting in ascites is invariably associated with significant portal hypertension (Chap. 301). Evaluation should include liver function tests and a hepatic imaging procedure (i.e., CT or ultrasound) to detect nodular changes in the liver suggesting portal hypertension. On occasion, a wedged hepatic venous pressure can be useful to document portal hypertension. Finally, if clinically indicated, a liver biopsy will confirm the diagnosis of cirrhosis and perhaps suggest its etiology. Other etiologies may result in hepatic venous congestion and resultant ascites. Right-sided cardiac valvular disease and particularly constrictive pericarditis should raise a high index of suspicion and may require cardiac imaging and cardiac catheterization for definitive diagnosis. Hepatic vein thrombosis is evaluated by visualizing the hepatic veins with imaging techniques (Doppler ultrasound, angiography, CT scans, MRI) to demonstrate obliteration, thrombosis, or obstruction by tumor. Uncommonly, transudative ascites may be associated with benign tumors of the ovary, particularly fibroma (Meigs' syndrome) with ascites and hydrothorax.

Low-gradient (exudative) ascites should initiate an evaluation for primary peritoneal processes, most importantly infection and tumor. Tuberculous peritonitis (Table 44-1) is best diagnosed by peritoneal biopsy, either percutaneously or via laparoscopy. Histologic examination invariably shows granulomata that may contain acid-fast bacilli. Since cultures of peritoneal fluid and biopsies for tuberculosis may require 6 weeks, characteristic histology with appropriate stains allows antituberculosis therapy to be started promptly. Similarly, the diagnosis of peritoneal seeding by tumor can usually be made by cytologic analysis of peritoneal fluid or by peritoneal biopsy if cytology is negative. Appropriate diagnostic studies can then be undertaken to determine the nature and site of the primary tumor. Pancreatic ascites (Table 44-1) is invariably associated with an extravasation of pancreatic fluid from the pancreatic ductal system, most commonly from a leaking pseudocyst. Ultrasound or CT examination of the pancreas followed by visualization of the pancreatic duct by direct cannulation [viz., endoscopic retrograde cholangiopancreatography (ERCP)] usually discloses the site of leakage and permits resective surgery to be carried out.

An analysis of the physiologic and metabolic factors involved in the production of ascites (detailed in Chap. 301), coupled with a complete evaluation of the nature of the ascitic fluid, invariably discloses the etiology of the ascites and permits appropriate therapy to be instituted.

ACKNOWLEDGMENT

SECTION 7 ALTERATIONS IN RENAL AND URINARY TRACT FUNCTION

45 Azotemia and Urinary Abnormalities

Bradley M. Denker, Barry M. Brenner

Normal kidney functions occur through numerous cellular processes to maintain body homeostasis. Disturbances in any of these functions can lead to a constellation of abnormalities that may be detrimental to survival. The clinical manifestations of these disorders will depend upon the pathophysiology of the renal injury and will often be initially identified as a complex of symptoms, abnormal physical findings, and laboratory changes that together make possible the identification of specific syndromes. These renal syndromes (Table 45-1) may arise as the consequence of a systemic illness or can occur as a primary renal disease. Nephrologic syndromes usually consist of several elements that reflect the underlying pathologic processes. The duration and severity of the disease will affect these findings and typically include one or more of the following: (1) disturbances in urine volume (oliguria, anuria, polyuria); (2) abnormalities of urine sediment [red blood cells (RBC); white blood cells, casts, and crystals]; (3) abnormal excretion of serum proteins (proteinuria); (4) reduction in glomerular filtration rate (GFR) (azotemia); (5) presence of hypertension and/or expanded total body fluid volume (edema); (6) electrolyte abnormalities; or (7) in some syndromes, fever/pain. The combination of these findings should permit identification of one of the major nephrologic syndromes (Table 45-1) and will allow differential diagnoses to be narrowed and the appropriate diagnostic evaluation and therapeutic course to be determined. Each of these syndromes and their associated diseases are discussed in more detail in subsequent chapters. This chapter will focus on several aspects of renal abnormalities that are critically important to distinguishing among these processes: (1) reduction in GFR leading to azotemia, (2) alterations of the urinary sediment and/or protein excretion, and (3) abnormalities of urinary volume.

TABLE 45-1 INITIAL CLINICAL AND LABORATORY DATA BASE FOR DEFINING MAJOR SYNDROMES IN NEPHROLOGY

Syndromes	Important Clues to Diagnosis	Findings That Are Common	Location of Discussion of Disease-Causing Syndrome
Acute or rapidly progressive renal failure	Anuria Oliguria Documented recent decline in GFR	Hypertension, hematuria Proteinuria, pyuria Casts, edema	Chaps. 273, 277, 279, 283
Acute nephritis	Hematuria, RBC casts Azotemia, oliguria Edema, hypertension	Proteinuria Pyuria Circulatory congestion	Chap. 277
Chronic renal failure	Azotemia for >3 months Prolonged symptoms or signs of uremia Symptoms or signs of renal osteodystrophy Kidneys reduced in size bilaterally Broad casts in urinary sediment	Proteinuria Casts Polyuria, nocturia Edema, hypertension Electrolyte disorders	Chaps. 272, 274
Nephrotic syndrome	Proteinuria >3.5 g per 1.73 m^2 per 24 h Hypoalbuminemia Edema Hyperlipidemia	Casts Lipiduria	Chap. 277
Asymptomatic urinary abnormalities	Hematuria Proteinuria (below nephrotic range) Sterile pyuria, casts		Chap. 277
Urinary tract infection/pyelonephritis	Bacteriuria >10^5 colonies per milliliter Other infectious agent documented in urine Pyuria, leukocyte casts Frequency, urgency Bladder tenderness, flank tenderness	Hematuria Mild azotemia Mild proteinuria Fever	Chap. 282
Renal tubule defects	Electrolyte disorders Polyuria, nocturia Renal calcification Large kidneys Renal transport defects	Hematuria "Tubular" proteinuria (<1 g/24 h) Enuresis	Chaps. 278, 279
Hypertension	Systolic/diastolic hypertension	Proteinuria Casts Azotemia	Chaps. 241, 280
Nephrolithiasis	Previous history of stone passage or removal Previous history of stone seen by x-ray Renal colic	Hematuria Pyuria Frequency, urgency	Chap. 281
Urinary tract obstruction	Azotemia, oliguria, anuria Polyuria, nocturia, urinary retention Slowing of urinary stream Large prostate, large kidneys Flank tenderness, full bladder after voiding	Hematuria Pyuria Enuresis, dysuria	Chap. 283

Note: GFR; glomerular filtration rate; RBC, red blood cell.

AZOTEMIA

ASSESSMENT OF GLOMERULAR FILTRATION RATE

Monitoring the GFR is important in both the hospital and outpatient settings, and several different methodologies are available (discussed below). In most acute clinical circumstances a measured GFR is not available, and the serum creatinine level is used to estimate the GFR in order to supply appropriate doses of renally excreted drugs and to follow short-term changes in GFR. Serum creatinine is the most widely used marker for GFR, and the GFR is related directly to the urine creatinine excretion and inversely to the serum creatinine (U_{Cr}/P_{Cr}). The creatinine clearance is calculated from these measurements for a defined time period (usually 24 h) and is expressed in mL/min. Based upon this relationship and some important caveats (discussed below), the GFR will fall in roughly inverse proportion to the rise in P_{Cr}. Failure to account for GFR reductions in drug dosing can lead to significant morbidity and mortality from drug toxicities (e.g., digoxin, aminoglycosides). In the outpatient setting, the serum creatinine is often used as a surrogate for GFR (although much less accurate; see below). In patients with chronic progressive renal disease there is an approximately linear relationship between $1/P_{Cr}$ and time. The slope of this line will remain constant for an individual patient, and when values are obtained that do not fall on this line, an investigation for a superimposed acute process (e.g., volume depletion, drug reaction) should be initiated. It should be emphasized that the signs and symptoms of uremia will develop at significantly different levels of serum creatinine depending upon the patient (size, age, and sex), the underlying renal disease, existence of concurrent diseases, and true GFR. In general, patients do not develop symptomatic uremia until renal insufficiency is usually quite severe (GFR < 15 mL/min).

A reduced GFR leads to retention of nitrogenous waste products (azotemia) such as urea and creatinine. Azotemia may result from reduced renal perfusion, intrinsic renal disease, or postrenal processes (ureteral obstruction; see below and Fig. 45-1). Precise determination of GFR is problematic as both commonly measured indices (urea and creatinine) have characteristics that affect their accuracy as markers of clearance. Urea clearance may significantly underestimate GFR because of tubule urea reabsorption. Creatinine is derived from muscle metabolism of creatine, and its generation varies little from day to day. Creatinine is useful for estimating GFR because it is a small, freely filtered solute. However, serum creatinine levels can increase acutely from dietary ingestion of cooked meat, and creatinine can be secreted into the proximal tubule through an organic cation pathway, leading to overestimation of the GFR. There are many clinical settings where a creatinine clearance is not available, and decisions concerning drug dosing must be made based on the serum creatinine. Two formulas are widely used to estimate GFR: (1) Cockcroft-Gault, which accounts for age and muscle mass (this value should be multiplied by 0.85 for women, since a lower fraction of the body weight is composed of muscle):

$$\text{Creatinine clearance (mL/min)} = \frac{(140 - \text{age}) \times \text{lean body weight (kg)}}{\text{plasma creatinine (mg/dL)} \times 72}$$

and (2) MDRD (modification of diet in renal disease):

$$\text{GFR (mL/min per 1.73 m}^2) = 186.3 \times P_{Cr}^{(-1.154)} \times \text{age}^{(-0.203)} \times (0.742 \text{ if female}) \times (1.21 \text{ if black}).$$

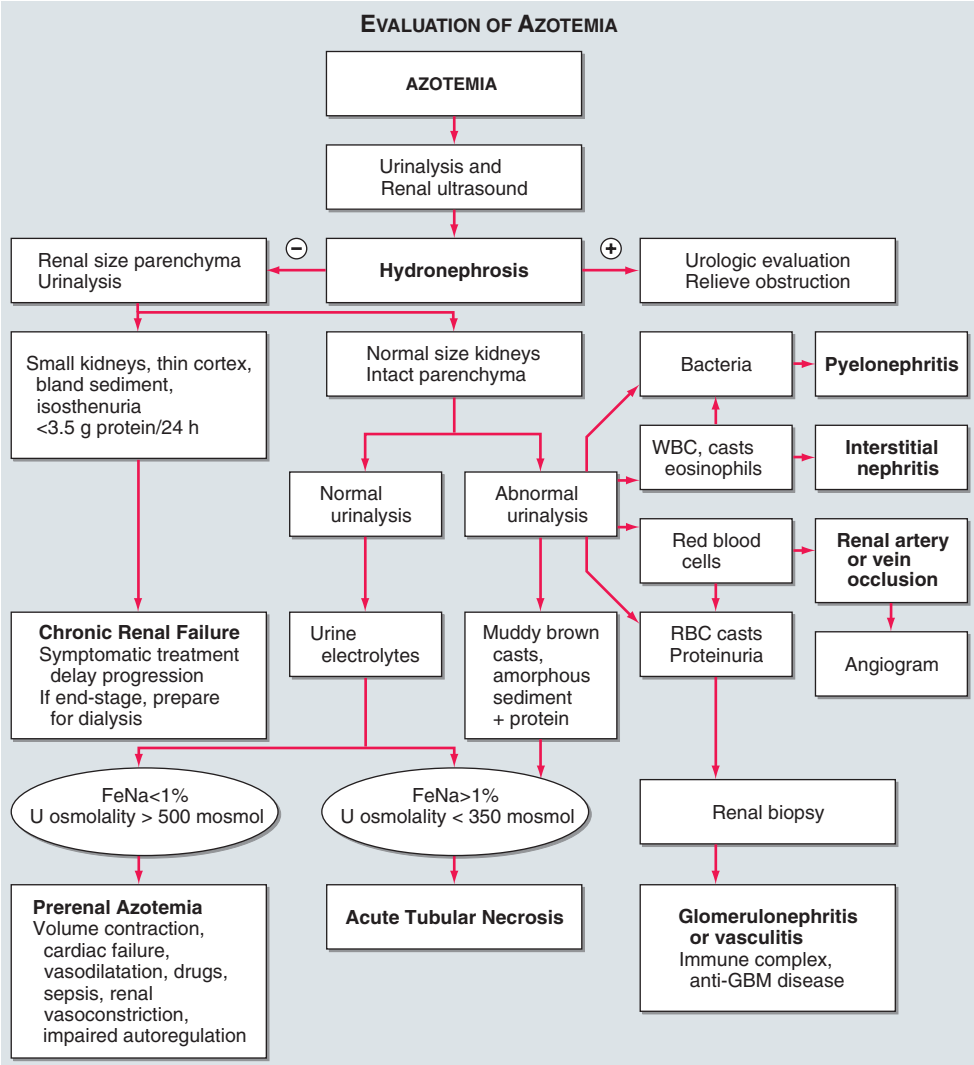

FIGURE 45-1 Approach to the patient with azotemia. WBC, white blood cell; RBC, red blood cell; GBM, glomerular basement membrane.

Although more cumbersome than Cockcroft-Gault, the MDRD equation is felt to be more accurate, and numerous websites are available for making the calculation (*www.kidney.org/professionals/kdoqi/gfr_calculator.cfm*).

The gradual loss of muscle from chronic illness, chronic use of glucocorticoids, or malnutrition can mask significant changes in GFR with small or imperceptible changes in serum creatinine concentration. More accurate determinations of GFR are available using inulin clearance or radionuclide-labeled markers such as ^{125}I-iothalamate or EDTA. These methods are highly accurate due to precise quantitation and the absence of any renal reabsorption/secretion and should be used to follow GFR in patients in whom creatinine is not likely to be a reliable indicator (patients with decreased muscle mass secondary to age, malnutrition, concurrent illnesses). (See also Table 274-2.) Cystatin C is a member of the cystatin superfamily of cysteine protease inhibitors and is produced at a relatively constant rate from all nucleated cells. Cystatin C production is not affected by diet or nutritional status and may provide a more sensitive indicator of GFR than the plasma creatinine concentration. However, it remains to be validated in many clinical settings.

APPROACH TO THE PATIENT: Azotemia

Once it has been established that GFR is reduced, the physician must decide if this represents acute or chronic renal injury. The clinical situation, history, and laboratory data often make this an easy distinction. However, the laboratory abnormalities characteristic of chronic renal failure, including anemia, hypocalcemia, and hyperphosphatemia, are often also present in patients presenting with acute renal failure. Radiographic evidence of renal osteodystrophy (Chap. 274) would be seen only in chronic renal failure but is a very late finding, and these patients are usually on dialysis. The urinalysis and renal ultrasound can occasionally facilitate distinguishing acute from chronic renal failure. An approach to the evaluation of azotemic patients is shown in Fig. 45-1. Patients with advanced chronic renal insufficiency often have some proteinuria, nonconcentrated urine (isosthenuria; isoosmotic with plasma), and small kidneys on ultrasound, characterized by increased echogenicity and cortical thinning. Treatment should be directed toward slowing the progression of renal disease and providing symptomatic relief for edema, acidosis, anemia, and hyperphosphatemia, as discussed in Chap. 274. Acute renal failure (Chap. 273) can result from processes affecting renal blood flow (prerenal azotemia), intrinsic renal diseases (affecting small vessels, glomeruli, or tubules), or postrenal processes (obstruction to urine flow in ureters, bladder, or urethra) (Chap. 283).

Prerenal Failure Decreased renal perfusion accounts for 40–80% of acute renal failure and, if appropriately treated, is readily reversible. The etiologies of prerenal azotemia include any cause of decreased circulating blood volume (gastrointestinal hemorrhage, burns, diarrhea, diuretics), volume sequestration (pancreatitis, peritonitis, rhabdomyolysis), or decreased effective arterial volume (cardiogenic shock, sepsis). Renal perfusion can also be affected by reductions in cardiac output from peripheral vasodilatation (sepsis, drugs) or profound renal vasoconstriction [severe heart failure, hepatorenal syndrome, drugs such as nonsteroidal anti-inflammatory drugs (NSAIDs)]. True, or "effective," arterial hypovolemia leads to a fall in mean arterial pressure, which in turn triggers a series of neural and humoral responses that include activation of the sympathetic nervous and renin-angiotensin-aldosterone systems and ADH release. GFR is maintained by prostaglandin-mediated relaxation of afferent arterioles and angiotensin II–mediated constriction of efferent arterioles. Once the mean arterial pressure falls below 80 mmHg, there is a steep decline in GFR.

Blockade of prostaglandin production by NSAIDs can result in severe vasoconstriction and acute renal failure. Angiotensin-converting enzyme (ACE) inhibitors decrease efferent arteriolar tone and in turn decrease glomerular capillary perfusion pressure. Patients on NSAIDs and/or ACE inhibitors are most susceptible to hemodynamically mediated acute renal failure when blood volume is reduced for any reason. Patients with bilateral renal artery stenosis (or stenosis in a solitary kidney) are dependent upon efferent arteriolar vasoconstriction for maintenance of glomerular filtra-

tion pressure and are particularly susceptible to precipitous decline in GFR when given ACE inhibitors.

Prolonged renal hypoperfusion can lead to acute tubular necrosis (ATN; an intrinsic renal disease discussed below). The urinalysis and urinary electrolytes can be useful in distinguishing prerenal azotemia from ATN (Table 45-2). The urine of patients with prerenal azotemia can be predicted from the stimulatory actions of norepinephrine, angiotensin II, ADH, and low tubule fluid flow rate on salt and water reabsorption. In prerenal conditions, the tubules are intact leading to a concentrated urine (>500 mosm), avid Na retention (urine Na concentration < 20 m*M*/L; fractional excretion of Na < 1%), and U_{Cr}/P_{Cr} > 40 (Table 45-2). The prerenal urine sediment is usually normal or has occasional hyaline and granular casts, while the sediment of ATN is usually filled with cellular debris and dark (muddy brown) granular casts.

Postrenal Azotemia Urinary tract obstruction accounts for <5% of cases of acute renal failure, but it is usually reversible and must be ruled out early in the evaluation (Fig. 45-1). Since a single kidney is capable of adequate clearance, acute renal failure from obstruction requires obstruction at the urethra or bladder outlet, bilateral ureteral obstruction, or unilateral obstruction in a patient with a single functioning kidney. Obstruction is usually diagnosed by the presence of ureteral and renal pelvic dilatation on renal ultrasound. However, early in the course of obstruction or if the ureters are unable to dilate (such as encasement by pelvic tumors or periureteral), the ultrasound examination may be negative. **The specific urologic conditions that cause obstruction are discussed in Chap. 283.**

Intrinsic Renal Disease When prerenal and postrenal azotemia have been excluded as etiologies of renal failure, an intrinsic parenchymal renal disease is present. Intrinsic renal disease can arise from processes involving large renal vessels, intrarenal microvasculature and glomeruli, or tubulointerstitium. Ischemic and toxic ATN account for ~90% of acute intrinsic renal failure. As outlined in Fig. 45-1, the clinical setting and urinalysis are helpful in separating the possible etiologies of acute intrinsic renal failure. Prerenal azotemia and ATN are part of a spectrum of renal hypoperfusion; evidence of structural tubule injury is present in ATN, whereas prompt reversibility occurs with prerenal azotemia upon restoration of adequate renal perfusion. Thus, ATN can often be distinguished from prerenal azotemia by urinalysis and urine electrolyte composition (Table 45-2 and Fig. 45-1). Ischemic ATN is observed most frequently in patients who have undergone major surgery, trauma, severe hypovolemia, overwhelming sepsis, or extensive burns. Nephrotoxic ATN complicates the administration of many common medications, usually by inducing a combination of intrarenal vasoconstriction, direct tubule toxicity, and/or tubule obstruction. The kidney is vulnerable to toxic injury by virtue of its rich blood supply (25% of cardiac output) and its ability to concentrate and metabolize toxins. A diligent search for hypotension and nephrotoxins will usually uncover the specific etiology of ATN.

TABLE 45-2 LABORATORY FINDINGS IN ACUTE RENAL FAILURE

Index	Prerenal Azotemia	Oliguric Acute Renal Failure
BUN/P_{Cr} Ratio	>20:1	10–15:1
Urine sodium (U_{Na}), meq/L	<20	>40
Urine osmolality, mosmol/L H_2O	>500	<350
Fractional excretion of sodium	<1%	>2%
$FE_{Na} = \frac{U_{Na} \times P_{Cr} \times 100}{P_{Na} \times U_{Cr}}$		
Urine/plasma creatinine (U_{Cr}/P_{Cr})	>40	<20

Note: BUN, Blood urea nitrogen; P_{Cr}, plasma creatinine; U_{Na}, urine sodium concentration; P_{Na}, plasma sodium concentration; U_{Cr}, urine creatinine concentration.

Discontinuation of nephrotoxins and stabilizing blood pressure will often suffice without the need for dialysis while the tubules recover. **An extensive list of potential drugs and toxins implicated in ATN can be found in Chap. 273.**

Processes that involve the tubules and interstitium can lead to acute renal failure. These include drug-induced interstitial nephritis (especially antibiotics, NSAIDs, and diuretics), severe infections (both bacterial and viral), systemic diseases (e.g., systemic lupus erythematosus), or infiltrative disorders (e.g., sarcoid, lymphoma, or leukemia). A list of drugs associated with allergic interstitial nephritis can be found in Chap. 279. The urinalysis usually shows mild to moderate proteinuria, hematuria, and pyuria (~75% of cases) and occasionally white blood cell casts. The finding of RBC casts in interstitial nephritis has been reported but should prompt a search for glomerular diseases (Fig. 45-1). Occasionally renal biopsy will be needed to distinguish among these possibilities. The finding of eosinophils in the urine is suggestive of allergic interstitial nephritis or atheroembolic renal disease and is optimally observed by using a Hansel stain. The absence of eosinophiluria, however, does not exclude these possible etiologies.

Occlusion of large renal vessels including arteries and veins is an uncommon cause of acute renal failure. A significant reduction in GFR by this mechanism suggests bilateral processes or a unilateral process in a patient with a single functioning kidney. Renal arteries can be occluded with atheroemboli, thromboemboli, in situ thrombosis, aortic dissection, or vasculitis. Atheroembolic renal failure can occur spontaneously but is most often associated with recent aortic instrumentation. The emboli are cholesterol-rich and lodge in medium and small renal arteries, leading to an eosinophil-rich inflammatory reaction. Patients with atheroembolic acute renal failure often have a normal urinalysis, but the urine may contain eosinophils and casts. The diagnosis can be confirmed by renal biopsy, but this is often unnecessary when other stigmata of atheroemboli are present (livedo reticularis, distal peripheral infarcts, eosinophilia). Renal artery thrombosis may lead to mild proteinuria and hematuria, whereas renal vein thrombosis typically induces heavy proteinuria and hematuria. **These vascular complications often require angiography for confirmation and are discussed in Chap. 280.**

Diseases of glomeruli (glomerulonephritis or vasculitis) and the renal microvasculature (hemolytic uremic syndromes, thrombotic thrombocytopenic purpura, or malignant hypertension) usually present with various combinations of glomerular injury: proteinuria, hematuria, reduced GFR, and alterations of Na excretion leading to hypertension, edema, and circulatory congestion (acute nephritic syndrome). These findings may occur as primary renal diseases or as renal manifestations of systemic diseases. The clinical setting and other laboratory data will help distinguish primary renal from systemic diseases. The finding of RBC casts in the urine is an indication for early renal biopsy (Fig. 45-1) as the pathologic pattern has important implications for diagnosis, prognosis, and treatment. Hematuria without RBC casts can also be an indication of glomerular disease, and this evaluation is summarized in **Fig. 45-2. A detailed discussion of glomerulonephritis and diseases of the microvasculature can be found in Chap. 277.**

Oliguria and Anuria *Oliguria* refers to a 24-h urine output of <500 mL, and *anuria* is the complete absence of urine formation (<50 mL). Anuria can be caused by total urinary tract obstruction, total renal artery or vein occlusion, and shock (manifested by severe hypotension and intense renal vasoconstriction). Cortical necrosis, ATN, and rapidly progressive glomerulonephritis can occasionally cause anuria. Oliguria can accompany any cause of acute renal failure and carries a more serious prognosis for renal recovery in all conditions except prerenal azotemia. *Nonoliguria* refers to urine output >500 mL/d in patients with acute or chronic azotemia. With nonoliguric ATN, disturbances of potassium and hydrogen balance are less severe than in oliguric patients, and recovery to normal renal function is usually more rapid.

ABNORMALITIES OF THE URINE

PROTEINURIA

The evaluation of proteinuria is shown schematically in Fig. 45-3 and is typically initiated after detection of proteinuria by dipstick examination. The dipstick measurement detects mostly albumin and gives false-positive results when pH > 7.0 and the urine is very concentrated or contaminated with blood. A very dilute urine may obscure significant proteinuria on dipstick examination, and proteinuria that is not predominantly albumin will be missed. This is particularly important for the detection of Bence-Jones proteins in the urine of patients with multiple myeloma. Tests to measure total urine concentration accurately rely on precipitation with sulfosalicylic or trichloracetic acids. Currently, ultrasensitive dipsticks are available to measure microalbuminuria (30–300 mg/d), an early marker of glomerular disease that has been shown to predict glomerular injury in early diabetic nephropathy (Fig. 45-3).

The magnitude of proteinuria and the protein composition of the urine depend upon the mechanism of renal injury leading to protein losses. Both charge and size selectivity normally prevent virtually all plasma albumin, globulins, and other large-molecular-weight proteins from crossing the glomerular wall. However, if this barrier is disrupted, there can be leakage of plasma proteins into the urine (glomerular proteinuria; Fig. 45-3). Smaller proteins (<20 kDa) are freely filtered but are readily reabsorbed by the proximal tubule. Normal individuals excrete <150 mg/d of total protein and <30 mg/d of albumin. The remainder of the protein in the urine is secreted by the tubules (Tamm-Horsfall, IgA, and urokinase) or represents small amounts of filtered β_2-microglobulin, apoproteins, enzymes, and peptide hormones. Another mechanism of proteinuria occurs when there is excessive production of an abnormal protein that exceeds the capacity of the tubule for reabsorption. This most commonly occurs with plasma cell dyscrasias such as multiple myeloma, amyloidosis, and lymphomas that are associated with monoclonal production of immunoglobulin light chains.

The normal glomerular endothelial cell forms a barrier composed of pores of ~100 nm that hold back blood cells but offer little impediment to passage of most proteins. The glomerular basement membrane traps most large proteins (>100 kDa), while the foot processes of epithelial cells (podocytes) cover the urinary side of the glomerular basement membrane and produce a series of narrow channels (slit diaphragms) to normally allow molecular passage of small solutes and water but not proteins. Some glomerular diseases, such as minimal change disease, cause fusion of glomerular epithelial cell foot processes, resulting in predominantly "selective" (Fig. 45-3) loss of albumin. Other glomerular diseases can present with disruption of the basement membrane and slit diaphragms (e.g., by immune complex deposition), resulting in losses of albumin and other plasma proteins. The fusion of foot processes causes increased pressure across the capillary basement membrane, resulting in areas with larger pore sizes. The combination of increased pressure and larger pores results in significant proteinuria ("nonselective"; Fig. 45-3).

When the total daily excretion of protein is >3.5 g, there is often associated hypoalbuminemia, hyperlipidemia, and edema (nephrotic syndrome; Fig. 45-3). However, total daily urinary protein excretion >3.5 g can occur without the other features of the nephrotic syndrome in a variety of other renal diseases (Fig. 45-3). Plasma cell dyscrasias (multiple myeloma) can be associated with large amounts of excreted light chains in the urine, which may not be detected by dipstick (which detects mostly albumin). The light chains produced from these disorders are filtered by the glomerulus and overwhelm the reabsorptive capacity of the proximal tubule. A sulfosalicylic acid precipitate that is out of proportion to the dipstick estimate is suggestive of light chains (Bence Jones protein), and light chains typically redissolve upon warming of the precipitate. Renal failure from these disorders occurs through a variety of mechanisms including tubule obstruction (cast nephropathy) and light chain deposition.

Hypoalbuminemia in nephrotic syndrome occurs through excessive urinary losses and increased proximal tubule catabolism of filtered albumin. Hepatic rates of albumin synthesis are increased although not to levels sufficient to prevent hypoalbuminemia. Edema forms from renal sodium retention and from reduced plasma oncotic pressure, which favors fluid movement from capillaries to interstitium. The mechanisms designed to correct the decrease in effective intravascular volume contribute to edema formation in some patients. These mechanisms include activation of the renin-angiotensin system, antidiuretic hormone, and the sympathetic nervous system, all of which promote excessive renal salt and water reabsorption.

The severity of edema correlates with the degree of hypoalbuminemia and is modified by other factors such as heart disease or peripheral vascular disease. The diminished plasma oncotic pressure and urinary losses of regulatory proteins appear to stimulate hepatic lipoprotein synthesis. The resulting hyperlipidemia results in lipid bodies (fatty casts, oval fat bodies) in the urine. Other proteins are lost in the urine, leading to a variety of metabolic disturbances. These include thyroxine-binding globulin, cholecalciferol-binding protein, transferrin, and metal-binding proteins. A hypercoagulable state frequently accompanies severe nephrotic syndrome due to urinary losses of antithrombin III, reduced serum levels of proteins S and C, hyperfibrinogenemia, and enhanced platelet aggregation. Some patients develop severe IgG deficiency with resulting defects in immunity. Many diseases (some listed in Fig. 45-3) and drugs can cause the nephrotic syndrome, and a complete list can be found in Chap. 277.

HEMATURIA, PYURIA, AND CASTS

Isolated hematuria without proteinuria, other cells, or casts is often indicative of bleeding from the urinary tract. Normal red blood cell excretion is up to 2 million RBCs per day. Hematuria is defined as two to five RBCs per high-power field (HPF) and can be detected by dipstick. Common causes of isolated hematuria include stones, neoplasms, tuberculosis, trauma, and prostatitis. Gross hematuria with blood clots is

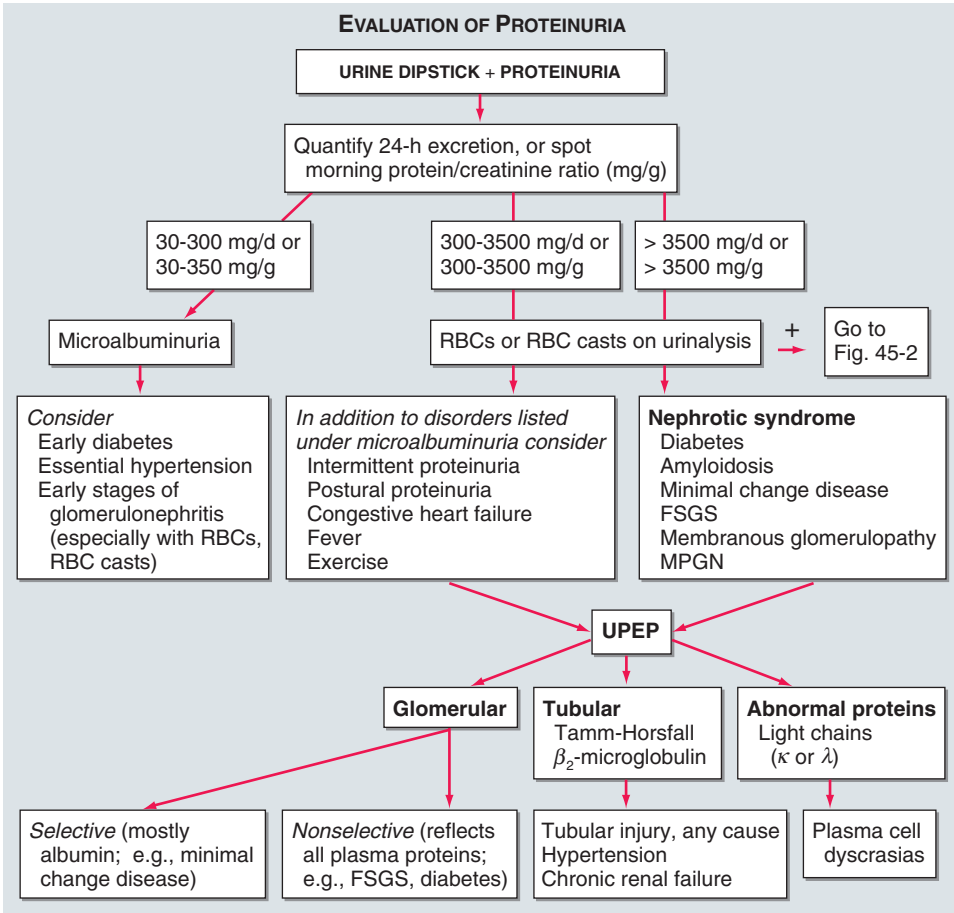

FIGURE 45-3 Approach to the patient with proteinuria. Investigation of proteinuria is often initiated by a positive dipstick on routine urinalysis. Conventional dipsticks detect predominantly albumin and cannot detect urinary albumin levels of 30–300 mg/d. However, more exact determination of proteinuria should employ a 24-h urine collection or a spot morning protein/creatinine ratio (mg/g). The pattern of proteinuria on UPEP (urine protein electrophoresis) can be classified as "glomerular," "tubular," or "abnormal" depending upon the origin of the urine proteins. Glomerular proteinuria is due to abnormal glomerular permeability. "Tubular proteins" such as Tamm-Horsfall are normally produced by the renal tubule and shed into the urine. Abnormal circulating proteins such as kappa or lambda light chains are readily filtered because of their small size. RBC, red blood cell; FSGS, focal segmental glomerulosclerosis; MPGN, membranoproliferative glomerulonephritis.

almost never indicative of glomerular bleeding; rather, it suggests a postrenal source in the urinary collecting system. Evaluation of patients presenting with microscopic hematuria is outlined in Fig. 45-2. A single urinalysis with hematuria is common and can result from menstruation, viral illness, allergy, exercise, or mild trauma. Annual urinalysis of servicemen over a 10-year period showed an incidence of 38%. However, persistent or significant hematuria (>three RBCs/HPF on three urinalyses, or a single urinalysis with >100 RBCs, or gross hematuria) identified significant renal or urologic lesions in 9.1%. Even patients who are chronically anticoagulated should be investigated as outlined in Fig. 45-2. The suspicion for urogenital neoplasms in patients with isolated painless hematuria (nondysmorphic RBCs) increases with age. Neoplasms are rare in the pediatric population, and isolated hematuria is more likely to be "idiopathic" or associated with a congenital anomaly. Hematuria with pyuria and bacteriuria is typical of infection and should be treated with antibiotics after appropriate cultures. Acute cystitis or urethritis in women can cause gross hematuria. Hypercalciuria and hyperuricosuria are also risk factors for unexplained isolated hematuria in both children and adults. In some of these patients (50–60%), reducing calcium and uric acid excretion through dietary interventions can eliminate the microscopic hematuria.

Isolated microscopic hematuria can be a manifestation of glomerular diseases. The RBCs of glomerular origin are often dysmorphic when examined by phase-contrast microscopy. Irregular shapes of RBCs may also occur due to pH and osmolarity changes produced along the distal nephron. There is, however, significant observer variability in detecting dysmorphic RBCs. The most common etiologies of isolated glomerular hematuria are IgA nephropathy, hereditary nephritis, and thin basement membrane disease. IgA nephropathy and hereditary nephritis can lead to episodic gross hematuria. A family history of renal failure is often present in patients with hereditary nephritis, and patients with thin basement membrane disease often have other family members with microscopic hematuria. A renal biopsy is needed for the definitive diagnosis of these disorders, which are discussed in more detail in Chap. 277. Hematuria with dysmorphic RBCs, RBC casts, and protein excretion >500 mg/d is virtually diagnostic of glomerulonephritis. RBC casts form as RBCs that enter the tubule fluid become trapped in a cylindrical mold of gelled Tamm-Horsfall protein. Even in the absence of azotemia, these patients should undergo serologic evaluation and renal biopsy as outlined in Fig. 45-2.

Isolated pyuria is unusual since inflammatory reactions in the kidney or collecting system are also associated with hematuria. The presence of bacteria suggests infection, and white blood cell casts with bacteria are indicative of pyelonephritis. White blood cells and/or white blood cell casts may also be seen in tubulointerstitial processes such as interstitial nephritis, systemic lupus erythematosus, and transplant rejection. In chronic renal diseases, degenerated cellular casts called *waxy casts* can be seen in the urine. *Broad casts* are thought to arise in the dilated tubules of enlarged nephrons that have undergone compensatory hypertrophy in response to reduced renal mass (i.e., chronic renal failure). A mixture of broad casts typically seen with chronic renal failure together with cellular casts and RBCs may be seen in smoldering processes such as chronic glomerulonephritis.

ABNORMALITIES OF URINE VOLUME

The volume of urine produced varies depending upon the fluid intake, renal function, and physiologic demands of the individual. See "Azotemia," above, for discussion of decreased (oliguria) or absent urine production (anuria). **The physiology of water formation and renal water conservation are discussed in Chap. 272.**

POLYURIA

By history, it is often difficult for patients to distinguish urinary frequency (often of small volumes) from polyuria (>3 L/d), and a 24-h urine collection is needed for evaluation (Fig. 45-4). Polyuria results from two potential mechanisms: (1) excretion of nonabsorbable solutes (such as glucose) or (2) excretion of water (usually from a defect in ADH production or renal responsiveness). To distinguish a solute diuresis from a water diuresis and to determine if the diuresis is appropriate for the clinical circumstances, a urine osmolality is measured.

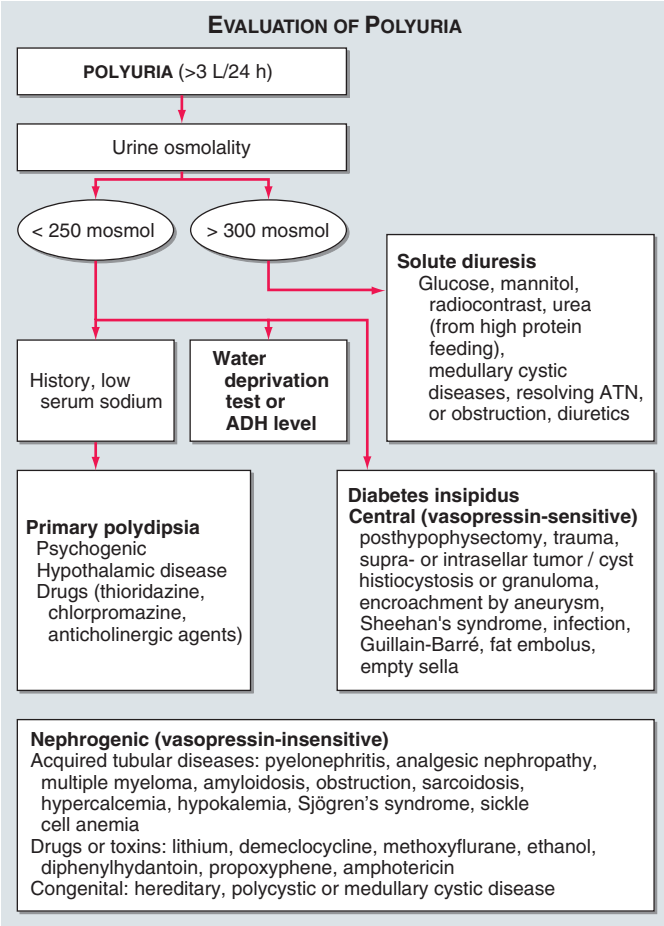

FIGURE 45-4 Approach to the patient with polyuria. ATN, acute tubular necrosis; ADH, antidiuretic hormone.

The average person excretes between 600 and 800 mosmol of solutes per day, primarily as urea and electrolytes. If the urine output is >3 L/d and the urine is dilute (<250 mosmol/L), then total mosmol excretion is normal and a water diuresis is present. This circumstance could arise from polydipsia, inadequate secretion of vasopressin (central diabetes insipidus), or failure of renal tubules to respond to vasopressin (nephrogenic diabetes insipidus). If the urine volume is >3 L/d and urine osmolality is >300 mosmol/L, then a solute diuresis is clearly present and a search for the responsible solute(s) is mandatory.

Excessive filtration of a poorly reabsorbed solute such as glucose, mannitol, or urea can depress reabsorption of NaCl and water in the proximal tubule and lead to enhanced excretion in the urine. Poorly controlled diabetes mellitus with glucosuria is the most common cause of a solute diuresis, leading to volume depletion and serum hypertonicity. Since the urine Na concentration is less than that of blood, more water than Na is lost, causing hypernatremia and hypertonicity. Common iatrogenic solute diuresis occurs from mannitol administration, radiocontrast media, and high-protein feedings (enterally or parenterally), leading to increased urea production and excretion. Less commonly, excessive Na loss may occur from cystic renal diseases, Bartter's syndrome, or during the course of a tubulointerstitial process (such as resolving ATN). In these so-called salt-wasting disorders, the tubule damage results in direct impairment of Na reabsorption and indirectly reduces the responsiveness of the tubule to aldosterone. Usually, the Na losses are mild, and the obligatory urine output is <2 L/d (resolving ATN and postobstructive diuresis are exceptions and may be associated with significant natriuresis and polyuria).

Formation of large volumes of dilute urine represent polydipsic states or diabetes insipidus. Primary polydipsia can result from habit, psychiatric disorders, neurologic lesions, or medications. During deliberate polydipsia, extracellular fluid volume is normal or expanded and plasma vasopressin levels are reduced because serum osmolality tends to be near the lower limits of normal.

Central diabetes insipidus may be idiopathic in origin or secondary to a variety of hypothalamic conditions including posthypophysectomy or trauma or neoplastic, inflammatory, vascular, or infectious hypothalamic diseases. Idiopathic central diabetes insipidus is associated with selective destruction of the vasopressin-secreting neurons in the supraoptic and paraventricular nuclei and can be inherited as an autosomal dominant trait or occur spontaneously. Nephrogenic diabetes insipidus can occur in a variety of clinical situations as summarized in Fig. 45-4.

A plasma vasopressin level is recommended as the best method for distinguishing between central and nephrogenic diabetes insipidus. Alternatively, a water deprivation test plus exogenous vasopressin may also distinguish primary polydipsia from central and nephrogenic diabetes insipidus. **For a detailed discussion, see Chap. 334.**

SODIUM AND WATER

Composition of Body Fluids Water is the most abundant constituent in the body, comprising approximately 50% of body weight in women and 60% in men. This difference is attributable to differences in the relative proportions of adipose tissue in men and women. Total body water is distributed in two major compartments: 55–75% is intracellular [intracellular fluid (ICF)], and 25–45% is extracellular [extracellular fluid (ECF)]. The ECF is further subdivided into intravascular (plasma water) and extravascular (interstitial) spaces in a ratio of 1:3.

The solute or particle concentration of a fluid is known as its *osmolality* and is expressed as milliosmoles per kilogram of water (mosmol/kg). Water crosses cell membranes to achieve osmotic equilibrium (ECF osmolality = ICF osmolality). The extracellular and intracellular solutes or osmoles are markedly different due to disparities in permeability and the presence of transporters and active pumps. The major ECF particles are Na^+ and its accompanying anions Cl^- and HCO_3^-, whereas K^+ and organic phosphate esters (ATP, creatine phosphate, and phospholipids) are the predominant ICF osmoles. Solutes that are re-

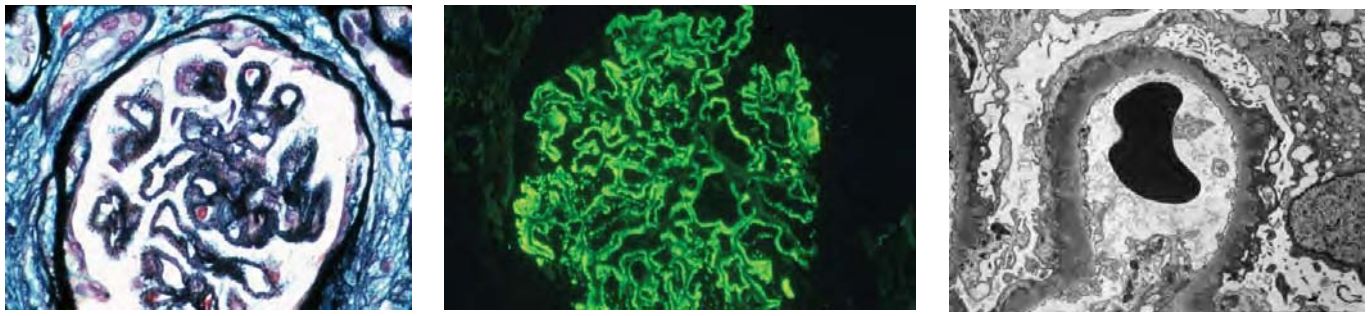

FIGURE e9-5 Membranous glomerulopathy. Membranous glomerulopathy is due to subepithelial deposits, with resulting basement membrane reaction, resulting in the appearance of spike-like projections on silver stain (***left***). The deposits are directly visualized by fluorescent anti-IgG, revealing diffuse granular capillary loop staining (***middle***). By electron microscopy, the subepithelial location of the deposits and early surrounding basement membrane reaction is evident, with overlying foot process effacement (***right***). *(ABF/Vanderbilt Collection.)*

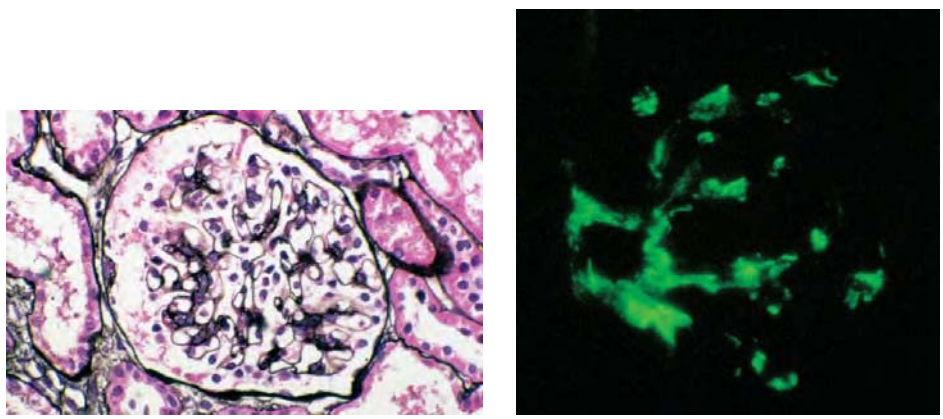

FIGURE e9-6 IgA nephropathy. There is variable mesangial expansion due to mesangial deposits, with some cases also showing endocapillary proliferation or segmental sclerosis (***left***). By immunofluorescence, deposits are evident (***right***). *(ABF/Vanderbilt Collection.)*

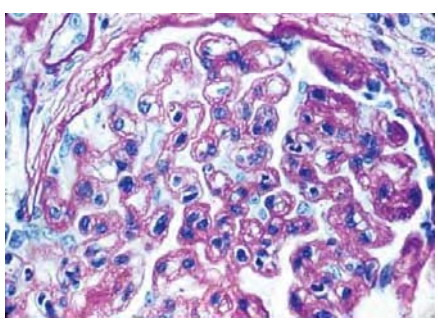

FIGURE e9-7 Membranoproliferative glomerulonephritis. There is mesangial expansion and endocapillary proliferation resulting in the "tram-track" sign of cellular interposition along the glomerular basement membrane. *(EGN/UPenn Collection.)*

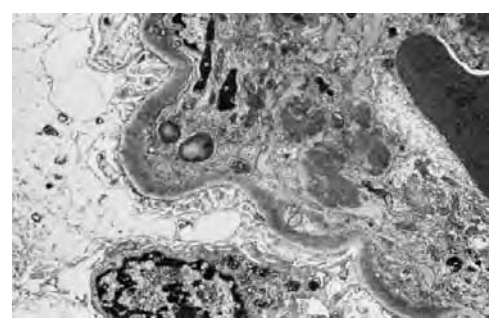

FIGURE e9-8 Dense deposit disease (membranoproliferative glomerulonephritis type II). By light microscopy, there is a membranoproliferative pattern. By electron microscopy, there is a dense transformation of the glomerular basement membrane with round, globular deposits within the mesangium. By immunofluorescence, only C3 staining is usually present. *(ABF/Vanderbilt Collection.)*

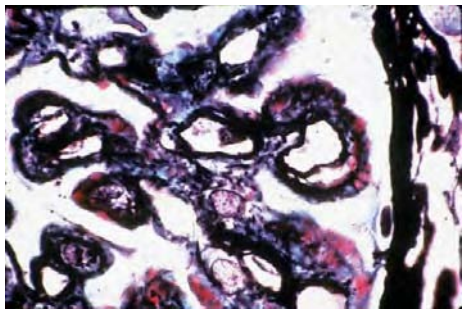

FIGURE e9-9 Membranoproliferative glomerulonephritis. This specimen shows pink subepithelial deposits with spike reaction and the "tram-track" sign of reduplication of glomerular basement membrane, resulting from subendothelial deposits, as may be seen in mixed membranous and proliferative lupus nephritis (ISN/RPS class V and IV) or membranoproliferative glomerulonephritis type III. *(EGN/UPenn Collection.)*

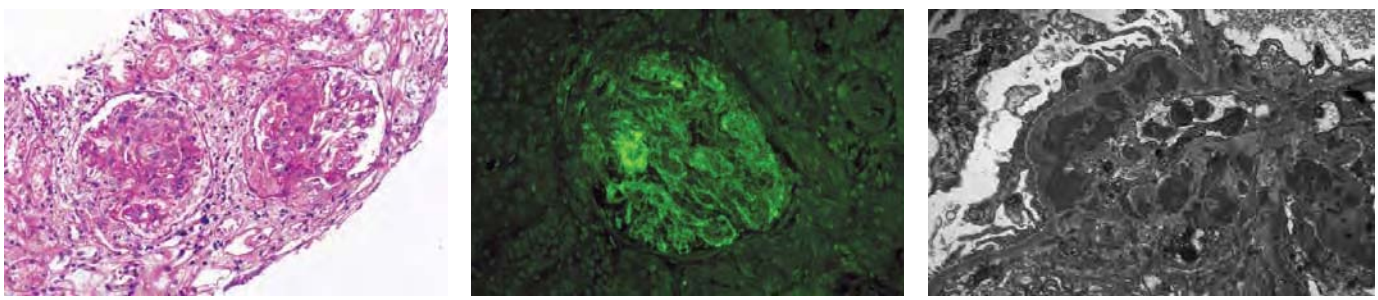

FIGURE e9-10 Lupus nephritis. Proliferative lupus nephritis, ISN/RPS class III or IV, manifests as endocapillary proliferation, which may result in segmental necrosis due to deposits, particularly in the subendothelial area (***left***). By immunofluorescence, chunky irregular mesangial and capillary loop deposits are evident, with some of the peripheral loop deposits having a smooth, molded outer contour due to their subendothelial location. These deposits typically stain for all three immunoglobulins, IgG, IgA, IgM, and both C3 and C1q (***middle***). By electron microscopy, subendothelial, mesangial, and rare subepithelial dense immune complex deposits are evident, along with extensive foot process effacement (***right***). *(ABF/Vanderbilt Collection.)*

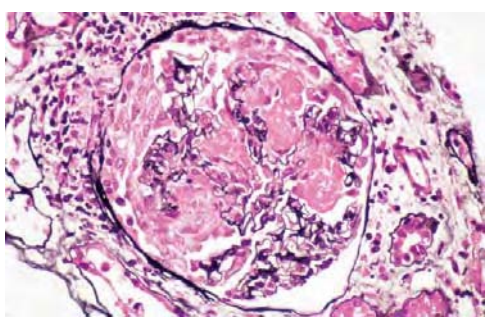

FIGURE e9-11 Wegener's granulomatosis. This pauci-immune necrotizing crescentic glomerulonephritis shows numerous breaks in the glomerular basement membrane with associated segmental fibrinoid necrosis, and a crescent formed by proliferation of the parietal epithelium. Note that the uninvolved segment of the glomerulus (at ~5 o'clock) shows no evidence of proliferation or immune complexes. *(ABF/Vanderbilt Collection.)*

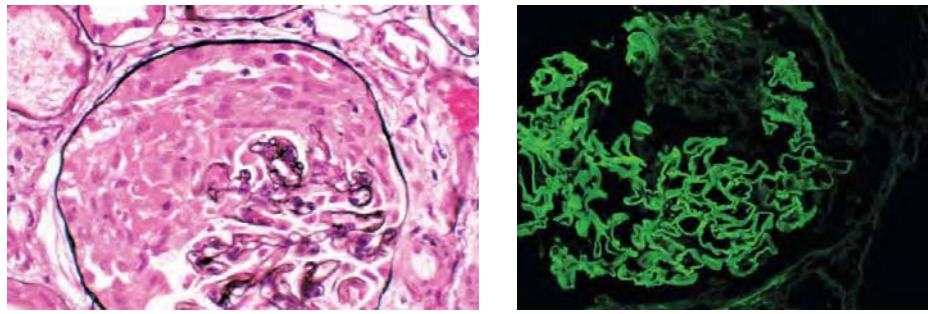

FIGURE e9-12 Anti-GBM antibody-mediated glomerulonephritis. There is segmental necrosis with a break of the glomerular basement membrane and a cellular crescent (***left***), and immunofluorescence for IgG shows linear staining of the glomerular basement membrane with a small crescent at ~1 o'clock. *(ABF/Vanderbilt Collection.)*

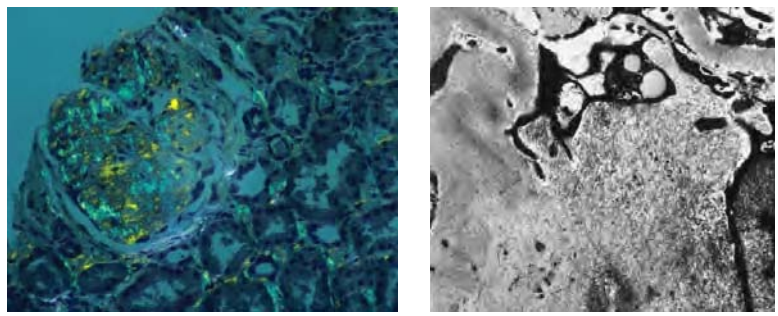

FIGURE e9-13 Amyloidosis. Amyloidosis shows amorphous, acellular expansion of the mesangium, with material often also infiltrating glomerular basement membranes, vessels, and in the interstitium, with apple-green birefringence by polarized Congo red stain (***left***). The deposits are composed of randomly organized 9- to 11-nm fibrils by electron microscopy (***right***). *(ABF/Vanderbilt Collection.)*

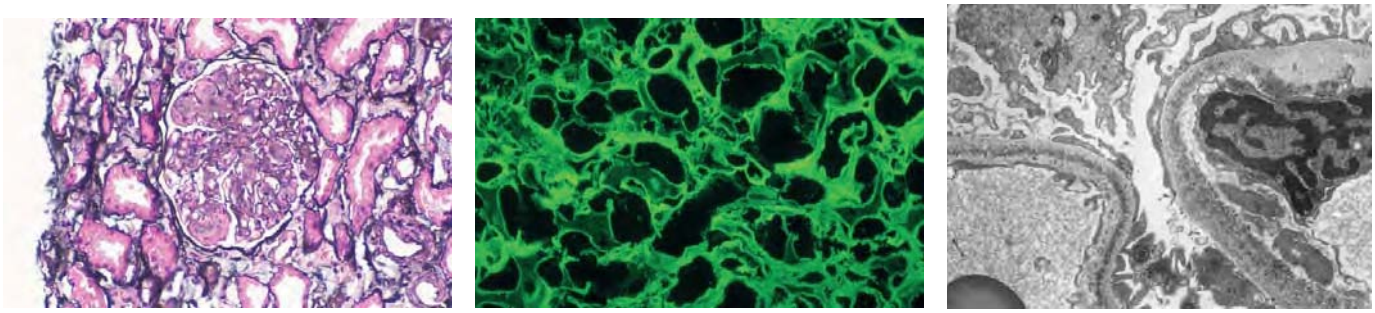

FIGURE e9-14 Light chain deposition disease. There is mesangial expansion, often nodular by light microscopy (***left***), with immunofluorescence showing monoclonal staining, more commonly with kappa than lambda light chain, of tubules (***middle***) and glomerular tufts. By electron microscopy (***right***), the deposits show an amorphous granular appearance and line the inside of the glomerular basement membrane and are also found along the tubular basement membranes. *(ABF/Vanderbilt Collection.)*

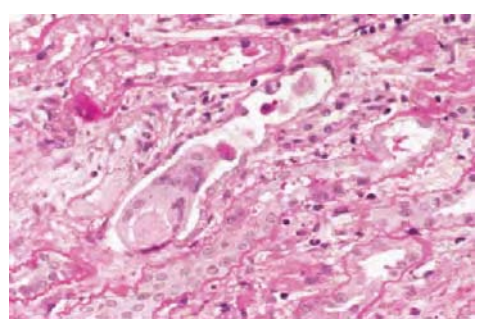

FIGURE e9-15 Light chain cast nephropathy (myeloma kidney). Monoclonal light chains precipitate in tubules and result in a syncytial giant cell reaction (***left***) surrounding the cast, and a surrounding chronic interstitial nephritis with tubulointerstitial fibrosis. *(ABF/Vanderbilt Collection.)*

Copyright © 2008 The McGraw-Hill Companies. All rights reserved.

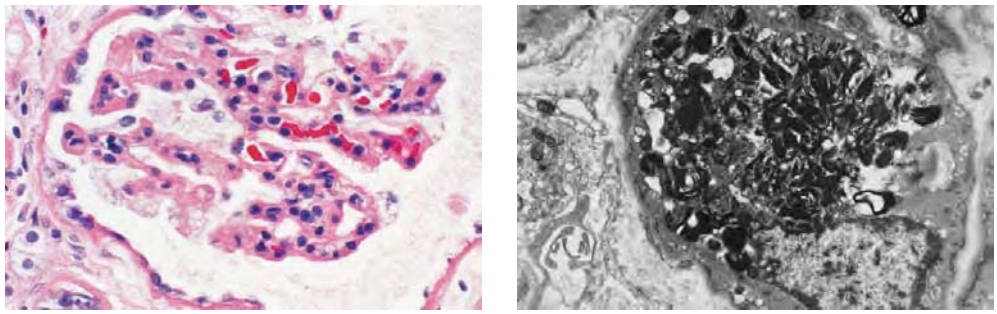

FIGURE e9-16 Fabry's disease. Due to deficiency of α-galactosidase, there is abnormal accumulation of glycolipids, resulting in foamy podocytes by light microscopy (***left***). These deposits can be directly visualized by electron microscopy (***right***), where the glycosphingolipid appears as whorled so-called myeloid bodies, particularly in the podocytes. *(ABF/Vanderbilt Collection.)*

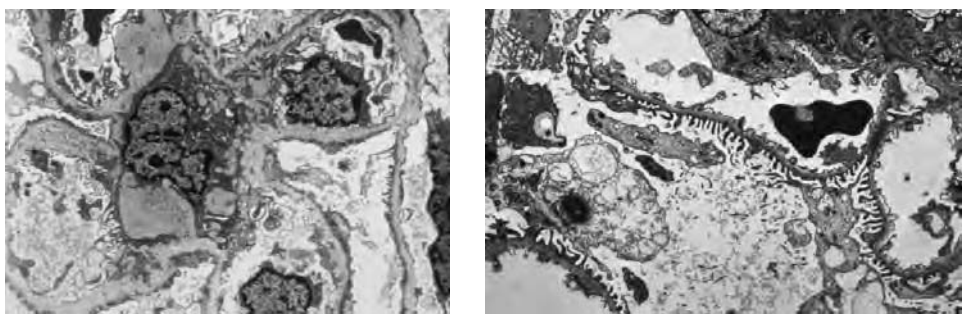

FIGURE e9-17 Alport's syndrome and thin glomerular basement membrane lesion. In Alport's syndrome, there is irregular thinning alternating with thickened so-called basket-weaving abnormal organization of the glomerular basement membrane (***left***). In benign familial hematuria, or in early cases of Alport's syndrome or female carriers, only extensive thinning of the GBM is seen by electron microscopy (***right***). *(ABF/Vanderbilt Collection.)*

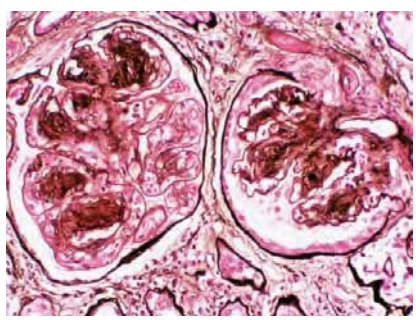

FIGURE e9-18 Diabetic nephropathy. There is nodular mesangial expansion, so-called Kimmelstiel-Wilson nodules, with increased mesangial matrix and cellularity, microaneurysm formation in the glomerulus on the left, and prominent glomerular basement membranes without evidence of immune deposits and arteriolar hyalinosis of both afferent and efferent arterioles. *(ABF/Vanderbilt Collection.)*

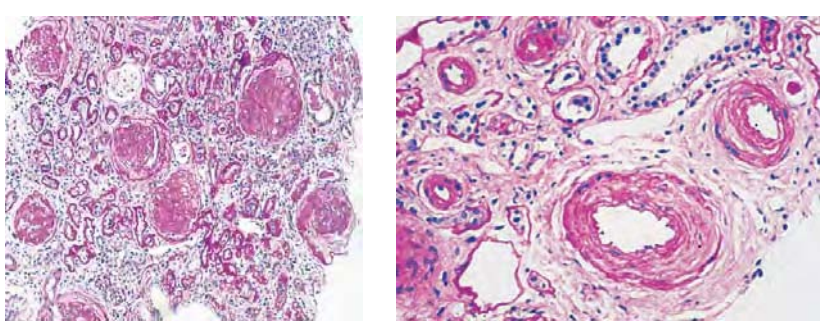

FIGURE e9-19 Arterionephrosclerosis. Hypertension-associated injury often manifests extensive global sclerosis of glomeruli, with accompanying and proportional tubulointerstitial fibrosis and pericapsular fibrosis, and there may be segmental sclerosis (***left***). The vessels show disproportionately severe changes of intimal fibrosis, medial hypertrophy, and arteriolar hyaline deposits (***right***). *(ABF/Vanderbilt Collection.)*

stricted to the ECF or the ICF determine the *effective osmolality* (or *tonicity*) of that compartment. Since Na^+ is largely restricted to the extracellular compartment, total body Na^+ content is a reflection of ECF volume. Likewise, K^+ and its attendant anions are predominantly limited to the ICF and are necessary for normal cell function. Therefore, the number of intracellular particles is relatively constant, and a change in ICF osmolality is usually due to a change in ICF water content. However, in certain situations, brain cells can vary the number of intracellular solutes in order to defend against large water shifts. This process of *osmotic adaptation* is important in the defense of cell volume and occurs in chronic hyponatremia and hypernatremia. This response is mediated initially by transcellular shifts of K^+ and Na^+, followed by synthesis, import, or export of organic solutes (so-called osmolytes) such as inositol, betaine, and glutamine. During chronic hyponatremia, brain cells lose solutes, thereby defending cell volume and diminishing neurologic symptoms. The converse occurs during chronic hypernatremia. Certain solutes, such as urea, do not contribute to water shift across cell membranes and are known as *ineffective osmoles*.

Fluid movement between the intravascular and interstitial spaces occurs across the capillary wall and is determined by the Starling forces—capillary hydraulic pressure and colloid osmotic pressure. The transcapillary hydraulic pressure gradient exceeds the corresponding oncotic pressure gradient, thereby favoring the movement of plasma ultrafiltrate into the extravascular space. The return of fluid into the intravascular compartment occurs via lymphatic flow.

Water Balance (See also Chap. 272) The normal plasma osmolality is 275–290 mosmol/kg and is kept within a narrow range by mechanisms capable of sensing a 1–2% change in tonicity. To maintain a steady state, water intake must equal water excretion. Disorders of water homeostasis result in hypo- or hypernatremia. Normal individuals have an obligate water loss consisting of urine, stool, and evaporation from the skin and respiratory tract. Gastrointestinal excretion is usually a minor component of total water output, except in patients with vomiting, diarrhea, or high enterostomy output states. Evaporative or insensitive water losses are important in the regulation of core body temperature. Obligatory renal water loss is mandated by the minimum solute excretion required to maintain a steady state. Normally, about 600 mosmols must be excreted per day, and since the maximal urine osmolality is 1200 mosmol/kg, a minimum urine output of 500 mL/d is required for neutral solute balance.

WATER INTAKE The primary stimulus for water ingestion is *thirst*, mediated either by an increase in effective osmolality or a decrease in ECF volume or blood pressure. *Osmoreceptors*, located in the anterolateral hypothalamus, are stimulated by a rise in tonicity. Ineffective osmoles, such as urea and glucose, do not play a role in stimulating thirst. The average osmotic threshold for thirst is approximately 295 mosmol/kg and varies among individuals. Under normal circumstances, daily water intake exceeds physiologic requirements.

WATER EXCRETION In contrast to the ingestion of water, its excretion is tightly regulated by physiologic factors. The principal determinant of renal water excretion is *arginine vasopressin* (AVP; formerly antidiuretic hormone), a polypeptide synthesized in the supraoptic and paraventricular nuclei of the hypothalamus and secreted by the posterior pituitary gland. The binding of AVP to V_2 receptors on the basolateral membrane of principal cells in the collecting duct activates adenylyl cyclase and initiates a sequence of events that leads to the insertion of water channels into the luminal membrane. These water channels that are specifically activated by AVP are encoded by the *aquaporin-2* gene (Chap. 334). The net effect is passive water reabsorption along an osmotic gradient from the lumen of the collecting duct to the hypertonic medullary interstitium. The major stimulus for AVP secretion is hypertonicity. Since the major ECF solutes are Na^+ salts, effective osmolality is primarily determined by the plasma Na^+ concentration. An increase or decrease in tonicity is sensed by hypothalamic osmoreceptors as a decrease or increase in cell volume, respectively, leading to enhancement or suppression of AVP secretion. The osmotic threshold for AVP release is 280–290 mosmol/kg, and the system is sufficiently sensitive that plasma osmolality varies by no more than 1–2%.

Nonosmotic factors that regulate AVP secretion include *effective circulating (arterial) volume*, nausea, pain, stress, hypoglycemia, pregnancy, and numerous drugs. The hemodynamic response is mediated by baroreceptors in the carotid sinus. The sensitivity of these receptors is significantly lower than that of the osmoreceptors. In fact, depletion of blood volume sufficient to result in a decreased mean arterial pressure is necessary to stimulate AVP release, whereas small changes in effective circulating volume have little effect.

To maintain homeostasis and a normal plasma Na^+ concentration, the ingestion of solute-free water must eventually lead to the loss of the same volume of electrolyte-free water. Three steps are required for the kidney to excrete a water load: (1) filtration and delivery of water (and electrolytes) to the diluting sites of the nephron; (2) active reabsorption of Na^+ and Cl^- without water in the thick ascending limb of the loop of Henle (TALH) and, to a lesser extent, in the distal nephron; and (3) maintenance of a dilute urine due to impermeability of the collecting duct to water in the absence of AVP. Abnormalities of any of these steps can result in impaired free water excretion, and eventual hyponatremia.

Sodium Balance Sodium is actively pumped out of cells by the Na^+, K^+-ATPase pump. As a result, 85–90% of all Na^+ is extracellular, and the ECF volume is a reflection of total body Na^+ content. Normal volume regulatory mechanisms ensure that Na^+ loss balances Na^+ gain. If this does not occur, conditions of Na^+ excess or deficit ensue and are manifest as edematous or hypovolemic states, respectively. It is important to distinguish between disorders of osmoregulation and disorders of volume regulation since water and Na^+ balance are regulated independently. Changes in Na^+ concentration generally reflect disturbed water homeostasis, whereas alterations in Na^+ content are manifest as ECF volume contraction or expansion and imply abnormal Na^+ balance.

SODIUM INTAKE Individuals eating a typical western diet consume approximately 150 mmol of NaCl daily. This normally exceeds basal requirements. As noted above, sodium is the principal extracellular cation. Therefore, dietary intake of Na^+ results in ECF volume expansion, which in turn promotes enhanced renal Na^+ excretion to maintain steady state Na^+ balance.

SODIUM EXCRETION (See also Chap. 272) The regulation of Na^+ excretion is multifactorial and is the major determinant of Na^+ balance. A Na^+ deficit or excess is manifest as a decreased or increased effective circulating volume, respectively. Changes in effective circulating volume tend to lead to parallel changes in glomerular filtration rate (GFR). However, tubule Na^+ reabsorption, and not GFR, is the major regulatory mechanism controlling Na^+ excretion. Almost two-thirds of filtered Na^+ is reabsorbed in the proximal convoluted tubule; this process is electroneutral and isoosmotic. Further reabsorption (25–30%) occurs in the TALH via the apical *Na^+-K^+-2Cl^- co-transporter;* this is an active process and is also electroneutral. Distal convoluted tubule reabsorption of Na^+ (5%) is mediated by the *thiazide-sensitive Na^+-Cl^- co-transporter*. Final Na^+ reabsorption occurs in the cortical and medullary collecting ducts, the amount excreted being reasonably equivalent to the amount ingested per day.

HYPOVOLEMIA

Etiology True volume depletion, or hypovolemia, generally refers to a state of combined salt and water loss exceeding intake, leading to ECF volume contraction. The loss of Na^+ may be renal or extrarenal (Table 46-1).

RENAL Many conditions are associated with excessive urinary NaCl and water losses, including diuretics. Pharmacologic diuretics inhibit specific pathways of Na^+ reabsorption along the nephron with a consequent increase in urinary Na^+ excretion. Enhanced filtration of nonreabsorbed solutes, such as glucose or urea, can also impair tubular reabsorption of Na^+ and water, leading to an osmotic or solute diuresis. This often occurs in poorly controlled diabetes mellitus and in patients receiving high-protein hyperalimentation. Mannitol is a diuretic

TABLE 46-1 CAUSES OF HYPOVOLEMIA

I. ECF volume contracted
  A. Extrarenal Na^+ loss
    1. Gastrointestinal (vomiting, nasogastric suction, drainage, fistula, diarrhea)
    2. Skin/respiratory (insensible losses, sweat, burns)
    3. Hemorrhage
  B. Renal Na^+ and water loss
    1. Diuretics
    2. Osmotic diuresis
    3. Hypoaldosteronism
    4. Salt-wasting nephropathies
  C. Renal water loss
    1. Diabetes insipidus (central or nephrogenic)
II. ECF volume normal or expanded
  A. Decreased cardiac output
    1. Myocardial, valvular, or pericardial disease
  B. Redistribution
    1. Hypoalbuminemia (hepatic cirrhosis, nephrotic syndrome)
    2. Capillary leak (acute pancreatitis, ischemic bowel, rhabdomyolysis)
  C. Increased venous capacitance
    1. Sepsis

Note: ECF, extracellular fluid.

that produces an osmotic diuresis because the renal tubule is impermeable to mannitol. Many tubule and interstitial renal disorders are associated with Na^+ wasting. Excessive renal losses of Na^+ and water may also occur during the diuretic phase of acute tubular necrosis (Chap. 273) and following the relief of bilateral urinary tract obstruction. Finally, mineralocorticoid deficiency (hypoaldosteronism) causes salt wasting in the presence of normal intrinsic renal function.

Massive renal water excretion can also lead to hypovolemia. The ECF volume contraction is usually less severe since two-thirds of the volume lost is intracellular. Conditions associated with excessive urinary water loss include *central diabetes insipidus* (CDI) and *nephrogenic diabetes insipidus* (NDI). These two disorders are due to impaired secretion of and renal unresponsiveness to AVP, respectively, and are discussed below.

EXTRARENAL Nonrenal causes of hypovolemia include fluid loss from the gastrointestinal tract, skin, and respiratory system and third-space accumulations (burns, pancreatitis, peritonitis). Approximately 9 L of fluid enters the gastrointestinal tract daily, 2 L by ingestion and 7 L by secretion. Almost 98% of this volume is reabsorbed so that fecal fluid loss is only 100–200 mL/d. Impaired gastrointestinal reabsorption or enhanced secretion leads to volume depletion. Since gastric secretions have a low pH (high H^+ concentration) and biliary, pancreatic, and intestinal secretions are alkaline (high HCO_3^- concentration), vomiting and diarrhea are often accompanied by metabolic alkalosis and acidosis, respectively.

Water evaporation from the skin and respiratory tract contributes to thermoregulation. These *insensible losses* amount to 500 mL/d. During febrile illnesses, prolonged heat exposure, exercise, or increased salt and water loss from skin, in the form of sweat, can be significant and lead to volume depletion. The Na^+ concentration of sweat is normally 20–50 mmol/L and decreases with profuse sweating due to the action of aldosterone. Since sweat is hypotonic, the loss of water exceeds that of Na^+. The water deficit is minimized by enhanced thirst. Nevertheless, ongoing Na^+ loss is manifest as hypovolemia. Enhanced evaporative water loss from the respiratory tract may be associated with hyperventilation, especially in mechanically ventilated febrile patients.

Certain conditions lead to fluid sequestration in a *third space*. This compartment is extracellular but is not in equilibrium with either the ECF or the ICF. The fluid is effectively lost from the ECF and can result in hypovolemia. Examples include the bowel lumen in gastrointestinal obstruction, subcutaneous tissues in severe burns, retroperitoneal space in acute pancreatitis, and peritoneal cavity in peritonitis. Finally, severe hemorrhage from any source can result in volume depletion.

Pathophysiology ECF volume contraction is manifest as a decreased plasma volume and hypotension. Hypotension is due to decreased venous return (preload) and diminished cardiac output; it triggers baroreceptors in the carotid sinus and aortic arch and leads to activation of the sympathetic nervous system and the renin-angiotensin system. The net effect is to maintain mean arterial pressure and cerebral and coronary perfusion. In contrast to the cardiovascular response, the renal response is aimed at restoring the ECF volume by decreasing the GFR and filtered load of Na^+ and, most importantly, by promoting tubular reabsorption of Na^+. Increased sympathetic tone increases proximal tubular Na^+ reabsorption and decreases GFR by causing preferential afferent arteriolar vasoconstriction. Sodium is also reabsorbed in the proximal convoluted tubule in response to increased angiotensin II and altered peritubular capillary hemodynamics (decreased hydraulic and increased oncotic pressure). Enhanced reabsorption of Na^+ by the collecting duct is an important component of the renal adaptation to ECF volume contraction. This occurs in response to increased *aldosterone* and AVP secretion and suppressed *atrial natriuretic peptide* secretion.

Clinical Features A careful history is often helpful in determining the etiology of ECF volume contraction (e.g., vomiting, diarrhea, polyuria, diaphoresis). Most symptoms are nonspecific and secondary to electrolyte imbalances and tissue hypoperfusion and include fatigue, weakness, muscle cramps, thirst, and postural dizziness. More severe degrees of volume contraction can lead to end-organ ischemia manifest as oliguria, cyanosis, abdominal and chest pain, and confusion or obtundation. Diminished skin turgor and dry oral mucous membranes are poor markers of decreased interstitial fluid. Signs of intravascular volume contraction include decreased jugular venous pressure, postural hypotension, and postural tachycardia. Larger and more acute fluid losses lead to hypovolemic shock, manifest as hypotension, tachycardia, peripheral vasoconstriction, and hypoperfusion—cyanosis, cold and clammy extremities, oliguria, and altered mental status.

Diagnosis A thorough history and physical examination are generally sufficient to diagnose the etiology of hypovolemia. Laboratory data usually confirm and support the clinical diagnosis. The blood urea nitrogen (BUN) and plasma creatinine concentrations tend to be elevated, reflecting a decreased GFR. Normally, the BUN:creatinine ratio is about 10:1. However, in *prerenal azotemia*, hypovolemia leads to increased urea reabsorption, a proportionately greater elevation in BUN than plasma creatinine, and a BUN:creatinine ratio of 20:1 or higher. An increased BUN (relative to creatinine) may also be due to increased urea production that occurs with hyperalimentation (high-protein), glucocorticoid therapy, and gastrointestinal bleeding.

The appropriate response to hypovolemia is enhanced renal Na^+ and water reabsorption, which is reflected in the urine composition. Therefore, the urine Na^+ concentration should usually be <20 mmol/L except in conditions associated with impaired Na^+ reabsorption, as in acute tubular necrosis (Chap. 273). Another exception is hypovolemia due to vomiting, since the associated metabolic alkalosis and increased filtered HCO_3^- impair proximal Na^+ reabsorption. In this case, the urine Cl^- is low (<20 mmol/L). The urine osmolality and specific gravity in hypovolemic subjects are generally >450 mosmol/kg and 1.015, respectively, reflecting the presence of enhanced AVP secretion. However, in hypovolemia due to diabetes insipidus, urine osmolality and specific gravity are indicative of inappropriately dilute urine.

Rx HYPOVOLEMIA

The therapeutic goals are to restore normovolemia with fluid similar in composition to that lost and to replace ongoing losses. Symptoms and signs, including weight loss, can help estimate the degree of volume contraction and should also be monitored to assess response to treatment. Mild volume contraction can usually be corrected via the oral route. More severe hypovolemia requires intravenous therapy. Isotonic or normal saline (0.9% NaCl or 154 mmol/L Na^+) is the solution of choice in normonatremic and most hyponatremic individuals and should be administered initially in patients with hypotension or shock. Hypernatremia reflects a proportionally greater deficit of water than Na^+, and its correction will therefore require a hypotonic solution such as half-normal saline (0.45% NaCl or 77 mmol/L Na^+) or 5% dextrose in water. Patients with significant hemorrhage, anemia,

or intravascular volume depletion may require blood transfusion or colloid-containing solutions (albumin, dextran). Hypokalemia may be present initially or may ensue as a result of increased urinary K^+ excretion; it should be corrected by adding appropriate amounts of KCl to replacement solutions.

HYPONATREMIA

Etiology A plasma Na^+ concentration <135 mmol/L usually reflects a hypotonic state. However, plasma osmolality may be normal or increased in some cases of hyponatremia. Isotonic or slightly hypotonic hyponatremia may complicate transurethral resection of the prostate or bladder because large volumes of isoosmotic (mannitol) or hypoosmotic (sorbitol or glycine) bladder irrigation solution can be absorbed and result in a dilutional hyponatremia. The metabolism of sorbitol and glycine to CO_2 and water may lead to hypotonicity if the accumulated fluid and solutes are not rapidly excreted. Hypertonic hyponatremia is usually due to hyperglycemia or, occasionally, intravenous administration of mannitol. Relative insulin deficiency causes myocytes to become impermeable to glucose. Therefore, during poorly controlled diabetes mellitus, glucose is an effective osmole and draws water from muscle cells, resulting in hyponatremia. Plasma Na^+ concentration falls by 1.4 mmol/L for every 100 mg/dL rise in the plasma glucose concentration.

Most causes of hyponatremia are associated with a low plasma osmolality (Table 46-2). In general, hypotonic hyponatremia is due either to a primary water gain (and secondary Na^+ loss) or a primary Na^+ loss (and secondary water gain). In the absence of water intake or hypotonic fluid replacement, hyponatremia is usually associated with hypovolemic shock due to a profound sodium deficit and transcellular water shift. Contraction of the ECF volume stimulates thirst and AVP secretion. The increased water ingestion and impaired renal excretion result in hyponatremia. It is important to note that *diuretic-induced hyponatremia* is almost always due to thiazide diuretics. Loop diuretics decrease the tonicity of the medullary interstitium and impair maximal urinary concentrating capacity. This limits the ability of AVP to promote water retention. In contrast, thiazide diuretics lead to Na^+ and K^+ depletion and AVP-mediated water retention. Hyponatremia can also occur by a process of *desalination*. This occurs when the urine tonicity (the sum of the concentrations of Na^+ and K^+) exceeds that of administered intravenous fluids (including isotonic saline). This accounts for some cases of acute postoperative hyponatremia and cerebral salt wasting after neurosurgery.

Hyponatremia in the setting of ECF volume expansion is usually associated with edematous states, such as congestive heart failure, hepatic cirrhosis, and the nephrotic syndrome. These disorders all have in common a decreased effective circulating arterial volume, leading to increased thirst and increased AVP levels. Additional factors impairing the excretion of solute-free water include a reduced GFR, decreased delivery of ultrafiltrate to the diluting site (due to increased proximal fractional reabsorption of Na^+ and water), and diuretic therapy. The degree of hyponatremia often correlates with the severity of the underlying condition and is an important prognostic factor. Oliguric acute and chronic renal failure may be associated with hyponatremia if water intake exceeds the ability to excrete equivalent volumes.

TABLE 46-2 CAUSES OF HYPONATREMIA

I. Pseudohyponatremia
  A. Normal plasma osmolality
    1. Hyperlipidemia
    2. Hyperproteinemia
    3. Posttransurethral resection of prostate/bladder tumor
  B. Increased plasma osmolality
    1. Hyperglycemia
    2. Mannitol
II. Hypoosmolal hyponatremia
  A. Primary Na^+ loss (secondary water gain)
    1. Integumentary loss: sweating, burns
    2. Gastrointestinal loss: vomiting, tube drainage, fistula, obstruction, diarrhea
    3. Renal loss: diuretics, osmotic diuresis, hypoaldosteronism, salt-wasting nephropathy, postobstructive diuresis, nonoliguric acute tubular necrosis
  B. Primary water gain (secondary Na^+ loss)
    1. Primary polydipsia
    2. Decreased solute intake (e.g., beer potomania)
    3. AVP release due to pain, nausea, drugs
    4. Syndrome of inappropriate AVP secretion
    5. Glucocorticoid deficiency
    6. Hypothyroidism
    7. Chronic renal insufficiency
  C. Primary Na^+ gain (exceeded by secondary water gain)
    1. Heart failure
    2. Hepatic cirrhosis
    3. Nephrotic syndrome

Hyponatremia in the absence of ECF volume contraction, decreased effective circulating arterial volume, or renal insufficiency is usually due to increased AVP secretion resulting in impaired water excretion. Ingestion or administration of water is also required since high levels of AVP alone are usually insufficient to produce hyponatremia. This disorder, commonly termed the *syndrome of inappropriate antidiuretic hormone secretion* (SIADH), is the most common cause of normovolemic hyponatremia and is due to the nonphysiologic release of AVP from the posterior pituitary or an ectopic source (Chap. 334). Renal free-water excretion is impaired while the regulation of Na^+ balance is unaffected. The most common causes of SIADH include neuropsychiatric and pulmonary diseases, malignant tumors, major surgery (postoperative pain), and pharmacologic agents. Severe pain and nausea are physiologic stimuli of AVP secretion; these stimuli are inappropriate in the absence of hypovolemia or hyperosmolality. The pattern of AVP secretion can be used to classify SIADH into four subtypes: (1) erratic autonomous AVP secretion (ectopic production); (2) normal regulation of AVP release around a lower osmolality set point or *reset osmostat* (cachexia, malnutrition); (3) normal AVP response to hypertonicity with failure to suppress completely at low osmolality (incomplete pituitary stalk section); and (4) normal AVP secretion with increased sensitivity to its actions or secretion of some other antidiuretic factor (rare). Patients with the nephrogenic syndrome of inappropriate antidiuresis have clinical and laboratory features consistent with SIADH but undetectable levels of AVP. It is hypothesized that this disorder is due to gain of function mutations in the V2 receptor.

Hormonal excess or deficiency may cause hyponatremia. Adrenal insufficiency (Chap. 336) and hypothyroidism (Chap. 335) may present with hyponatremia and should not be confused with SIADH. Although decreased mineralocorticoids may contribute to the hyponatremia of adrenal insufficiency, it is the cortisol deficiency that leads to hypersecretion of AVP both indirectly (secondary to volume depletion) and directly (cosecreted with corticotropin-releasing factor). The mechanisms by which hypothyroidism leads to hyponatremia include decreased cardiac output and GFR and increased AVP secretion in response to hemodynamic stimuli.

Finally, hyponatremia may occur in the absence of AVP or renal failure if the kidney is unable to excrete the dietary water load. In psychogenic or primary polydipsia, compulsive water consumption may overwhelm the normally large renal excretory capacity of 12 L/d (Chap. 334). These patients often have psychiatric illnesses and may be taking medications, such as phenothiazines, that enhance the sensation of thirst by causing a dry mouth. The maximal urine output is a function of the minimum urine osmolality achievable and the mandatory solute excretion. Metabolism of a normal diet generates about 600 mosmol/d, and the minimum urine osmolality in humans is 50 mosmol/kg. Therefore, the maximum daily urine output will be about 12 L (600 ÷ 50 = 12). A solute excretion rate of greater than ~750 mosmol/d is, by definition, an *osmotic diuresis*. A low-protein diet may yield as few as 250 mosmol/d, which translates into a maximal urine output of 5 L/d at a minimum urine tonicity of 50 mosmol/kg. Beer drinkers typically have a poor dietary intake of protein and electrolytes and consume large volumes (of beer), which may exceed the renal excretory capacity and result in hyponatremia. This phenomenon is referred to as *beer potomania*.

Clinical Features The clinical manifestations of hyponatremia are related to osmotic water shift leading to increased ICF volume, specifically brain cell swelling or cerebral edema. Therefore the symptoms are primarily neurologic, and their severity is dependent on the rapidity of on-

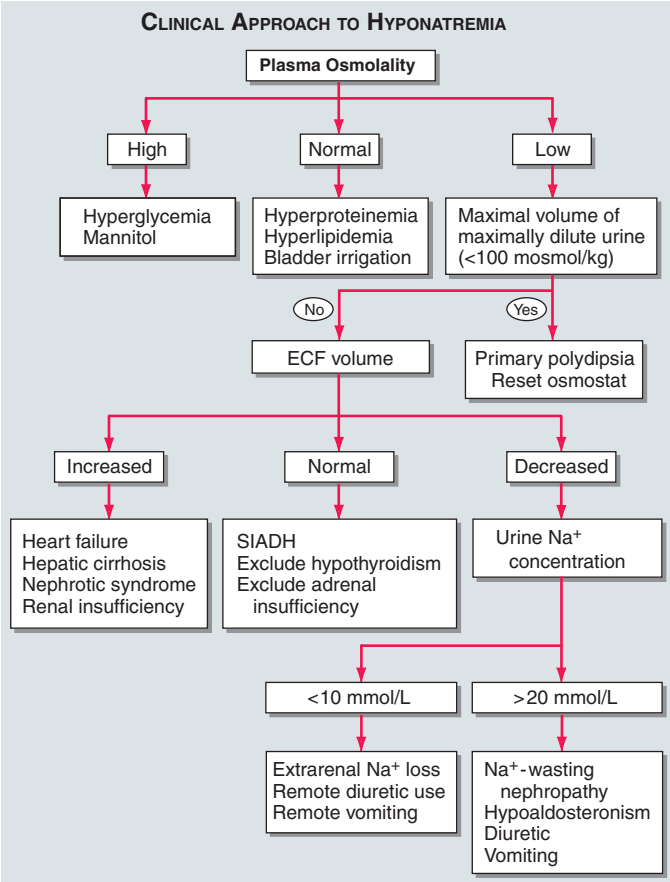

FIGURE 46-1 Algorithm depicting clinical approach to hyponatremia. ECF, extracellular fluid; SIADH, syndrome of inappropriate antidiuretic hormone secretion.

set and absolute decrease in plasma Na^+ concentration. Patients may be asymptomatic or complain of nausea and malaise. As the plasma Na^+ concentration falls, the symptoms progress to include headache, lethargy, confusion, and obtundation. Stupor, seizures, and coma do not usually occur unless the plasma Na^+ concentration falls acutely below 120 mmol/L or decreases rapidly. As described above, adaptive mechanisms designed to protect cell volume occur in chronic hyponatremia. Loss of Na^+ and K^+, followed by organic osmolytes, from brain cells decreases brain swelling due to secondary transcellular water shifts (from ICF to ECF). The net effect is to minimize cerebral edema and its symptoms.

Diagnosis (Fig. 46-1) Hyponatremia is not a disease but a manifestation of a variety of disorders. The underlying cause can often be ascertained from an accurate history and physical examination, including an assessment of ECF volume status and effective circulating arterial volume. The differential diagnosis of hyponatremia, an expanded ECF volume, and decreased effective circulating volume includes congestive heart failure, hepatic cirrhosis, and the nephrotic syndrome. Hypothyroidism and adrenal insufficiency tend to present with a near-normal ECF volume and decreased effective circulating arterial volume. All of these diseases have characteristic signs and symptoms. Patients with SIADH are usually euvolemic.

Four laboratory findings often provide useful information and can narrow the differential diagnosis of hyponatremia: (1) the plasma osmolality, (2) the urine osmolality, (3) the urine Na^+ concentration, and (4) the urine K^+ concentration. Since ECF tonicity is determined primarily by the Na^+ concentration, most patients with hyponatremia have a decreased plasma osmolality. The appropriate renal response to hypoosmolality is to excrete the maximum volume of dilute urine, i.e., urine osmolality and specific gravity of <100 mosmol/kg and 1.003, respectively. This occurs in patients with primary polydipsia. If this is not present, it suggests impaired free-water excretion due to the action of AVP on the kidney. The secretion of AVP may be a physiologic response to hemodynamic stimuli or it may be inappropriate in the presence of hyponatremia and euvolemia. Since Na^+ is the major ECF cation and is largely restricted to this compartment, ECF volume contraction represents a deficit in total body Na^+ content. Therefore, volume depletion in patients with normal underlying renal function results in enhanced tubule Na^+ reabsorption and a urine Na^+ concentration <20 mmol/L. The finding of a urine Na^+ concentration >20 mmol/L in hypovolemic hyponatremia implies a salt-wasting nephropathy, diuretic therapy, hypoaldosteronism, or occasionally vomiting. Both the urine osmolality and the urine Na^+ concentration can be followed serially when assessing response to therapy.

SIADH is characterized by hypoosmotic hyponatremia in the setting of an inappropriately concentrated urine (urine osmolality >100 mosmol/kg). Patients are typically normovolemic and have normal Na^+ balance. They tend to be mildly volume-expanded secondary to water retention and have a urine Na^+ excretion rate equal to intake (urine Na^+ concentration usually >40 mmol/L). By definition, they have normal renal, adrenal, and thyroid function and usually have normal K^+ and acid-base balance. SIADH is often associated with hypouricemia due to the uricosuric state induced by volume expansion. In contrast, hypovolemic patients tend to be hyperuricemic secondary to increased proximal urate reabsorption.

Rx HYPONATREMIA

The goals of therapy are twofold: (1) to raise the plasma Na^+ concentration by restricting water intake and promoting water loss and (2) to correct the underlying disorder. Mild asymptomatic hyponatremia is generally of little clinical significance and requires no treatment. The management of asymptomatic hyponatremia associated with ECF volume contraction should include Na^+ repletion, generally in the form of isotonic saline. The direct effect of the administered NaCl on the plasma Na^+ concentration is trivial. However, restoration of euvolemia removes the hemodynamic stimulus for AVP release, allowing the excess free water to be excreted. The hyponatremia associated with edematous states tends to reflect the severity of the underlying disease and is usually asymptomatic. These patients have increased total body water that exceeds the increase in total body Na^+ content. Treatment should include restriction of Na^+ and water intake, correction of hypokalemia, and promotion of water loss in excess of Na^+. The latter may require the use of loop diuretics with replacement of a proportion of the urinary Na^+ loss to ensure net free-water excretion. Dietary water restriction should be less than the urine output. Correction of the K^+ deficit may raise the plasma Na^+ concentration by favoring a shift of Na^+ out of cells as K^+ moves in. Water restriction is also a component of the therapeutic approach to hyponatremia associated with primary polydipsia, renal failure, and SIADH (Chap. 334). The recent development of nonpeptide vasopressin antagonists has introduced a new selective treatment for euvolemic and hypervolemic hyponatremia.

The rate of correction of hyponatremia depends on the absence or presence of neurologic dysfunction. This, in turn, is related to the rapidity of onset and magnitude of the fall in plasma Na^+ concentration. In asymptomatic patients, the plasma Na^+ concentration should be raised by no more than 0.5–1.0 mmol/L per h and by less than 10–12 mmol/L over the first 24 h. Acute or severe hyponatremia (plasma Na^+ concentration <110–115 mmol/L) tends to present with altered mental status and/or seizures and requires more rapid correction. Severe symptomatic hyponatremia should be treated with hypertonic saline, and the plasma Na^+ concentration should be raised by 1–2 mmol/L per hour for the first 3–4 h or until the seizures subside. Once again, the plasma Na^+ concentration should probably be raised by no more than 12 mmol/L during the first 24 h. The quantity of Na^+ required to increase the plasma Na^+ concentration by a given amount can be estimated by multiplying the deficit in plasma Na^+ concentration by the total body water.

Under normal conditions, total body water is 50 or 60% of lean body weight in women or men, respectively. Therefore, to raise the plasma Na^+ concentration from 105 to 115 mmol/L in a 70-kg man requires 420 mmol $[(115 - 105) \times 70 \times 0.6]$ of Na^+. The risk of correcting hyponatremia too rapidly is the development of the *osmotic demyelination syndrome* (ODS). This is a neurologic disorder characterized by flaccid paralysis, dysarthria, and dysphagia. The diagnosis is usually suspected clinically and can be confirmed by appropriate neuroimaging studies. There is no specific treatment for the disorder, which is associated with significant morbidity and mortality. Patients with chronic hyponatremia are most susceptible to the development of

ODS, since their brain cell volume has returned to near normal as a result of the osmotic adaptive mechanisms described above. Therefore, administration of hypertonic saline to these individuals can cause sudden osmotic shrinkage of brain cells. In addition to rapid or overcorrection of hyponatremia, risk factors for ODS include prior cerebral anoxic injury, hypokalemia, and malnutrition, especially secondary to alcoholism. Water restriction in primary polydipsia and intravenous saline therapy in ECF volume–contracted patients may also lead to overly rapid correction of hyponatremia as a result of AVP suppression and a brisk water diuresis. This can be prevented by administration of water or use of an AVP analogue to slow down the rate of free water excretion. **For further discussion, see Chap. 334.**

HYPERNATREMIA

Etiology Hypernatremia is defined as a plasma Na^+ concentration >145 mmol/L. Since Na^+ and its accompanying anions are the major effective ECF osmoles, hypernatremia is a state of hyperosmolality. As a result of the fixed number of ICF particles, maintenance of osmotic equilibrium in hypernatremia results in ICF volume contraction. Hypernatremia may be due to primary Na^+ gain or water deficit. The two components of an appropriate response to hypernatremia are increased water intake stimulated by thirst and the excretion of the minimum volume of maximally concentrated urine reflecting AVP secretion in response to an osmotic stimulus.

In practice, the majority of cases of hypernatremia result from the loss of water. Since water is distributed between the ICF and the ECF in a 2:1 ratio, a given amount of solute-free water loss will result in a twofold greater reduction in the ICF compartment than the ECF compartment. For example, consider three scenarios: the loss of 1 L of water, isotonic NaCl, or half-isotonic NaCl. If 1 L of water is lost, the ICF volume will decrease by 667 mL, whereas the ECF volume will fall by only 333 mL. Due to the fact that Na^+ is largely restricted to the ECF, this compartment will decrease by 1 L if the fluid lost is isoosmotic. One liter of half-isotonic NaCl is equivalent to 500 mL of water (one-third ECF, two-thirds ICF) plus 500 mL of isotonic saline (all ECF). Therefore, the loss of 1 L of half-isotonic saline decreases the ECF and ICF volumes by 667 mL and 333 mL, respectively.

The degree of hyperosmolality is typically mild unless the thirst mechanism is abnormal or access to water is limited. The latter occurs in infants, the physically handicapped, and patients with impaired mental status; in the postoperative state; and in intubated patients in the intensive care unit. On rare occasions, impaired thirst may be due to *primary hypodipsia*. This usually occurs as a result of damage to the hypothalamic osmoreceptors that control thirst and tends to be associated with abnormal osmotic regulation of AVP secretion. Primary hypodipsia may be due to a variety of pathologic changes, including granulomatous disease, vascular occlusion, and tumors. A subset of hypodipsic hypernatremia, referred to as *essential hypernatremia*, does not respond to forced water intake. This appears to be due to a specific osmoreceptor defect resulting in nonosmotic regulation of AVP release. Thus, the hemodynamic effects of water loading lead to AVP suppression and excretion of dilute urine.

The source of free water loss is either renal or extrarenal. Nonrenal loss of water may be due to evaporation from the skin and respiratory tract (insensible losses) or loss from the gastrointestinal tract. Insensible losses are increased with fever, exercise, heat exposure, and severe burns and in mechanically ventilated patients. Furthermore, the Na^+ concentration of sweat decreases with profuse perspiration, thereby increasing solute-free water loss. Diarrhea is the most common gastrointestinal cause of hypernatremia. Specifically, osmotic diarrheas (induced by lactulose, sorbitol, or malabsorption of carbohydrate) and viral gastroenteritides result in water loss exceeding that of Na^+ and K^+. In contrast, secretory diarrheas (e.g., cholera, carcinoid, VIPoma) have a fecal osmolality (twice the sum of the concentrations of Na^+ and K^+) similar to that of plasma and present with ECF volume contraction and a normal plasma Na^+ concentration or hyponatremia.

Renal water loss is the most common cause of hypernatremia and is due to drug-induced or osmotic diuresis or diabetes insipidus (Chap. 334). Loop diuretics interfere with the countercurrent mechanism and produce an isoosmotic solute diuresis. This results in a decreased medullary interstitial tonicity and impaired renal concentrating ability. The presence of non-reabsorbed organic solutes in the tubule lumen impairs the osmotic reabsorption of water. This leads to water loss in excess of Na^+ and K^+, known as an osmotic diuresis. The most frequent cause of an osmotic diuresis is hyperglycemia and glucosuria in poorly controlled diabetes mellitus. Intravenous administration of mannitol and increased endogenous production of urea (high-protein diet) can also result in an osmotic diuresis.

Hypernatremia secondary to nonosmotic urinary water loss is usually due to: (1) Central diabetes insipidus (CDI) characterized by impaired AVP secretion, or (2) NDI resulting from end-organ (renal) resistance to the actions of AVP. The most common cause of CDI is destruction of the neurohypophysis. This may occur as a result of trauma, neurosurgery, granulomatous disease, neoplasms, vascular accidents, or infection. In many cases, CDI is idiopathic and may occasionally be hereditary. The familial form of the disease is inherited in an autosomal dominant fashion and has been attributed to mutations in the propressophysin (AVP precursor) gene. Nephrogenic diabetes insipidus (NDI) may be either inherited or acquired. Congenital NDI is an X-linked recessive trait due to mutations in the V_2 receptor gene. Mutations in the autosomal *aquaporin-2* gene may also result in NDI. The *aquaporin-2* gene encodes the water channel protein whose membrane insertion is stimulated by AVP. The causes of sporadic NDI are numerous and include drugs (especially lithium), hypercalcemia, hypokalemia, and conditions that impair medullary hypertonicity (e.g., papillary necrosis or osmotic diuresis). Pregnant women, in the second or third trimester, may develop NDI as a result of excessive elaboration of vasopressinase by the placenta.

Finally, although infrequent, a primary Na^+ gain may cause hypernatremia. For example, inadvertent administration of hypertonic NaCl or $NaHCO_3$ or replacing sugar with salt in infant formula can produce this complication.

Clinical Features As a consequence of hypertonicity, water shifts out of cells, leading to a contracted ICF volume. A decreased brain cell volume is associated with an increased risk of subarachnoid or intracerebral hemorrhage. Hence, the major symptoms of hypernatremia are neurologic and include altered mental status, weakness, neuromuscular irritability, focal neurologic deficits, and occasionally coma or seizures. Patients may also complain of polyuria or thirst. For unknown reasons, patients with polydipsia from CDI tend to prefer ice-cold water. The signs and symptoms of volume depletion are often present in patients with a history of excessive sweating, diarrhea, or an osmotic diuresis. As with hyponatremia, the severity of the clinical manifestations is related to the acuity and magnitude of the rise in plasma Na^+ concentration. Chronic hypernatremia is generally less symptomatic as a result of adaptive mechanisms designed to defend cell volume. Brain cells initially take up Na^+ and K^+ salts, later followed by accumulation of organic osmolytes such as inositol. This serves to restore the brain ICF volume toward normal.

Diagnosis (Fig. 46-2) A complete history and physical examination will often provide clues as to the underlying cause of hypernatremia. Relevant symptoms and signs include the absence or presence of thirst, diaphoresis, diarrhea, polyuria, and the features of ECF volume contraction. The history should include a list of current and recent medications, and the physical examination is incomplete without a thorough mental status and neurologic assessment. Measurement of urine volume and osmolality are essential in the evaluation of hyperosmolality. The appropriate renal response to hypernatremia is the excretion of the minimum volume (500 mL/d) of maximally concentrated urine (urine osmolality >800 mosmol/kg). These findings suggest extrarenal or remote renal water loss or administration of hypertonic Na^+ salt solutions. The presence of a primary Na^+ excess can be confirmed by the presence of ECF volume expansion and natriuresis (urine Na^+ concentration usually >100 mmol/L).

Many causes of hypernatremia are associated with polyuria and a submaximal urine osmolality. The product of the urine volume and osmolality, i.e., the solute excretion rate, is helpful in determining the

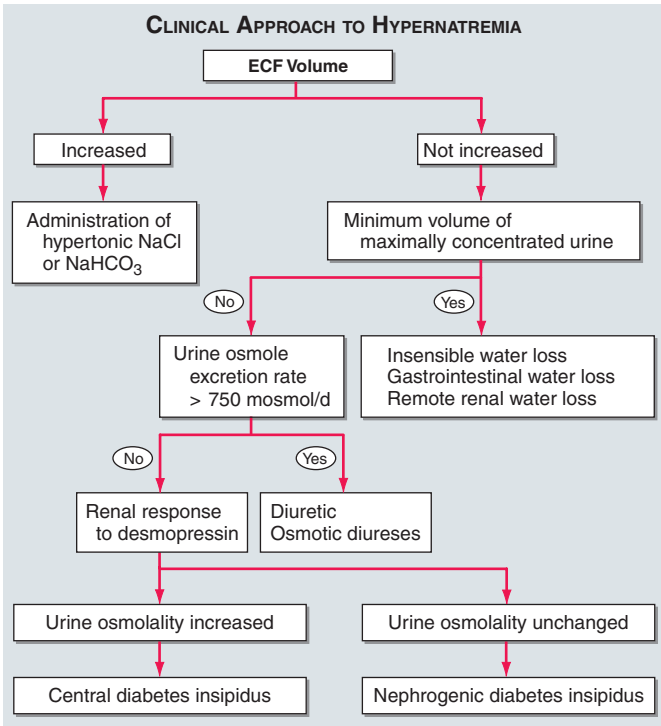

FIGURE 46-2 Algorithm depicting clinical approach to hypernatremia.

basis of the polyuria (see above). To maintain a steady state, total solute excretion must equal solute production. As stated above, individuals eating a normal diet generate ~600 mosmol/d. Therefore, daily solute excretion in excess of 750 mosmol defines an osmotic diuresis. This can be confirmed by measuring the urine glucose and urea. In general, both CDI and NDI present with polyuria and hypotonic urine (urine osmolality <250 mosmol/kg). The degree of hypernatremia is usually mild unless there is an associated thirst abnormality. The clinical history, physical examination, and pertinent laboratory data can often rule out causes of acquired NDI. CDI and NDI can generally be distinguished by administering the AVP analogue desmopressin (10 μg intranasally) after careful water restriction. The urine osmolality should increase by at least 50% in CDI and will not change in NDI. Unfortunately, the diagnosis may sometimes be difficult due to partial defects in AVP secretion and action.

Rx HYPERNATREMIA

The therapeutic goals are to stop ongoing water loss by treating the underlying cause and to correct the water deficit. The ECF volume should be restored in hypovolemic patients. The quantity of water required to correct the deficit can be calculated from the following equation:

$$\text{Water deficit} = \frac{\text{Plasma } Na^+ \text{ concentration} - 140}{140} \times \text{Total body water}$$

In hypernatremia due to water loss, total body water is approximately 50 and 40% of lean body weight in men and women, respectively. For example, a 50-kg woman with a plasma Na^+ concentration of 160 mmol/L has an estimated free-water deficit of 2.9 L {[(160 – 140) ÷ 140] × (0.4 × 50)}. As in hyponatremia, rapid correction of hypernatremia is potentially dangerous. In this case, a sudden decrease in osmolality could potentially cause a rapid shift of water into cells that have undergone osmotic adaptation. This would result in swollen brain cells and increase the risk of seizures or permanent neurologic damage. Therefore, the water deficit should be corrected slowly over at least 48–72 h. When calculating the rate of water replacement, ongoing losses should be taken into account, and the plasma Na^+ concentration should be lowered by 0.5 mmol/L per h and by no more than 12 mmol/L over the first 24 h.

The safest route of administration of water is by mouth or via a nasogastric tube (or other feeding tube). Alternatively, 5% dextrose in water or half-isotonic saline can be given intravenously. The appropriate treatment of CDI consists of administering desmopressin intranasally (Chap. 334). Other options for decreasing urine output include a low-salt diet in combination with low-dose thiazide diuretic therapy. In some patients with partial CDI, drugs that either stimulate AVP secretion or enhance its action on the kidney have been useful. These include chlorpropamide, clofibrate, carbamazepine, and nonsteroidal anti-inflammatory drugs (NSAIDs). The concentrating defect in NDI may be reversible by treating the underlying disorder or eliminating the offending drug. Symptomatic polyuria due to NDI can be treated with a low-Na^+ diet and thiazide diuretics, as described above. This induces mild volume depletion, which leads to enhanced proximal reabsorption of salt and water and decreased delivery to the site of action of AVP, the collecting duct. By impairing renal prostaglandin synthesis, NSAIDs potentiate AVP action and thereby increase urine osmolality and decrease urine volume. Amiloride may be useful in patients with NDI who need to be on lithium. The nephrotoxicity of lithium requires the drug to be taken up into collecting duct cells via the amiloride-sensitive Na^+ channel.

POTASSIUM

Potassium Balance Potassium is the major intracellular cation. The normal plasma K^+ concentration is 3.5–5.0 mmol/L, whereas that inside cells is about 150 mmol/L. Therefore, the amount of K^+ in the ECF (30–70 mmol) constitutes <2% of the total body K^+ content (2500–4500 mmol). The ratio of ICF to ECF K^+ concentration (normally 38:1) is the principal result of the resting membrane potential and is crucial for normal neuromuscular function. The basolateral Na^+, K^+-ATPase pump actively transports K^+ in and Na^+ out of the cell in a 2:3 ratio, and the passive outward diffusion of K^+ is quantitatively the most important factor that generates the resting membrane potential. The activity of the electrogenic Na^+, K^+-ATPase pump may be stimulated as a result of an increased intracellular Na^+ concentration and inhibited in the setting of digoxin toxicity or chronic illness such as heart failure or renal failure.

The K^+ intake of individuals on an average western diet is 40–120 mmol/d, or approximately 1 mmol/kg per day, 90% of which is absorbed by the gastrointestinal tract. Maintenance of the steady state necessitates matching K^+ ingestion with excretion. Initially, extrarenal adaptive mechanisms, followed later by urinary excretion, prevent a doubling of the plasma K^+ concentration that would occur if the dietary K^+ load remained in the ECF compartment. Immediately following a meal, most of the absorbed K^+ enters cells as a result of the initial elevation in the plasma K^+ concentration and facilitated by insulin release and basal catecholamine levels. Eventually, however, the excess K^+ is excreted in the urine (see below). The regulation of gastrointestinal K^+ handling is not well understood. The amount of K^+ lost in the stool can increase from 10 to 50% or 60% (of dietary intake) in chronic renal insufficiency. In addition, colonic secretion of K^+ is stimulated in patients with large volumes of diarrhea, resulting in potentially severe K^+ depletion.

Potassium Excretion (See also Chap. 272) Renal excretion is the major route of elimination of dietary and other sources of excess K^+. The filtered load of K^+ (GFR × plasma K^+ concentration = 180 L/d × 4 mmol/L = 720 mmol/d) is ten- to twentyfold greater than the ECF K^+ content. Some 90% of filtered K^+ is reabsorbed by the proximal convoluted tubule and loop of Henle. Proximally, K^+ is reabsorbed passively with Na^+ and water, whereas the luminal Na^+-K^+-$2Cl^-$ co-transporter mediates K^+ uptake in the thick ascending limb of the loop of Henle. Therefore, K^+ delivery to the distal nephron [distal convoluted tubule and cortical collecting duct (CCD)] approximates dietary intake. Net distal K^+ secretion or reabsorption occurs in the setting of K^+ excess or depletion, respectively. The cell responsible for K^+ secretion in the late distal convoluted tubule (or connecting tubule) and CCD is the principal cell. Virtually all regulation of renal K^+ excretion and total body K^+ balance occurs in the distal nephron. Potassium secretion is regulated by two physiologic stimuli—aldosterone and hyperkalemia. Aldosterone is secreted by the zona glomerulosa cells of the adrenal cortex in response to high renin and angiotensin II or hyperkalemia. The plasma K^+ concentration, independent of

TABLE 46-3 CAUSES OF HYPOKALEMIA

I. Decreased intake
  A. Starvation
  B. Clay ingestion
II. Redistribution into cells
  A. Acid-base
    1. Metabolic alkalosis
  B. Hormonal
    1. Insulin
    2. β_2-Adrenergic agonists (endogenous or exogenous)
    3. α-Adrenergic antagonists
  C. Anabolic state
    1. Vitamin B_{12} or folic acid (red blood cell production)
    2. Granulocyte-macrophage colony stimulating factor (white blood cell production)
    3. Total parenteral nutrition
  D. Other
    1. Pseudohypokalemia
    2. Hypothermia
    3. Hypokalemic periodic paralysis
    4. Barium toxicity
III. Increased loss
  A. Nonrenal
    1. Gastrointestinal loss (diarrhea)
    2. Integumentary loss (sweat)
  B. Renal
    1. Increased distal flow: diuretics, osmotic diuresis, salt-wasting nephropathies
    2. Increased secretion of potassium
      a. Mineralocorticoid excess: primary hyperaldosteronism, secondary hyperaldosteronism (malignant hypertension, renin-secreting tumors, renal artery stenosis, hypovolemia), apparent mineralocorticoid excess (licorice, chewing tobacco, carbenoxolone), congenital adrenal hyperplasia, Cushing's syndrome, Bartter's syndrome
      b. Distal delivery of non-reabsorbed anions: vomiting, nasogastric suction, proximal (type 2) renal tubular acidosis, diabetic ketoacidosis, glue-sniffing (toluene abuse), penicillin derivatives
      c. Other: amphotericin B, Liddle's syndrome, hypomagnesemia

aldosterone, can directly affect K^+ secretion. In addition to the K^+ concentration in the lumen of the CCD, renal K^+ loss depends on the urine flow rate, a function of daily solute excretion (see above). Since excretion is equal to the product of concentration and volume, increased distal flow rate can significantly enhance urinary K^+ output. Finally, in severe K^+ depletion, secretion of K^+ is reduced and reabsorption in the cortical and medullary collecting ducts is upregulated.

HYPOKALEMIA

Etiology

(Table 46-3) Hypokalemia, defined as a plasma K^+ concentration <3.5 mmol/L, may result from one (or more) of the following: decreased net intake, shift into cells, increased net loss. Diminished intake is seldom the sole cause of K^+ depletion since urinary excretion can be effectively decreased to <15 mmol/d as a result of net K^+ reabsorption in the distal nephron. With the exception of the urban poor and certain cultural groups, the amount of K^+ in the diet almost always exceeds that excreted in the urine. However, dietary K^+ restriction may exacerbate the hypokalemia secondary to increased gastrointestinal or renal loss. An unusual cause of decreased K^+ intake is ingestion of clay (geophagia), which binds dietary K^+ and iron. This custom was previously common among African Americans in the American South.

REDISTRIBUTION INTO CELLS Movement of K^+ into cells may transiently decrease the plasma K^+ concentration without altering total body K^+ content. For any given cause, the magnitude of the change is relatively small, often <1 mmol/L. However, a combination of factors may lead to a significant fall in the plasma K^+ concentration and may amplify the hypokalemia due to K^+ wasting. Metabolic alkalosis is often associated with hypokalemia. This occurs as a result of K^+ redistribution as well as excessive renal K^+ loss. Treatment of diabetic ketoacidosis with insulin may lead to hypokalemia due to stimulation of the Na^+-H^+ antiporter and (secondarily) the Na^+, K^+-ATPase pump. Furthermore, uncontrolled hyperglycemia often leads to K^+ depletion from an osmotic diuresis (see below). Stress-induced catecholamine release and administration of β_2-adrenergic agonists directly induce cellular uptake of K^+ and promote insulin secretion by pancreatic islet β cells. *Hypokalemic periodic paralysis* is a rare condition characterized by recurrent episodic weakness or paralysis (Chap. 382). Since K^+ is the major ICF cation, anabolic states can potentially result in hypokalemia due to a K^+ shift into cells. This may occur following rapid cell growth seen in patients with pernicious anemia treated with vitamin B_{12} or with neutropenia after treatment with granulocyte-macrophage colony stimulating factor. Massive transfusion with thawed washed red blood cells (RBCs) could cause hypokalemia since frozen RBCs lose up to half of their K^+ during storage.

NONRENAL LOSS OF POTASSIUM Excessive sweating may result in K^+ depletion from increased integumentary and renal K^+ loss. Hyperaldosteronism, secondary to ECF volume contraction, enhances K^+ excretion in the urine (Chap. 336). Normally, K^+ lost in the stool amounts to 5–10 mmol/d in a volume of 100–200 mL. Hypokalemia subsequent to increased gastrointestinal loss can occur in patients with profuse diarrhea (usually secretory), villous adenomas, VIPomas, or laxative abuse. However, the loss of gastric secretions does not account for the moderate to severe K^+ depletion often associated with vomiting or nasogastric suction. Since the K^+ concentration of gastric fluid is 5–10 mmol/L, it would take 30–80 L of vomitus to achieve a K^+ deficit of 300–400 mmol typically seen in these patients. In fact, the hypokalemia is primarily due to increased renal K^+ excretion. Loss of gastric contents results in volume depletion and metabolic alkalosis, both of which promote kaliuresis. Hypovolemia stimulates aldosterone release, which augments K^+ secretion by the principal cells. In addition, the filtered load of HCO_3^- exceeds the reabsorptive capacity of the proximal convoluted tubule, thereby increasing distal delivery of $NaHCO_3$, which enhances the electrochemical gradient favoring K^+ loss in the urine.

RENAL LOSS OF POTASSIUM (See also Chap. 336) In general, most cases of chronic hypokalemia are due to renal K^+ wasting. This may be due to factors that increase the K^+ concentration in the lumen of the CCD or augment distal flow rate. Mineralocorticoid excess commonly results in hypokalemia. *Primary hyperaldosteronism* is due to dysregulated aldosterone secretion by an adrenal adenoma (Conn's syndrome) or carcinoma or to adrenocortical hyperplasia. In a rare subset of patients, the disorder is familial (autosomal dominant) and aldosterone levels can be suppressed by administering low doses of exogenous glucocorticoid. The molecular defect responsible for *glucocorticoid-remediable hyperaldosteronism* is a rearranged gene (due to a chromosomal crossover), containing the 5′-regulatory region of the 11β-hydroxylase gene and the coding sequence of the aldosterone synthase gene. Consequently, mineralocorticoid is synthesized in the zona fasciculata and regulated by corticotropin. A number of conditions associated with hyperreninemia result in secondary hyperaldosteronism and renal K^+ wasting. High renin levels are commonly seen in both renovascular and malignant hypertension. Renin-secreting tumors of the juxtaglomerular apparatus are a rare cause of hypokalemia. Other tumors that have been reported to produce renin include renal cell carcinoma, ovarian carcinoma, and Wilms' tumor. Hyperreninemia may also occur secondary to decreased effective circulating arterial volume.

In the absence of elevated renin or aldosterone levels, enhanced distal nephron secretion of K^+ may result from increased production of nonaldosterone mineralocorticoids in *congenital adrenal hyperplasia*. Glucocorticoid-stimulated kaliuresis does not normally occur due to the conversion of cortisol to cortisone by 11β-hydroxysteroid dehydrogenase (11β-HSDH). Therefore, 11β-HSDH deficiency or suppression allows cortisol to bind to the aldosterone receptor and leads to the *syndrome of apparent mineralocorticoid excess*. Drugs that inhibit the activity of 11β-HSDH include glycyrrhetinic acid, present in licorice, chewing tobacco, and carbenoxolone. The presentation of Cushing's syndrome may include hypokalemia if the capacity of 11β-HSDH to inactivate cortisol is overwhelmed by persistently elevated glucocorticoid levels.

Liddle's syndrome is a rare familial (autosomal dominant) disease characterized by hypertension, hypokalemic metabolic alkalosis, renal

K^+ wasting, and suppressed renin and aldosterone secretion. Increased distal delivery of Na^+ with a nonreabsorbable anion (not Cl^-) enhances K^+ secretion. Classically, this is seen with *proximal (type 2) renal tubular acidosis* (RTA) and vomiting, associated with bicarbonaturia. Diabetic ketoacidosis and toluene abuse (glue sniffing) can lead to increased delivery of β-hydroxybutyrate and hippurate, respectively, to the CCD and to renal K^+ loss. High doses of penicillin derivatives administered to volume-depleted patients may likewise promote renal K^+ secretion as well as an osmotic diuresis. *Classic distal (type 1) RTA* is associated with hypokalemia due to increased renal K^+ loss, the mechanism of which is uncertain. Amphotericin B causes hypokalemia due to increased distal nephron permeability to Na^+ and K^+ and to renal K^+ wasting.

Bartter's syndrome is a disorder characterized by hypokalemia, metabolic alkalosis, hyperreninemic hyperaldosteronism secondary to ECF volume contraction, and juxtaglomerular apparatus hyperplasia. Finally, diuretic use and abuse are common causes of K^+ depletion. Carbonic anhydrase inhibitors, loop diuretics, and thiazides are all kaliuretic. The degree of hypokalemia tends to be greater with long-acting agents and is dose-dependent. Increased renal K^+ excretion is due primarily to increased distal solute delivery and secondary hyperaldosteronism (due to volume depletion). See also Chap. 278.

Clinical Features The clinical manifestations of K^+ depletion vary greatly between individual patients, and their severity depends on the degree of hypokalemia. Symptoms seldom occur unless the plasma K^+ concentration is <3 mmol/L. Fatigue, myalgia, and muscular weakness of the lower extremities are common complaints and are due to a lower (more negative) resting membrane potential. More severe hypokalemia may lead to progressive weakness, hypoventilation (due to respiratory muscle involvement), and eventually complete paralysis. Impaired muscle metabolism and the blunted hyperemic response to exercise associated with profound K^+ depletion increase the risk of rhabdomyolysis. Smooth-muscle function may also be affected and manifest as paralytic ileus.

The electrocardiographic changes of hypokalemia (Fig. 221-16) are due to delayed ventricular repolarization and do not correlate well with the plasma K^+ concentration. Early changes include flattening or inversion of the T wave, a prominent U wave, ST-segment depression, and a prolonged QU interval. Severe K^+ depletion may result in a prolonged PR interval, decreased voltage and widening of the QRS complex, and an increased risk of ventricular arrhythmias, especially in patients with myocardial ischemia or left ventricular hypertrophy. Hypokalemia may also predispose to digitalis toxicity. Hypokalemia is often associated with acid-base disturbances related to the underlying disorder. In addition, K^+ depletion results in intracellular acidification and an increase in net acid excretion or new HCO_3^- production. This is a consequence of enhanced proximal HCO_3^- reabsorption, increased renal ammoniagenesis, and increased distal H^+ secretion. This contributes to the generation of metabolic alkalosis frequently present in hypokalemic patients. NDI (see above) is not uncommonly seen in K^+ depletion and is manifest as polydipsia and polyuria. Glucose intolerance may also occur with hypokalemia and has been attributed to either impaired insulin secretion or peripheral insulin resistance.

Diagnosis (Fig. 46-3) In most cases, the etiology of K^+ depletion can be determined by a careful history. Diuretic and laxative abuse as well as surreptitious vomiting may be difficult to identify but should be excluded. Rarely, patients with a marked leukocytosis (e.g., acute myeloid leukemia) and normokalemia may have a low measured plasma K^+ concentration due to white blood cell uptake of K^+ at room temperature. This *pseudohypokalemia* can be avoided by storing the blood sample on ice or rapidly separating the plasma (or serum) from the cells.

After eliminating decreased intake and intracellular shift as potential causes of hypokalemia, examination of the renal response can help to clarify the source of K^+ loss. The appropriate response to K^+ depletion is to excrete <15 mmol/d of K^+ in the urine, due to increased reabsorption and decreased distal secretion. Hypokalemia with minimal renal K^+ excretion suggests that K^+ was lost via the skin or gastrointestinal tract or that there is a remote history of vomiting or diuretic use. As described above, renal K^+ wasting may be due to factors that either increase the K^+ concentration in the CCD or increase the distal flow rate (or both). The ECF volume status, blood pressure, and associated acid-base disorder may help to differentiate the causes of excessive renal K^+ loss. A rapid and simple test designed to evaluate the driving force for net K^+ secretion is the *transtubular K^+ concentration gradient* (TTKG). The TTKG is the ratio of the K^+ concentration in the lumen of the CCD ($[K^+]_{CCD}$) to that in peritubular capillaries or plasma ($[K^+]_P$). The validity of this measurement depends on three assumptions: (1) few solutes are reabsorbed in the medullary collecting duct (MCD), (2) K^+ is neither secreted nor reabsorbed in the MCD, and (3) the osmolality of the fluid in the terminal CCD is known. Significant reabsorption or secretion of K^+ in the MCD seldom occurs, except in profound K^+ depletion or excess, respectively. When AVP is acting ($OSM_U \geq OSM_P$), the osmolality in the terminal CCD is the same as that of plasma, and the K^+ concentration in the lumen of the distal nephron can be estimated by dividing the urine K^+ concentration ($[K^+]_U$) by the ratio of the urine to plasma osmolality (OSM_U/OSM_P):

$$[K^+]_{CCD} = [K^+]_U \div (OSM_U/OSM_P)TTKG$$
$$= [K^+]_{CCD}/[K^+]_P = [K^+]_U \div (OSM_U/OSM_P)/[K^+]_P$$

Hypokalemia with a TTKG greater than 4 suggests renal K^+ loss due to increased distal K^+ secretion. Plasma renin and aldosterone levels are often helpful in differentiating the various causes of hyperaldosteronism. Bicarbonaturia and the presence of other non-reabsorbed anions also increase the TTKG and lead to renal K^+-wasting.

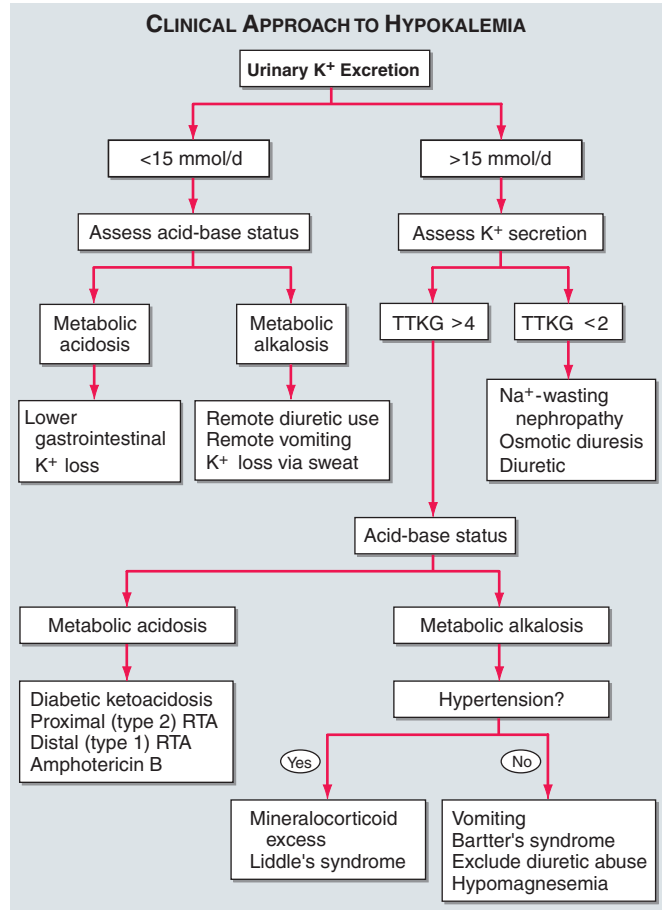

FIGURE 46-3 Algorithm depicting clinical approach to hypokalemia. TTKG, transtubular K^+ concentration gradient; RTA, renal tubular acidosis.

Rx HYPOKALEMIA

The therapeutic goals are to correct the K^+ deficit and to minimize ongoing losses. With the exception of periodic paralysis, hypokalemia resulting from

transcellular shifts rarely requires intravenous K^+ supplementation, which can lead to rebound hyperkalemia. It is generally safer to correct hypokalemia via the oral route. The degree of K^+ depletion does not correlate well with the plasma K^+ concentration. A decrement of 1 mmol/L in the plasma K^+ concentration (from 4.0 to 3.0 mmol/L) may represent a total body K^+ deficit of 200–400 mmol, and patients with plasma levels under 3.0 mmol/L often require in excess of 600 mmol of K^+ to correct the deficit. Furthermore, factors promoting K^+ shift out of cells (e.g., insulin deficiency in diabetic ketoacidosis) may result in underestimation of the K^+ deficit. Therefore, the plasma K^+ concentration should be monitored frequently when assessing the response to treatment. Potassium chloride is usually the preparation of choice and will promote more rapid correction of hypokalemia and metabolic alkalosis. Potassium bicarbonate and citrate (metabolized to HCO_3^-) tend to alkalinize the patient and would be more appropriate for hypokalemia associated with chronic diarrhea or RTA.

Patients with severe hypokalemia or those unable to take anything by mouth require intravenous replacement therapy with KCl. The maximum concentration of administered K^+ should be no more than 40 mmol/L via a peripheral vein or 60 mmol/L via a central vein. The rate of infusion should not exceed 20 mmol/h unless paralysis or malignant ventricular arrhythmias are present. Ideally, KCl should be mixed in normal saline since dextrose solutions may initially exacerbate hypokalemia due to insulin-mediated movement of K^+ into cells. Rapid intravenous administration of K^+ should be used judiciously and requires close observation of the clinical manifestations of hypokalemia (electrocardiogram and neuromuscular examination).

HYPERKALEMIA

Etiology Hyperkalemia, defined as a plasma K^+ concentration >5.0 mmol/L, occurs as a result of either K^+ release from cells or decreased renal loss. Increased K^+ intake is rarely the sole cause of hyperkalemia since the phenomenon of *potassium adaptation* ensures rapid K^+ excretion in response to increases in dietary consumption. Iatrogenic hyperkalemia may result from overzealous parenteral K^+ replacement or in patients with renal insufficiency. *Pseudohyperkalemia* represents an artificially elevated plasma K^+ concentration due to K^+ movement out of cells immediately prior to or following venipuncture. Contributing factors include prolonged use of a tourniquet with or without repeated fist clenching, hemolysis, and marked leukocytosis or thrombocytosis. The latter two result in an elevated serum K^+ concentration due to release of intracellular K^+ following clot formation. Pseudohyperkalemia should be suspected in an otherwise asymptomatic patient with no obvious underlying cause. If proper venipuncture technique is used and a plasma (not serum) K^+ concentration is measured, it should be normal. Intravascular hemolysis, tumor lysis syndrome, and rhabdomyolysis all lead to K^+ release from cells as a result of tissue breakdown.

Metabolic acidoses, with the exception of those due to the accumulation of organic anions, can be associated with mild hyperkalemia resulting from intracellular buffering of H^+ (see above). Insulin deficiency and hypertonicity (e.g., hyperglycemia) promote K^+ shift from the ICF to the ECF. The severity of exercise-induced hyperkalemia is related to the degree of exertion. It is due to release of K^+ from muscles and is usually rapidly reversible, often associated with rebound hypokalemia. Treatment with beta blockers rarely causes hyperkalemia but may contribute to the elevation in plasma K^+ concentration seen with other conditions. *Hyperkalemic periodic paralysis* (Chap. 382) is a rare autosomal dominant disorder characterized by episodic weakness or paralysis, precipitated by stimuli that normally lead to mild hyperkalemia (e.g., exercise). The genetic defect appears to be a single amino acid substitution due to a mutation in the gene for the skeletal muscle Na^+ channel. Hyperkalemia may occur with severe digitalis toxicity due to inhibition of the Na^+,K^+-ATPase pump. Depolarizing muscle relaxants such as succinylcholine can increase the plasma K^+ concentration, especially in patients with massive trauma, burns, or neuromuscular disease.

Chronic hyperkalemia is virtually always associated with decreased renal K^+ excretion due to either impaired secretion or diminished distal solute delivery (Table 46-4). The latter is seldom the only cause of impaired K^+ excretion but may significantly contribute to hyperkalemia in protein-malnourished (low urea excretion) and ECF volume–contracted (decreased distal NaCl delivery) patients. Decreased K^+ secretion by the principal cells results from either impaired Na^+ reabsorption or increased Cl^- reabsorption.

TABLE 46-4 CAUSES OF HYPERKALEMIA

I. Renal failure
II. Decreased distal flow (i.e., decreased effective circulating arterial volume)
III. Decreased K^+ secretion
  A. Impaired Na^+ reabsorption
    1. Primary hypoaldosteronism: adrenal insufficiency, adrenal enzyme deficiency (21-hydroxylase, 3β-hydroxysteroid dehydrogenase, corticosterone methyl oxidase)
    2. Secondary hypoaldosteronism: hyporeninemia, drugs (ACE inhibitors, NSAIDs, heparin)
    3. Resistance to aldosterone: pseudohypoaldosteronism, tubulointerstitial disease, drugs (K^+-sparing diuretics, trimethoprim, pentamidine)
  B. Enhanced Cl^- reabsorption (chloride shunt)
    1. Gordon's syndrome
    2. Cyclosporine

Note: ACE, angiotensin-converting enzyme; NSAIDs, nonsteroidal anti-inflammatory drugs.

Hyporeninemic hypoaldosteronism is a syndrome characterized by euvolemia or ECF volume expansion and suppressed renin and aldosterone levels (Chaps. 336 and 338). This disorder is commonly seen in mild renal insufficiency, diabetic nephropathy, or chronic tubulointerstitial disease. Patients frequently have an impaired kaliuretic response to exogenous mineralocorticoid administration, suggesting that enhanced distal Cl^- reabsorption (electroneutral Na^+ reabsorption) may account for many of the findings of hyporeninemic hypoaldosteronism. NSAIDs inhibit renin secretion and the synthesis of vasodilatory renal prostaglandins. The resultant decrease in GFR and K^+ secretion is often manifest as hyperkalemia. As a rule, the degree of hyperkalemia due to hypoaldosteronism is mild in the absence of increased K^+ intake or renal dysfunction.

Angiotensin-converting enzyme (ACE) inhibitors block the conversion of angiotensin I to angiotensin II. Angiotensin receptor antagonists directly inhibit the actions of angiotensin II on AT1 angiotensin II receptors. The actions of both of these classes of drugs result in impaired aldosterone release. Patients at increased risk of ACE inhibitor or angiotensin receptor antagonist–induced hyperkalemia include those with diabetes mellitus, renal insufficiency, decreased effective circulating arterial volume, bilateral renal artery stenosis, or concurrent use of K^+-sparing diuretics or NSAIDs.

Decreased aldosterone synthesis may be due to *primary adrenal insufficiency* (Addison's disease) or congenital adrenal enzyme deficiency (Chap. 336). Heparin (including low-molecular-weight heparin) inhibits production of aldosterone by the cells of the zona glomerulosa and can lead to severe hyperkalemia in a subset of patients with underlying renal disease, diabetes mellitus, or those receiving K^+-sparing diuretics, ACE inhibitors, or NSAIDs. *Pseudohypoaldosteronism* is a rare familial disorder characterized by hyperkalemia, metabolic acidosis, renal Na^+ wasting, hypotension, high renin and aldosterone levels, and end-organ resistance to aldosterone. The gene encoding the mineralocorticoid receptor is normal in these patients, and the electrolyte abnormalities can be reversed with supraphysiologic doses of an exogenous mineralocorticoid (e.g., 9α-fludrocortisone) or an inhibitor of 11β-HSDH (e.g., carbenoxolone). The kaliuretic response to aldosterone is impaired by K^+-sparing diuretics. Spironolactone is a competitive mineralocorticoid antagonist, whereas amiloride and triamterene block the apical Na^+ channel of the principal cell. Two other drugs that impair K^+ secretion by blocking distal nephron Na^+ reabsorption are trimethoprim and pentamidine. These antimicrobial agents may contribute to the hyperkalemia often seen in patients infected with HIV who are being treated for *Pneumocystis carinii* pneumonia.

Hyperkalemia frequently complicates acute oliguric renal failure due to increased K^+ release from cells (acidosis, catabolism) and decreased excretion. Increased distal flow rate and K^+ secretion per nephron compensate for decreased renal mass in chronic renal insufficiency. However, these adaptive mechanisms eventually fail to maintain K^+ balance when the GFR falls below 10–15 mL/min or oliguria ensues. Otherwise asymptomatic urinary tract obstruction is an often overlooked cause of hyperkalemia. Other nephropathies associated

with impaired K^+ excretion include drug-induced interstitial nephritis, lupus nephritis, sickle cell disease, and diabetic nephropathy.

Gordon's syndrome is a rare condition characterized by hyperkalemia, metabolic acidosis, and a normal GFR. These patients are usually volume-expanded with suppressed renin and aldosterone levels as well as refractory to the kaliuretic effect of exogenous mineralocorticoids. It has been suggested that these findings could all be accounted for by increased distal Cl^- reabsorption (electroneutral Na^+ reabsorption), also referred to as a *Cl^- shunt*. A similar mechanism may be partially responsible for the hyperkalemia associated with cyclosporine nephrotoxicity. *Hyperkalemic distal (type 4) RTA* may be due to either hypoaldosteronism or a Cl^- shunt (aldosterone-resistant).

Clinical Features Since the resting membrane potential is related to the ratio of the ICF to ECF K^+ concentration, hyperkalemia partially depolarizes the cell membrane. Prolonged depolarization impairs membrane excitability and is manifest as weakness, which may progress to flaccid paralysis and hypoventilation if the respiratory muscles are involved. Hyperkalemia also inhibits renal ammoniagenesis and reabsorption of NH_4^+ in the TALH. Thus, net acid excretion is impaired and results in metabolic acidosis, which may further exacerbate the hyperkalemia due to K^+ movement out of cells.

The most serious effect of hyperkalemia is cardiac toxicity, which does not correlate well with the plasma K^+ concentration. The earliest electrocardiographic changes include increased T-wave amplitude, or peaked T waves. More severe degrees of hyperkalemia result in a prolonged PR interval and QRS duration, atrioventricular conduction delay, and loss of P waves. Progressive widening of the QRS complex and merging with the T wave produces a sine wave pattern. The terminal event is usually ventricular fibrillation or asystole.

Diagnosis (Fig. 46-4) With rare exceptions, chronic hyperkalemia is always due to impaired K^+ excretion. If the etiology is not readily apparent and the patient is asymptomatic, pseudohyperkalemia should be excluded, as described above. Oliguric acute renal failure and severe chronic renal insufficiency should also be ruled out. The history should focus on medications that impair K^+ handling and potential sources of K^+ intake. Evaluation of the ECF compartment, effective circulating volume, and urine output are essential components of the physical examination. The severity of hyperkalemia is determined by the symptoms, plasma K^+ concentration, and electrocardiographic abnormalities.

The appropriate renal response to hyperkalemia is to excrete at least 200 mmol of K^+ daily. In most cases, diminished renal K^+ loss is due to impaired K^+ secretion, which can be assessed by measuring the transtubular K^+ concentration gradient (TTKG). A TTKG <10 implies a decreased driving force for K^+ secretion due to either hypoaldosteronism or resistance to the renal effects of mineralocorticoid. This can be determined by evaluating the kaliuretic response to administration of mineralocorticoid (e.g., 9α-fludrocortisone). Primary adrenal insufficiency can be differentiated from hyporeninemic hypoaldosteronism by examining the renin-aldosterone axis. Renin and aldosterone levels should be measured in the supine and upright positions following 3 days of Na^+ restriction (Na^+ intake <10 mmol/d) in combination with a loop diuretic to induce mild volume contraction. Aldosterone-resistant hyperkalemia can result from the various causes of impaired distal Na^+ reabsorption or from a Cl^- shunt. The former leads to salt wasting, ECF volume contraction, and high renin and aldosterone levels. In contrast, enhanced distal Cl^- reabsorption is associated with volume expansion and suppressed renin and aldosterone secretion. As mentioned above, hypoaldosteronism seldom causes severe hyperkalemia in the absence of increased dietary K^+ intake, renal insufficiency, transcellular K^+ shifts, or antikaliuretic drugs.

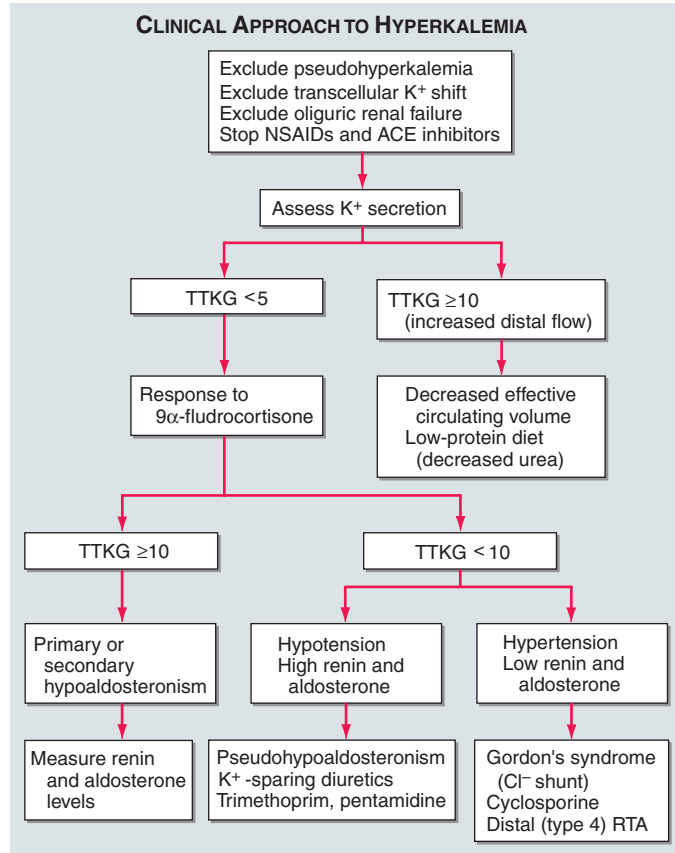

FIGURE 46-4 Algorithm depicting clinical approach to hyperkalemia. NSAID, nonsteroidal anti-inflammatory drug; ACE, angiotensin-converting enzyme; RTA, renal tubular acidosis; TTKG, transtubular K^+ concentration gradient.

℞ HYPERKALEMIA

The approach to therapy depends on the degree of hyperkalemia as determined by the plasma K^+ concentration, associated muscular weakness, and changes on the electrocardiogram. Potentially fatal hyperkalemia rarely occurs unless the plasma K^+ concentration exceeds 7.5 mmol/L and is usually associated with profound weakness and absent P waves, QRS widening, or ventricular arrhythmias on the electrocardiogram.

Severe hyperkalemia requires emergent treatment directed at minimizing membrane depolarization, shifting K^+ into cells, and promoting K^+ loss. In addition, exogenous K^+ intake and antikaliuretic drugs should be discontinued. Administration of calcium gluconate decreases membrane excitability. The usual dose is 10 mL of a 10% solution infused over 2–3 min. The effect begins within minutes but is short-lived (30–60 min), and the dose can be repeated if no change in the electrocardiogram is seen after 5–10 min. Insulin causes K^+ to shift into cells by mechanisms described previously and will temporarily lower the plasma K^+ concentration. Although glucose alone will stimulate insulin release from normal pancreatic β cells, a more rapid response generally occurs when exogenous insulin is administered (with glucose to prevent hypoglycemia). A commonly recommended combination is 10–20 units of regular insulin and 25–50 g of glucose. Obviously, hyperglycemic patients should not be given glucose. If effective, the plasma K^+ concentration will fall by 0.5–1.5 mmol/L in 15–30 min, and the effect will last for several hours. Alkali therapy with intravenous $NaHCO_3$ can also shift K^+ into cells. This is safest when administered as an isotonic solution of 3 ampules per liter (134 mmol/L $NaHCO_3$) and ideally should be reserved for severe hyperkalemia associated with metabolic acidosis. Patients with end-stage renal disease seldom respond to this intervention and may not tolerate the Na^+ load and resultant volume expansion. When administered parenterally or in nebulized form, β_2-adrenergic agonists promote cellular uptake of K^+ (see above). The onset of action is 30 min, lowering the plasma K^+ concentration by 0.5 to 1.5 mmol/L, and the effect lasts 2–4 h.

Removal of K^+ can be achieved using diuretics, cation-exchange resin, or dialysis. Loop and thiazide diuretics, often in combination, may enhance K^+ excretion if renal function is adequate. Sodium polystyrene sulfonate is a cation-exchange resin that promotes the exchange of Na^+ for K^+ in the gastrointestinal tract. Each gram binds 1 mmol of K^+ and releases 2–3 mmol of Na^+. When given by mouth, the usual dose is 25–50 g mixed with 100 mL of 20% sorbitol to prevent constipation. This will generally lower the plasma K^+ concentration by 0.5–1.0 mmol/L within 1–2 h and last for 4–6 h. Sodium polystyrene sulfonate can

also be administered as a retention enema consisting of 50 g of resin and 50 mL of 70% sorbitol mixed in 150 mL of tap water. The sorbitol should be omitted from the enema in postoperative patients due to the increased incidence of sorbitol-induced colonic necrosis, especially following renal transplantation. The most rapid and effective way of lowering the plasma K^+ concentration is hemodialysis. This should be reserved for patients with renal failure and those with severe life-threatening hyperkalemia unresponsive to more conservative measures. Peritoneal dialysis also removes K^+ but is only 15–20% as effective as hemodialysis. Finally, the underlying cause of the hyperkalemia should be treated. This may involve dietary modification, correction of metabolic acidosis, cautious volume expansion, and administration of exogenous mineralocorticoid.

47 Hypercalcemia and Hypocalcemia

Sundeep Khosla

The calcium ion plays a critical role in normal cellular function and signaling, regulating diverse physiologic processes such as neuromuscular signaling, cardiac contractility, hormone secretion, and blood coagulation. Thus, extracellular calcium concentrations are maintained within an exquisitely narrow range through a series of feedback mechanisms that involve parathyroid hormone (PTH) and the active vitamin D metabolite 1,25-dihydroxyvitmin D [1,25$(OH)_2$D]. These feedback mechanisms are orchestrated by integrating signals between the parathyroid glands, kidney, intestine, and bone (Fig. 47-1) (Chap. 346).

Disorders of serum calcium concentration are relatively common and often serve as a harbinger of underlying disease. This chapter provides a brief summary of the approach to patients with altered serum calcium levels. See Chap. 347 for a detailed discussion of this topic.

HYPERCALCEMIA

ETIOLOGY

The causes of hypercalcemia can be understood and classified based on derangements in the normal feedback mechanisms that regulate serum calcium (Table 47-1). Excess PTH production, which is not appropriately suppressed by increased serum calcium concentrations, occurs in primary neoplastic disorders of the parathyroid glands (parathyroid adenomas, hyperplasia, or, rarely, carcinoma) that are associated with increased parathyroid cell mass and impaired feedback inhibition by calcium. Inappropriate PTH secretion for the ambient level of serum calcium also occurs with heterozygous inactivating calcium sensor receptor (CaSR) mutations, which impair extracellular calcium sensing by the parathyroid glands and the kidneys, resulting in familial hypocalciuric hypercalcemia (FHH). Although PTH secretion by tumors is extremely rare, many solid tumors produce PTH-related peptide (PTHrP), which shares homology with PTH in the first 13 amino acids and binds the PTH receptor, thus mimicking effects of PTH on bone and the kidney. In PTHrP-mediated hypercalcemia of malignancy, PTH levels are suppressed by the high serum calcium levels. Hypercalcemia associated with granulomatous disease (e.g., sarcoidosis) or lymphomas is caused by enhanced conversion of 25(OH)D to the potent 1,25$(OH)_2$D. In these disorders, 1,25$(OH)_2$D enhances intestinal calcium absorption, resulting in hypercalcemia and suppressed PTH. Disorders that directly increase calcium mobilization from bone, such as hyperthyroidism or osteolytic metastases, also lead to hypercalcemia with suppressed PTH secretion, as does exogenous calcium overload, as in milk-alkali syndrome, or total parenteral nutrition with excessive calcium supplementation.

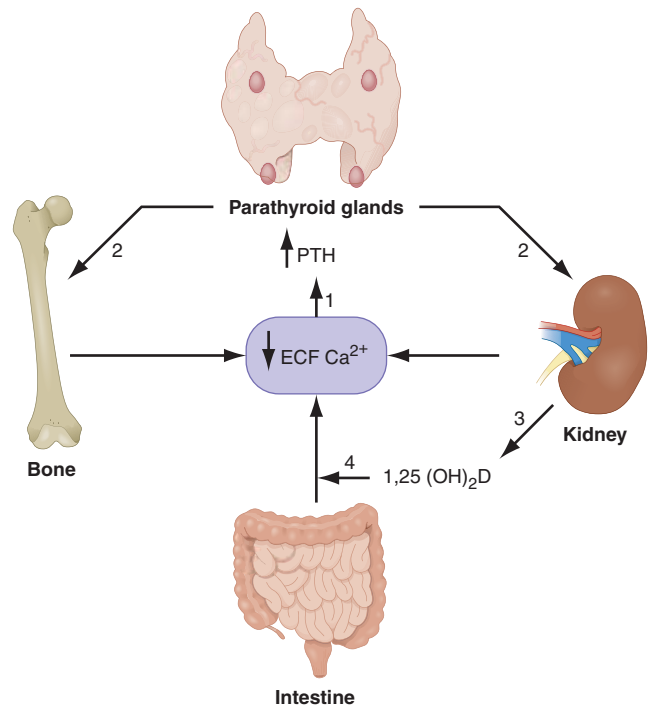

FIGURE 47-1 Feedback mechanisms maintaining extracellular calcium concentrations within a narrow, physiologic range [8.9–10.1 mg/dL (2.2–2.5 m*M*)]. A decrease in extracellular (ECF) calcium (Ca^{2+}) triggers an increase in parathyroid hormone (PTH) secretion (1) via activation of the calcium sensor receptor on parathyroid cells. PTH, in turn, results in increased tubular reabsorption of calcium by the kidney (2) and resorption of calcium from bone (2) and also stimulates renal 1,25$(OH)_2$D production (3). 1,25$(OH)_2$D, in turn, acts principally on the intestine to increase calcium absorption (4). Collectively, these homeostatic mechanisms serve to restore serum calcium levels to normal.

CLINICAL MANIFESTATIONS

Mild hypercalcemia (up to 11–11.5 mg/dL) is usually asymptomatic and recognized only on routine calcium measurements. Some patients may complain of vague neuropsychiatric symptoms, including trouble concentrating, personality changes, or depression. Other presenting symptoms

TABLE 47-1 CAUSES OF HYPERCALCEMIA

Excessive PTH production
Primary hyperparathyroidism (adenoma, hyperplasia, rarely carcinoma)
Tertiary hyperparathyroidism (long-term stimulation of PTH secretion in renal insufficiency)
Ectopic PTH secretion (very rare)
Inactivating mutations in the CaSR (FHH)
Alterations in CaSR function (lithium therapy)
Hypercalcemia of malignancy
Overproduction of PTHrP (many solid tumors)
Lytic skeletal metastases (breast, myeloma)
Excessive $1,25(OH)_2D$ production
Granulomatous diseases (sarcoidosis, tuberculosis, silicosis)
Lymphomas
Vitamin D intoxication
Primary increase in bone resorption
Hyperthyroidism
Immobilization
Excessive calcium intake
Milk-alkali syndrome
Total parenteral nutrition
Other causes
Endocrine disorders (adrenal insufficiency, pheochromocytoma, VIPoma)
Medications (thiazides, vitamin A, antiestrogens)

Note: CaSR, calcium sensor receptor; FHH, familial hypocalciuric hypercalcemia; PTH, parathyroid hormone; PTHrP, PTH-related peptide.

may include peptic ulcer disease or nephrolithiasis, and fracture risk may be increased. More severe hypercalcemia (>12–13 mg/dL), particularly if it develops acutely, may result in lethargy, stupor, or coma, as well as gastrointestinal symptoms (nausea, anorexia, constipation, or pancreatitis). Hypercalcemia decreases renal concentrating ability, which may cause polyuria and polydipsia. With long-standing hyperparathyroidism, patients may present with bone pain or pathologic fractures. Finally, hypercalcemia can result in significant electrocardiographic changes, including bradycardia, AV block, and short QT interval; changes in serum calcium can be monitored by following the QT interval (Fig. 221-16).

DIAGNOSTIC APPROACH

The first step in the diagnostic evaluation of hyper- or hypocalcemia is to ensure that the alteration in serum calcium levels is not due to abnormal albumin concentrations. About 50% of total calcium is ionized, and the rest is bound principally to albumin. Although direct measurements of ionized calcium are possible, they are easily influenced by collection methods and other artifacts; thus, it is generally preferable to measure total calcium and albumin to "correct" the serum calcium. When serum albumin concentrations are reduced, a corrected calcium concentration is calculated by adding 0.2 m*M* (0.8 mg/dL) to the total calcium level for every decrement in serum albumin of 1.0 g/dL below the reference value of 4.1 g/dL for albumin, and conversely for elevations in serum albumin.

A detailed history may provide important clues regarding the etiology of the hypercalcemia (Table 47-1). Chronic hypercalcemia is most commonly caused by primary hyperparathyroidism, as opposed to the second most common etiology of hypercalcemia, an underlying malignancy. The history should include medication use, previous neck surgery, and systemic symptoms suggestive of sarcoidosis or lymphoma.

Once true hypercalcemia is established, the second most important laboratory test in the diagnostic evaluation is a PTH level using a two-site assay for the intact hormone. Increases in PTH are often accompanied by hypophosphatemia. In addition, serum creatinine should be measured to assess renal function; hypercalcemia may impair renal function, and renal clearance of PTH may be altered depending on the fragments detected by the assay. If the PTH level is increased (or "inappropriately normal") in the setting of an elevated calcium and low phosphorus, the diagnosis is almost always primary hyperparathyroidism. Since individuals with familial hypocalciuric hypercalcemia (FHH) may also present with mildly elevated PTH levels and hypercalcemia, this diagnosis should be considered and excluded because parathyroid surgery is ineffective in this condition. A calcium/creatinine clearance ratio (calculated as urine calcium/serum calcium divided by urine creatinine/serum creatinine) of <0.01 is suggestive of FHH, particularly when there is a family history of mild, asymptomatic hypercalcemia. Ectopic PTH secretion is extremely rare.

A suppressed PTH level in the face of hypercalcemia is consistent with non-parathyroid-mediated hypercalcemia, most often due to underlying malignancy. Although a tumor that causes hypercalcemia is generally overt, a PTHrP level may be needed to establish the diagnosis of hypercalcemia of malignancy. Serum $1,25(OH)_2D$ levels are increased in granulomatous disorders, and clinical evaluation in combination with laboratory testing will generally provide a diagnosis for the various disorders listed in Table 47-1.

Rx HYPERCALCEMIA

Mild, asymptomatic hypercalcemia does not require immediate therapy, and management should be dictated by the underlying diagnosis. By contrast, significant, symptomatic hypercalcemia usually requires therapeutic intervention independent of the etiology of hypercalcemia. Initial therapy of significant hypercalcemia begins with volume expansion since hypercalcemia invariably leads to dehydration; 4–6 L of intravenous saline may be required over the first 24 h, keeping in mind that underlying comorbidities (e.g., congestive heart failure) may require the use of loop diuretics to enhance sodium and calcium excretion. However, loop diuretics should not be initiated until the volume status has been restored to normal. If there is increased calcium mobilization from bone (as in malignancy or severe hyperparathyroidism), drugs that inhibit bone resorption should be considered. Zoledronic acid (e.g., 4 mg intravenously over ~30 min), pamidronate (e.g., 60–90 mg intravenously over 2–4 h), and etidronate (e.g., 7.5 mg/kg per day for 3–7 consecutive days) are approved by the U.S. Food and Drug Administration for the treatment of hypercalcemia of malignancy in adults. Onset of action is within 1–3 days, with normalization of serum calcium levels occurring in 60–90% of patients. Bisphosphonate infusions may need to be repeated if hypercalcemia relapses. Because of their effectiveness, bisphosphonates have replaced calcitonin or plicamycin, which are rarely used in current practice for the management of hypercalcemia. In rare instances, dialysis may be necessary. Finally, while intravenous phosphate chelates calcium and decreases serum calcium levels, this therapy can be toxic because calcium-phosphate complexes may deposit in tissues and cause extensive organ damage.

In patients with $1,25(OH)_2D$-mediated hypercalcemia, glucocorticoids are the preferred therapy, as they decrease $1,25(OH)_2D$ production. Intravenous hydrocortisone (100–300 mg daily) or oral prednisone (40–60 mg daily) for 3–7 days are used most often. Other drugs, such as ketoconazole, chloroquine, and hydroxychloroquine, may also decrease $1,25(OH)_2D$ production and are used occasionally.

HYPOCALCEMIA

ETIOLOGY

The causes of hypocalcemia can be differentiated according to whether serum PTH levels are low (hypoparathyroidism) or high (secondary hyperparathyroidism). Although there are many potential causes of hypocalcemia, impaired PTH or vitamin D production are the most common etiologies (Table 47-2) (Chap. 347). Because PTH is the main defense against hypocalcemia, disorders associated with deficient PTH production or secretion may be associated with profound, life-threatening hypocalcemia. In adults, hypoparathyroidism most commonly results from inadvertent damage to all four glands during thyroid or parathyroid gland surgery. Hypoparathyroidism is a cardinal feature of autoimmune endocrinopathies (Chap. 345); rarely, it may be associated with infiltrative diseases such as sarcoidosis. Impaired PTH secretion may be secondary to magnesium deficiency or to activating mutations in the CaSR, which suppress PTH, leading to effects that are opposite to those that occur in FHH.

Vitamin D deficiency, impaired $1,25(OH)_2D$ production (primarily secondary to renal insufficiency), or, rarely, vitamin D resistance also cause hypocalcemia. However, the degree of hypocalcemia in these disorders is generally not as severe as that seen with hypoparathyroidism because the parathyroids are capable of mounting a compensatory increase in PTH secretion. Hypocalcemia may also occur in conditions associated with severe tissue injury such as burns, rhabdomyolysis, tumor lysis, or pancreatitis. The cause of hypocalcemia in these settings

TABLE 47-2 CAUSES OF HYPOCALCEMIA

Low Parathyroid Hormone Levels (Hypoparathyroidism)
Parathyroid agenesis
Isolated
DiGeorge syndrome
Parathyroid destruction
Surgical
Radiation
Infiltration by metastases or systemic diseases
Autoimmune
Reduced parathyroid function
Hypomagnesemia
Activating CaSR mutations
High Parathyroid Hormone Levels (Secondary Hyperparathyroidism)
Vitamin D deficiency or impaired $1,25(OH)_2D$ production/action
Nutritional vitamin D deficiency (poor intake or absorption)
Renal insufficiency with impaired $1,25(OH)_2D$ production
Vitamin D resistance, including receptor defects
Parathyroid hormone resistance syndromes
PTH receptor mutations
Pseudohypoparathyroidism (G protein mutations)
Drugs
Calcium chelators
Inhibitors of bone resorption (bisphosphonates, plicamycin)
Altered vitamin D metabolism (phenytoin, ketoconazole)
Miscellaneous causes
Acute pancreatitis
Acute rhabdomyolysis
Hungry bone syndrome after parathyroidectomy
Osteoblastic metastases with marked stimulation of bone formation (prostate cancer)

Note: CaSR, calcium sensor receptor; PTH, parathyroid hormone.

may include a combination of low albumin, hyperphosphatemia, tissue deposition of calcium, and impaired PTH secretion.

CLINICAL MANIFESTATIONS

Patients with hypocalcemia may be asymptomatic if the decreases in serum calcium are relatively mild and chronic, or they may present with life-threatening complications. Moderate to severe hypocalcemia is associated with paresthesias, usually of the fingers, toes, and circumoral regions, and is caused by increased neuromuscular irritability. On physical examination, a Chvostek's sign (twitching of the circumoral muscles in response to gentle tapping of the facial nerve just anterior to the ear) may be elicited, although it is also present in ~10% of normal individuals. Carpal spasm may be induced by inflation of a blood pressure cuff to 20 mmHg above the patient's systolic blood pressure for 3 min (Trousseau's sign). Severe hypocalcemia can induce seizures, carpopedal spasm, bronchospasm, laryngospasm, and prolongation of the QT interval.

DIAGNOSTIC APPROACH

In addition to measuring serum calcium, it is useful to determine albumin, phosphorus, and magnesium levels. As for the evaluation of hypercalcemia, determining the PTH level is central to the evaluation of hypocalcemia. A suppressed (or "inappropriately low") PTH level in the setting of hypocalcemia establishes absent or reduced PTH secretion (hypoparathyroidism) as the cause of the hypocalcemia. Further history will often elicit the underlying cause (i.e., parathyroid agenesis vs. destruction). By contrast, an elevated PTH level (secondary hyperparathyroidism) should direct attention to the vitamin D axis as the cause of the hypocalcemia. Nutritional vitamin D deficiency is best assessed by obtaining serum 25-hydroxyvitamin D levels, which reflect vitamin D stores. In the setting of renal insufficiency or suspected vitamin D resistance, serum $1,25(OH)_2D$ levels are informative.

Rx HYPOCALCEMIA

The approach to treatment depends on the severity of the hypocalcemia, the rapidity with which it develops, and the accompanying complications (e.g., seizures, laryngospasm). Acute, symptomatic hypocalcemia is initially managed with calcium gluconate, 10 mL 10% wt/vol (90 mg or 2.2 mmol) intravenously, diluted in 50 mL of 5% dextrose or 0.9% sodium chloride, given intravenously over 5 min. Continuing hypocalcemia often requires a constant intravenous infusion (typically 10 ampuls of calcium gluconate or 900 mg of calcium in 1 L of 5% dextrose or 0.9% sodium chloride administered over 24 h). Accompanying hypomagnesemia, if present, should be treated with appropriate magnesium supplementation.

Chronic hypocalcemia due to hypoparathyroidism is treated with calcium supplements (1000–1500 mg/d elemental calcium in divided doses) and either vitamin D_2 or D_3 (25,000–100,000 U daily) or calcitriol [$1,25(OH)_2D$, 0.25–2 μg/d]. Other vitamin D metabolites (dihydrotachysterol, alfacalcidiol) are now used less frequently. Vitamin D deficiency, however, is best treated using vitamin D supplementation, with the dose depending on the severity of the deficit and the underlying cause. Thus, nutritional vitamin D deficiency generally responds to relatively low doses of vitamin D (50,000 U, 2–3 times per week for several months), while vitamin D deficiency due to malabsorption may require much higher doses (100,000 U/d or more). The treatment goal is to bring serum calcium into the low normal range and to avoid hypercalciuria, which may lead to nephrolithiasis.

48 Acidosis and Alkalosis

Thomas D. DuBose, Jr.

NORMAL ACID-BASE HOMEOSTASIS

Systemic arterial pH is maintained between 7.35 and 7.45 by extracellular and intracellular chemical buffering together with respiratory and renal regulatory mechanisms. The control of arterial CO_2 tension (Pa_{CO_2}) by the central nervous system and respiratory systems and the control of the plasma bicarbonate by the kidneys stabilize the arterial pH by excretion or retention of acid or alkali. The metabolic and respiratory components that regulate systemic pH are described by the Henderson-Hasselbalch equation:

$$pH = 6.1 + \log \frac{HCO_3^-}{Pa_{CO_2} \times 0.0301}$$

Under most circumstances, CO_2 production and excretion are matched, and the usual steady-state Pa_{CO_2} is maintained at 40 mmHg.

Underexcretion of CO_2 produces hypercapnia, and overexcretion causes hypocapnia. Nevertheless, production and excretion are again matched at a new steady-state Pa_{CO_2}. Therefore, the Pa_{CO_2} is regulated primarily by neural respiratory factors (Chap. 258) and is not subject to regulation by the rate of CO_2 production. Hypercapnia is usually the result of hypoventilation rather than of increased CO_2 production. Increases or decreases in Pa_{CO_2} represent derangements of neural respiratory control or are due to compensatory changes in response to a primary alteration in the plasma $[HCO_3^-]$.

The kidneys regulate plasma $[HCO_3^-]$ through three main processes: (1) "reabsorption" of filtered HCO_3^-, (2) formation of titratable acid, and (3) excretion of NH_4^+ in the urine. The kidney filters ~4000 mmol of HCO_3^- per day. To reabsorb the filtered load of HCO_3^-, the renal tubules must therefore secrete 4000 mmol of hydrogen ions. Between 80 and 90% of HCO_3^- is reabsorbed in the proximal tubule. The distal nephron reabsorbs the remainder and secretes protons, as generated from metabolism, to defend systemic pH. While this quantity of protons, 40–60 mmol/d, is small, it must be secreted to prevent chronic positive H^+ balance and metabolic acidosis. This quantity of secreted protons is represented in the urine as titratable acid and NH_4^+. Metabolic acidosis in the face of normal renal function increases NH_4^+ production and excretion. NH_4^+ production and excretion are impaired in chronic renal failure, hyperkalemia, and renal tubular acidosis.

In sum, these regulatory responses, including chemical buffering, the regulation of Pa_{CO_2} by the respiratory system, and the regulation of $[HCO_3^-]$ by the kidneys, act in concert to maintain a systemic arterial pH between 7.35 and 7.45.

TABLE 48-1 PREDICTION OF COMPENSATORY RESPONSES ON SIMPLE ACID-BASE DISTURBANCES AND PATTERN OF CHANGES

Disorder	Prediction of Compensation	Range of Values		
		pH	HCO_3^-	Pa_{CO_2}
Metabolic acidosis	$Pa_{CO_2} = (1.5 \times HCO_3^-) + 8 \pm 2$ *or* Pa_{CO_2} will ↓ 1.25 mmHg per mmol/L ↓ in $[HCO_3^-]$ *or* $Pa_{CO_2} = [HCO_3^-] + 15$	Low	Low	Low
Metabolic alkalosis	Pa_{CO_2} will ↑ 0.75 mmHg per mmol/L ↑ in $[HCO_3^-]$ *or* Pa_{CO_2} will ↑ 6 mmHg per 10 mmol/L ↑ in $[HCO_3^-]$ *or* $Pa_{CO_2} = [HCO_3^-] + 15$	High	High	High
Respiratory alkalosis		High	Low	Low
Acute	$[HCO_3^-]$ will ↓ 0.2 mmol/L per mmHg ↓ in Pa_{CO_2}			
Chronic	$[HCO_3^-]$ will ↓ 0.4 mmol/L per mmHg ↓ in Pa_{CO_2}			
Respiratory acidosis		Low	High	High
Acute	$[HCO_3^-]$ will ↑ 0.1 mmol/L per mmHg ↑ in Pa_{CO_2}			
Chronic	$[HCO_3^-]$ will ↑ 0.4 mmol/L per mmHg ↑ in Pa_{CO_2}			

DIAGNOSIS OF GENERAL TYPES OF DISTURBANCES

The most common clinical disturbances are simple acid-base disorders, i.e., metabolic acidosis or alkalosis or respiratory acidosis or alkalosis. Since compensation is not complete, the pH is abnormal in simple disturbances. More complicated clinical situations can give rise to mixed acid-base disturbances.

SIMPLE ACID-BASE DISORDERS

Primary respiratory disturbances (primary changes in Pa_{CO_2}) invoke compensatory metabolic responses (secondary changes in $[HCO_3^-]$), and primary metabolic disturbances elicit predictable compensatory respiratory responses. Physiologic compensation can be predicted from the relationships displayed in Table 48-1. Metabolic acidosis due to an increase in endogenous acids (e.g., ketoacidosis) lowers extracellular fluid $[HCO_3^-]$ and decreases extracellular pH. This stimulates the medullary chemoreceptors to increase ventilation and to return the ratio of $[HCO_3^-]$ to Pa_{CO_2}, and thus pH, toward normal, although not to normal. The degree of respiratory compensation expected in a simple form of metabolic acidosis can be predicted from the relationship: $Pa_{CO_2} = (1.5 \times [HCO_3^-]) + 8 \pm 2$, i.e., the Pa_{CO_2} is expected to decrease 1.25 mmHg for each mmol per liter decrease in $[HCO_3^-]$. Thus, a patient with metabolic acidosis and $[HCO_3^-]$ of 12 mmol/L would be expected to have a Pa_{CO_2} between 24 and 28 mmHg. Values for Pa_{CO_2} <24 or >28 mmHg define a mixed disturbance (metabolic acidosis and respiratory alkalosis or metabolic alkalosis and respiratory acidosis, respectively). Another way to judge the appropriateness of the response in $[HCO_3^-]$ or Pa_{CO_2} is to use an acid-base nomogram (Fig. 48-1). While the shaded areas of the nomogram show the 95% confidence limits for normal compensation in simple disturbances, finding acid-base values within the shaded area does not necessarily rule out a mixed disturbance. Imposition of one disorder over another may result in values lying within the area of a third. Thus, the nomogram, while convenient, is not a substitute for the equations in Table 48-1.

MIXED ACID-BASE DISORDERS

Mixed acid-base disorders—defined as independently coexisting disorders, not merely compensatory responses—are often seen in patients in critical care units and can lead to dangerous extremes of pH (Table 48-2). A patient with diabetic ketoacidosis (metabolic acidosis) may develop an independent respiratory problem leading to respiratory acidosis or alkalosis. Patients with underlying pulmonary disease may not respond to metabolic acidosis with an appropriate ventilatory response because of insufficient respiratory reserve. Such imposition of respiratory acidosis on metabolic acidosis can lead to severe acidemia and a poor outcome. When metabolic acidosis and metabolic alkalosis coexist in the same patient, the pH may be normal or near normal. When the pH is normal, an elevated anion gap (AG; see below) denotes the presence of a metabolic acidosis. A discrepancy in the ΔAG (prevailing minus nor-

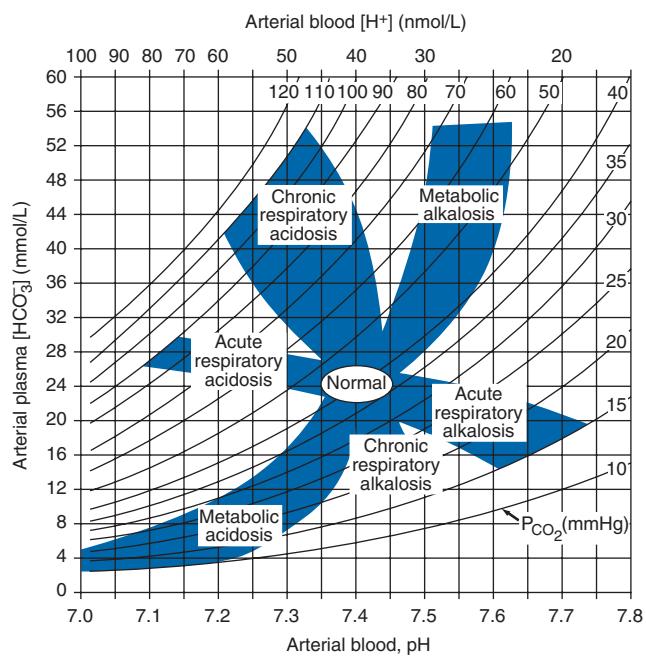

FIGURE 48-1 Acid-base nomogram. Shown are the 90% confidence limits (range of values) of the normal respiratory and metabolic compensations for primary acid-base disturbances. *(From DuBose, used with permission.)*

TABLE 48-2 EXAMPLES OF MIXED ACID-BASE DISORDERS

Mixed Metabolic and Respiratory
Metabolic acidosis – respiratory alkalosis Key: High- or normal-AG metabolic acidosis; prevailing Pa_{CO_2} *below* predicted value (Table 48-1) Example: Na^+, 140; K^+, 4.0; Cl^-, 106; HCO_3^-, 14; AG, 20; Pa_{CO_2}, 24; pH, 7.39 (lactic acidosis, sepsis in ICU)
Metabolic acidosis – respiratory acidosis Key: High- or normal-AG metabolic acidosis; prevailing Pa_{CO_2} *above* predicted value (Table 48-1) Example: Na^+, 140; K^+, 4.0; Cl^-, 102; HCO_3^-, 18; AG, 20; Pa_{CO_2}, 38; pH, 7.30 (severe pneumonia, pulmonary edema)
Metabolic alkalosis – respiratory alkalosis Key: Pa_{CO_2} does not increase as predicted; pH higher than expected Example: Na^+, 140; K^+, 4.0; Cl^-, 91; HCO_3^-, 33; AG, 16; Pa_{CO_2}, 38; pH, 7.55 (liver disease and diuretics)
Metabolic alkalosis – respiratory acidosis Key: Pa_{CO_2} higher than predicted; pH normal Example: Na^+, 140; K^+, 3.5; Cl^-, 88; HCO_3^-, 42; AG, 10; Pa_{CO_2}, 67; pH, 7.42 (COPD on diuretics)
Mixed Metabolic Disorders
Metabolic acidosis – metabolic alkalosis Key: Only detectable with high-AG acidosis; $\Delta AG >> \Delta HCO_3^-$ Example: Na^+, 140; K^+, 3.0; Cl^-, 95; HCO_3^-, 25; AG, 20; Pa_{CO_2}, 40; pH, 7.42 (uremia with vomiting)
Metabolic acidosis – metabolic acidosis Key: Mixed high-AG – normal-AG acidosis; ΔHCO_3^- accounted for by combined change in ΔAG and ΔCl^- Example: Na^+, 135; K^+, 3.0; Cl^-, 110; HCO_3^-, 10; AG, 15; Pa_{CO_2}, 25; pH, 7.20 (diarrhea and lactic acidosis, toluene toxicity, treatment of diabetic ketoacidosis)

Note: AG, anion gap; ICU, intensive care unit; COPD, chronic obstructive pulmonary disease.

mal AG) and the ΔHCO_3^- (normal minus prevailing HCO_3^-) indicates the presence of a mixed high-gap acidosis—metabolic alkalosis (see example below). A diabetic patient with ketoacidosis may have renal dysfunction resulting in simultaneous metabolic acidosis. Patients who have ingested an overdose of drug combinations such as sedatives and salicylates may have mixed disturbances as a result of the acid-base response to the individual drugs (metabolic acidosis mixed with respiratory acidosis or respiratory alkalosis, respectively). Even more complex are triple acid-base disturbances. For example, patients with metabolic acidosis due to alcoholic ketoacidosis may develop metabolic alkalosis due to vomiting and superimposed respiratory alkalosis due to the hyperventilation of hepatic dysfunction or alcohol withdrawal.

APPROACH TO THE PATIENT: Acid-Base Disorders

A stepwise approach to the diagnosis of acid-base disorders follows (Table 48-3). Care should be taken when measuring blood gases to obtain the arterial blood sample without using excessive heparin. Blood for electrolytes and arterial blood gases should be drawn simultaneously prior to therapy, since an increase in $[HCO_3^-]$ occurs with metabolic alkalosis and respiratory acidosis. Conversely, a decrease in $[HCO_3^-]$ occurs in metabolic acidosis and respiratory alkalosis. In the determination of arterial blood gases by the clinical laboratory, both pH and Pa_{CO_2} are measured, and the $[HCO_3^-]$ is calculated from the Henderson-Hasselbalch equation. This calculated value should be compared with the measured $[HCO_3^-]$ (total CO_2) on the electrolyte panel. These two values should agree within 2 mmol/L. If they do not, the values may not have been drawn simultaneously, a laboratory error may be present, or an error could have been made in calculating the $[HCO_3^-]$. After verifying the blood acid-base values, one can then identify the precise acid-base disorder.

TABLE 48-3 STEPS IN ACID-BASE DIAGNOSIS

1. Obtain arterial blood gas (ABG) and electrolytes simultaneously.
2. Compare $[HCO_3^-]$ on ABG and electrolytes to verify accuracy.
3. Calculate anion gap (AG).
4. Know four causes of high-AG acidosis (ketoacidosis, lactic acid acidosis, renal failure, and toxins).
5. Know two causes of hyperchloremic or nongap acidosis (bicarbonate loss from GI tract, renal tubular acidosis).
6. Estimate compensatory response (Table 48-1).
7. Compare ΔAG and ΔHCO_3^-.
8. Compare change in $[Cl^-]$ with change in $[Na^+]$.

CALCULATE THE ANION GAP All evaluations of acid-base disorders should include a simple calculation of the AG; it represents those unmeasured anions in plasma (normally 10 to 12 mmol/L) and is calculated as follows: $AG = Na^+ - (Cl^- + HCO_3^-)$. The unmeasured anions include anionic proteins, phosphate, sulfate, and organic anions. When acid anions, such as acetoacetate and lactate, accumulate in extracellular fluid, the AG increases, causing a high-AG acidosis. An increase in the AG is most often due to an increase in unmeasured anions and less commonly is due to a decrease in unmeasured cations (calcium, magnesium, potassium). In addition, the AG may increase with an increase in anionic albumin, because of either increased albumin concentration or alkalosis, which alters albumin charge. A decrease in the AG can be due to (1) an increase in unmeasured cations; (2) the addition to the blood of abnormal cations, such as lithium (lithium intoxication) or cationic immunoglobulins (plasma cell dyscrasias); (3) a reduction in the major plasma anion albumin concentration (nephrotic syndrome); (4) a decrease in the effective anionic charge on albumin by acidosis; or (5) hyperviscosity and severe hyperlipidemia, which can lead to an underestimation of sodium and chloride concentrations. A fall in serum albumin by 1 g/dL from the normal value (4.5 g/dL) decreases the anion gap by 2.5 meq/L. Know the common causes of a high-AG acidosis (Table 48-3).

In the face of a normal serum albumin, a high AG is usually due to non-chloride-containing acids that contain inorganic (phosphate, sulfate), organic (ketoacids, lactate, uremic organic anions), exogenous (salicylate or ingested toxins with organic acid production), or unidentified anions. The high AG is significant even if an additional acid-base disorder is superimposed to modify the $[HCO_3^-]$ independently. Simultaneous metabolic acidosis of the high-AG variety plus either chronic respiratory acidosis or metabolic alkalosis represents such a situation in which $[HCO_3^-]$ may be normal or even high (Table 48-2). Compare the change in $[HCO_3^-]$ (ΔHCO_3^-) and the change in the AG (ΔAG).

Similarly, normal values for $[HCO_3^-]$, Pa_{CO_2}, and pH do not ensure the absence of an acid-base disturbance. For instance, an alcoholic who has been vomiting may develop a metabolic alkalosis with a pH of 7.55, Pa_{CO_2} of 48 mmHg, $[HCO_3^-]$ of 40 mmol/L, $[Na^+]$ of 135, $[Cl^-]$ of 80, and $[K^+]$ of 2.8. If such a patient were then to develop a superimposed alcoholic ketoacidosis with a β-hydroxybutyrate concentration of 15 m*M*, arterial pH would fall to 7.40, $[HCO_3^-]$ to 25 mmol/L, and the Pa_{CO_2} to 40 mmHg. Although these blood gases are normal, the AG is elevated at 30 mmol/L, indicating a mixed metabolic alkalosis and metabolic acidosis. A mixture of high-gap acidosis and metabolic alkalosis is recognized easily by comparing the differences (Δ values) in the normal to prevailing patient values. In this example, the ΔHCO_3^- is 0 (25 – 25 mmol/L) but the ΔAG is 20 (30 – 10 mmol/L). Therefore, 20 mmol/L is unaccounted for in the Δ/Δ value (ΔAG to ΔHCO_3^-).

METABOLIC ACIDOSIS

Metabolic acidosis can occur because of an increase in endogenous acid production (such as lactate and ketoacids), loss of bicarbonate (as in diarrhea), or accumulation of endogenous acids (as in renal failure). Metabolic acidosis has profound effects on the respiratory, cardiac, and

TABLE 48-4 CAUSES OF HIGH-ANION-GAP METABOLIC ACIDOSIS

Lactic acidosis	Toxins
Ketoacidosis	Ethylene glycol
Diabetic	Methanol
Alcoholic	Salicylates
Starvation	Propylene glycol
	Pyroglutamic acid
	Renal failure (acute and chronic)

nervous systems. The fall in blood pH is accompanied by a characteristic increase in ventilation, especially the tidal volume (Kussmaul respiration). Intrinsic cardiac contractility may be depressed, but inotropic function can be normal because of catecholamine release. Both peripheral arterial vasodilation and central venoconstriction can be present; the decrease in central and pulmonary vascular compliance predisposes to pulmonary edema with even minimal volume overload. Central nervous system function is depressed, with headache, lethargy, stupor, and, in some cases, even coma. Glucose intolerance may also occur.

There are two major categories of clinical metabolic acidosis: high-AG and normal-AG, or hyperchloremic acidosis (Table 48-3 and Table 48-4).

℞ METABOLIC ACIDOSIS

Treatment of metabolic acidosis with alkali should be reserved for severe acidemia except when the patient has no "potential HCO_3^-" in plasma. Potential [HCO_3^-] can be estimated from the increment (Δ) in the AG (ΔAG = patient's AG – 10). It must be determined if the acid anion in plasma is metabolizable (i.e., β-hydroxybutyrate, acetoacetate, and lactate) or nonmetabolizable (anions that accumulate in chronic renal failure and after toxin ingestion). The latter requires return of renal function to replenish the [HCO_3^-] deficit, a slow and often unpredictable process. Consequently, patients with a normal AG acidosis (hyperchloremic acidosis), a slightly elevated AG (mixed hyperchloremic and AG acidosis), or an AG attributable to a nonmetabolizable anion in the face of renal failure should receive alkali therapy, either PO ($NaHCO_3$ or Shohl's solution) or IV ($NaHCO_3$), in an amount necessary to slowly increase the plasma [HCO_3^-] into the 20–22 mmol/L range.

Controversy exists, however, in regard to the use of alkali in patients with a pure AG acidosis owing to accumulation of a metabolizable organic acid anion (ketoacidosis or lactic acidosis). In general, severe acidosis (pH < 7.20) warrants the IV administration of 50–100 meq of $NaHCO_3$, over 30–45 min, during the initial 1–2 h of therapy. Provision of such modest quantities of alkali in this situation seems to provide an added measure of safety, but it is essential to monitor plasma electrolytes during the course of therapy, since the [K^+] may decline as pH rises. The goal is to increase the [HCO_3^-] to 10 meq/L and the pH to 7.15, not to increase these values to normal.

HIGH-ANION-GAP ACIDOSES

APPROACH TO THE PATIENT: High-Anion-Gap Acidoses

There are four principal causes of a high-AG acidosis: (1) lactic acidosis, (2) ketoacidosis, (3) ingested toxins, and (4) acute and chronic renal failure (Table 48-4). Initial screening to differentiate the high-AG acidoses should include (1) a probe of the history for evidence of drug and toxin ingestion and measurement of arterial blood gas to detect coexistent respiratory alkalosis (salicylates); (2) determination of whether diabetes mellitus is present (diabetic ketoacidosis); (3) a search for evidence of alcoholism or increased levels of β-hydroxybutyrate (alcoholic ketoacidosis); (4) observation for clinical signs of uremia and determination of the blood urea nitrogen (BUN) and creatinine (uremic acidosis); (5) inspection of the urine for oxalate crystals (ethylene glycol); and (6) recognition of the numerous clinical settings in which lactate levels may be increased (hypotension, shock, cardiac failure, leukemia, cancer, and drug or toxin ingestion).

Lactic Acidosis An increase in plasma L-lactate may be secondary to poor tissue perfusion (type A)—circulatory insufficiency (shock, cardiac failure), severe anemia, mitochondrial enzyme defects, and inhibitors (carbon monoxide, cyanide)—or to aerobic disorders (type B)—malignancies, nucleoside analogue reverse transcriptase inhibitors in HIV, diabetes mellitus, renal or hepatic failure, thiamine deficiency, severe infections (cholera, malaria), seizures, or drugs/toxins (biguanides, ethanol, methanol, propylene glycol, isoniazid, and fructose). Propylene glycol may be used as a vehicle for IV medications including lorazepam, and toxicity has been reported in several settings. Unrecognized bowel ischemia or infarction in a patient with severe atherosclerosis or cardiac decompensation receiving vasopressors is a common cause of lactic acidosis. Pyroglutamic acidemia has been reported in critically ill patients receiving acetaminophen, which is associated with depletion of glutathione. D-Lactic acid acidosis, which may be associated with jejunoileal bypass, short bowel syndrome, or intestinal obstruction, is due to formation of D-lactate by gut bacteria.

APPROACH TO THE PATIENT: Lactic Acid Acidosis

The underlying condition that disrupts lactate metabolism must first be corrected; tissue perfusion must be restored when inadequate. Vasoconstrictors should be avoided, if possible, since they may worsen tissue perfusion. Alkali therapy is generally advocated for acute, severe acidemia (pH < 7.15) to improve cardiac function and lactate utilization. However, $NaHCO_3$ therapy may paradoxically depress cardiac performance and exacerbate acidosis by enhancing lactate production (HCO_3^- stimulates phosphofructokinase). While the use of alkali in moderate lactic acidosis is controversial, it is generally agreed that attempts to return the pH or [HCO_3^-] to normal by administration of exogenous $NaHCO_3$ are deleterious. A reasonable approach is to infuse sufficient $NaHCO_3$ to raise the arterial pH to no more than 7.2 over 30–40 min.

$NaHCO_3$ therapy can cause fluid overload and hypertension because the amount required can be massive when accumulation of lactic acid is relentless. Fluid administration is poorly tolerated because of central venoconstriction, especially in the oliguric patient. When the underlying cause of the lactic acidosis can be remedied, blood lactate will be converted to HCO_3^- and may result in an overshoot alkalosis.

Ketoacidosis • ***DIABETIC KETOACIDOSIS (DKA)*** This condition is caused by increased fatty acid metabolism and the accumulation of ketoacids (acetoacetate and β-hydroxybutyrate). DKA usually occurs in insulin-dependent diabetes mellitus in association with cessation of insulin or an intercurrent illness, such as an infection, gastroenteritis, pancreatitis, or myocardial infarction, which increases insulin requirements temporarily and acutely. The accumulation of ketoacids accounts for the increment in the AG and is accompanied most often by hyperglycemia [glucose > 17 mmol/L (300 mg/dL)]. The relationship between the ΔAG and ΔHCO_3^- is ~1:1 in DKA but may decrease in the well-hydrated patient with preservation of renal function. Ketoacid excretion in the urine reduces the anion gap in this situation. It should be noted that since insulin prevents production of ketones, bicarbonate therapy is rarely needed except with extreme acidemia (pH < 7.1), and then in only limited amounts. Patients with DKA are typically volume depleted and require fluid resuscitation with isotonic saline. Volume overexpansion is not uncommon, however, after IV fluid administration, and contributes to the development of a hyperchloremic acidosis during treatment of DKA because volume expansion increases urinary ketoacid anion excretion (loss of potential bicarbonate). The mainstay for treatment of this condition is IV regular insulin and is described in Chap. 338 in more detail.

ALCOHOLIC KETOACIDOSIS (AKA) Chronic alcoholics can develop ketoacidosis when alcohol consumption is abruptly curtailed and nutrition is poor. AKA is usually associated with binge drinking, vomiting, abdominal pain, starvation, and volume depletion. The glucose concentration is variable, and acidosis may be severe because of elevated ketones, predominantly β-hydroxybutyrate. Hypoperfusion may enhance lactic acid production, chronic respiratory alkalosis may accompany liver disease, and metabolic

alkalosis can result from vomiting (refer to the relationship between ΔAG and ΔHCO_3^-). Thus, mixed acid-base disorders are common in AKA. As the circulation is restored by administration of isotonic saline, the preferential accumulation of β-hydroxybutyrate is then shifted to acetoacetate. This explains the common clinical observation of an increasingly positive nitroprusside reaction as the patient improves. The nitroprusside ketone reaction (Acetest) can detect acetoacetic acid but not β-hydroxybutyrate, so that the degree of ketosis and ketonuria can not only change with therapy, but can be underestimated initially. Patients with AKA usually present with relatively normal renal function, as opposed to DKA where renal function is often compromised because of volume depletion (osmotic diuresis) or diabetic nephropathy. The AKA patient with normal renal function may excrete relatively large quantities of ketoacids in the urine, therefore, and may have a relatively normal AG and a discrepancy in the $\Delta AG/\Delta HCO_3^-$ relationship. Typically, insulin levels are low, and concentrations of triglyceride, cortisol, glucagon, and growth hormone are increased.

℞ ALCOHOLIC KETOACIDOSIS

Extracellular fluid deficits almost always accompany AKA and should be repleted by IV administration of saline and glucose (5% dextrose in 0.9% NaCl). Hypophosphatemia, hypokalemia, and hypomagnesemia may coexist and should be corrected. Hypophosphatemia usually emerges 12–24 h after admission, may be exacerbated by glucose infusion, and, if severe, may induce rhabdomyolysis. Upper gastrointestinal hemorrhage, pancreatitis, and pneumonia may accompany this disorder.

Drug- and Toxin-Induced Acidosis • ***SALICYLATES*** (See also **Chap. e34**) Salicylate intoxication in adults usually causes respiratory alkalosis or a mixture of high-AG metabolic acidosis and respiratory alkalosis. Only a portion of the AG is due to salicylates. Lactic acid production is also often increased.

℞ SALICYLATE-INDUCED ACIDOSIS

Vigorous gastric lavage with isotonic saline (not $NaHCO_3$) should be initiated immediately followed by administration of activated charcoal per NG tube. In the acidotic patient, to facilitate removal of salicylate, intravenous $NaHCO_3$ is administered in amounts adequate to alkalinize the urine and to maintain urine output (urine pH > 7.5). While this form of therapy is straightforward in acidotic patients, a coexisting respiratory alkalosis may make this approach hazardous. Alkalemic patients should not receive $NaHCO_3^-$. Acetazolamide may be administered in the face of alkalemia, when an alkaline diuresis cannot be achieved, or to ameliorate volume overload associated with $NaHCO_3^-$ administration, but this drug can cause systemic metabolic acidosis if HCO_3^- is not replaced. Hypokalemia should be anticipated with an alkaline diuresis and should be treated promptly and aggressively. Glucose-containing fluids should be administered because of the danger of hypoglycemia. Excessive insensible fluid losses may cause severe volume depletion and hypernatremia. If renal failure prevents rapid clearance of salicylate, hemodialysis can be performed against a bicarbonate dialysate.

ALCOHOLS Under most physiologic conditions, sodium, urea, and glucose generate the osmotic pressure of blood. Plasma osmolality is calculated according to the following expression: $P_{osm} = 2Na^+ + Glu + BUN$ (all in mmol/L), or, using conventional laboratory values in which glucose and BUN are expressed in milligrams per deciliter: $P_{osm} = 2Na^+ + Glu/18 + BUN/2.8$. The calculated and determined osmolality should agree within 10–15 mmol/kg H_2O. When the measured osmolality exceeds the calculated osmolality by >15–20 mmol/kg H_2O, one of two circumstances prevails. Either the serum sodium is spuriously low, as with hyperlipidemia or hyperproteinemia (pseudohyponatremia), or osmolytes other than sodium salts, glucose, or urea have accumulated in plasma. Examples include mannitol, radiocontrast media, isopropyl alcohol, ethylene glycol, propylene glycol, ethanol, methanol, and acetone. In this situation, the difference between the calculated osmolality and the measured osmolality (*osmolar gap*) is proportional to the concentration of the unmeasured solute. With an appropriate clinical history and index of suspicion, identification of an osmolar gap is helpful in identifying the presence of poison-associated AG acidosis. Three alcohols may cause fatal intoxications: ethylene glycol, methanol, and isopropyl alcohol. All cause an elevated osmolal gap, but only the first two cause a high-AG acidosis.

ETHYLENE GLYCOL (See also **Chap. e34**) Ingestion of ethylene glycol (commonly used in antifreeze) leads to a metabolic acidosis and severe damage to the central nervous system, heart, lungs, and kidneys. The increased AG and osmolar gap are attributable to ethylene glycol and its metabolites, oxalic acid, glycolic acid, and other organic acids. Lactic acid production increases secondary to inhibition of the tricarboxylic acid cycle and altered intracellular redox state. Diagnosis is facilitated by recognizing oxalate crystals in the urine, the presence of an osmolar gap in serum, and a high-AG acidosis. If antifreeze containing a fluorescent dye is ingested, a Wood's lamp applied to the urine may be revealing. Treatment should not be delayed while awaiting measurement of ethylene glycol levels in this setting.

℞ ETHYLENE GLYCOL–INDUCED ACIDOSIS

This includes the prompt institution of a saline or osmotic diuresis, thiamine and pyridoxine supplements, fomepizole or ethanol, and hemodialysis. The IV administration of the alcohol dehydrogenase inhibitor fomepizole (4-methylpyrazole; 7 mg/kg as a loading dose) or ethanol IV to achieve a level of 22 mmol/L (100 mg/dL) serves to lessen toxicity because they compete with ethylene glycol for metabolism by alcohol dehydrogenase. Fomepizole, although expensive, offers the advantages of a predictable decline in ethylene glycol levels without excessive obtundation during ethyl alcohol infusion.

METHANOL (See also **Chap. e34**) The ingestion of methanol (wood alcohol) causes metabolic acidosis, and its metabolites formaldehyde and formic acid cause severe optic nerve and central nervous system damage. Lactic acid, ketoacids, and other unidentified organic acids may contribute to the acidosis. Due to its low molecular weight (32 Da), an osmolar gap is usually present.

℞ METHANOL-INDUCED ACIDOSIS

This is similar to that for ethylene glycol intoxication, including general supportive measures, fomepizole or ethanol administration, and hemodialysis.

ISOPROPYL ALCOHOL Ingested isopropanol is absorbed rapidly and may be fatal when as little as 150 mL of rubbing alcohol, solvent, or de-icer is consumed. A plasma level >400 mg/dL is life threatening. Isopropyl alcohol differs from ethylene glycol and methanol in that the parent compound, not the metabolites, causes toxicity, and acidosis is not present because acetone is rapidly excreted.

℞ ISOPROPYL ALCOHOL TOXICITY

Isopropanol alcohol toxicity is treated by watchful waiting and supportive therapy; IV fluids, pressors, ventilatory support if needed, and occasionally hemodialysis for prolonged coma or levels >400 mg/dL.

Renal Failure (See also Chaps. 273 and 274) The hyperchloremic acidosis of moderate renal insufficiency is eventually converted to the high-AG acidosis of advanced renal failure. Poor filtration and reabsorption of organic anions contribute to the pathogenesis. As renal disease progresses, the number of functioning nephrons eventually becomes insufficient to keep pace with net acid production. Uremic acidosis is characterized, therefore, by a reduced rate of NH_4^+ production and excretion, primarily due to decreased renal mass. $[HCO_3^-]$ rarely falls to <15 mmol/L, and the AG is rarely >20 mmol/L. The acid retained in chronic renal disease is buffered by alkaline salts from bone. Despite significant retention of acid (up to 20 mmol/d), the serum $[HCO_3^-]$ does not decrease further, indicating participation of buffers

TABLE 48-5 CAUSES OF NON-ANION-GAP ACIDOSIS

I. Gastrointestinal bicarbonate loss
- A. Diarrhea
- B. External pancreatic or small-bowel drainage
- C. Ureterosigmoidostomy, jejunal loop, ileal loop
- D. Drugs
  - 1. Calcium chloride (acidifying agent)
  - 2. Magnesium sulfate (diarrhea)
  - 3. Cholestyramine (bile acid diarrhea)

II. Renal acidosis
- A. Hypokalemia
  - 1. Proximal RTA (type 2)
  - 2. Distal (classic) RTA (type 1)
- B. Hyperkalemia
  - 1. Generalized distal nephron dysfunction (type 4 RTA)
    - a. Mineralocorticoid deficiency
    - b. Mineralocorticoid resistance (autosomal dominant PHA I)
    - c. Voltage defect (autosomal dominant PHA I and PHA II)
    - d. Tubulointerstitial disease

III. Drug-induced hyperkalemia (with renal insufficiency)
- A. Potassium-sparing diuretics (amiloride, triamterene, spironolactone)
- B. Trimethoprim
- C. Pentamidine
- D. ACE-Is and ARBs
- E. Nonsteroidal anti-inflammatory drugs
- F. Cyclosporine and tacrolimus

IV. Other
- A. Acid loads (ammonium chloride, hyperalimentation)
- B. Loss of potential bicarbonate: ketosis with ketone excretion
- C. Expansion acidosis (rapid saline administration)
- D. Hippurate
- E. Cation exchange resins

Note: RTA, renal tubular acidosis; ACE-I, angiotensin-converting enzyme inhibitors; ARB, angiotensin receptor blocker; PHA, pseudohypoaldosteronism.

outside the extracellular compartment. Chronic metabolic acidosis results in significant loss of bone mass due to reduction in bone calcium carbonate. Chronic acidosis also increases urinary calcium excretion, proportional to cumulative acid retention.

℞ RENAL FAILURE

Because of the association of renal failure acidosis with muscle catabolism and bone disease, both uremic acidosis and the hyperchloremic acidosis of renal failure require oral alkali replacement to maintain the $[HCO_3^-]$ between 20 and 24 mmol/L. This can be accomplished with relatively modest amounts of alkali (1.0–1.5 mmol/kg body weight per day). Sodium citrate (Shohl's solution) or $NaHCO_3$ tablets (650-mg tablets contain 7.8 meq) are equally effective alkalinizing salts. Citrate enhances the absorption of aluminum from the gastrointestinal tract and should never be given together with aluminum-containing antacids because of the risk of aluminum intoxication. When hyperkalemia is present, furosemide (60–80 mg/d) should be added.

HYPERCHLOREMIC (NONGAP) METABOLIC ACIDOSES

Alkali can be lost from the gastrointestinal tract in diarrhea or from the kidneys (renal tubular acidosis, RTA). In these disorders (Table 48-5), reciprocal changes in $[Cl^-]$ and $[HCO_3^-]$ result in a normal AG. In pure hyperchloremic acidosis, therefore, the increase in $[Cl^-]$ above the normal value approximates the decrease in $[HCO_3^-]$. The absence of such a relationship suggests a mixed disturbance.

APPROACH TO THE PATIENT: Hyperchloremic Metabolic Acidoses

In diarrhea, stools contain a higher $[HCO_3^-]$ and decomposed HCO_3^- than plasma so that metabolic acidosis develops along with volume depletion. Instead of an acid urine pH (as anticipated with systemic acidosis), urine pH is usually around 6 because metabolic acidosis and hypokalemia increase renal synthesis and excretion of NH_4^+, thus providing a urinary buffer that increases urine pH. Metabolic acidosis due to gastrointestinal losses with a high urine pH can be differentiated from RTA (Chap. 278) because urinary NH_4^+ excretion is typically low in RTA and high with diarrhea. Urinary NH_4^+ levels can be estimated by calculating the urine anion gap (UAG): $UAG = [Na^+ + K^+]_u - [Cl^-]_u$. When $[Cl^-]_u > [Na^+ + K^+]$, the urine gap is negative by definition. This indicates that the urine ammonium level is appropriately increased, suggesting an extrarenal cause of the acidosis. Conversely, when the urine anion gap is positive, the urine ammonium level is low, suggesting a renal cause of the acidosis.

Loss of functioning renal parenchyma by progressive renal disease leads to hyperchloremic acidosis when the glomerular filtration rate (GFR) is between 20 and 50 mL/min and to uremic acidosis with a high AG when the GFR falls to <20 mL/min. Such a progression occurs commonly with tubulointerstitial forms of renal disease, but hyperchloremic metabolic acidosis can persist with advanced glomerular disease. In advanced renal failure, ammoniagenesis is reduced in proportion to the loss of functional renal mass, and ammonium accumulation and trapping in the outer medullary collecting tubule may also be impaired. Because of adaptive increases in K^+ secretion by the collecting duct and colon, the acidosis of chronic renal insufficiency is typically normokalemic.

Proximal RTA (type 2 RTA) (Chap. 278) is most often due to generalized proximal tubular dysfunction manifested by glycosuria, generalized aminoaciduria, and phosphaturia (Fanconi syndrome). With a low plasma $[HCO_3^-]$, the urine pH is acid (pH < 5.5). The fractional excretion of $[HCO_3^-]$ may exceed 10–15% when the serum HCO_3^- > 20 mmol/L. Since HCO_3^- is not reabsorbed normally in the proximal tubule, therapy with $NaHCO_3$ will enhance renal potassium wasting and hypokalemia.

The typical findings in acquired or inherited forms of classic distal RTA (type 1 RTA) include hypokalemia, hyperchloremic acidosis, low urinary NH_4^+ excretion (positive UAG, low urine $[NH_4^+]$), and inappropriately high urine pH (pH > 5.5). Such patients are unable to acidify the urine below a pH of 5.5. Most patients have hypocitraturia and hypercalciuria, so nephrolithiasis, nephrocalcinosis, and bone disease are common. In generalized distal nephron dysfunction (type 4 RTA), hyperkalemia is disproportionate to the reduction in GFR because of coexisting dysfunction of potassium and acid secretion. Urinary ammonium excretion is invariably depressed, and renal function may be compromised, for example, due to diabetic nephropathy, amyloidosis, or tubulointerstitial disease.

Hyporeninemic hypoaldosteronism typically causes hyperchloremic metabolic acidosis, most commonly in older adults with diabetes mellitus or tubulointerstitial disease and renal insufficiency. Patients usually have mild to moderate renal insufficiency (GRF, 20–50 mL/min) and acidosis, with elevation in serum $[K^+]$ (5.2–6.0 mmol/L), concurrent hypertension, and congestive heart failure. Both the metabolic acidosis and the hyperkalemia are out of proportion to impairment in GFR. Nonsteroidal anti-inflammatory drugs, trimethoprim, pentamidine, and angiotensin-converting enzyme (ACE) inhibitors can also cause hyperkalemia with hyperchloremic metabolic acidosis in patients with renal insufficiency (Table 48-5). **See Chap. 278 for the pathophysiology, diagnosis, and treatment of RTA.**

METABOLIC ALKALOSIS

Metabolic alkalosis is manifested by an elevated arterial pH, an increase in the serum $[HCO_3^-]$, and an increase in Pa_{CO_2} as a result of compensatory alveolar hypoventilation (Table 48-1). It is often accompanied by hypochloremia and hypokalemia. The arterial pH establishes the diagnosis, since it is increased in metabolic alkalosis and decreased or normal in respiratory acidosis. Metabolic alkalosis frequently occurs in association with other disorders such as respiratory acidosis or alkalosis or metabolic acidosis.

PATHOGENESIS

Metabolic alkalosis occurs as a result of net gain of $[HCO_3^-]$ or loss of nonvolatile acid (usually HCl by vomiting) from the extracellular fluid. Since it is unusual for alkali to be added to the body, the disorder

involves a generative stage, in which the loss of acid usually causes alkalosis, and a maintenance stage, in which the kidneys fail to compensate by excreting HCO_3^-.

Under normal circumstances, the kidneys have an impressive capacity to excrete HCO_3^-. Continuation of metabolic alkalosis represents a failure of the kidneys to eliminate HCO_3^- in the usual manner. For HCO_3^- to be added to the extracellular fluid, it must be administered exogenously or synthesized endogenously, in part or entirely by the kidneys. The kidneys will retain, rather than excrete, the excess alkali and maintain the alkalosis if (1) volume deficiency, chloride deficiency, and K^+ deficiency exist in combination with a reduced GFR, which augments distal tubule H^+ secretion; or (2) hypokalemia exists because of autonomous hyperaldosteronism. In the first example, alkalosis is corrected by administration of NaCl and KCl, whereas in the latter it is necessary to repair the alkalosis by pharmacologic or surgical intervention, not with saline administration.

DIFFERENTIAL DIAGNOSIS

To establish the cause of metabolic alkalosis (Table 48-6), it is necessary to assess the status of the extracellular fluid volume (ECFV), the recumbent and upright blood pressure, the serum $[K^+]$, and the renin-aldosterone system. For example, the presence of chronic hypertension and chronic hypokalemia in an alkalotic patient suggests either mineralocorticoid excess or that the hypertensive patient is receiving diuretics. Low plasma renin activity and normal urine $[Na^+]$ and $[Cl^-]$ in a patient who is not taking diuretics indicate a primary mineralocorticoid excess syndrome. The combination of hypokalemia and alkalosis in a normotensive, nonedematous patient can be due to Bartter's or Gitelman's syndrome, magnesium deficiency, vomiting, exogenous alkali, or diuretic ingestion. Determination of urine electrolytes (especially the urine $[Cl^-]$) and screening of the urine for diuretics may be helpful. If the urine is alkaline, with an elevated $[Na^+]$ and $[K^+]$ but low $[Cl^-]$, the diagnosis is usually either vomiting (overt or surreptitious) or alkali ingestion. If the urine is relatively acid and has low concentrations of Na^+, K^+, and Cl^-, the most likely possibilities are prior vomiting, the posthypercapnic state, or prior diuretic ingestion. If, on the other hand, neither the urine sodium, potassium, nor chloride concentrations are depressed, magnesium deficiency, Bartter's or Gitelman's syndrome, or current diuretic ingestion should be considered. Bartter's syndrome is distinguished from Gitelman's syndrome because of hypocalciuria and hypomagnesemia in the latter disorder. The genetic and molecular basis of these two disorders has been elucidated recently (Chap. 278).

TABLE 48-6 CAUSES OF METABOLIC ALKALOSIS

I. Exogenous HCO_3^- loads
  A. Acute alkali administration
  B. Milk-alkali syndrome
II. Effective ECFV contraction, normotension, K^+ deficiency, and secondary hyperreninemic hyperaldosteronism
  A. Gastrointestinal origin
    1. Vomiting
    2. Gastric aspiration
    3. Congenital chloridorrhea
    4. Villous adenoma
  B. Renal origin
    1. Diuretics
    2. Posthypercapnic state
    3. Hypercalcemia/hypoparathyroidism
    4. Recovery from lactic acidosis or ketoacidosis
    5. Nonreabsorbable anions including penicillin, carbenicillin
    6. Mg^{2+} deficiency
    7. K^+ depletion
    8. Bartter's syndrome (loss of function mutations in TALH)
    9. Gitelman's syndrome (loss of function mutation in Na^+-Cl^- cotransporter in DCT)
III. ECFV expansion, hypertension, K^+ deficiency, and mineralocorticoid excess
  A. High renin
    1. Renal artery stenosis
    2. Accelerated hypertension
    3. Renin-secreting tumor
    4. Estrogen therapy
  B. Low renin
    1. Primary aldosteronism
      a. Adenoma
      b. Hyperplasia
      c. Carcinoma
    2. Adrenal enzyme defects
      a. 11 β-Hydroxylase deficiency
      b. 17 α-Hydroxylase deficiency
    3. Cushing's syndrome or disease
    4. Other
      a. Licorice
      b. Carbenoxolone
      c. Chewer's tobacco
IV. Gain-of-function mutation of renal sodium channel with ECFV expansion, hypertension, K^+ deficiency, and hyporeninemic-hypoaldosteronism
  A. Liddle's syndrome

Note: ECFV, extracellular fluid volume; TALH, thick ascending limb of Henle's loop; DCT, distal convoluted tubule.

Alkali Administration Chronic administration of alkali to individuals with normal renal function rarely, if ever, causes alkalosis. However, in patients with coexistent hemodynamic disturbances, alkalosis can develop because the normal capacity to excrete HCO_3^- may be exceeded or there may be enhanced reabsorption of HCO_3^-. Such patients include those who receive HCO_3^- (PO or IV), acetate loads (parenteral hyperalimentation solutions), citrate loads (transfusions), or antacids plus cation-exchange resins (aluminum hydroxide and sodium polystyrene sulfonate).

METABOLIC ALKALOSIS ASSOCIATED WITH ECFV CONTRACTION, K^+ DEPLETION, AND SECONDARY HYPERRENINEMIC HYPERALDOSTERONISM

Gastrointestinal Origin Gastrointestinal loss of H^+ from vomiting or gastric aspiration results in retention of HCO_3^-. The loss of fluid and NaCl in vomitus or nasogastric suction results in contraction of the ECFV and an increase in the secretion of renin and aldosterone. Volume contraction through a reduction in GFR results in an enhanced capacity of the renal tubule to reabsorb HCO_3^-. During active vomiting, however, the filtered load of bicarbonate is acutely increased to the point that the reabsorptive capacity of the proximal tubule for HCO_3^- is exceeded. The excess $NaHCO_3$ issuing out of the proximal tubule reaches the distal tubule, where H^+ secretion is enhanced by an aldosterone and the delivery of the poorly reabsorbed anion, HCO_3^-. Correction of the contracted ECFV with NaCl and repair of K^+ deficits corrects the acid-base disorder, and chloride deficiency.

Renal Origin • ***DIURETICS*** (See also Chap. 227) Drugs that induce chloruresis, such as thiazides and loop diuretics (furosemide, bumetanide, torsemide, and ethacrynic acid), acutely diminish the ECFV without altering the total body bicarbonate content. The serum $[HCO_3^-]$ increases because the reduced ECFV "contracts" the $[HCO_3^-]$ in the plasma (contraction alkalosis). The chronic administration of diuretics tends to generate an alkalosis by increasing distal salt delivery, so that K^+ and H^+ secretion are stimulated. The alkalosis is maintained by persistence of the contraction of the ECFV, secondary hyperaldosteronism, K^+ deficiency, and the direct effect of the diuretic (as long as diuretic administration continues). Repair of the alkalosis is achieved by providing isotonic saline to correct the ECFV deficit.

SOLUTE LOSING DISORDERS: BARTTER'S SYNDROME AND GITELMAN'S SYNDROME See Chap. 278.

NONREABSORBABLE ANIONS AND MAGNESIUM DEFICIENCY Administration of large quantities of nonreabsorbable anions, such as penicillin or carbenicillin, can enhance distal acidification and K^+ secretion by increasing the transepithelial potential difference (lumen negative). Mg^{2+} deficiency results in hypokalemic alkalosis by enhancing distal acidification through stimulation of renin and hence aldosterone secretion.

POTASSIUM DEPLETION Chronic K^+ depletion may cause metabolic alkalosis by increasing urinary acid excretion. Both NH_4^+ production and absorption are enhanced and HCO_3^- reabsorption is stimulated.

Chronic K^+ deficiency upregulates the renal H^+, K^+-ATPase to increase K^+ absorption at the expense of enhanced H^+ secretion. Alkalosis associated with severe K^+ depletion is resistant to salt administration, but repair of the K^+ deficiency corrects the alkalosis.

AFTER TREATMENT OF LACTIC ACIDOSIS OR KETOACIDOSIS When an underlying stimulus for the generation of lactic acid or ketoacid is removed rapidly, as with repair of circulatory insufficiency or with insulin therapy, the lactate or ketones are metabolized to yield an equivalent amount of HCO_3^-. Other sources of new HCO_3^- are additive with the original amount generated by organic anion metabolism to create a surfeit of HCO_3^-. Such sources include (1) new HCO_3^- added to the blood by the kidneys as a result of enhanced acid excretion during the preexisting period of acidosis, and (2) alkali therapy during the treatment phase of the acidosis. Acidosis-induced contraction of the ECFV and K^+ deficiency act to sustain the alkalosis.

POSTHYPERCAPNIA Prolonged CO_2 retention with chronic respiratory acidosis enhances renal HCO_3^- absorption and the generation of new HCO_3^- (increased net acid excretion). If the Pa_{CO_2} is returned to normal, metabolic alkalosis results from the persistently elevated $[HCO_3^-]$. Alkalosis develops if the elevated Pa_{CO_2} is abruptly returned toward normal by a change in mechanically controlled ventilation. Associated ECFV contraction does not allow complete repair of the alkalosis by correction of the Pa_{CO_2} alone, and alkalosis persists until Cl^- supplementation is provided.

METABOLIC ALKALOSIS ASSOCIATED WITH ECFV EXPANSION, HYPERTENSION, AND HYPERALDOSTERONISM

Increased aldosterone levels may be the result of autonomous primary adrenal overproduction or of secondary aldosterone release due to renal overproduction of renin. Mineralocorticoid excess increases net acid excretion and may result in metabolic alkalosis, which may be worsened by associated K^+ deficiency. ECFV expansion from salt retention causes hypertension. The kaliuresis persists because of mineralocorticoid excess and distal Na^+ absorption causing enhanced K^+ excretion, continued K^+ depletion with polydipsia, inability to concentrate the urine, and polyuria.

Liddle's syndrome (Chap. 278) results from increased activity of the collecting duct Na^+ channel (ENaC) and is a rare inherited disorder associated with hypertension due to volume expansion manifested as hypokalemic alkalosis and normal aldosterone levels.

Symptoms With metabolic alkalosis, changes in central and peripheral nervous system function are similar to those of hypocalcemia (Chap. 346); symptoms include mental confusion, obtundation, and a predisposition to seizures, paresthesia, muscular cramping, tetany, aggravation of arrhythmias, and hypoxemia in chronic obstructive pulmonary disease. Related electrolyte abnormalities include hypokalemia and hypophosphatemia.

Rx METABOLIC ALKALOSIS

This is primarily directed at correcting the underlying stimulus for HCO_3^- generation. If primary aldosteronism, renal artery stenosis, or Cushing's syndrome is present, correction of the underlying cause will reverse the alkalosis. $[H^+]$ loss by the stomach or kidneys can be mitigated by the use of proton pump inhibitors or the discontinuation of diuretics. The second aspect of treatment is to remove the factors that sustain the inappropriate increase in HCO_3^- reabsorption, such as ECFV contraction or K^+ deficiency. Although K^+ deficits should be repaired, NaCl therapy is usually sufficient to reverse the alkalosis if ECFV contraction is present, as indicated by a low urine $[Cl^-]$.

If associated conditions preclude infusion of saline, renal HCO_3^- loss can be accelerated by administration of acetazolamide, a carbonic anhydrase inhibitor, which is usually effective in patients with adequate renal function but can worsen K^+ losses. Dilute hydrochloric acid (0.1 *N* HCl) is also effective but can cause hemolysis, and must be delivered centrally and slowly. Hemodialysis against a dialysate low in $[HCO_3^-]$ and high in $[Cl^-]$ can be effective when renal function is impaired.

TABLE 48-7 RESPIRATORY ACID-BASE DISORDERS

I. Alkalosis
- A. Central nervous system stimulation
  - 1. Pain
  - 2. Anxiety, psychosis
  - 3. Fever
  - 4. Cerebrovascular accident
  - 5. Meningitis, encephalitis
  - 6. Tumor

  - 3. Myasthenia
  - 4. Muscular dystrophies
- E. Miscellaneous
  - 1. Obesity
  - 2. Hypoventilation
  - 3. Permissive hypercapnia

RESPIRATORY ACIDOSIS

Respiratory acidosis can be due to severe pulmonary disease, respiratory muscle fatigue, or abnormalities in ventilatory control and is recognized by an increase in Pa_{CO_2} and decrease in pH (Table 48-7). In acute respiratory acidosis, there is an immediate compensatory elevation (due to cellular buffering mechanisms) in HCO_3^-, which increases 1 mmol/L for every 10-mmHg increase in Pa_{CO_2}. In chronic respiratory acidosis (>24 h), renal adaptation increases the $[HCO_3^-]$ by 4 mmol/L for every 10-mmHg increase in Pa_{CO_2}. The serum HCO_3^- usually does not increase above 38 mmol/L.

The clinical features vary according to the severity and duration of the respiratory acidosis, the underlying disease, and whether there is accompanying hypoxemia. A rapid increase in Pa_{CO_2} may cause anxiety, dyspnea, confusion, psychosis, and hallucinations and may progress to coma. Lesser degrees of dysfunction in chronic hypercapnia include sleep disturbances, loss of memory, daytime somnolence, personality changes, impairment of coordination, and motor disturbances such as tremor, myoclonic jerks, and asterixis. Headaches and other signs that mimic raised intracranial pressure, such as papilledema, abnormal reflexes, and focal muscle weakness, are due to vasoconstriction secondary to loss of the vasodilator effects of CO_2.

Depression of the respiratory center by a variety of drugs, injury, or disease can produce respiratory acidosis. This may occur acutely with general anesthetics, sedatives, and head trauma or chronically with sedatives, alcohol, intracranial tumors, and the syndromes of sleep-disordered breathing, including the primary alveolar and obesity-hypoventilation syndromes (Chaps. 258 and 259). Abnormalities or disease in the motor neurons, neuromuscular junction, and skeletal muscle can cause hypoventilation via respiratory muscle fatigue. Mechanical ventilation, when not properly adjusted and supervised, may result in respiratory acidosis, particularly if CO_2 production suddenly rises (because of fever, agitation, sepsis, or overfeeding) or alveolar ventilation falls because of worsening pulmonary function. High levels of positive end-expiratory pressure in the presence of reduced cardiac output may cause hypercapnia as a result of large increases in alveolar dead space (Chap. 246). Permissive hypercapnia is being used with increasing frequency because of studies suggesting lower mortality rates than with conventional mechanical ventilation, especially with severe central nervous system or heart disease. The potential beneficial effects of permissive hypercapnia may be mitigated by correction of the acidemia by administration of $NaHCO_3$.

Acute hypercapnia follows sudden occlusion of the upper airway or generalized bronchospasm as in severe asthma, anaphylaxis, inhalational burn, or toxin injury. Chronic hypercapnia and respiratory acidosis occur in end-stage obstructive lung disease. Restrictive disorders involving both the chest wall and the lungs can cause respiratory acidosis because the high metabolic cost of respiration causes ventilatory muscle fatigue. Advanced stages of intrapulmonary and extrapulmonary restrictive defects present as chronic respiratory acidosis.

The diagnosis of respiratory acidosis requires, by definition, the measurement of Pa_{CO_2} and arterial pH. A detailed history and physical examination often indicate the cause. Pulmonary function studies (Chap. 246), including spirometry, diffusion capacity for carbon monoxide, lung volumes, and arterial Pa_{CO_2} and O_2 saturation, usually make it possible to determine if respiratory acidosis is secondary to lung disease. The workup for nonpulmonary causes should include a detailed drug history, measurement of hematocrit, and assessment of upper airway, chest wall, pleura, and neuromuscular function.

Rx RESPIRATORY ACIDOSIS

The management of respiratory acidosis depends on its severity and rate of onset. Acute respiratory acidosis can be life threatening, and measures to reverse the underlying cause should be undertaken simultaneously with restoration of adequate alveolar ventilation. This may necessitate tracheal intubation and assisted mechanical ventilation. Oxygen administration should be titrated carefully in patients with severe obstructive pulmonary disease and chronic CO_2 retention who are breathing spontaneously (Chap. 254). When oxygen is used injudiciously, these patients may experience progression of the respiratory acidosis. Aggressive and rapid correction of hypercapnia should be avoided, because the falling Pa_{CO_2} may provoke the same complications noted with acute respiratory alkalosis (i.e., cardiac arrhythmias, reduced cerebral perfusion, and seizures). The Pa_{CO_2} should be lowered gradually in chronic respiratory acidosis, aiming to restore the Pa_{CO_2} to baseline levels and to provide sufficient Cl^- and K^+ to enhance the renal excretion of HCO_3^-.

Chronic respiratory acidosis is frequently difficult to correct, but measures aimed at improving lung function (Chap. 254) can help some patients and forestall further deterioration in most.

RESPIRATORY ALKALOSIS

Alveolar hyperventilation decreases Pa_{CO_2} and increases the HCO_3^-/Pa_{CO_2} ratio, thus increasing pH (Table 48-7). Nonbicarbonate cellular buffers respond by consuming HCO_3^-. Hypocapnia develops when a sufficiently strong ventilatory stimulus causes CO_2 output in the lungs to exceed its metabolic production by tissues. Plasma pH and $[HCO_3^-]$ appear to vary proportionately with Pa_{CO_2} over a range from 40–15 mmHg. The relationship between arterial $[H^+]$ concentration and Pa_{CO_2} is ~0.7 mmol/L per mmHg (or 0.01 pH unit/mmHg), and that for plasma $[HCO_3^-]$ is 0.2 mmol/L per mmHg. Hypocapnia sustained for >2–6 h is further compensated by a decrease in renal ammonium and titratable acid excretion and a reduction in filtered HCO_3^- reabsorption. Full renal adaptation to respiratory alkalosis may take several days and requires normal volume status and renal function. The kidneys appear to respond directly to the lowered Pa_{CO_2} rather than to alkalosis per se. In chronic respiratory alkalosis a 1-mmHg fall in Pa_{CO_2} causes a 0.4- to 0.5-mmol/L drop in $[HCO_3^-]$ and a 0.3-mmol/L fall (or 0.003 rise in pH) in $[H^+]$.

The effects of respiratory alkalosis vary according to duration and severity but are primarily those of the underlying disease. Reduced cerebral blood flow as a consequence of a rapid decline in Pa_{CO_2} may cause dizziness, mental confusion, and seizures, even in the absence of hypoxemia. The cardiovascular effects of acute hypocapnia in the conscious human are generally minimal, but in the anesthetized or mechanically ventilated patient, cardiac output and blood pressure may fall because of the depressant effects of anesthesia and positive-pressure ventilation on heart rate, systemic resistance, and venous return. Cardiac arrhythmias may occur in patients with heart disease as a result of changes in oxygen unloading by blood from a left shift in the hemoglobin-oxygen dissociation curve (Bohr effect). Acute respiratory alkalosis causes intracellular shifts of Na^+, K^+, and PO_4^- and reduces free $[Ca^{2+}]$ by increasing the protein-bound fraction. Hypocapnia-induced hypokalemia is usually minor.

Chronic respiratory alkalosis is the most common acid-base disturbance in critically ill patients and, when severe, portends a poor prognosis. Many cardiopulmonary disorders manifest respiratory alkalosis in their early to intermediate stages, and the finding of normocapnia and hypoxemia in a patient with hyperventilation may herald the onset of rapid respiratory failure and should prompt an assessment to determine if the patient is becoming fatigued. Respiratory alkalosis is common during mechanical ventilation.

The hyperventilation syndrome may be disabling. Paresthesia, circumoral numbness, chest wall tightness or pain, dizziness, inability to take an adequate breath, and, rarely, tetany may themselves be sufficiently stressful to perpetuate the disorder. Arterial blood-gas analysis demonstrates an acute or chronic respiratory alkalosis, often with hypocapnia in the range of 15–30 mmHg and no hypoxemia. Central nervous system diseases or injury can produce several patterns of hyperventilation and sustained Pa_{CO_2} levels of 20–30 mmHg. Hyperthyroidism, high caloric loads, and exercise raise the basal metabolic rate, but ventilation usually rises in proportion so that arterial blood gases are unchanged and respiratory alkalosis does not develop. Salicylates are the most common cause of drug-induced respiratory alkalosis as a result of direct stimulation of the medullary chemoreceptor (**Chap. e34**). The methylxanthines, theophylline, and aminophylline stimulate ventilation and increase the ventilatory response to CO_2. Progesterone increases ventilation and lowers arterial Pa_{CO_2} by as much as 5–10 mmHg. Therefore, chronic respiratory alkalosis is a common feature of pregnancy. Respiratory alkalosis is also prominent in liver failure, and the severity correlates with the degree of hepatic insufficiency. Respiratory alkalosis is often an early finding in gram-negative septicemia, before fever, hypoxemia, or hypotension develops.

The diagnosis of respiratory alkalosis depends on measurement of arterial pH and Pa_{CO_2}. The plasma $[K^+]$ is often reduced and the $[Cl^-]$ increased. In the acute phase, respiratory alkalosis is not associated with increased renal HCO_3^- excretion, but within hours net acid excretion is reduced. In general, the HCO_3^- concentration falls by 2.0 mmol/L for each 10-mmHg decrease in Pa_{CO_2}. Chronic hypocapnia reduces the serum $[HCO_3^-]$ by 4.0 mmol/L for each 10-mmHg decrease in Pa_{CO_2}. It is unusual to observe a plasma $HCO_3^- < 12$ mmol/L as a result of a pure respiratory alkalosis.

When a diagnosis of respiratory alkalosis is made, its cause should be investigated. The diagnosis of hyperventilation syndrome is made by exclusion. In difficult cases, it may be important to rule out other conditions such as pulmonary embolism, coronary artery disease, and hyperthyroidism.

Rx RESPIRATORY ALKALOSIS

The management of respiratory alkalosis is directed toward alleviation of the underlying disorder. If respiratory alkalosis complicates ventilator management, changes in dead space, tidal volume, and frequency can minimize the hypocapnia. Patients with the hyperventilation syndrome may benefit from reassurance, rebreathing from a paper bag during symptomatic attacks, and attention to underlying psychological stress. Antidepressants and sedatives are not recommended. β-Adrenergic blockers may ameliorate peripheral manifestations of the hyperadrenergic state.

SECTION 8 ALTERATIONS IN SEXUAL FUNCTION AND REPRODUCTION

49 Sexual Dysfunction

Kevin T. McVary

Male sexual dysfunction affects 10–25% of middle-aged and elderly men. Female sexual dysfunction occurs with a similar frequency. Demographic changes, the popularity of newer treatments, and greater awareness of sexual dysfunction by patients and society have led to increased diagnosis and associated health care expenditures for the management of this common disorder. Because many patients are reluctant to initiate discussion of their sex lives, the physician should address this topic directly to elicit a history of sexual dysfunction.

MALE SEXUAL DYSFUNCTION

PHYSIOLOGY OF MALE SEXUAL RESPONSE

Normal male sexual function requires (1) an intact libido, (2) the ability to achieve and maintain penile erection, (3) ejaculation, and (4) detumescence. *Libido* refers to sexual desire and is influenced by a variety of visual, olfactory, tactile, auditory, imaginative, and hormonal stimuli. Sex steroids, particularly testosterone, act to increase libido. Libido can be diminished by hormonal or psychiatric disorders or by medications.

Penile tumescence leading to erection depends on the increased flow of blood into the lacunar network accompanied by the complete relaxation of the arteries and corporal smooth muscle. The microarchitecture of the corpora is composed of a mass of smooth muscle (trabecula) which contains a network of endothelial-lined vessels (lacunar spaces). Subsequent compression of the trabecular smooth muscle against the fibroelastic tunica albuginea causes a passive closure of the emissary veins and accumulation of blood in the corpora. In the presence of a full erection and a competent valve mechanism, the corpora become noncompressible cylinders from which blood does not escape.

The central nervous system (CNS) exerts an important influence by either stimulating or antagonizing spinal pathways that mediate erectile function and ejaculation. The erectile response is mediated by a combination of central (psychogenic) and peripheral (reflexogenic) innervation. Sensory nerves that originate from receptors in the penile skin and glans converge to form the dorsal nerve of the penis, which travels to the S2-S4 dorsal root ganglia via the pudendal nerve. Parasympathetic nerve fibers to the penis arise from neurons in the intermediolateral columns of S2-S4 sacral spinal segments. Sympathetic innervation originates from the T-11 to the L-2 spinal segments and descends through the hypogastric plexus.

Neural input to smooth-muscle tone is crucial to the initiation and maintenance of an erection. There is also an intricate interaction between the corporal smooth muscle cell and its overlying endothelial cell lining (Fig. 49-1*A*). Nitric oxide, which induces vascular relaxation, promotes erection and is opposed by endothelin-1 (ET-1) and Rho kinase, which mediate vascular contraction. Nitric oxide is synthesized from L-arginine by nitric oxide synthase and is released from the nonadrenergic, noncholinergic (NANC) autonomic nerve supply to act postjunctionally on smooth-muscle cells. Nitric oxide increases the production of cyclic 3′,5′-guanosine monophosphate (cyclic GMP), which induces relaxation of the smooth muscle (Fig. 49-1*B*). Cyclic GMP is gradually broken down by phosphodiesterase type 5 (PDE-5). Inhibitors of PDE-5, such as the oral medications sildenafil, vardenifil, and tadalafil maintain erections by reducing the breakdown of cyclic GMP. However, if nitric oxide is not produced at some level, PDE-5 inhibitors are ineffective, as these drugs facilitate, but do not initiate, the initial enzyme cascade. In addition to nitric oxide, vasoactive prostaglandins (PGE_1, $PGF_{2\alpha}$) are synthesized within the cavernosal tissue and increase cyclic AMP levels, also leading to relaxation of cavernosal smooth-muscle cells.

Ejaculation is stimulated by the sympathetic nervous system, which results in contraction of the epididymis, vas deferens, seminal vesicles,

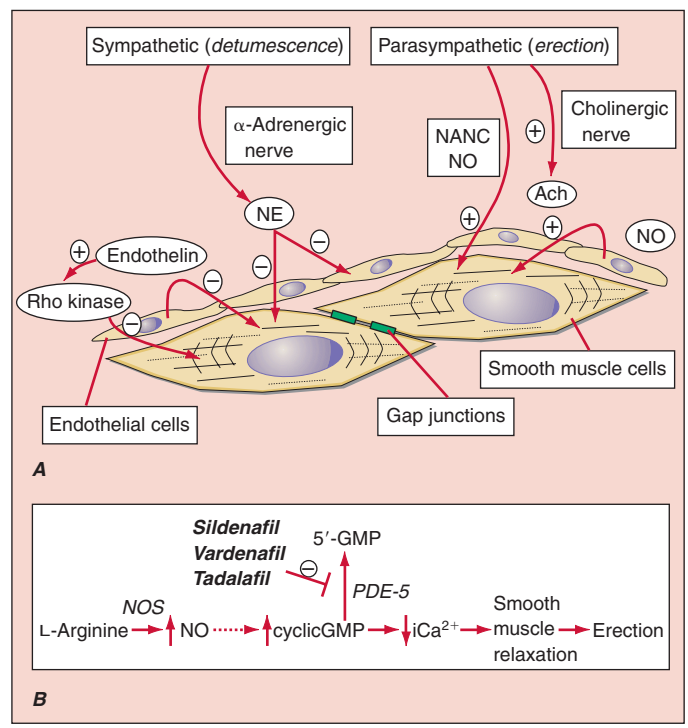

FIGURE 49-1 Pathways that control erection and detumescence. ***A.*** Erection is mediated by cholinergic parasympathetic pathways, and nonadrenergic, noncholinergic (NANC) pathways, which release nitric oxide (NO). Endothelial cells also release NO, which induces vascular smooth-muscle cell relaxation, allowing enhanced blood flow, and leading to erection. Detumescence is mediated by sympathetic pathways that release norepinephrine and stimulate α-adrenergic pathways, leading to contraction of vascular smooth-muscle cells. Endothelin, released from endothelial cells, also induces contraction. Rho kinase activation via endothelin activity (among others) also contributes to detumescence by alteration of calcium signaling. ***B.*** Biochemical pathways of NO synthesis and action. Sildenafil, vardenafil, and tadalafil enhance erectile function by inhibiting phosphodiesterase type 5 (PDE-5), thereby maintaining high levels of cyclic 3′,5′-guanosine monophosphate (cyclic GMP). NOS, nitric oxide synthase; iCa^{2+}, intracellular calcium.

and prostate, causing seminal fluid to enter the urethra. Seminal fluid emission is followed by rhythmic contractions of the bulbocavernosus and ischiocavernosus muscles, leading to ejaculation. *Premature ejaculation* is usually related to anxiety or a learned behavior and is amenable to behavioral therapy or treatment with medications such as selective serotonin reuptake inhibitors (SSRIs). *Retrograde ejaculation* results when the internal urethral sphincter does not close; it may occur in men with diabetes or after surgery involving the bladder neck.

Detumescence is mediated by norepinephrine from the sympathetic nerves, endothelin from the vascular surface, and smooth-muscle contraction induced by postsynaptic α-adrenergic receptors and activation of Rho kinase. These events increase venous outflow and restore the flaccid state. Venous leak can cause premature detumescence and is caused by insufficient relaxation of the corporal smooth muscle rather than a specific anatomic defect. *Priapism* refers to a persistent and painful erection and may be associated with sickle cell anemia, hypercoagulable states, spinal cord injury, or injection of vasodilator agents into the penis.

ERECTILE DYSFUNCTION

Epidemiology Erectile dysfunction (ED) is not considered a normal part of the aging process. Nonetheless, it is associated with certain physiologic and psychological changes related to age. In the Massachusetts Male Aging Study (MMAS), a community-based survey of men between the ages of 40 and 70, 52% of responders reported some degree of ED. Complete ED occurred in 10% of respondents, moderate ED occurred in 25%, and minimal ED in 17%. The incidence of moderate or severe ED more than doubled between the ages of 40 and 70. In the National Health and Social Life Survey (NHSLS), which was a nationally representative sample of men and women ages 18–59, 10% of men reported being unable to maintain an erection (corresponding to the proportion of men in the MMAS reporting severe ED). Incidence was highest among men in the 50–59 age group (21%) and among men who were poor (14%), divorced (14%), and less educated (13%).

The incidence of ED is also higher among men with certain medical disorders such as diabetes mellitus, obesity, lower urinary tract symptoms secondary to benign prostatic hyperplasia (BPH), heart disease, hypertension, and decreased HDL levels. Smoking is a significant risk factor in the development of ED. Medications used to treat diabetes or cardiovascular disease are additional risk factors (see below). There is a higher incidence of ED among men who have undergone radiation or surgery for prostate cancer and in those with a lower spinal cord injury. Psychological causes of ED include depression, anger, or stress from unemployment or other causes.

Pathophysiology ED may result from three basic mechanisms: (1) failure to initiate (psychogenic, endocrinologic, or neurogenic); (2) failure to fill (arteriogenic); or (3) failure to store adequate blood volume within the lacunar network (venoocclusive dysfunction). These categories are not mutually exclusive, and multiple factors contribute to ED in many patients. For example, diminished filling pressure can lead secondarily to venous leak. Psychogenic factor frequently coexist with other etiologic factors and should be considered in all cases. Diabetic, atherosclerotic, and drug-related causes account for >80% of cases of ED in older men.

VASCULOGENIC The most frequent organic cause of ED is a disturbance of blood flow to and from the penis. Atherosclerotic or traumatic arterial disease can decrease flow to the lacunar spaces, resulting in decreased rigidity and an increased time to full erection. Excessive outflow through the veins, despite adequate inflow, may also contribute to ED. Structural alterations to the fibroelastic components of the corpora may cause a loss of compliance and an inability to compress the tunical veins. This condition may result from aging, increased cross-linking of collagen fibers induced by nonenzymatic glycosylation, hypoxia, or altered synthesis of collagen associated with hypercholesterolemia.

NEUROGENIC Disorders that affect the sacral spinal cord or the autonomic fibers to the penis preclude nervous system relaxation of penile smooth muscle, thus leading to ED. In patients with spinal cord injury, the degree of ED depends on the completeness and level of the lesion. Patients with incomplete lesions or injuries to the upper part of the spinal cord are more likely to retain erectile capabilities than those with complete lesions or injuries to the lower part. Although 75% of patients with spinal cord injuries have some erectile capability, only 25% have erections sufficient for penetration. Other neurologic disorders commonly associated with ED include multiple sclerosis and peripheral neuropathy. The latter is often due to either diabetes or alcoholism. Pelvic surgery may cause ED through disruption of the autonomic nerve supply.

ENDOCRINOLOGIC Androgens increase libido, but their exact role in erectile function remains unclear. Individuals with castrate levels of testosterone can achieve erections from visual or sexual stimuli. Nonetheless, normal levels of testosterone appear to be important for erectile function, particularly in older males. Androgen replacement therapy can improve depressed erectile function when it is secondary to hypogonadism; however, it is not useful for ED when endogenous testosterone levels are normal. Increased prolactin may decrease libido by suppressing gonadotropin-releasing hormone (GnRH), and it also leads to decreased testosterone levels. Treatment of hyperprolactinemia with dopamine agonists can restore libido and testosterone.

DIABETIC ED occurs in 35–75% of men with diabetes mellitus. Pathologic mechanisms are primarily related to diabetes-associated vascular and neurologic complications. Diabetic macrovascular complications are mainly related to age, whereas microvascular complications correlate with the duration of diabetes and the degree of glycemic control (Chap. 338). Individuals with diabetes also have reduced amounts of nitric oxide synthase in both endothelial and neural tissues.

PSYCHOGENIC Two mechanisms contribute to the inhibition of erections in psychogenic ED. First, psychogenic stimuli to the sacral cord may inhibit reflexogenic responses, thereby blocking activation of vasodilator outflow to the penis. Second, excess sympathetic stimulation in an anxious man may increase penile smooth-muscle tone. The most common causes of psychogenic ED are performance anxiety, depression, relationship conflict, loss of attraction, sexual inhibition, conflicts over sexual preference, sexual abuse in childhood, and fear of pregnancy or sexually transmitted disease. Almost all patients with ED, even when it has a clear-cut organic basis, develop a psychogenic component as a reaction to ED.

MEDICATION-RELATED Medication-induced ED (Table 49-1) is estimated to occur in 25% of men seen in general medical outpatient clinics. Among the antihypertensive agents, the thiazide diuretics and beta blockers have been implicated most frequently. Calcium channel blockers and angiotensin-converting enzyme inhibitors are less frequently cited. These drugs may act directly at the corporal level (e.g., calcium channel blockers) or indirectly by reducing pelvic blood pressure, which is important in the development of penile rigidity. α Adrenergic blockers are less likely to cause ED. Estrogens, GnRH agonists, H_2 antagonists, and spironolactone cause ED by suppressing gonadotropin production or by blocking androgen action. Antidepressant and antipsychotic agents—particularly neuroleptics, tricyclics, and SSRIs—are associated with erectile, ejaculatory, orgasmic, and sexual desire difficulties.

Although many medications can cause ED, patients frequently have concomitant risk factors that confound the clinical picture. If there is a strong association between the institution of a drug and the onset of ED, alternative medications should be considered. Otherwise, it is often practical to treat the ED without attempting multiple changes in medications, as it may be difficult to establish a causal role for the drug.

APPROACH TO THE PATIENT: Erectile Dysfunction

A good physician-patient relationship helps to unravel the possible causes of ED, many of which require discussion of personal and some-

TABLE 49-1 DRUGS ASSOCIATED WITH ERECTILE DYSFUNCTION

Classification	Drugs
Diuretics	Thiazides
	Spironolactone
Antihypertensives	Calcium channel blockers
	Methyldopa
	Clonidine
	Reserpine
	β-Blockers
	Guanethidine
Cardiac/anti-hyperlipidemics	Digoxin
	Gemfibrozil
	Clofibrate
Antidepressants	Selective serotonin reuptake inhibitors
	Tricyclic antidepressants
	Lithium
	Monoamine oxidase inhibitors
Tranquilizers	Butyrophenones
	Phenothiazines
H_2 antagonists	Ranitidine
	Cimetidine
Hormones	Progesterone
	Estrogens
	Corticosteroids
	GnRH agonists
	5α-Reductase inhibitors
	Cyproterone acetate
Cytotoxic agents	Cyclophosphamide
	Methotrexate
	Roferon-A
Anticholinergics	Disopyramide
	Anticonvulsants
Recreational	Ethanol
	Cocaine
	Marijuana

times embarrassing topics. For this reason, a primary care provider is often ideally suited to initiate the evaluation. A complete medical and sexual history should be taken in an effort to assess whether the cause of ED is organic, psychogenic, or multifactorial (Fig. 49-2). Initial questions should focus on the onset of symptoms, the presence and duration of partial erections, and the progression of ED. A history of nocturnal or early morning erections is useful for distinguishing physiologic from psychogenic ED. Nocturnal erections occur during rapid eye movement (REM) sleep and require intact neurologic and circulatory systems. Organic causes of ED are generally characterized by a gradual and persistent change in rigidity or the inability to sustain nocturnal, coital, or self-stimulated erections. The patient should be questioned about the presence of penile curvature or pain with coitus. It is also important to address libido, as decreased sexual drive and ED are sometimes the earliest signs of endocrine abnormalities (e.g., increased prolactin, decreased testosterone levels). It is useful to ask whether the problem is confined to coitus with one or other partners; ED arises not uncommonly in association with new or extramarital sexual relationships. Situational ED, as opposed to consistent ED, suggests psychogenic causes. Ejaculation is much less commonly affected than erection, but questions should be asked about whether ejaculation is normal, premature, delayed, or absent. Relevant risk factors should be identified, such as diabetes mellitus, coronary artery disease (CAD), or neurologic disorders. The patient's surgical history should be explored with an emphasis on bowel, bladder, prostate, or vascular procedures. A complete drug history is also important. Social changes that may precipitate ED are also crucial to the evaluation, including health worries, spousal death, divorce, relationship difficulties, and financial concerns.

Because ED commonly involves a host of endothelial cell risk factors, men with ED report higher rates of overt and silent myocardial infarction. As such, ED in an otherwise asymptomatic male warrants consideration of other vascular disorders including CAD.

The physical examination is an essential element in the assessment of ED. Signs of hypertension as well as evidence of thyroid,

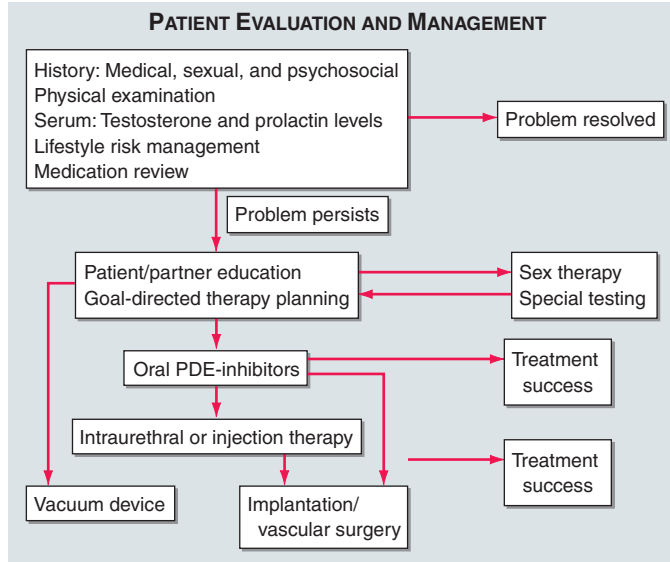

FIGURE 49-2 Algorithm for the evaluation and management of patients with ED.

hepatic, hematologic, cardiovascular, or renal diseases should be sought. An assessment should be made of the endocrine and vascular systems, the external genitalia, and the prostate gland. The penis should be carefully palpated along the corpora to detect fibrotic plaques. Reduced testicular size and loss of secondary sexual characteristics are suggestive of hypogonadism. Neurologic examination should include assessment of anal sphincter tone, the bulbocavernosus reflex, and testing for peripheral neuropathy.

Although hyperprolactinemia is uncommon, a serum prolactin level should be measured, as decreased libido and/or erectile dysfunction may be the presenting symptoms of a prolactinoma or other mass lesions of the sella (Chap. 333). The serum testosterone level should be measured and, if low, gonadotropins should be measured to determine whether hypogonadism is primary (testicular) or secondary (hypothalamic-pituitary) in origin (Chap. 340). If not performed recently, serum chemistries, CBC, and lipid profiles may be of value, as they can yield evidence of anemia, diabetes, hyperlipidemia, or other systemic diseases associated with ED. Determination of serum prostate specific antigen (PSA) should be conducted according to recommended clinical guidelines (Chap. 91).

Additional diagnostic testing is rarely necessary in the evaluation of ED. However, in selected patients, specialized testing may provide insight into pathologic mechanisms of ED and aid in the selection of treatment options. Optional specialized testing includes: (1) studies of nocturnal penile tumescence and rigidity; (2) vascular testing (in-office injection of vasoactive substances, penile Doppler ultrasound, penile angiography, dynamic infusion cavernosography/cavernosometry); (3) neurologic testing (biothesiometry-graded vibratory perception; somatosensory evoked potentials); and (4) psychological diagnostic tests. The information potentially gained from these procedures must be balanced against their invasiveness and cost.

MALE SEXUAL DYSFUNCTION

PATIENT EDUCATION Patient and partner education is essential in the treatment of ED. In goal-directed therapy, education facilitates understanding of the disease, results of the tests, and selection of treatment. Discussion of treatment options helps to clarify how treatment is best offered and stratify first- and second-line therapies. Patients with high-risk lifestyle issues, such as smoking, alcohol abuse, or recreational drug use, should be counseled on the role these factors play in the development of ED.

ORAL AGENTS Sildenafil, tadalafil, and vardenifil are the only approved and effective oral agents for the treatment of ED. These three medications

have markedly improved the management of ED because they are effective for the treatment of a broad range of causes, including psychogenic, diabetic, vasculogenic, postradical prostatectomy (nerve-sparing procedures), and spinal cord injury. They belong to a class of medications that are selective and potent inhibitors of PDE-5, the predominant phosphodiesterase isoform found in the penis. They are administered in graduated doses and enhance erections after sexual stimulation. The onset of action is approximately 60–120 min, depending on the medication used and other factors such as recent food intake. Reduced initial doses should be considered for patients who are elderly, taking concomitant alpha blockers, have renal insufficiency, or are taking medications that inhibit the CYP3A4 metabolic pathway in the liver (e.g., erythromycin, cimetidine, ketoconazole, and, possibly, itraconazole and mibefradil), as they may increase the serum concentration of the PDE-5 inhibitors or promote hypotension. Testosterone supplementation combined with a PDE-5 inhibitor may be beneficial in improving erectile function in hypogonadal men with erectile dysfunction who are unresponsive to PDE-5 inhibitors alone. These drugs do not affect ejaculation, orgasm, or sexual drive. Side effects associated with PDE-5 inhibitors include headaches (19%), facial flushing (9%), dyspepsia (6%), and nasal congestion (4%). Approximately 7% of men using sildenafil may experience transient altered color vision (blue halo effect), while 6% of men taking tadalafil may experience loin pain. PDE-5 inhibitors are contraindicated in men receiving nitrate therapy for cardiovascular disease, including agents delivered by oral, sublingual, transnasal, or topical routes. These agents can potentiate its hypotensive effect and may result in profound shock. Likewise, amyl/butyl nitrate "poppers" may have a fatal synergistic effect on blood pressure. PDE-5 inhibitors should also be avoided in patients with congestive heart failure and cardiomyopathy because of the risk of vascular collapse. Because sexual activity leads to an increase in physiologic expenditure [5–6 metabolic equivalents (METS)], physicians have been advised to exercise caution in prescribing any drug for sexual activity to those with active coronary disease, heart failure, borderline hypotension, or hypovolemia, and to those on complex antihypertensive regimens.

Although the PDE-5 inhibitors share a common mechanism of action, there are a few differences among the three agents. Having been on the market the longest, sildenafil has the most robust data confirming its activity, safety, and tolerability. It has recently been released for use in pulmonary hypertension as well as ED. Tadalafil is unique in its longer half-life. All three drugs are effective for patients with ED of all ages, severities, and etiologies. While there are pharmacokinetic and pharmacodynamic differences among these agents, clinically relevant differences are not clear.

ANDROGEN THERAPY Testosterone replacement is used to treat both primary and secondary causes of hypogonadism (Chap. 340). Androgen supplementation in the setting of normal testosterone is rarely efficacious and is discouraged. Methods of androgen replacement include transdermal patches and gels, parenteral administration of long-acting testosterone esters (enanthate and cypionate), and oral preparations (17 α-alkylated derivatives) (Chap. 340). Transdermal delivery of testosterone using patches or gels (50–100 mg/d) more closely mimics physiologic testosterone levels, but it is unclear whether this translates into improved sexual function. The administration of 200–300 mg intramuscularly every 2–3 weeks provides another option but is far from an ideal physiologic replacement. Oral androgen preparations have the potential for hepatotoxicity and should be avoided. Testosterone therapy is contraindicated in men with androgen-sensitive cancers (e.g., prostate) and may be inappropriate for men with bladder neck obstruction. It is generally advisable to measure PSA before giving androgen. Hepatic function should be tested before and during testosterone therapy.

VACUUM CONSTRICTION DEVICES Vacuum constriction devices (VCD) are a well-established, noninvasive therapy. They are a reasonable treatment alternative for select patients who cannot take sildenafil or do not desire other interventions. VCD draw venous blood into the penis and use a constriction ring to restrict venous return and maintain tumescence. Adverse events with VCD include pain, numbness, bruising, and altered ejaculation. Additionally, many patients complain that the devices are cumbersome and that the induced erections have a nonphysiologic appearance and feel.

INTRAURETHRAL ALPROSTADIL If a patient fails to respond to oral agents, a reasonable next choice is intraurethral or self-injection of vasoactive substances. Intraurethral prostaglandin E_1 (alprostadil), in the form of a semisolid pellet (doses of 125–1000 μg), is delivered with an applicator. Approximately 65% of men receiving intraurethral alprostadil respond with an erection when tested in the office, but only 50% of those achieve successful coitus at home. Intraurethral insertion is associated with a markedly reduced incidence of priapism in comparison to intracavernosal injection.

INTRACAVERNOSAL SELF-INJECTION Injection of synthetic formulations of alprostadil is effective in 70–80% of patients with ED, but discontinuation rates are high because of the invasive nature of administration. Doses range between 1 and 40 μg. Injection therapy is contraindicated in men with a history of hypersensitivity to the drug and in men at risk for priapism (hypercoagulable states, sickle cell disease). Side effects include local adverse events, prolonged erections, pain, and fibrosis with chronic use. Various combinations of alprostadil, phentolamine, and/or papaverine are sometimes used.

SURGERY A less frequently used form of therapy for ED involves the surgical implantation of a semirigid or inflatable penile prosthesis. These surgical treatments are invasive, associated with potential complications, and generally reserved for treatment of refractory ED. Despite their high cost and invasiveness, penile prostheses are associated with high rates of patient and partner satisfaction.

SEX THERAPY A course of sex therapy may be useful for addressing specific interpersonal factors that may affect sexual functioning. Sex therapy generally consists of in-session discussion and at-home exercises specific to the person and the relationship. It is preferable if therapy includes both partners, provided the patient is involved in an ongoing relationship.

FEMALE SEXUAL DYSFUNCTION

Female sexual dysfunction (FSD) has traditionally included disorders of desire, arousal, pain, and muted orgasm. The associated risk factors for FSD are similar to those in males: cardiovascular disease, endocrine disorders, hypertension, neurologic disorders, and smoking (Table 49-2).

EPIDEMIOLOGY

Epidemiologic data are limited, but the available estimates suggest that as many as 43% of women complain of at least one sexual problem. Despite the recent interest in organic causes of FSD, desire and arousal phase disorders (including lubrication complaints) remain the most common presenting problems when surveyed in a community-based population.

PHYSIOLOGY OF THE FEMALE SEXUAL RESPONSE

The female sexual response requires the presence of estrogens. A role for androgens is also likely but less well-established. In the CNS, estrogens and androgens work synergistically to enhance sexual arousal and response. A number of studies report enhanced libido in women during preovulatory phases of the menstrual cycle, suggesting that hormones involved in the ovulatory surge (e.g., estrogens) increase desire.

Sexual motivation is heavily influenced by context, including the environment and partner factors. Once sufficient sexual desire is reached, sexual arousal is mediated by the central and autonomic nervous systems. Cerebral sympathetic outflow is thought to increase desire, while peripheral parasympathetic activity results in clitoral vasocongestion and vaginal secretion (lubrication).

The neurotransmitters for clitoral corporal engorgement are similar to those in the male, with a prominent role for neural, smooth muscle,

TABLE 49-2 RISK FACTORS FOR FEMALE SEXUAL DYSFUNCTION

Neurologic disease: stroke, spinal cord injury, Parkinsonism
Trauma, genital surgery, radiation
Endocrinopathies: diabetes, hyperprolactinemia
Liver and/or renal failure
Cardiovascular disease
Psychological factors and interpersonal relationship disorders: sexual abuse, life stressors
Medications
Antiandrogens: cimetidine, spironolactone
Antidepressants, alcohol, hypnotics, sedatives
Antiestrogens or GnRH antagonists
Antihistamines, sympathomimetic amines
Antihypertensives: diuretics, calcium channel blockers
Alkylating agents
Anticholinergics

and endothelial released nitric oxide (NO). A fine network of vaginal nerves and arterioles promote a vaginal transudate. The major transmitters of this complex vaginal response are not certain, but roles for NO and vasointestinal polypeptide (VIP) are suspected. Investigators studying the normal female sexual response have challenged the long-held construct of a linear and unmitigated relationship between initial desire, arousal, vasocongestion, lubrication, and eventual orgasm. Caregivers should consider a paradigm of a positive emotional and physical outcome with one, many, or no orgasmic peak and release.

Although there are the obvious anatomic differences as well as variation in the density of vascular and neural beds in males and females, the primary effectors of sexual response are strikingly similar. Intact sensation is important for arousal. Thus, reduced levels of sexual functioning are more common in women with peripheral neuropathies (e.g., diabetes). Vaginal lubrication is a transudate of serum that results from the increased pelvic blood flow associated with arousal. Vascular insufficiency from a variety of causes may compromise adequate lubrication and result in dyspareunia. Cavernosal and arteriole smooth-muscle relaxation occurs via increased nitric oxide synthase (NOS) activity and produces engorgement in the clitoris and surrounding vestibule. Orgasm requires an intact sympathetic outflow tract; hence, orgasmic disorders are common in female patients with spinal cord injuries.

APPROACH TO THE PATIENT: Female Sexual Dysfunction

Many women do not volunteer information concerning their sexual response. Open-ended questions in a supportive atmosphere are helpful for initiating a discussion of sexual fitness in women who are reluctant to discuss such issues. Once a complaint has been voiced, a comprehensive evaluation should be performed, including a medical history, psychosocial history, physical examination, and limited laboratory testing.

The history should include the usual medical, surgical, obstetric, psychological, gynecologic, sexual, and social information. Past experiences, intimacy, knowledge, and partner availability should also be ascertained. Medical disorders that may impact sexual health should be delineated. These include diabetes, cardiovascular disease, gynecologic conditions, obstetric history, depression, anxiety disorders, and neurologic disease. Medications should be reviewed as they may impact arousal, libido, and orgasm. The need for counseling and life stresses should be identified. The physical examination should assess the genitalia, including clitoris. Pelvic floor examination may identify prolapse or other disorders. Laboratory studies are needed, especially if menopausal status is uncertain. Estradiol, FSH, and LH are usually obtained, and dehydroepiandrosterone (DHEA) should be considered as it reflects adrenal androgen secretion. A complete blood count, liver function assessment, and lipid studies may be useful, if not otherwise obtained. Complicated diagnostic evaluation, such as clitoral Doppler ultrasonography and biothesiometry, require expensive equipment and are of uncertain utility. It is important for the patient to identify which symptoms are most distressing.

The evaluation of FSD previously occurred mainly in a psychosocial context. However, inconsistencies between diagnostic categories based on only psychosocial considerations, and the emerging recognition of organic etiologies, has led to a new classification of FSD. This diagnostic scheme is based on four components that are not mutually exclusive: (1) *Hypoactive sexual desire*—the persistent or recurrent lack of sexual thoughts and/or receptivity to sexual activity, which causes personal distress. Hypoactive sexual desire may result from endocrine failure or may be associated with psychological or emotional disorders, (2) *Sexual arousal disorder*—the persistent or recurrent inability to attain or maintain sexual excitement, which causes personal distress, (3) *Orgasmic disorder*—the persistent or recurrent loss of orgasmic potential after sufficient sexual stimulation and arousal, which causes personal distress, (4) *Sexual pain disorder*—persistent or recurrent genital pain associated with noncoital sexual stimulation, which causes personal distress. This newer classification emphasizes "personal distress" as a requirement for dysfunction and provides clinicians with an organized framework for evaluation prior to or in conjunction with more traditional counseling methods.

℞ FEMALE SEXUAL DYSFUNCTION

GENERAL An open discussion with the patient is important as couples may need to be educated about normal anatomy and physiologic responses, including role of orgasm in sexual encounters. Physiologic changes associated with aging and/or disease should be explained. Couples may need to be reminded that clitoral stimulation rather than coital intromission may be more beneficial.

Behavioral modification and nonpharmacologic therapies should be a first step. Patient and partner counseling may improve communication and relationship strains. Lifestyle changes involving known risk factors can be an important part of the treatment process. Emphasis on maximizing physical health and avoiding lifestyles (e.g., smoking, alcohol abuse) and medications likely to produce FSD is important (Table 49-2). The use of topical lubricants may address complaints of dyspareunia and dryness. Contributing medications, such as antidepressants, may need to be altered, including the use of medications with less impact on sexual function, dose reduction, medication switching, or drug holidays.

HORMONAL THERAPY In postmenopausal women, estrogen replacement therapy may be helpful in treating vaginal atrophy, decreasing coital pain, and improving clitoral sensitivity (Chap. 342). Estrogen replacement in the form of local cream is the preferred method, as it avoids systemic side effects. Androgen levels in women decline substantially before menopause. However, low levels of testosterone or DHEA are not effective predictors of a positive therapeutic outcome with androgen therapy. The widespread use of exogenous androgens is not supported by the literature except in select circumstances (premature ovarian failure or menopausal states) and in secondary arousal disorders.

ORAL AGENTS The efficacy of PDE-5 inhibitors in FDS has been a marked disappointment given the proposed role of nitric oxide-dependent physiology in the normal female sexual response. The use of PDE-5 inhibitors for FSD should be discouraged pending proof that it is effective.

CLITORAL VACUUM DEVICE In patients with arousal and orgasmic difficulties, the option of using a clitoral vacuum device may be explored. This handheld battery-operated device has a small soft plastic cup that applies a vacuum over the stimulated clitoris. This causes increased cavernosal blood flow, engorgement, and vaginal lubrication.

50 Hirsutism and Virilization

David A. Ehrmann

Hirsutism, defined as excessive male-pattern hair growth, affects approximately 10% of women. It usually represents a variation of normal hair growth, but rarely it is a harbinger of a serious underlying condition. Hirsutism is often idiopathic but may be caused by conditions associated with androgen excess, such as polycystic ovarian syndrome (PCOS) or congenital adrenal hyperplasia (CAH) (Table 50-1). Cutaneous manifestations commonly associated with hirsutism include acne and male-pattern balding (androgenic alopecia). *Virilization* refers to a condition in which androgen levels are sufficiently high to cause additional signs and symptoms such as deepening of the voice, breast atrophy, increased muscle bulk, clitoromegaly, and increased libido; virilization is an ominous sign that suggests the possibility of an ovarian or adrenal neoplasm.

HAIR FOLLICLE GROWTH AND DIFFERENTIATION

Hair can be categorized as either *vellus* (fine, soft, and not pigmented) or *terminal* (long, coarse, and pigmented). The number of hair follicles does not change over an individual's lifetime, but the follicle size and type of hair can change in response to numerous factors, particularly androgens. Androgens are necessary for terminal hair and sebaceous gland development and mediate differentiation of pilosebaceous units (PSUs) into either a terminal hair follicle or a sebaceous gland. In the former case, androgens transform the vellus hair into a terminal hair; in the latter, the sebaceous component proliferates and the hair remains vellus.

There are three phases in the cycle of hair growth: (1) *anagen* (growth phase), (2) *catagen* (involution phase), and (3) *telogen* (rest phase). Depending on the body site, hormonal regulation may play an important role in the hair growth cycle. For example, the eyebrows, eyelashes, and vellus hairs are androgen-insensitive, whereas the axillary and pubic areas are sensitive to low levels of androgens. Hair growth on the face, chest, upper abdomen, and back requires greater levels of androgens and is therefore more characteristic of the pattern typically seen in men. Androgen excess in women leads to increased hair growth in most androgen-sensitive sites except in the scalp region, where hair loss occurs because androgens cause scalp hairs to spend less time in the anagen phase.

Although androgen excess underlies most cases of hirsutism, there is only a modest correlation between androgen levels and the quantity of hair growth. This is due to the fact that hair growth from the follicle also depends on local growth factors, and there is variability in end-organ sensitivity. Genetic factors and ethnic background also influence hair growth. In general, dark-haired individuals tend to be more hirsute than blonde or fair individuals. Asians and Native Americans have relatively sparse hair in regions sensitive to high androgen levels, whereas people of Mediterranean descent are more hirsute.

TABLE 50-1 CAUSES OF HIRSUTISM

Gonadal hyperandrogenism
Ovarian hyperandrogenism
Polycystic ovary syndrome/functional ovarian hyperandrogenism

Minoxidil
Phenytoin
Diazoxide
Cyclosporine
True hermaphroditism

CLINICAL ASSESSMENT

Historic elements relevant to the assessment of hirsutism include the age of onset and rate of progression of hair growth and associated symptoms or signs (e.g., acne). Depending on the cause, excess hair growth is typically first noted during the second and third decades. The growth is usually slow but progressive. Sudden development and rapid progression of hirsutism suggest the possibility of an androgen-secreting neoplasm, in which case virilization also may be present.

The age of onset of menstrual cycles (menarche) and the pattern of the menstrual cycle should be ascertained; irregular cycles from the time of menarche onward are more likely to result from ovarian rather than adrenal androgen excess. Associated symptoms such as galactorrhea should prompt evaluation for hyperprolactinemia (Chap. 333) and possibly hypothyroidism (Chap. 335). Hypertension, striae, easy bruising, centripetal weight gain, and weakness suggest hypercortisolism (Cushing's syndrome; Chap. 336). Rarely, patients with growth hormone excess (i.e., acromegaly) will present with hirsutism. Use of medications such as phenytoin, minoxidil, or cyclosporine may be associated with androgen-independent excess hair growth (i.e., hypertrichosis). A family history of infertility and/or hirsutism may indicate disorders such as nonclassic CAH (Chap. 336).

Physical examination should include measurement of height, weight, and calculation of body mass index (BMI). A BMI >25 kg/m^2 is indicative of excess weight for height, and values >30 kg/m^2 are often seen in association with hirsutism. Notation should be made of blood pressure, as adrenal causes may be associated with hypertension. Cutaneous signs sometimes associated with androgen excess and insulin resistance include acanthosis nigricans and skin tags.

An objective clinical assessment of hair distribution and quantity is central to the evaluation in any woman presenting with hirsutism. This assessment permits the distinction between hirsutism and hypertrichosis and provides a baseline reference point to gauge the response to treatment. A simple and commonly used method to grade hair growth is the modified scale of Ferriman and Gallwey (Fig. 50-1), where each of nine androgen-sensitive sites is graded from 0 to 4. Approximately 95% of Caucasian women have a score below 8 on this scale; thus, it is normal for most women to have some hair growth in androgen-sensitive sites. Scores above 8 suggest excess androgen-mediated hair growth, a finding that should be assessed further by hormonal evaluation (see below). In racial/ethnic groups that are less likely to manifest hirsutism (e.g., Asian women), additional cutaneous evidence of androgen excess should be sought, including pustular acne or thinning hair.

HORMONAL EVALUATION

Androgens are secreted by the ovaries and adrenal glands in response to their respective tropic hormones, luteinizing hormone (LH) and adrenocorticotropic hormone (ACTH). The principal circulating steroids involved in the etiology of hirsutism are testosterone, androstenedione, and dehydroepiandrosterone (DHEA) and its sulfated form (DHEAS). The ovaries and adrenal glands normally contribute about equally to testosterone production. Approximately half of the total testosterone originates from direct glandular secretion, and the remainder is derived from the peripheral conversion of androstenedione and DHEA (Chap. 340).

Although it is the most important circulating androgen, testosterone is, in effect, the penultimate androgen in mediating hirsutism;

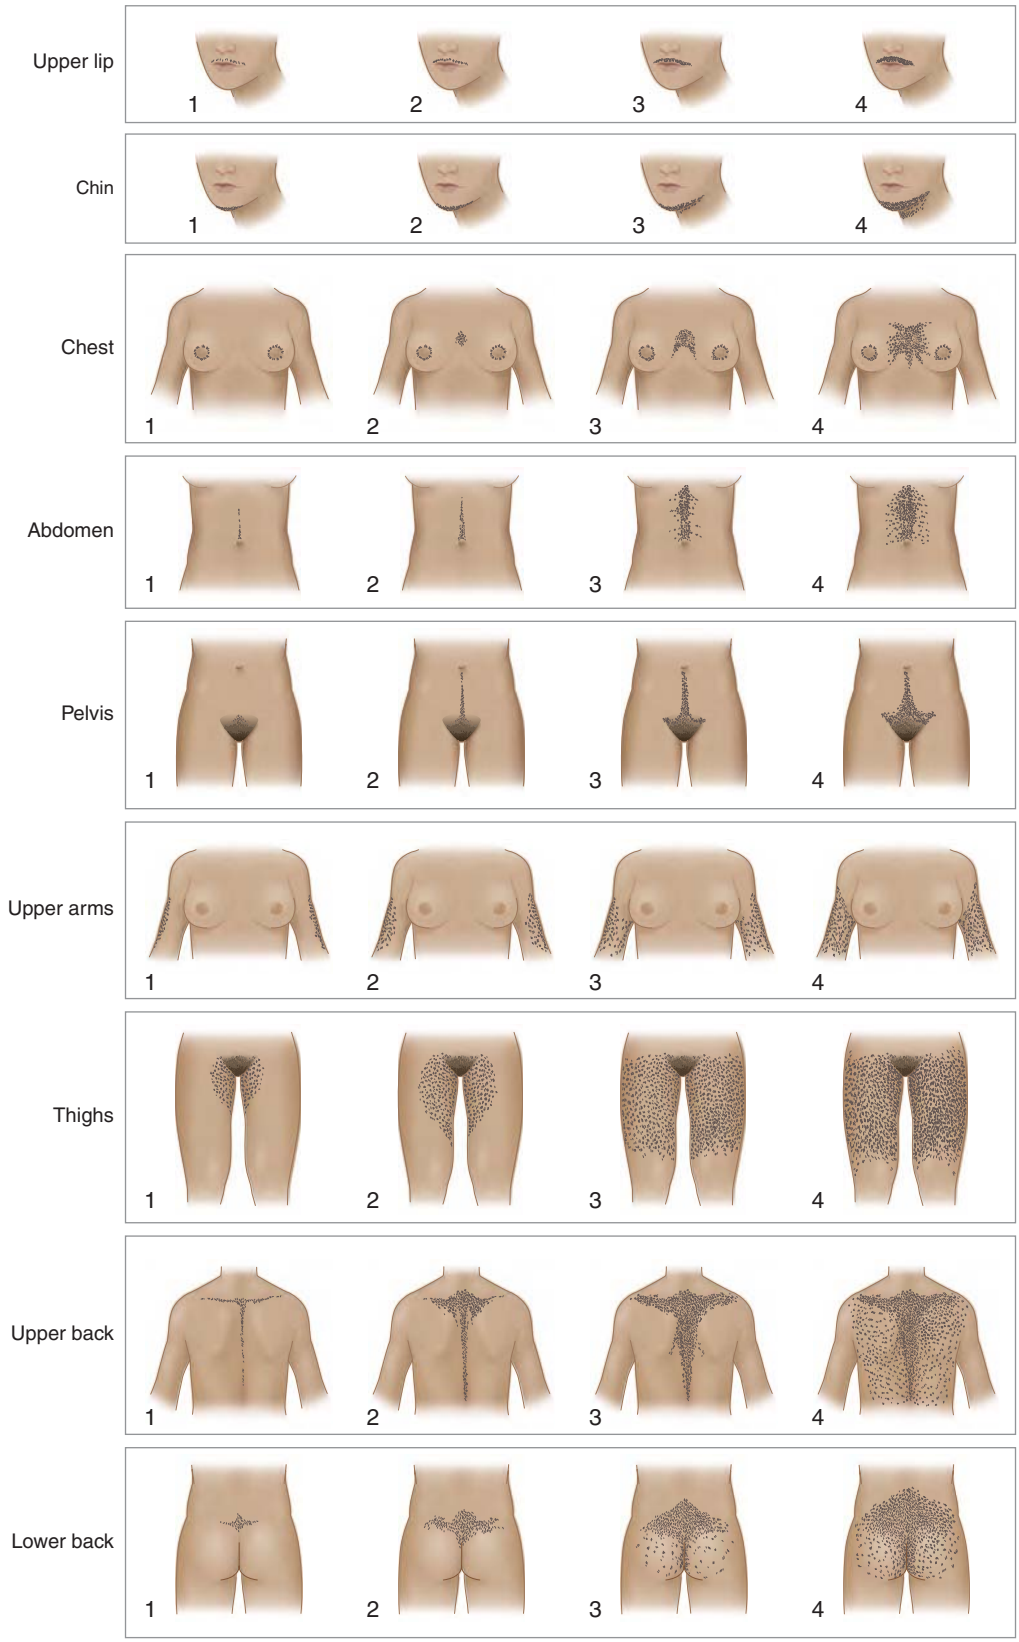

FIGURE 50-1 Hirsutism scoring scale of Ferriman and Gallwey. The nine body areas possessing androgen-sensitive areas are graded from 0 (no terminal hair) to 4 (frankly virile) to obtain a total score. A normal hirsutism score is less than 8. [*Modified from DA Ehrmann et al: Hyperandrogenism, hirsutism, and polycystic ovary syndrome, in LJ DeGroot and JL Jameson (eds), Endocrinology, 5th ed. Philadelphia, Saunders, 2006; with permission.*]

it is converted to the more potent dihydrotestosterone (DHT) by the enzyme 5α-reductase, which is located in the PSU. DHT has a higher affinity for, and slower dissociation from, the androgen receptor. The local production of DHT allows it to serve as the primary mediator of androgen action at the level of the pilosebaceous unit. There are two isoenzymes of 5α-reductase: type 2 is found in the prostate gland and in hair follicles, whereas type 1 is found primarily in sebaceous glands.

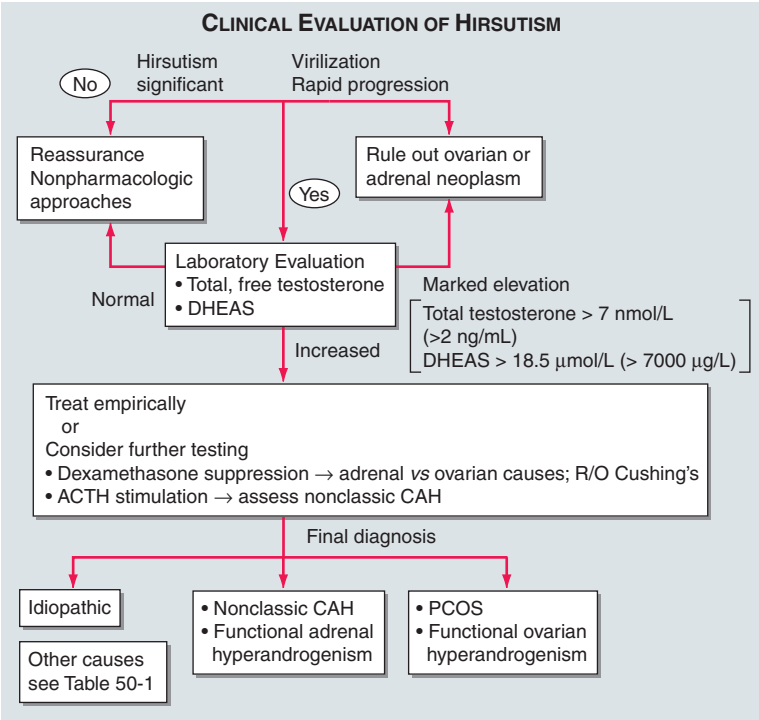

FIGURE 50-2 Algorithm for the evaluation and differential diagnosis of hirsutism. ACTH, adrenocorticotropic hormone; CAH, congenital adrenal hyperplasia; DHEAS, sulfated form of dehydroepiandrosterone; PCOS, polycystic ovarian syndrome.

One approach to testing for hyperandrogenemia is depicted in Fig. 50-2. In addition to measuring blood levels of testosterone and DHEAS, it is also important to measure the level of free (or unbound) testosterone. The fraction of testosterone that is not bound to its carrier protein, sex-hormone binding globulin (SHBG), is biologically available for conversion to DHT and for binding to androgen receptors. Hyperinsulinemia and/or androgen excess decrease hepatic production of SHBG, resulting in levels of total testosterone within the high-normal range, whereas the unbound hormone is more substantially elevated. Although there is a decline in ovarian testosterone production after menopause, ovarian estrogen production decreases to an even greater extent, and the concentration of SHBG is reduced. Consequently, there is an increase in the relative proportion of unbound testosterone, and it may exacerbate hirsutism after menopause.

A baseline plasma total testosterone level >12 nmol/L (>3.5 ng/mL) usually indicates a virilizing tumor, whereas a level >7 nmol/L (>2 ng/mL) is suggestive. A basal DHEAS level >18.5 µmol/L (>7000 µg/L) suggests an adrenal tumor. Although DHEAS has been proposed as a "marker" of predominant adrenal androgen excess, it is not unusual to find modest elevations in DHEAS among women with PCOS. Computed tomography (CT) or magnetic resonance imaging (MRI) should be used to localize an adrenal mass, and ultrasound will usually suffice to identify an ovarian mass if clinical evaluation and hormonal levels suggest these possibilities.

PCOS is the most common cause of ovarian androgen excess (Chap. 341). However, the increased ratio of LH to follicle-stimulating hormone that is characteristic of carefully studied patients with PCOS is not seen in up to half of these women due to the pulsatility of gonadotropins. If performed, ultrasound shows enlarged ovaries and increased stroma in many women with PCOS. However, polycystic ovaries may also be found in women without clinical or laboratory features of PCOS. Therefore, polycystic ovaries are a relatively insensitive and nonspecific finding for the diagnosis of ovarian hyperandrogenism. Although not usually necessary, gonadotropin-releasing hormone agonist testing can be used to make a specific diagnosis of ovarian hyperandrogenism. A peak 17-hydroxyprogesterone level ≥7.8 nmol/L (≥2.6 µg/L), after the administration of 100 µg nafarelin (or 10 µg/kg leuprolide) subcutaneously, is virtually diagnostic of ovarian hyperandrogenism.

Because adrenal androgens are readily suppressed by low doses of glucocorticoids, the dexamethasone androgen-suppression test may broadly distinguish ovarian from adrenal androgen overproduction. A blood sample is obtained before and after administering dexamethasone (0.5 mg orally every 6 h for 4 days). An adrenal source is suggested by suppression of unbound testosterone into the normal range; incomplete suppression suggests ovarian androgen excess. An overnight 1-mg dexamethasone suppression test, with measurement of 8:00 A.M. serum cortisol, is useful when there is clinical suspicion of Cushing's syndrome (Chap. 336).

Nonclassic CAH is most commonly due to 21-hydroxylase deficiency but can also be caused by autosomal recessive defects in other steroidogenic enzymes necessary for adrenal corticosteroid synthesis (Chap. 336). Because of the enzyme defect, the adrenal gland cannot secrete glucocorticoids efficiently (especially cortisol). This results in diminished negative feedback inhibition of ACTH, leading to compensatory adrenal hyperplasia and the accumulation of steroid precursors that are subsequently converted to androgen. Deficiency of 21-hydroxylase can be reliably excluded by determining a morning 17-hydroxyprogesterone level <6 nmol/L (<2 µg/L) (drawn in the follicular phase). Alternatively, 21-hydroxylase deficiency can be diagnosed by measurement of 17-hydroxyprogesterone 1 h after administration of 250 µg of synthetic ACTH (cosyntropin) intravenously.

Rx HIRSUTISM

Treatment of hirsutism may be accomplished pharmacologically or by mechanical means of hair removal. Nonpharmacologic treatments should be considered in all patients, either as the only treatment or as an adjunct to drug therapy.

Nonpharmacologic treatments include (1) bleaching; (2) depilatory (removal from the skin surface) such as shaving and chemical treatments; or (3) epilatory (removal of the hair including the root) such as plucking, waxing, electrolysis, and laser therapy. Despite perceptions to the contrary, shaving does not increase the rate or density of hair growth. Chemical depilatory treatments may be useful for mild hirsutism that affects only limited skin areas, though they can cause skin irritation. Wax treatment removes hair temporarily but is uncomfortable. Electrolysis is effective for more permanent hair removal, particularly in the hands of a skilled electrologist. Laser phototherapy appears to be efficacious for hair removal. It delays hair regrowth and causes permanent hair removal in most patients. The long-term effects and complications associated with laser treatment are still being evaluated.

Pharmacologic therapy is directed at interrupting one or more of the steps in the pathway of androgen synthesis and action: (1) suppression of adrenal and/or ovarian androgen production; (2) enhancement of androgen-binding to plasma-binding proteins, particularly SHBG; (3) impairment of the peripheral conversion of androgen precursors to active androgen; and (4) inhibition of androgen action at the target tissue level. Attenuation of hair growth is typically not evident until 4–6 months after initiation of medical treatment and, in most cases, leads to only a modest reduction in hair growth.

Combination estrogen-progestin therapy, in the form of an oral contraceptive, is usually the first-line endocrine treatment for hirsutism and acne, after cosmetic and dermatologic management. The estrogenic component of most oral contraceptives currently in use is either ethinyl estradiol or mestranol. The suppression of LH leads to reduced production of ovarian androgens. The reduced androgen levels also result in a dose-related increase in SHBG, thereby lowering the fraction of unbound plasma testosterone. Combination therapy has also been demonstrated to decrease DHEAS, perhaps by reducing ACTH levels. Estrogens also have a direct, dose-dependent suppressive effect on sebaceous cell function.

The choice of a specific oral contraceptive should be predicated on the progestational component, as progestins vary in their suppressive effect on SHBG levels and in their androgenic potential. Ethynodiol diacetate has relatively low androgenic potential, whereas progestins such as norgestrel and levonorgestrel are particularly androgenic, as judged from their attenuation of the estrogen-induced increase in SHBG. Norgestimate exemplifies the newer generation of progestins that are virtually nonandrogenic. Drospirenone, an analogue of spironolactone that has both antimineralocorticoid and antiandrogenic activities, has been approved for use as a progestational agent in combination with ethinyl estradiol. Its properties suggest that it should be the preferred choice for the treatment of hirsutism.

Oral contraceptives are contraindicated in women with a history of thromboembolic disease or in women with increased risk of breast or other estrogen-dependent cancers (Chap. 342). There is a relative contraindication to the use of oral contraceptives in smokers or in those with hypertension or a history of migraine headaches. In most trials, estrogen-progestin therapy alone improves the extent of acne by a maximum of 50–70%. The effect on hair growth may not be evident for 6 months, and the maximum effect may require 9–12 months owing to the length of the hair growth cycle. Improvements in hirsutism are typically in the range of 20%, but there may be an arrest of further progression of hair growth.

Adrenal androgens are more sensitive than cortisol to the suppressive effects of glucocorticoids. Therefore, glucocorticoids are the mainstay of treatment in patients with CAH. Although glucocorticoids have been reported to restore ovulatory function in some women with PCOS, this effect is highly variable. Because of side effects from excessive glucocorticoids, low doses should be used. Dexamethasone (0.2–0.5 mg) or prednisone (5–10 mg) should be taken at bedtime to achieve maximal suppression by inhibiting the nocturnal surge of ACTH.

Cyproterone acetate is the prototypic antiandrogen. It acts mainly by competitive inhibition of the binding of testosterone and DHT to the androgen receptor. In addition, it may enhance the metabolic clearance of testosterone by inducing hepatic enzymes. Although not available for use in the United States, cyproterone acetate is widely used in Canada, Mexico, and Europe. Cyproterone (50–100 mg) is given on days 1–15 and ethinyl estradiol (50 μg) is given on days 5–26 of the menstrual cycle. Side effects include irregular uterine bleeding, nausea, headache, fatigue, weight gain, and decreased libido.

Spironolactone, usually used as a mineralocorticoid antagonist, is also a weak antiandrogen. It is almost as effective as cyproterone acetate when used at high enough doses (100–200 mg daily). Patients should be monitored intermittently for hyperkalemia or hypotension, though these side effects are uncommon. Pregnancy should be avoided because of the risk of feminization of a male fetus. Spironolactone can also cause menstrual irregularity. It is often used in combination with an oral contraceptive, which suppresses ovarian androgen production and helps prevent pregnancy.

Flutamide is a potent nonsteroidal antiandrogen that is effective in treating hirsutism, but concerns about the induction of hepatocellular dysfunction have limited its use. Finasteride is a competitive inhibitor of 5α-reductase type 2. Beneficial effects on hirsutism have been reported, but the predominance of 5α-reductase type 1 in the PSU appears to account for its limited efficacy. Finasteride would also be expected to impair sexual differentiation in a male fetus, and it should not be used in women who may become pregnant.

Eflornithine cream (Vaniqa) has been approved as a novel treatment for unwanted facial hair in women, but long-term efficacy remains to be established. It can cause skin irritation under exaggerated conditions of use. Ultimately, the choice of any specific agent(s) must be tailored to the unique needs of the patient being treated. As noted previously, pharmacologic treatments for hirsutism should be used in conjunction with nonpharmacologic approaches. It is also helpful to review the pattern of female hair distribution in the normal population to dispel unrealistic expectations.

51 Menstrual Disorders and Pelvic Pain

Janet E. Hall

Menstrual dysfunction can signal an underlying abnormality that may have long-term health consequences. Although frequent or prolonged bleeding usually prompts a woman to seek medical attention, infrequent or absent bleeding may seem less troubling, and the patient may not bring it to the attention of the physician. Thus, a focused menstrual history is a critical part of every female patient encounter. Pelvic pain is a common complaint that may relate to an abnormality of the reproductive organs but may also be of gastrointestinal, urinary tract, or musculoskeletal origin. Depending on its cause, pelvic pain may require urgent surgical attention.

MENSTRUAL DISORDERS

DEFINITION AND PREVALENCE

Amenorrhea refers to the absence of menstrual periods. Amenorrhea is classified as *primary* if menstrual bleeding has never occurred in the absence of hormonal treatment or *secondary* if menstrual periods are absent for 3–6 months. *Oligoamenorrhea* is defined as a cycle length >35 days or <10 menses per year. Both the frequency and amount of vaginal bleeding are irregular in oligoamenorrhea. It is often associated with anovulation, which can also occur with intermenstrual intervals of <24 days or vaginal bleeding for >7 days. Frequent or heavy irregular bleeding is termed *dysfunctional uterine bleeding* if anatomic uterine lesions or a bleeding diathesis have been excluded.

Primary Amenorrhea This is a rare disorder occurring in <1% of the female population. However, between 3 and 5% of women experience at least 3 months of secondary amenorrhea in a given year. There is no evidence that race or ethnicity influence the prevalence of amenorrhea. However, because of the importance of adequate nutrition for normal reproductive function, both the age at menarche and the prevalence of secondary amenorrhea vary significantly in different parts of the world.

The absence of menses by age 16 has been used traditionally to define primary amenorrhea. However, other factors such as growth, secondary sexual characteristics, the presence of cyclic pelvic pain, and the secular trend to an earlier age of menarche, particularly in African-American girls, also influence the age at which primary amenorrhea should be investigated. Thus, an evaluation for amenorrhea should be initiated by age 15 or 16 in the presence of normal growth and secondary sexual characteristics; age 13 in the absence of secondary sexual characteristics or if height is less than the third percentile; age 12 or 13 in the presence of breast development and cyclic pelvic pain; or within 2 years of breast development if menarche has not occurred.

Secondary Amenorrhea or Oligoamenorrhea Anovulation and irregular cycles are relatively common for 2–4 years after menarche and for 1–2 years before the final menstrual period. In the intervening years, menstrual cycle length is ~28 days, with an intermenstrual interval normally ranging between 25 and 35 days. Cycle-to-cycle variability in an individual woman who is consistently ovulating is generally +/– 2 days. Pregnancy is the most common cause of amenorrhea and should be excluded early in

any evaluation of menstrual irregularity. However, many women will occasionally miss a single period. Three or more months of secondary amenorrhea should prompt an evaluation, as should a history of intermenstrual intervals of >35 or <21 days, or bleeding that persists for >7 days.

DIAGNOSIS

Evaluation of menstrual dysfunction depends on understanding the interrelationships between the four critical components of the reproductive tract: (1) the hypothalamus, (2) the pituitary, (3) the ovaries, and (4) the uterus and outflow tract (Fig. 51-1; Chap. 341). This system is maintained by complex negative and positive feedback loops involving the ovarian steroids (estradiol and progesterone) and peptides (inhibin B and inhibin A) and the hypothalamic [gonadotropin-releasing hormone (GnRH)] and pituitary [follicle-stimulating hormone (FSH) and luteinizing hormone (LH)] components of this system (Fig. 51-1).

Disorders of menstrual function can be thought of in two main categories: disorders of the uterus and outflow tract and disorders of ovulation. Many of the conditions that cause primary amenorrhea are congenital but go unrecognized until the time of normal puberty (e.g., genetic, chromosomal, and anatomic abnormalities). All causes of secondary amenorrhea can also cause primary amenorrhea.

	Primary	Secondary
Hypothalamus	27%	36%
Pituitary	2%	15%
PCOS	7%	30%
Ovary	43%	12%
Uterus/outflow tract	19%	7%

FIGURE 51-1 Role of the hypothalamic-pituitary-gonadal axis in the etiology of amenorrhea. Gonadotropin-releasing hormone (GnRH) secretion from the hypothalamus stimulates follicle-stimulating hormone (FSH) and luteinizing hormone (LH) secretion from the pituitary to induce ovarian folliculogenesis and steroidogenesis. Ovarian secretion of estradiol and progesterone controls the shedding of the endometrium, resulting in menses and, in combination with the inhibins, provides feedback regulation of the hypothalamus and pituitary to control secretion of FSH and LH. The prevalence of amenorrhea resulting from abnormalities at each level of the reproductive system (hypothalamus, pituitary, ovary, uterus, and outflow tract) varies depending on whether amenorrhea is primary or secondary. PCOS, polycystic ovarian syndrome.

Disorders of the Uterus or Outflow Tract Abnormalities of the uterus and outflow tract typically present as primary amenorrhea. In patients with normal pubertal development and a blind vagina, the differential diagnosis includes *obstruction* by a transverse vaginal septum or imperforate hymen; *müllerian agenesis* (Mayer-Rokitansky-Kuster-Hauser syndrome), which has been associated with mutations in the *WNT4* gene; and *androgen insensitivity syndrome* (AIS), which is an X-linked recessive disorder that accounts for ~10% of all cases of primary amenorrhea (Chap. 340). Patients with AIS have a 46, XY karyotype, but because of the lack of androgen receptor responsiveness, they have severe underandrogenization and female external genitalia. The absence of pubic and axillary hair distinguishes them clinically from patients with müllerian agenesis. *Asherman syndrome* presents as secondary amenorrhea or hypomenorrhea and results from partial or complete obliteration of the uterine cavity by adhesions that prevent normal growth and shedding of the endometrium. Curettage performed for pregnancy complications accounts for >90% of cases; genital tuberculosis is an important cause in endemic regions.

℞ DISORDERS OF UTERUS OR OUTFLOW TRACT

Obstruction of the outflow tract requires surgical correction. The risk of endometriosis is increased with this condition, perhaps because of retrograde menstrual flow. *Müllerian agenesis* may also require surgical intervention, although vaginal dilatation is adequate in some patients. Because ovarian function is normal, assisted reproductive techniques can be used with a surrogate carrier. *Androgen resistance syndrome* requires gonadectomy because there is risk of gonadoblastoma in the dysgenetic gonads. Whether this should be performed in early childhood or after completion of breast development is controversial. Estrogen replacement is indicated after gonadectomy, and vaginal dilatation may be required to allow sexual intercourse.

Disorders of Ovulation Once uterus and outflow tract abnormalities have been excluded, all other causes of amenorrhea involve disorders of ovulation. The differential diagnosis is based on the results of initial tests including a pregnancy test, gonadotropins, and assessment of hyperandrogenism (Fig. 51-2).

HYPOGONADOTROPIC HYPOGONADISM Low estrogen levels in combination with normal or low levels of LH and FSH are seen with anatomic, genetic, or functional abnormalities that interfere with hypothalamic GnRH secretion or normal pituitary responsiveness to GnRH. Although relatively uncommon, tumors and infiltrative diseases should be considered in the differential diagnosis of hypogonadotropic hypogonadism (Chap. 333). These disorders may present with primary or secondary amenorrhea. They may occur in association with other features suggestive of hypothalamic or pituitary dysfunction such as short stature, diabetes insipidus, galactorrhea, or headache. Hypogonadotropic hypogonadism may also be seen following cranial irradiation. In the postpartum period, it may be due to pituitary necrosis (Sheehan syndrome) or lymphocytic hypophysitis. Because reproductive dysfunction is commonly associated with hyperprolactinemia, either from neuroanatomic lesions or medications, prolactin should be measured in all patients with hypogonadotropic hypogonadism (Chap. 333).

Isolated hypogonadotropic hypogonadism (IHH) is more common in men than women and is often associated with anosmia. IHH generally presents with primary amenorrhea. A number of genetic causes of IHH have been identified (Chaps. 340 and 341).

Functional hypothalamic amenorrhea (HA) is caused by a mismatch between energy expenditure and energy intake. Leptin secretion may play a key role in transducing the signals from the periphery to the hypothalamus in HA. The hypothalamic-pituitary-adrenal axis may also play a role. The diagnosis of HA can generally be made on the basis of a careful history, physical examination, and the demonstration of low levels of gonadotropins and normal prolactin levels. Eating disorders and chronic disease must be specifically excluded (Chap. 76). An atypical history, headache, signs of other hypothalamic dysfunction, or hyper-

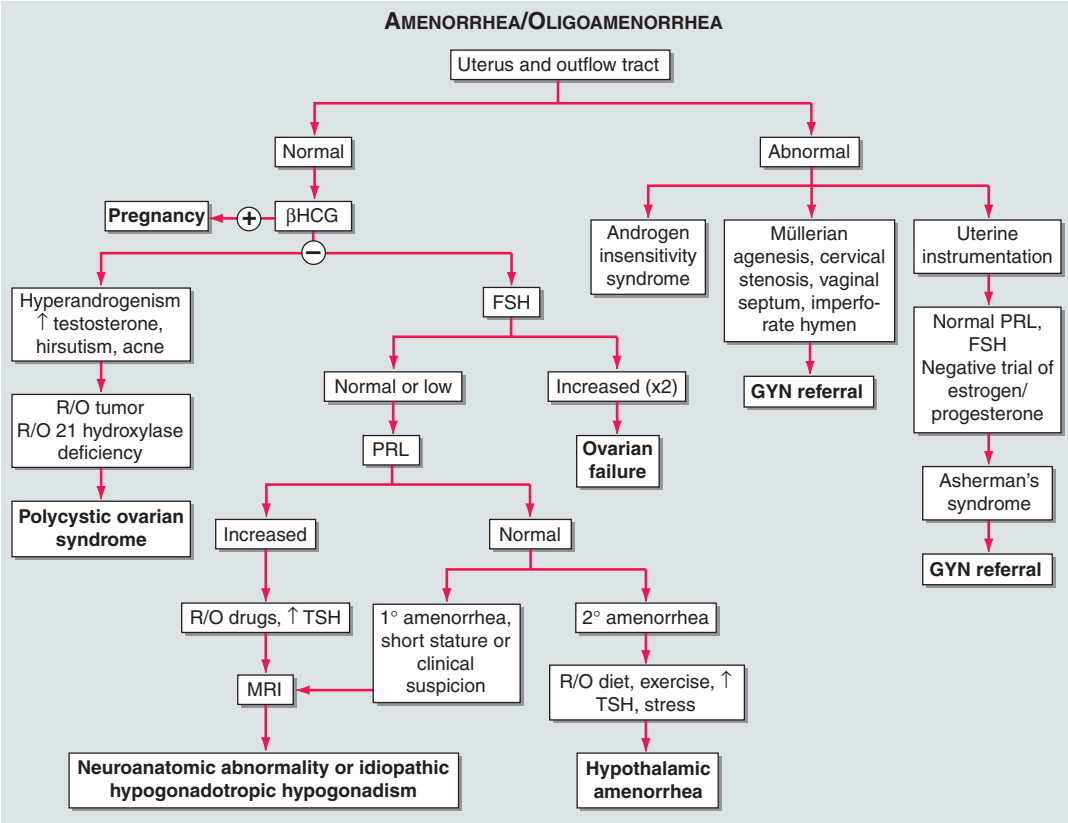

FIGURE 51-2 Algorithm for evaluation of amenorrhea. β-hCG, human chorionic gonadotropin; PRL, prolactin; FSH, follicle-stimulating hormone; TSH, thyroid-stimulating hormone.

prolactinemia, even if mild, necessitates cranial imaging with CT or MRI to exclude a neuroanatomic cause.

HYPERGONADOTROPIC HYPOGONADISM Ovarian failure is considered premature when it occurs in women younger than age 40. Ovarian failure is associated with the loss of negative-feedback restraint on the hypothalamus and pituitary, resulting in increased FSH and LH levels. FSH is a better marker of ovarian failure as its levels are less variable than LH. As with natural menopause, premature ovarian failure (POF) may wax and wane, and serial measurements may be necessary to establish the diagnosis.

Once the diagnosis of POF has been established, further evaluation is indicated because of other health problems that may be associated with POF. For example, POF is seen in association with a variety of chromosomal abnormalities including Turner syndrome, autoimmune polyglandular failure syndromes, radio- and chemotherapy, and galactosemia. In the majority of cases, however, a cause is not determined. The recognition that early ovarian failure occurs in premutation carriers of the fragile X syndrome is important because of increased risk of severe mental retardation in male children with *FMR1* mutations.

Hypergonadotropic hypogonadism occurs rarely in other disorders, such as mutations in the FSH or LH receptors. Aromatase deficiency and 17α-hydroxylase deficiency are associated with elevated gonadotropins with hyperandrogenism and hypertension, respectively. Gonadotropin-secreting tumors in women of reproductive age generally present with high, rather than low, estrogen levels and cause ovarian hyperstimulation or dysfunctional bleeding.

Rx AMENORRHEA CAUSED BY OVULATORY DISORDERS

Amenorrhea is almost always associated with chronically low levels of estrogen, whether it is caused by hypogonadotropic hypogonadism or ovarian failure. Development of secondary sexual characteristics requires gradual titration of estradiol replacement with eventual addition of a progestin. Symptoms of hypoestrogenism can be treated with hormone replacement therapy or oral contraceptive pills. Patients with hypogonadotropic hypogonadism who are interested in fertility require treatment with pulsatile GnRH or exogenous FSH and LH, whereas patients with ovarian failure can consider oocyte donation, which has a high chance of success in this population.

POLYCYSTIC OVARIAN SYNDROME (PCOS) This is diagnosed based on the presence of clinical or biochemical evidence of hyperandrogenism in association with amenorrhea or oligomenorrhea. Symptoms generally begin shortly after menarche and are slowly progressive. Lean patients with PCOS generally have high LH levels in the presence of normal to low levels of FSH and estradiol. The LH/FSH abnormality is less pronounced in obese patients in whom insulin resistance is a more prominent feature. Most patients also have a polycystic ovarian morphology on ultrasound, although there is controversy as to whether this morphology in combination with hyperandrogenism is sufficient for the diagnosis of PCOS.

Rx POLYCYSTIC OVARIAN SYNDROME

The major abnormality in patients with PCOS is the failure of regular, predictable ovulation. Thus, these patients are at risk for the development of dysfunctional bleeding and endometrial hyperplasia associated with unopposed estrogen exposure. Endometrial protection can be achieved with the use of oral contraceptives or progestins (medroxyprogesterone acetate, 5–10 mg, or prometrium, 200 mg daily for 10–14 days of each month). Oral contraceptives are also useful for management of hyperandrogenic symptoms, as is spironolactone, which functions as a weak androgen receptor antagonist. Management of the associated metabolic syndrome may be appropriate for some patients (Chap. 236). For patients interested in fertility, weight control is a critical first step. Clomiphene citrate is highly effective as first-line treatment, with or without the addition of metformin. Exogenous gonadotropins can be used by experienced practitioners.

PELVIC PAIN

The mechanisms causing pelvic pain are similar to those causing abdominal pain (Chap. 14) and include inflammation of the parietal peritoneum, obstruction of hollow viscera, vascular disturbances, and pain originating in the abdominal wall. Pelvic pain may reflect pelvic disease per se but may also reflect extrapelvic disorders that refer pain to the pel-

TABLE 51-1 CAUSES OF PELVIC PAIN

	Acute	Chronic
Cyclic pelvic pain		Premenstrual symptoms Mittelschmerz Dysmenorrhea Endometriosis
Noncyclic pelvic pain	Pelvic inflammatory disease Ruptured or hemorrhagic ovarian cyst or ovarian torsion Ectopic pregnancy Endometritis Acute growth or degeneration of uterine myoma	Pelvic congestion syndrome Adhesions and retroversion of the uterus Pelvic malignancy Vulvodynia History of sexual abuse

vis. In up to 60% of cases, pelvic pain can be attributed to gastrointestinal problems including appendicitis, cholecystitis, infections, intestinal obstruction, diverticulitis, or inflammatory bowel disease. Urinary tract and musculoskeletal disorders are also common causes of pelvic pain.

APPROACH TO THE PATIENT: Pelvic Pain

A thorough history including the type, location, radiation, and status with respect to increasing or decreasing severity can help to identify the cause of acute pelvic pain. Specific associations with vaginal bleeding, sexual activity, defecation, urination, movement, or eating should be specifically sought. A careful menstrual history is essential to assess the possibility of pregnancy. Determination of whether the pain is acute versus chronic and cyclic versus noncyclic will direct further investigation (Table 51-1). However, disorders that cause cyclic pain may occasionally cause noncyclic pain, and the converse is also true.

ACUTE PELVIC PAIN

Pelvic inflammatory disease most commonly presents with bilateral lower abdominal pain. It is generally of recent onset and is exacerbated by intercourse or jarring movements. Fever is present in about half of patients; abnormal uterine bleeding occurs in about one-third. New vaginal discharge, urethritis, and chills may be present but are less specific signs. *Adnexal pathology* can present acutely and may be due to rupture, bleeding or torsion of cysts, or, much less commonly, neoplasms of the ovary, fallopian tubes, or paraovarian areas. Fever may be present with ovarian torsion. *Ectopic pregnancy* is associated with right or left sided lower abdominal pain, vaginal bleeding and menstrual cycle abnormalities, with clinical signs generally appearing 6–8 weeks after the last normal menstrual period. Orthostatic signs and fever may be present. Risk factors include the presence of known tubal disease, previous ectopic pregnancies, or a history of infertility, DES exposure of the mother in utero, or a history of pelvic infections. *Uterine pathology* includes endometritis and, less frequently, degenerating leiomyomas (fibroids). Endometritis is often associated with vaginal bleeding and systemic signs of infection. It occurs in the setting of sexually transmitted infections, uterine instrumentation, or postpartum infection.

A sensitive pregnancy test, complete blood count with differential, urinalysis, tests for chlamydial and gonococcal infections, and abdominal ultrasound aid in making the diagnosis and directing further management.

℞ ACUTE PELVIC PAIN

Treatment of acute pelvic pain depends on the suspected etiology but may require surgical or gynecologic intervention. Conservative management is an important consideration for ovarian cysts, if torsion is not suspected, to avoid unnecessary pelvic surgery and the subsequent risk of infertility due to adhesions. The majority of unruptured ectopic pregnancies are now treated with methotrexate, which is effective in 84–96% of cases. However, surgical treatment may be required.

CHRONIC PELVIC PAIN

Some women experience discomfort at the time of ovulation (*mittelschmerz*). Pain can be quite intense but is generally of short duration. The mechanism is thought to involve rapid expansion of the dominant follicle, although it may also be caused by peritoneal irritation by follicular fluid released at the time of ovulation. Many women experience premenstrual symptoms such as breast discomfort, food cravings, and abdominal bloating or discomfort. These moliminal symptoms are a good predictor of ovulation, although their absence is less helpful.

Dysmenorrhea *Dysmenorrhea* refers to the crampy lower abdominal discomfort that begins with the onset of menstrual bleeding and gradually decreases over the next 12–72 h. It may be associated with nausea, diarrhea, fatigue, and headache and occurs in 60–93% of adolescents, beginning with the establishment of regular ovulatory cycles. Its prevalence decreases after pregnancy and with the use of oral contraceptives.

Primary dysmenorrhea results from increased stores of prostaglandin precursors, which are generated by sequential stimulation of the uterus by estrogen and progesterone. During menstruation these precursors are converted to prostaglandins, which cause intense uterine contractions, decreased blood flow, and increased peripheral nerve hypersensitivity, resulting in pain.

Secondary dysmenorrhea is caused by underlying pelvic pathology. *Endometriosis* results from the presence of endometrial glands and stroma outside of the uterus. These deposits of ectopic endometrium respond to hormonal stimulation and cause dysmenorrhea, which generally precedes menstruation by several days. Endometriosis may also be associated with painful intercourse, painful bowel movements, and tender nodules in the uterosacral ligament. Fibrosis and adhesions can produce lateral displacement of the cervix. The CA125 level may be increased, but it has low negative predictive value. Definitive diagnosis requires laparoscopy. Symptomatology does not always predict the extent of endometriosis. Other secondary causes of dysmenorrhea include adenomyosis, a condition caused by the presence of ectopic endometrial glands and stroma within the myometrium. Cervical stenosis may result from trauma, infection, or surgery.

℞ DYSMENORRHEA

Local application of heat; use of vitamins B_1, B_6, and E and magnesium; acupuncture; yoga; and exercise are of some benefit for the treatment of dysmenorrhea. However, nonsteroidal anti-inflammatory drugs (NSAIDs) are the most effective treatment and provide >80% sustained response rates. Ibuprofen, naproxen, ketoprofen, mefanamic acid, and nimesulide are all superior to placebo. Treatment should be started a day before expected menses and is generally continued for 2–3 days. Oral contraceptives also reduce symptoms of dysmenorrhea. Failure of response to NSAIDs and oral contraceptives is suggestive of a pelvic disorder, such as endometriosis, and diagnostic laparoscopy should be considered to guide further treatment.

SECTION 9 ALTERATIONS IN THE SKIN

52 Approach to the Patient with a Skin Disorder

Thomas J. Lawley, Kim B. Yancey

The challenge of examining the skin lies in distinguishing normal from abnormal, significant findings from trivial ones, and in integrating pertinent signs and symptoms into an appropriate differential diagnosis. The fact that the largest organ in the body is visible is both an advantage and a disadvantage to those who examine it. It is advantageous because no special instrumentation is necessary and because the skin can be biopsied with little morbidity. However, the casual observer can be misled by a variety of stimuli and overlook important, subtle signs of skin or systemic disease. For instance, the sometimes minor differences in color and shape that distinguish a melanoma (Fig. 52-1) from a benign nevomelanocytic nevus (Fig. 52-2) can be difficult to recognize. To aid in the interpretation of skin lesions, a variety of descriptive terms have been developed to characterize cutaneous lesions (Tables 52-1, 52-2, and 52-3 as well as Fig. 52-3) and to formulate a differential diagnosis (Table 52-4). For instance, the finding of scaling papules (present in patients with psoriasis or atopic dermatitis) places the patient in a different diagnostic category than would hemorrhagic papules, which may indicate vasculitis or sepsis (Figs. 52-4 and 52-5, respectively). It is also important to differentiate primary from secondary skin lesions. If the examiner focuses on linear erosions overlying an area of erythema and scaling, he or she may incorrectly assume that the erosion is the primary lesion and the redness and scale are secondary, while the correct interpretation would be that the patient has a pruritic eczematous dermatitis with erosions caused by scratching.

APPROACH TO THE PATIENT: Skin Disorder

In examining the skin it is usually advisable to assess the patient before taking an extensive history. This way, the entire cutaneous surface is sure to be evaluated, and objective findings can be integrated with relevant historic data. Four basic features of a skin lesion must be noted and considered during a physical examination: the distribution of the eruption, the types of primary and secondary lesions, the shape of individual lesions, and the arrangement of the lesions. An ideal skin examination includes evaluation of the skin, hair, and

FIGURE 52-1 Superficial spreading melanoma. This is the most common type of melanoma. Such lesions usually demonstrate asymmetry, border irregularity, color variegation (black, blue, brown, pink, and white), a diameter >6 mm, and a history of change (e.g., an increase in size or development of associated symptoms such as pruritus or pain).

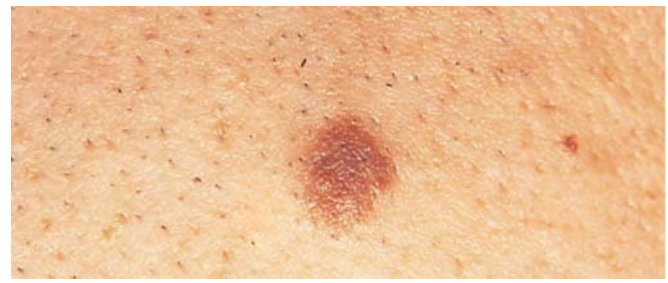

FIGURE 52-2 Nevomelanocytic nevus. Nevi are benign proliferations of nevomelanocytes characterized by regularly shaped hyperpigmented macules or papules of a uniform color.

TABLE 52-1 DESCRIPTION OF PRIMARY SKIN LESIONS

Macule: A flat, colored lesion, <2 cm in diameter, not raised above the surface of the surrounding skin. A "freckle," or ephelid, is a prototype pigmented macule.
Patch: A large (>2 cm) flat lesion with a color different from the surrounding skin. This differs from a macule only in size.
Papule: A small, solid lesion, <0.5 cm in diameter, raised above the surface of the surrounding skin and hence palpable (e.g., a closed comedone, or whitehead, in acne).
Nodule: A larger (0.5–5.0 cm), firm lesion raised above the surface of the surrounding skin. This differs from a papule only in size (e.g., a dermal nevomelanocytic nevus).
Tumor: A solid, raised growth >5 cm in diameter.
Plaque: A large (>1 cm), flat-topped, raised lesion; edges may either be distinct (e.g., in psoriasis) or gradually blend with surrounding skin (e.g., in eczematous dermatitis).
Vesicle: A small, fluid-filled lesion, <0.5 cm in diameter, raised above the plane of surrounding skin. Fluid is often visible, and the lesions are translucent [e.g., vesicles in allergic contact dermatitis caused by *Toxicodendron* (poison ivy)].
Pustule: A vesicle filled with leukocytes. Note: The presence of pustules does not necessarily signify the existence of an infection.
Bulla: A fluid-filled, raised, often translucent lesion >0.5 cm in diameter.
Wheal: A raised, erythematous, edematous papule or plaque, usually representing short-lived vasodilatation and vasopermeability.
Telangiectasia: A dilated, superficial blood vessel.

TABLE 52-2 DESCRIPTION OF SECONDARY SKIN LESIONS

Lichenification: A distinctive thickening of the skin that is characterized by accentuated skin-fold markings.
Scale: Excessive accumulation of stratum corneum.
Crust: Dried exudate of body fluids that may be either yellow (i.e., serous crust) or red (i.e., hemorrhagic crust).
Erosion: Loss of epidermis without an associated loss of dermis.
Ulcer: Loss of epidermis and at least a portion of the underlying dermis.
Excoriation: Linear, angular erosions that may be covered by crust and are caused by scratching.
Atrophy: An acquired loss of substance. In the skin, this may appear as a depression with intact epidermis (i.e., loss of dermal or subcutaneous tissue) or as sites of shiny, delicate, wrinkled lesions (i.e., epidermal atrophy).
Scar: A change in the skin secondary to trauma or inflammation. Sites may be erythematous, hypopigmented, or hyperpigmented depending on their age or character. Sites on hair-bearing areas may be characterized by destruction of hair follicles.

TABLE 52-3 COMMON DERMATOLOGIC TERMS

Alopecia: Hair loss; it may be partial or complete.
Annular: Ring-shaped lesions.
Cyst: A soft, raised, encapsulated lesion filled with semisolid or liquid contents.
Herpetiform: Grouped lesions.
Lichenoid: Violaceous to purple, polygonal lesions that resemble those seen in lichen planus.
Milia: Small, firm, white papules filled with keratin.
Morbilliform: Generalized, small erythematous macules and/or papules that resemble lesions seen in measles.
Nummular: Coin-shaped lesions.
Poikiloderma: Skin that displays variegated pigmentation, atrophy, and telangiectases.
Polycyclic: A configuration of skin lesions formed from coalescing rings or incomplete rings.
Pruritus: A sensation that elicits the desire to scratch. Pruritus is often the predominant symptom of inflammatory skin diseases (e.g., atopic dermatitis, allergic contact dermatitis); it is also commonly associated with xerosis and aged skin. Systemic conditions that can be associated with pruritus include chronic renal disease, cholestasis, pregnancy, malignancy, thyroid disease, polycythemia vera, and delusions of parasitosis.

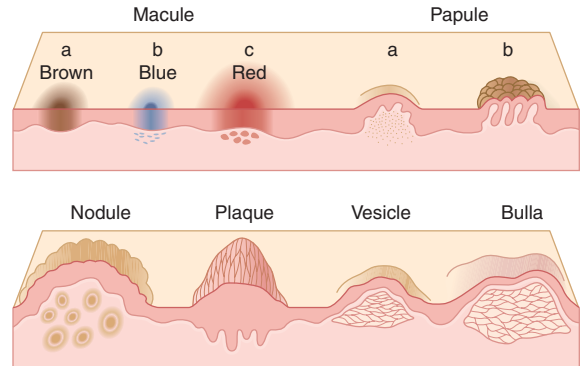

FIGURE 52-3 A schematic representation of several common primary skin lesions (see Table 52-1).

nails as well as the mucous membranes of the mouth, eyes, nose, nasopharynx, and anogenital region. In the initial examination it is important that the patient be disrobed as completely as possible. This will minimize chances of missing important individual skin

TABLE 52-4 SELECTED COMMON DERMATOLOGIC CONDITIONS

Diagnosis	Common Distribution	Usual Morphology	Diagnosis	Common Distribution	Usual Morphology
Acne vulgaris	Face, upper back	Open and closed comedones, erythematous papules, pustules, cysts	Seborrheic keratosis	Trunk, face	Brown plaques with adherent, greasy scale; "stuck on" appearance
Rosacea	Blush area of cheeks, nose, forehead, chin	Erythema, telangiectases, papules, pustules	Folliculitis	Any hair-bearing area	Follicular pustules
			Impetigo	Anywhere	Papules, vesicles, pustules, often with honey-colored crusts
Seborrheic dermatitis	Scalp, eyebrows, perinasal areas	Erythema with greasy yellow-brown scale	Herpes simplex	Lips, genitalia	Grouped vesicles progressing to crusted erosions
Atopic dermatitis	Antecubital and popliteal fossae; may be widespread	Patches and plaques of erythema, scaling, and lichenification; pruritus	Herpes zoster	Dermatomal, usually trunk but may be anywhere	Vesicles limited to a dermatome (often painful)
Stasis dermatitis	Ankles, lower legs	Patches of erythema and scaling on background of hyperpigmentation associated with signs of venous insufficiency	Varicella	Face, trunk, relative sparing of extremities	Lesions arise in crops and quickly progress from erythematous macules to papules to vesicles to pustules to crusted sites
Dyshidrotic eczema	Palms, soles, sides of fingers and toes	Deep vesicles	Pityriasis rosea	Trunk (Christmas tree pattern); herald patch followed by multiple smaller lesions	Symmetric erythematous patches with a collarette of scale
Allergic contact dermatitis	Anywhere	Localized erythema, vesicles, scale, and pruritus (e.g., fingers, earlobes—nickel; dorsal aspect of foot—shoe; exposed surfaces—poison ivy)	Tinea versicolor	Chest, back, abdomen, proximal extremities	Scaly hyper- or hypopigmented macules
Psoriasis	Elbows, knees, scalp, lower back, fingernails (may be generalized)	Papules and plaques covered with silvery scale; nails have pits	Candidiasis	Groin, beneath breasts, vagina, oral cavity	Erythematous macerated areas with satellite pustules; white, friable patches on mucous membranes
Lichen planus	Wrists, ankles, mouth (may be widespread)	Violaceous flat-topped papules and plaques	Dermatophytosis	Feet, groin, beard, or scalp	Varies with site, (e.g., tinea corporis—scaly annular patch)
Keratosis pilaris	Extensor surfaces of arms and thighs, buttocks	Keratotic follicular papules with surrounding erythema	Scabies	Groin, axillae, between fingers and toes, beneath breasts	Excoriated papules, burrows, pruritus
Melasma	Forehead, cheeks, temples, upper lip	Tan to brown patches	Insect bites	Anywhere	Erythematous papules with central puncta
Vitiligo	Periorificial, trunk, extensor surfaces of extremities, flexor wrists, axillae	Chalk-white macules	Cherry angioma	Trunk	Red, blood-filled papules
			Keloid	Anywhere (site of previous injury)	Firm tumor, pink, purple, or brown
			Dermatofibroma	Anywhere	Firm red to brown nodule that shows dimpling of overlying skin with lateral compression
Actinic keratosis	Sun-exposed areas	Skin-colored or red-brown macule or papule with dry, rough, adherent scale	Acrochordons (skin tags)	Groin, axilla, neck	Fleshy papules
Basal cell carcinoma	Face	Papule with pearly, telangiectatic border on sun-damaged skin	Urticaria	Anywhere	Wheals, sometimes with surrounding flare; pruritus
Squamous cell carcinoma	Face, especially lower lip, ears	Indurated and possibly hyperkeratotic lesions often showing ulceration and/or crusting	Transient acantholytic dermatosis	Trunk, especially anterior chest	Erythematous papules
			Xerosis	Extensor extremities, especially legs	Dry, erythematous, scaling patches; pruritus

FIGURE 52-4 Necrotizing vasculitis. Palpable purpuric papules on the lower legs are seen in this patient with cutaneous small vessel vasculitis. *(Courtesy of Robert Swerlick, MD; with permission.)*

FIGURE 52-5 Meningococcemia. An example of fulminant meningococcemia with extensive angular purpuric patches. *(Courtesy of Stephen E. Gellis, MD; with permission.)*

lesions and make it possible to assess the distribution of the eruption accurately. The patient should first be viewed from a distance of about 1.5–2 m (4–6 ft) so that the general character of the skin and the distribution of lesions can be evaluated. Indeed, distribution of lesions often correlates highly with diagnosis (Fig. 52-6). For example, a hospitalized patient with a generalized erythematous exanthem is more likely to have a drug eruption than is a patient with a similar rash limited to the sun-exposed portions of the face. Once the distribution of the lesions has been established, the nature of the primary lesion must be determined. Thus, when lesions are distributed on elbows, knees, and scalp, the most likely possibility based solely on distribution is psoriasis or dermatitis herpetiformis (Figs. 52-7 and 52-8, respectively). The primary lesion in psoriasis is a scaly papule that soon forms erythematous plaques covered with a white scale, whereas that of dermatitis herpetiformis is an urticarial papule that quickly becomes a small vesicle. In this manner, identification of the primary lesion directs the examiner toward the proper diagnosis. Secondary changes in skin can also be quite helpful. For example, scale represents excessive epidermis, while crust is the result of a discontinuous epithelial cell layer. Palpation of skin lesions can also yield insight into the character of an eruption. Thus, red papules on the lower extremities that blanch with pressure can be a manifestation of many different diseases, but hemorrhagic red papules that do not blanch with pressure indicate palpable purpura characteristic of necrotizing vasculitis (Fig. 52-4).

The shape of lesions is also an important feature. Flat, round, erythematous papules and plaques are common in many cutaneous diseases. However, target-shaped lesions that consist in part of erythematous plaques are specific for erythema multiforme (Fig. 52-9). In the same way, the arrangement of individual lesions is important. Erythematous papules and vesicles can occur in many conditions, but their arrangement in a specific linear array suggests an external etiology such as allergic contact (Fig. 52-10) or primary irritant dermatitis. In contrast, lesions with a generalized arrangement are common and suggest a systemic etiology.

As in other branches of medicine, a complete history should be obtained to emphasize the following features:

1. Evolution of lesions
   a. Site of onset
   b. Manner in which the eruption progressed or spread

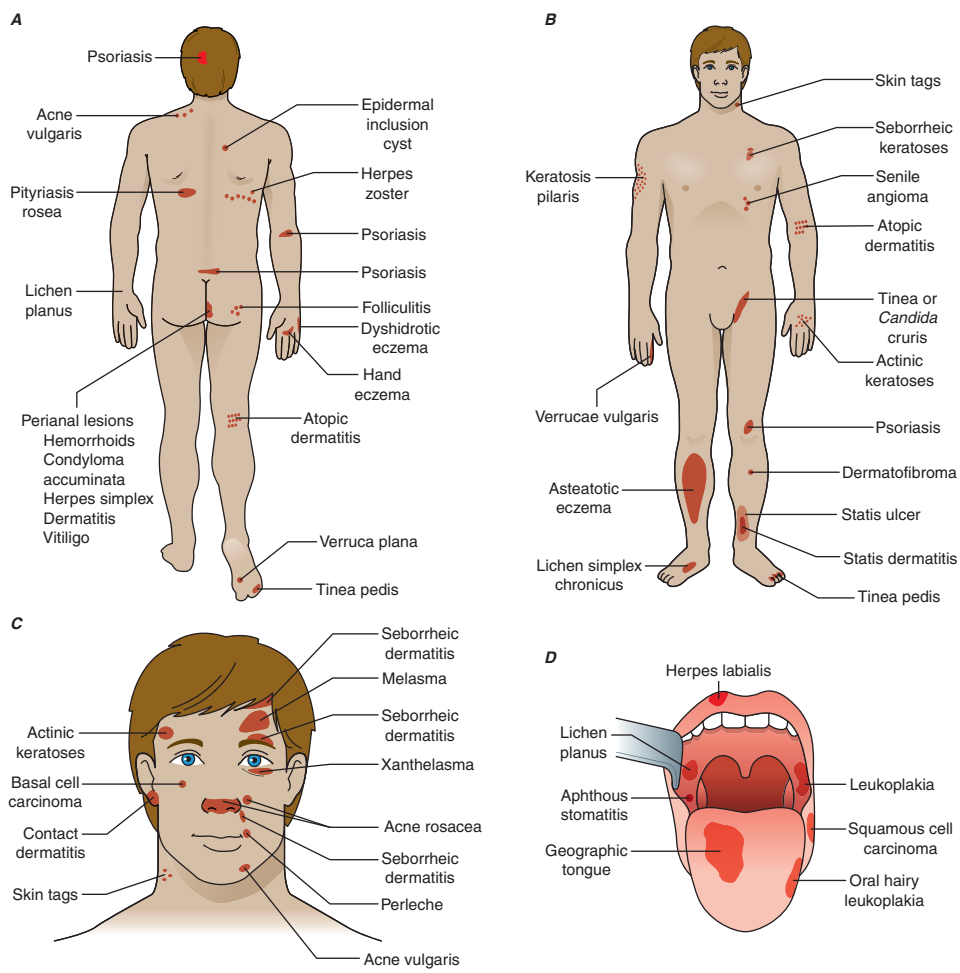

FIGURE 52-6 ***A–D.*** **The distribution of some common dermatologic diseases and lesions.**

FIGURE 52-7 Psoriasis. This papulosquamous skin disease is characterized by small and large erythematous papules and plaques with overlying adherent silvery scale.

c. Duration
d. Periods of resolution or improvement in chronic eruptions

2. Symptoms associated with the eruption
   a. Itching, burning, pain, numbness
   b. What, if anything, has relieved symptoms
   c. Time of day when symptoms are most severe
3. Current or recent medications (prescribed as well as over-the-counter)
4. Associated systemic symptoms (e.g., malaise, fever, arthralgias)
5. Ongoing or previous illnesses
6. History of allergies
7. Presence of photosensitivity
8. Review of systems
9. Family history (particularly relevant for patients with melanoma, atopy, psoriasis, or acne)
10. Social, sexual, or travel history as relevant to the patient

DIAGNOSTIC TECHNIQUES

Many skin diseases can be diagnosed on gross clinical appearance, but sometimes relatively simple diagnostic procedures can yield valuable information. In most instances, they can be performed at the bedside with a minimum of equipment.

Skin Biopsy A skin biopsy is a straightforward minor surgical procedure; however, it is important to biopsy a lesion that is most likely to yield diagnostic findings. This decision may require expertise in skin diseases and knowledge of superficial anatomic structures in selected areas of the body. In this procedure, a small area of skin is anesthetized with 1% lidocaine with or without epinephrine. The skin lesion in question can be excised or saucerized with a scalpel or removed by punch biopsy. In the latter technique, a punch is pressed against the surface of the skin and rotated with downward pressure until it penetrates to the subcutaneous tissue. The circular biopsy is then lifted with forceps, and the bottom is cut with iris scissors. Biopsy sites may or may not need suture closure, depending on size and location.

FIGURE 52-8 Dermatitis herpetiformis. This disorder typically displays pruritic, grouped papulovesicles on elbows, knees, buttocks, and posterior scalp. Vesicles are often excoriated due to associated pruritus.

FIGURE 52-9 Erythema multiforme. This eruption is characterized by multiple erythematous plaques with a target or iris morphology. It usually represents a hypersensitivity reaction to drugs (e.g., sulfonylamides) or infections (e.g., HSV). *(Courtesy of the Yale Resident's Slide Collection; with permission.)*

FIGURE 52-10 Allergic contact dermatitis (ACD). *A.* An example of ACD in its acute phase, with sharply demarcated, weeping, eczematous plaques in a perioral distribution. ***B.*** ACD in its chronic phase demonstrating an erythematous, lichenified, weeping plaque on skin chronically exposed to nickel in a metal snap. *(B, Courtesy of Robert Swerlick, MD; with permission.)*

FIGURE 52-11 Urticaria. Discrete and confluent, edematous, erythematous papules and plaques are characteristic of this whealing eruption.

KOH Preparation A potassium hydroxide (KOH) preparation is performed on scaling skin lesions where a fungal infection is suspected. The edge of such a lesion is scraped gently with a no. 15 scalpel blade, and the removed scale is collected on a glass microscope slide then treated with 1 to 2 drops of a solution of 10–20% KOH. KOH dissolves keratin and allows easier visualization of fungal elements. Brief heating of the slide accelerates dissolution of keratin. When the preparation is viewed under the microscope, the refractile hyphae will be seen more easily when the light intensity is reduced and the condenser is lowered. This technique can be utilized to identify hyphae in dermatophyte infections, pseudohyphae and budding yeast in *Candida* infections (see Fig. 196-1), and "spaghetti and meatballs" yeast forms in tinea versicolor. The same sampling technique can be used to obtain scale for culture of selected pathogenic organisms.

Tzanck Smear A Tzanck smear is a cytologic technique most often used in the diagnosis of herpesvirus infections [herpes simplex virus (HSV) or varicella zoster virus (VZV)] (see Figs. 173-1 and 173-3). An early vesicle, not a pustule or crusted lesion, is unroofed, and the base of the lesion is scraped gently with a scalpel blade. The material is placed on a glass slide, air-dried, and stained with Giemsa or Wright's stain. Multinucleated epithelial giant cells suggest the presence of HSV or VZV; culture or immunofluorescence testing must be performed to identify the specific virus.

Diascopy Diascopy is designed to assess whether a skin lesion will blanch with pressure as, for example, in determining whether a red lesion is hemorrhagic or simply blood-filled. Urticaria (Fig. 52-11) will blanch with pressure, whereas a purpuric lesion caused by necrotizing vasculitis (Fig. 52-4) will not. Diascopy is performed by pressing a microscope slide or magnifying lens against a lesion and noting the amount of blanching that occurs. Granulomas often have an opaque to transparent, brown-pink "apple jelly" appearance on diascopy.

FIGURE 52-12 Vitiligo. Characteristic lesions display an acral distribution and striking depigmentation as a result of loss of melanocytes.

Wood's Light A Wood's lamp generates 360-nm ultraviolet (or "black") light that can be used to aid the evaluation of certain skin disorders. For example, a Wood's lamp will cause erythrasma (a superficial, intertriginous infection caused by *Corynebacterium minutissimum*) to show a characteristic coral pink color, and wounds colonized by *Pseudomonas* to appear pale blue. Tinea capitis caused by certain dermatophytes such as *Microsporum canis* or *M. audouini* exhibits a yellow fluorescence. Pigmented lesions of the epidermis such as freckles are accentuated, while dermal pigment such as postinflammatory hyperpigmentation fades under a Wood's light. Vitiligo (Fig. 52-12) appears totally white under a Wood's lamp, and previously unsuspected areas of involvement often become apparent. A Wood's lamp may also aid in the demonstration of tinea versicolor and in recognition of ash leaf spots in patients with tuberous sclerosis.

Patch Tests Patch testing is designed to document sensitivity to a specific antigen. In this procedure, a battery of suspected allergens is applied to the patient's back under occlusive dressings and allowed to remain in contact with the skin for 48 h. The dressings are removed, and the area is examined for evidence of delayed hypersensitivity reactions (e.g., erythema, edema, or papulovesicles). This test is best performed by physicians with special expertise in patch testing and is often helpful in the evaluation of patients with chronic dermatitis.

53 Eczema, Psoriasis, Cutaneous Infections, Acne, and Other Common Skin Disorders

Calvin O. McCall, Thomas J. Lawley

ECZEMA AND DERMATITIS

Eczema is a type of dermatitis and these terms are often used synonymously (atopic eczema or atopic dermatitis). Eczema is a reaction pattern that presents with variable clinical findings and the common histologic finding of spongiosis (intercellular edema of the epidermis). Eczema is the final common expression for a number of disorders, including those discussed in the following sections. Primary lesions may include erythematous macules, papules, and vesicles, which can coalesce to form patches and plaques. In severe eczema, secondary lesions from infection or excoriation, marked by weeping and crusting, may predominate. In chronic eczematous conditions, lichenification (cutaneous hypertrophy and accentuation of normal skin markings) may alter the characteristic appearance of eczema.

ATOPIC DERMATITIS

Atopic dermatitis (AD) is the cutaneous expression of the atopic state, characterized by a family history of asthma, allergic rhinitis, or ecze-

TABLE 53-1 CLINICAL FEATURES OF ATOPIC DERMATITIS

1. Pruritus and scratching
2. Course marked by exacerbations and remissions
3. Lesions typical of eczematous dermatitis
4. Personal or family history of atopy (asthma, allergic rhinitis, food allergies, or eczema)
5. Clinical course lasting longer than 6 weeks
6. Lichenification of skin

ma. The prevalence of AD is increasing worldwide. Some of its features are shown in Table 53-1.

The etiology of AD is only partially defined, but there is a clear genetic predisposition. When both parents are affected by AD, >80% of their children manifest the disease. When only one parent is affected, the prevalence drops to slightly over 50%. Patients with AD may display a variety of immunoregulatory abnormalities including increased IgE synthesis, increased serum IgE, and impaired delayed-type hypersensitivity reactions.

The clinical presentation often varies with age. Half of patients with AD present within the first year of life, and 80% present by 5 years of age. About 80% ultimately coexpress allergic rhinitis or asthma. The infantile pattern is characterized by weeping inflammatory patches and crusted plaques on the face, neck, and extensor surfaces. The childhood and adolescent pattern is marked by dermatitis of flexural skin, particularly in the antecubital and popliteal fossae (Fig. 53-1). AD may resolve spontaneously, but over half of all individuals affected as children will have dermatitis in adult life. The distribution of lesions may be similar to those seen in childhood; however, adults frequently have localized disease, manifesting as lichen simplex chronicus or hand eczema (see below). In patients with localized disease, AD may be suspected because of a typical personal history, family history, or the presence of cutaneous stigmata of AD such as perioral pallor, an extra fold of skin beneath the lower eyelid (Dennie's line), increased palmar skin markings, and an increased incidence of cutaneous infections, particularly with *Staphylococcus aureus*. Regardless of other manifestations, pruritus is a prominent characteristic of AD in all age groups and is exacerbated by dry skin. Many of the cutaneous findings in affected patients, such as lichenification, are secondary to rubbing and scratching.

℞ ATOPIC DERMATITIS

Therapy of AD should include avoidance of cutaneous irritants, adequate moisturizing through the application of emollients, judicious use of topical anti-inflammatory agents, and prompt treatment of secondary infection. Patients should be instructed to bathe no more often than daily using warm or cool water, and to use only mild bath soap. Immediately after bathing while the skin is still moist, a topical anti-inflammatory agent in a cream or ointment base should be applied to areas of dermatitis, and all other skin areas should be lubricated with a moisturizer. Approximately 30 g of a topical agent is required to cover the entire body surface of an average adult.

Low- to midpotency topical glucocorticoids are employed in most treatment regimens for AD. Skin atrophy and the potential for systemic absorption are constant concerns, especially with more potent agents. Low-potency topical glucocorticoids or non-glucocorticoid anti-inflammatory agents should be selected for use on the face and intertriginous areas to minimize the risk of skin atrophy. Two non-glucocorticoid anti-inflammatory agents are now available, tacrolimus ointment and pimecrolimus cream. These agents are macrolide immunosuppressants that are approved by the U.S. Food and Drug Administration (FDA) for topical use in AD. Reports of broader effectiveness appear in the literature. These agents do not cause skin atrophy, nor do they suppress the hypothalamic-pituitary-adrenal axis. Recently, however, concerns have emerged regarding the potential for lymphomas in patients treated with these agents. Thus, caution should be exercised when considering these agents. Currently, they are also more costly than topical glucocorticoids.

Secondary infection of eczematous skin may lead to exacerbation of AD. Crusted and weeping skin lesions may be infected with *S. aureus*. When secondary infection is suspected, eczematous lesions should be cultured and patients treated with systemic antibiotics active against *S. aureus*. The initial use of penicillinase-resistant penicillins or cephalosporins is preferable. Dicloxacillin or cephalexin (250 mg qid for 7–10 days) is generally adequate; however, antibiotic selection must be directed by culture results and clinical response. More than 50% of *S. aureus* (SA) isolates are now methacillin resistant (MR) in some communities—community acquired MRSA (CA-MRSA). Current recommendations for the treatment of CA-MRSA infection in adults include trimethoprim/sulfamethoxazole (1–2 double strength bid), minocycline (100 mg bid), doxycycline (100 mg bid), or clindamycin (300–450 mg qid). Duration of therapy should be 7–10 days. Inducible resistance may limit clindamycin's usefulness. The latter can be detected by the double-disc diffusion test, which should be ordered if the isolate is erythromycin-resistant and clindamycin-sensitive. As an adjunct, the use of triclosan-containing antibacterial washes and intermittent nasal mupirocin may be useful.

Control of pruritus is essential for treatment, since AD often represents "an itch that rashes." Antihistamines are most often used to control pruritus, and mild sedation may be responsible for their antipruritic action. Sedation may also limit their usefulness; however, when used at bedtime, sedating antihistamines may improve the patient's sleep. Unlike their effects in urticaria, nonsedating antihistamines and selective H_2 blockers are of little use in controlling the pruritus of AD.

Treatment with systemic glucocorticoids should be limited to severe exacerbations unresponsive to topical therapy. In the patient with chronic AD, therapy with systemic glucocorticoids will generally clear the skin only briefly, and cessation of the systemic therapy will invariably be accompanied by return, if not worsening, of the dermatitis. Patients who do not respond to conventional therapies should be considered for patch testing to rule out allergic contact dermatitis. The role of dietary allergens in atopic dermatitis is controversial, and there is little evidence they play any role outside of infancy. Immunotherapy with aeroallergens has not proven useful in AD.

FIGURE 53-1 Atopic dermatitis. Hyperpigmentation, lichenification, and scaling in the antecubital fossae are seen in this patient with atopic dermatitis. (*Courtesy of Robert Swerlick, MD; with permission.*)

LICHEN SIMPLEX CHRONICUS

Lichen simplex chronicus may represent the end stage of a variety of pruritic and eczematous disorders, including atopic dermatitis. It consists of a circumscribed plaque or plaques of lichenified skin (thickening of the skin and accentuation of normal skin markings) due to chronic scratching or rubbing. Common areas involved include the posterior nuchal region, dorsum of the feet, and ankles. Treatment of lichen simplex chronicus centers on breaking the cycle of chronic itching and scratching. High-potency topical glucocorticoids are helpful in most cases, but in recalcitrant cases, application of topical glucocorticoids under occlusion, or intralesional injection of glucocorticoids may be required. Oral antihistamines such as hydroxyzine (10–25 mg every 6 h) or tricyclic antidepressants with antihistaminic activity, such as doxepin (10–25 mg at bedtime), are useful primarily due to their sedating action. Higher doses of these agents may be required, but sedation can become bothersome. Patients need to be counseled regarding driving or operating heavy equipment after taking these medications.

CONTACT DERMATITIS

Contact dermatitis is an inflammatory process in skin caused by an exogenous agent or agents that directly or indirectly injure the skin. This

injury may be caused by an inherent characteristic of a compound—irritant contact dermatitis (ICD). An example of ICD would be dermatitis induced by a concentrated acid or base. Agents that cause allergic contact dermatitis (ACD) induce an antigen-specific immune response (poison ivy dermatitis). The clinical lesions of contact dermatitis may be acute (wet and edematous) or chronic (dry, thickened, and scaly), depending on the persistence of the insult (see Fig. 52-10).

Irritant Contact Dermatitis ICD is generally well demarcated and often localized to areas of thin skin (eyelids, intertriginous areas) or to areas where the irritant was occluded. Lesions may range from minimal skin erythema to areas of marked edema, vesicles, and ulcers. Chronic low-grade irritant dermatitis is the most common type of ICD, and the most common area of involvement is the hands (see below). The most common irritants encountered are chronic wet work, soaps, and detergents. Treatment should be directed to avoidance of irritants and use of protective gloves or clothing.

Allergic Contact Dermatitis ACD is a manifestation of delayed-type hypersensitivity mediated by memory T lymphocytes in the skin. The most common cause of ACD is exposure to plants, especially to members of the family Anacardiaceae, including the genus *Toxicodendron*. Poison ivy, poison oak, and poison sumac are members of this genus and cause an allergic reaction marked by erythema, vesiculation, and severe pruritus. The eruption is often linear or angular, corresponding to areas where plants have touched the skin. The sensitizing antigen common to these plants is urushiol, an oleoresin containing the active ingredient pentadecylcatechol. The oleoresin may adhere to skin, clothing, tools, and pets, and contaminated articles may cause dermatitis even after prolonged storage. Blister fluid does not contain urushiol and is not capable of inducing skin eruption in exposed subjects.

℞ CONTACT DERMATITIS

If contact dermatitis is suspected and an offending agent is identified and removed, the eruption will resolve. Usually, treatment with high-potency topical glucocorticoids is enough to relieve symptoms while the dermatitis runs its course. For those patients who require systemic therapy, daily oral prednisone beginning at 1 mg/kg, but usually ≤60 mg/d, is sufficient. It should be tapered over 2–3 weeks, and each daily dose given in the morning with food.

Identification of a contact allergen can be a difficult and time-consuming task. Patients with dermatitis unresponsive to conventional therapy or with an unusual and patterned distribution should be suspected of having ACD. They should be questioned carefully regarding occupational exposures and topical medications. Common sensitizers include preservatives in topical preparations, nickel sulfate, potassium dichromate, thimerosal, neomycin sulfate, fragrances, formaldehyde, and rubber-curing agents. Patch testing is helpful in identifying these agents but should not be attempted on patients with widespread active dermatitis or on those taking systemic glucocorticoids.

HAND ECZEMA

Hand eczema is a very common, chronic skin disorder in which both exogenous and endogenous factors play important roles. It may be associated with other cutaneous disorders such as atopic dermatitis, and contact with various agents may be involved. It represents a large proportion of occupation-associated skin disease. Chronic, excessive exposure to water and detergents, harsh chemicals, or allergens may initiate or aggravate this disorder. It may present with dryness and cracking of the skin of the hands as well as with variable amounts of erythema and edema. Often, the dermatitis will begin under rings where water and irritants are trapped. Dyshidrotic eczema, a variant of hand eczema, presents with multiple, intensely pruritic, small papules and vesicles occurring on the thenar and hypothenar eminences and the sides of the fingers (Fig. 53-2). Lesions tend to occur in crops that slowly form crusts and heal.

The evaluation of a patient with hand eczema should include an assessment of potential occupation-associated exposures. The history should be directed to identifying possible irritant or allergen exposures.

FIGURE 53-2 Dyshidrotic eczema. This example is characterized by deep-seated vesicles and scaling on palms and lateral fingers, and the disease is often associated with an atopic diathesis.

℞ HAND ECZEMA

Therapy of hand dermatitis is directed toward avoidance of irritants, identification of possible contact allergens, treatment of coexistent infection, and application of topical glucocorticoids. Whenever possible, the hands should be protected by gloves, preferably vinyl. The use of rubber gloves (latex) to protect dermatitic skin is sometimes associated with the development of hypersensitivity reactions to components of the gloves. Patients can be treated with cool moist compresses, followed by application of a mid- to high-potency topical glucocorticoid in a cream or ointment base. As with atopic dermatitis, treatment of secondary infection is essential for good control. Additionally, patients with hand dermatitis should be examined for dermatophyte infection by KOH preparation and culture (see below).

NUMMULAR ECZEMA

Nummular eczema is characterized by circular or oval "coinlike" lesions, beginning as small edematous papules that become crusted and scaly. The etiology of nummular eczema is unknown, but dry skin is a contributing factor. Common locations are the trunk or the extensor surfaces of the extremities, particularly on the pretibial areas or dorsum of the hands. It occurs more frequently in men and is most commonly seen in middle age. The treatment of nummular eczema is similar to that for atopic dermatitis.

ASTEATOTIC ECZEMA

Asteatotic eczema, also known as *xerotic eczema* or "*winter itch*," is a mildly inflammatory dermatitis that develops in areas of extremely dry skin, especially during the dry winter months. Clinically, there may be considerable overlap with nummular eczema. This form of eczema accounts for a large number of physician visits because of the associated pruritus. Fine cracks and scale, with or without erythema, characteristically develop in areas of dry skin, especially on the anterior surfaces of the lower extremities in elderly patients. Asteatotic eczema responds well to topical moisturizers and the avoidance of cutaneous irritants. Overbathing and the use of harsh soaps exacerbate asteatotic eczema.

STASIS DERMATITIS AND STASIS ULCERATION

Stasis dermatitis develops on the lower extremities secondary to venous incompetence and chronic edema. Patients may give a history of deep venous thrombosis, have evidence of vein removal, or varicose veins. Early findings in stasis dermatitis consist of mild erythema and scaling associated with pruritus. The typical initial site of involvement is the medial aspect of the ankle, often over a distended vein (Fig. 53-3). Stasis dermatitis may become acutely inflamed, with crusting and exudate. In this state, it is easily confused with cellulitis. Chronic stasis dermatitis is often associated with dermal fibrosis that is recognized clinically as

FIGURE 53-3 Stasis dermatitis. An example of stasis dermatitis showing erythematous, scaly, and oozing patches over the lower leg. Several stasis ulcers are also seen in this patient.

brawny edema of the skin. As the disorder progresses, the dermatitis becomes progressively pigmented, due to chronic erythrocyte extravasation leading to cutaneous hemosiderin deposition. Stasis dermatitis may be complicated by secondary infection and contact dermatitis. Severe stasis dermatitis may precede the development of stasis ulcers.

℞ STASIS DERMATITIS AND STASIS ULCERATION

Patients with stasis dermatitis and stasis ulceration benefit greatly from leg elevation and the routine use of compression stockings with a gradient of at least 30–40 mmHg. Stockings providing less compression, such as antiembolism hose, are poor substitutes. Use of emollients and/or midpotency topical glucocorticoids and avoidance of irritants are also helpful in treating stasis dermatitis. Protecting the legs from injury, including scratching, and control of chronic edema are essential to prevent ulcers. Diuretics may be required to adequately control chronic edema.

Stasis ulcers are difficult to treat, and resolution is slow. It is extremely important to elevate the affected limb as much as possible. The ulcer should be kept clear of necrotic material by gentle debridement and covered with a semipermeable dressing and a compression dressing or compression stocking. Glucocorticoids should not be applied to ulcers, since they may retard healing; however, they may be applied to the surrounding skin to control itching, scratching, and additional trauma. Secondarily infected lesions should be treated with appropriate oral antibiotics, but it should be noted that all ulcers will become colonized with bacteria, and the purpose of antibiotic therapy should not be to clear all bacterial growth. Care must be taken to exclude treatable causes of leg ulcers (hypercoagulation, vasculitis) before beginning the chronic management outlined above.

SEBORRHEIC DERMATITIS

Seborrheic dermatitis is a common, chronic disorder, characterized by greasy scales overlying erythematous patches or plaques. Induration and scale are generally less prominent than in psoriasis, but clinical overlap exists between these diseases—"sebopsoriasis." The most common location is in the scalp where it may be recognized as severe dandruff. On the face, seborrheic dermatitis affects the eyebrows, eyelids, glabella, and nasolabial folds (Fig. 53-4). Scaling of the external auditory canal is common in seborrheic dermatitis. Additionally, the postauricular areas often become macerated and tender. Seborrheic dermatitis may also develop in the central chest, axilla, groin, submammary folds, and gluteal cleft. Rarely, it may cause a widespread generalized dermatitis. Pruritus is variable.

FIGURE 53-4 Seborrheic dermatitis. Central facial erythema with overlying greasy, yellowish scale is seen in this patient. (*Courtesy of Jean Bolognia, MD; with permission.*)

Seborrheic dermatitis may be evident within the first few weeks of life, and within this context it occurs in the scalp ("cradle cap"), face, or groin. It is rarely seen in children beyond infancy but becomes evident again during adult life. Although it is frequently seen in patients with Parkinson's disease, in those who have had cerebrovascular accidents, and in those with HIV infection, the overwhelming majority of individuals with seborrheic dermatitis have no underlying disorder.

℞ SEBORRHEIC DERMATITIS

Treatment with low-potency topical glucocorticoids in conjunction with a topical antifungal agent, such as ketoconazole cream or ciclopirox cream, is often effective. The scalp and beard areas may benefit from anti-dandruff shampoos, which should be left in place 3–5 min before rinsing. High-potency topical glucocorticoid solutions (betamethasone or clobetasol) are effective for control of severe scalp involvement. High potency glucocorticoids should not be used on the face since this is often associated with steroid-induced rosacea or atrophy. Tacrolimus and pimecrolimus are alternatives to topical glucocorticoids, especially when seborrheic dermatitis involves eyelids, although they are not FDA-approved for these indications.

PAPULOSQUAMOUS DISORDERS (Table 53-2)

PSORIASIS

Psoriasis is one of the most common dermatologic diseases, affecting up to 1% of the world's population. It is a chronic inflammatory skin disor-

TABLE 53-2 PAPULOSQUAMOUS DISORDERS

	Clinical Features	Other Notable Features	Histologic Features
Psoriasis	Sharply demarcated, erythematous plaques with mica-like scale; predominantly elbows, knees, and scalp; atypical forms may localize to intertriginous areas; eruptive forms may be associated with infection	May be aggravated by certain drugs, infection; severe forms seen associated with HIV	Acanthosis, vascular proliferation
Lichen planus	Purple polygonal papules marked by severe pruritus; lacy white markings, especially associated with mucous membrane lesions	Certain drugs may induce: thiazides, antimalarial drugs	Interface dermatitis
Pityriasis rosea	Rash often preceded by herald patch; oval to round plaques with trailing scale; most often affects the trunk, and eruption lines up in skin folds giving a "fir tree"-like appearance; generally spares palms and soles	Variable pruritus; self-limited resolving in 2–8 weeks; may be imitated by secondary syphilis	Pathologic features often nonspecific
Dermatophytosis	Polymorphous appearance depending on dermatophyte, body site, and host response; sharply defined to ill-demarcated scaly plaques with or without inflammation; may be associated with hair loss	KOH preparation may show branching hyphae; culture helpful	Hyphae and neutrophils in stratum corneum

der clinically characterized by erythematous, sharply demarcated papules and rounded plaques, covered by silvery micaceous scale. The skin lesions of psoriasis are variably pruritic. Traumatized areas often develop lesions of psoriasis (Koebner or isomorphic phenomenon). Additionally, other external factors may exacerbate psoriasis including infections, stress, and medications (lithium, beta blockers, and antimalarials).

The most common variety of psoriasis is called *plaque-type*. Patients with plaque-type psoriasis will have stable, slowly enlarging plaques, which remain basically unchanged for long periods of time. The most commonly involved areas are the elbows, knees, gluteal cleft, and the scalp. Involvement tends to be symmetric. Plaque psoriasis generally develops slowly and runs an indolent course. It rarely remits spontaneously. *Inverse psoriasis* affects the intertriginous regions including the axilla, groin, submammary region, and navel; it also tends to affect the scalp, palms, and soles. The individual lesions are sharply demarcated plaques (see Fig. 52-7), but they may be moist and without scale due to their location.

Guttate psoriasis (eruptive psoriasis) is most common in children and young adults. It develops acutely in individuals without psoriasis or in those with chronic plaque psoriasis. Patients present with many small erythematous, scaling papules, frequently after upper respiratory tract infection with β-hemolytic streptococci. The differential diagnosis should include pityriasis rosea and secondary syphilis.

Pustular psoriasis is another variant. Patients may have disease localized to the palms and soles, or the disease may be generalized. Regardless of the extent of disease, the skin is erythematous with pustules and variable scale. Localized to the palms and soles, it is easily confused with eczema. When generalized, episodes are characterized by fever (39°–40°C) lasting several days, an accompanying generalized eruption of sterile pustules, and a background of intense erythema; patients may become erythrodermic. Episodes of fever and pustules are recurrent. Local irritants, pregnancy, medications, infections, and systemic glucocorticoid withdrawal can precipitate this form of psoriasis. Oral retinoids are the treatment of choice in nonpregnant patients.

About half of all patients with psoriasis have fingernail involvement, appearing as punctate pitting, onycholysis, nail thickening, or subungual hyperkeratosis. About 5–10% of patients with psoriasis have associated arthralgias, and these are most often found in patients with fingernail involvement. Although some have the coincident occurrence of classic rheumatoid arthritis (Chap. 314), many have psoriatic arthritis that falls into one of three types: (1) asymmetric inflammatory arthritis most commonly involving the distal and proximal interphalangeal joints and less commonly the knees, hips, ankles, and wrists; (2) a seronegative rheumatoid arthritis–like disease; a significant portion of these patients go on to develop a severe destructive arthritis; or (3) disease limited to the spine (psoriatic spondylitis).

The etiology of psoriasis is still poorly understood, but there is clearly a genetic component to the disease. Over 50% of patients with psoriasis report a positive family history. Psoriatic lesions demonstrate infiltrates of activated T cells that are thought to elaborate cytokines responsible for keratinocyte hyperproliferation, which results in the characteristic clinical findings. Agents inhibiting T cell activation, clonal expansion, or release of proinflammatory cytokines are often effective for the treatment of severe psoriasis (see below).

℞ PSORIASIS

Treatment of psoriasis depends on the type, location, and extent of disease. All patients should be instructed to avoid excess drying or irritation of their skin and to maintain adequate cutaneous hydration. Most patients with localized, plaque-type psoriasis can be managed with midpotency topical glucocorticoids, although their long-term use is often accompanied by loss of effectiveness (tachyphylaxis) and atrophy of the skin. A topical vitamin D analogue (calcipotriene) and a retinoid (tazarotene) are also efficacious in the treatment of limited psoriasis and have largely replaced other topical agents such as coal tar, salicylic acid, and anthralin.

Ultraviolet light, natural or artificial, is an effective therapy for many patients with widespread psoriasis. Ultraviolet B (UV-B) light, narrowband UV-B, and ultraviolet A (UV-A) spectrum with either oral or topical psoralens (PUVA) are also extremely effective. The long-term use of UV light may be associated with an increased incidence of non-melanoma and melanoma skin cancer. UV light therapy is contraindicated in patients receiving cyclosporine and should be used with great care in all immunocompromised patients due to an increased risk of developing skin cancers.

Various systemic agents can be used for severe, widespread psoriatic disease **(Table 53-3)**. Oral glucocorticoids should not be used for the treatment of psoriasis due to the potential for developing life-threatening pustular psoriasis when therapy is discontinued. Methotrexate is an effective agent, especially in patients with psoriatic arthritis. The synthetic retinoid, acitretin, is useful, especially when immunosuppression must be avoided; however, teratogenicity limits its use.

The evidence implicating psoriasis as a T cell–mediated disorder has directed therapeutic efforts to immunoregulation. Cyclosporine and other immunosuppressive agents can be very effective in the treatment of psoriasis, and much attention is currently directed toward the development of biologic agents with more selective immunosuppressive properties and better safety profiles **(Table 53-4)**. Experience with these agents is limited and information regarding combination therapy and adverse events continues to emerge. Use of TNF-α inhibitors may worsen congestive heart failure (CHF), and they should be used with caution in those at risk of or known to have CHF. Further, none of the immunosuppressive agents used in the treatment of psoriasis should be initiated if the patient has a severe infection; patients on such therapy should be routinely screened for tuberculosis. Malignancies, including a risk or history of certain malignancies, may limit the use of these systemic agents.

TABLE 53-3 FDA-APPROVED SYSTEMIC THERAPY FOR PSORIASIS

Agent	Medication Class	Administration		Adverse Events (Selected)
		Route	Frequency	
Methotrexate	Antimetabolite	Oral	Weekly	Hepatotoxicity, pulmonary toxicity, pancytopenia, potential for increased malignancies, ulcerative stomatitis, nausea, diarrhea, teratogenicity
Acitretin	Retinoid	Oral	Daily	Teratogenicity, osteophyte formation, hyperlipidemia, flare of inflammatory bowel disease, hepatoxicity, depression
Cyclosporine	Calcineurin inhibitor	Oral	Twice daily	Renal dysfunction, hypertension, hyperkalemia, hyperuricemia, hypomagnesemia, hyperlipidemia, increased risk of malignancies

LICHEN PLANUS

Lichen planus (LP) is a papulosquamous disorder that may affect the skin, scalp, nails, and mucous membranes. The primary cutaneous lesions are pruritic, polygonal, flat-topped, violaceous papules. Close examination of the surface of these papules often reveals a network of gray lines (Wickham's striae). The skin lesions may occur anywhere but have a predilection for the wrists, shins, lower back, and genitalia **(Fig. 53-5)**. Involvement of the scalp, lichen planopilaris, may lead to scarring alopecia, and nail involvement may lead to permanent deformity or loss of fingernails and toenails. LP commonly involves mucous membranes, particularly the buccal mucosa, where it can present a spectrum of disease from a mild, white, reticulate eruption of the mucosa, to a severe, erosive stomatitis. Erosive stomatitis may persist for years and may be linked to an increased risk of oral squamous cell carcinoma. Cutaneous eruptions clinically resembling LP have been observed after administration of numerous drugs, including thiazide diuretics, gold, antimalarials, penicillamine, and phenothiazines, and in patients with skin lesions of chronic graft-versus-host disease. Additionally, LP may be associated with hepatitis C infection. The course of LP is variable, but most patients have spontaneous remissions 6 months to 2 years after the onset of disease. Topical glucocorticoids are the mainstay of therapy.

TABLE 53-4 BIOLOGICS APPROVED FOR PSORIASIS OR PSORIATIC ARTHRITIS

Agent	Mechanism of Action	Indication	Administration		Warnings
			Route	Frequency	
Alefacept	Anti-CD-2	Ps	IM	Once weekly × 12 weeks; may repeat	Lymphopenia, potential for increased malignancies, serious infections
Etanercept	Anti TNF-α	Ps, PsA	SC	Once or twice weekly	Serious infections, neurologic events, hematologic events, potential for increased malignancies
Efalizumab	Anti CD-11a	Ps	SC	Once weekly	Serious infections, potential for increased malignancies, thrombocytopenia, hemolytic anemia, psoriasis worsening
Adalimumab	Anti TNF-α	PsA	SC	Every other week	Serious infections, neurologic events, potential for increased malignancies, hypersensitivity reactions, hematologic events
Infliximab	Anti TNF-α	PsA	IV	Initial infusion followed by infusions at week 2, 6, then every 8 weeks	Serious infections, hepatotoxicity, hematologic events, hypersensitivity reactions, neurologic events, potential for increased malignancies

Ps, psoriasis; PsA, psoriatic arthritis; IM, intramuscular; SC, subcutaneous; TNF, tumor necrosis factor.

PITYRIASIS ROSEA

Pityriasis rosea (PR) is a papulosquamous eruption of unknown etiology occurring more commonly in the spring and fall. Its first manifestation is the development of a 2- to 6-cm annular lesion (the herald patch). This is followed in a few days to a few weeks by the appearance of many smaller annular or papular lesions with a predilection to occur on the trunk (Fig. 53-6). The lesions are generally oval, with their long axis parallel to the skin-fold lines. Individual lesions may range in color from red to brown and have a trailing scale. PR shares many clinical features with the eruption of secondary syphilis, but palm and sole lesions are extremely rare in PR and common in secondary syphilis. The eruption tends to be moderately pruritic and lasts 3–8 weeks. Treatment is directed at alleviating pruritus and consists of oral antihistamines, midpotency topical glucocorticoids, and, in some cases, the use of UV-B phototherapy.

CUTANEOUS INFECTIONS (Table 53-5)

IMPETIGO, ECTHYMA, AND FURUNCULOSIS

Impetigo is a common superficial bacterial infection of skin caused most often by *S. aureus* (Chap. 129), and in some cases by group A β-hemolytic streptococci (Chap. 130). The primary lesion is a superficial pustule that ruptures and forms a characteristic yellow-brown honey-colored crust (Chap. 130). Lesions may occur on normal skin—primary infection—or in areas already affected by another skin disease—secondary infection. Lesions caused by staphylococci may be tense, clear bullae, and this less common form of the disease is called *bullous impetigo*. Blisters are caused by the production of exfoliative toxin by *S. aureus* phage type II. This is the same toxin responsible for staphylococcal scalded-skin syndrome (SSSS), often resulting in dramatic loss of the superficial epidermis due to blistering. SSSS is much more common in children than in adults; however, it should be considered along with toxic epidermal necrolysis and severe drug eruptions in patients with widespread blistering of the skin. *Ecthyma* is a variant of impetigo that causes punched-out ulcerative lesions. It may result from neglected or inadequately treated impetigo. Treatment of both ecthyma and impetigo involves gentle debridement of adherent crusts, which is facilitated by the use of soaks and topical antibiotics, in conjunction with appropriate oral antibiotics. *Furunculosis* is also caused by *S. aureus*, and this disorder has gained prominence in the last decade because of CA-MRSA. A furuncle, or boil, is a painful, erythematous, nodule that can occur on any cutaneous surface. The lesions may be solitary but are most often multiple. Patients frequently believe they have been bitten by spiders or insects. Family members or close contacts may also be affected. Furuncles can rupture and drain spontaneously or may need incision and drainage, which may be adequate therapy for small solitary furuncles without cellulitis or systemic symptoms. Whenever possible, lesional material should be sent for culture. Current recommendations for methicillin-sensitive infections are β-lactam antibiotics. Therapy for CA-MRSA was discussed previously (see "Atopic Dermatitis"). Warm compresses and nasal mupirocin are helpful therapeutic additions. Severe infections may require IV antibiotics.

ERYSIPELAS AND CELLULITIS

See Chap. 119

FIGURE 53-5 Lichen planus. An example of lichen planus showing multiple flat-topped, violaceous papules and plaques. Nail dystrophy as seen in this patient's thumbnail may also be a feature. (*Courtesy of Robert Swerlick, MD; with permission.*)

FIGURE 53-6 Pityriasis rosea. In this patient with pityriasis rosea, multiple round to oval erythematous patches with fine central scale are distributed along the skin tension lines on the trunk.

TABLE 53-5 COMMON SKIN INFECTIONS

	Clinical Features	Etiologic Agent	Treatment
Impetigo	Honey-colored crusted papules, plaques, or bullae	Group A Streptococcus and *Staphylococcus aureus*	Systemic or topical antistaphylococcal antibiotics
Dermatophytosis	Inflammatory or noninflammatory annular scaly plaques; may have hair loss; groin involvement spares scrotum; hyphae on KOH preparation	*Trichophyton*, *Epidermophyton*, or *Microsporum* sp.	Topical azoles, systemic griseofulvin, terbinafine, or azoles
Candidiasis	Inflammatory papules and plaques with satellite pustules, frequently in intertriginous areas; may involve scrotum; pseudohyphae on KOH preparation	*Candida albicans* and other *Candida* species	Topical nystatin or azoles; systemic azoles for resistant disease
Tinea versicolor	Hyperpigmented or hypopigmented scaly patches on the trunk; characteristic mixture of hyphae and spores on KOH preparation ("spaghetti and meatballs")	*Malassezia furfur*	Topical selenium sulfide lotion or azoles

DERMATOPHYTOSIS

Dermatophytes are fungi that infect skin, hair, and nails and include members of the genera *Trichophyton*, *Microsporum*, and *Epidermophyton*. Tinea corporis, or infection of the relatively hairless skin of the body (glabrous skin), may have a variable appearance depending on the extent of the associated inflammatory reaction (see Fig. 52-11). Typical infections have an annular appearance that patients refer to as "ringworm." Deep inflammatory nodules or granulomas occur in some infections—especially in those infections inappropriately treated with mid- to high-potency topical glucocorticoids. Involvement of the groin (tinea cruris) is more common in males than females. It presents as a scaling, erythematous eruption sparing the scrotum. Infection of the foot (tinea pedis) is the most common dermatophyte infection and is often chronic; it is characterized by variable erythema, edema, scaling, pruritus, and occasionally vesiculation. Involvement may be widespread or localized but generally involves the web space between the fourth and fifth toes. Infection of the nails (tinea unguium or onychomycosis) occurs in many patients with tinea pedis and is characterized by opacified, thickened nails and subungual debris. The distal-lateral variant is most common. Proximal subungual onychomycosis may be a marker for HIV infection or other immunocompromised states. Dermatophyte infection of the scalp (tinea capitis) has returned in epidemic proportions, particularly affecting inner-city children, but it also affects adults. The predominant organism is *T. tonsurans*, which can produce a relatively noninflammatory infection with mild scale and hair loss that is diffuse or localized. *T. tonsurans* can also cause a markedly inflammatory dermatosis with edema and nodules. This latter presentation is a kerion.

The diagnosis of tinea can be made from skin scrapings, nail scrapings, or hair by culture or direct microscopic examination with potassium hydroxide (KOH). Nail clippings may be sent for histologic examination with periodic acid Schiff (PAS) stain.

℞ DERMATOPHYTOSIS

Both topical and systemic therapies may be used to treat dermatophyte infections. Treatment depends on the site involved and the type of infection. Topical therapy is generally effective for uncomplicated tinea corporis, tinea cruris, and limited tinea pedis. It is not effective as a monotherapy for tinea capitis or onychomycosis. Topical imidazoles, triazoles, and allylamines may be effective therapies for dermatophyte infections, but nystatin is not active against dermatophytes. Topicals are generally applied twice daily, and treatment should continue 1 week beyond clinical resolution of the infection. Tinea pedis often requires longer treatment courses and frequently relapses. Oral antifungal agents may be required for recalcitrant tinea pedis or tinea corporis.

Oral antifungal agents are required for dermatophyte infections involving the hair and nails and for other infections unresponsive to topical therapy. A fungal etiology should be confirmed by direct microscopic examination or by culture prior to prescribing oral antifungal agents. All of the oral agents may cause hepatotoxicity and should not be used in women who are pregnant or breast-feeding.

Griseofulvin is the only oral agent approved in the United States for dermatophyte infections involving the skin, hair, or nails. When griseofulvin is used, a daily dose of 500 mg microsized or 375 mg ultramicrosized griseofulvin administered with a fatty meal is an adequate dose for most dermatophyte infections. Higher doses are required for some cases of tinea pedis and tinea capitis. The usual adult dose of griseofulvin for tinea capitis is 1 g microsized or 0.5 g ultramicrosized given daily. Markedly inflammatory tinea capitis may result in scarring and hair loss, and systemic or topical glucocorticoids may be helpful in preventing these sequelae. The duration of therapy may be 2 weeks for uncomplicated tinea corporis, 8–12 weeks for tinea capitis, or as long as 6–18 months for nail infections. Due to high relapse rates, griseofulvin is seldom used for nail infections. Common side effects of griseofulvin include gastrointestinal distress, headache, and urticaria.

Oral itraconazole and terbinafine are approved for onychomycosis. Itraconazole is given as either continuous daily therapy (200 mg/d) or pulses (200 mg bid for 1 week per month) administered with food. Fingernails require 2 months of continuous therapy or two pulses. Toenails require 3 months of continuous therapy or three pulses. Itraconazole has the potential for serious interactions with other drugs requiring the P450 enzyme system for metabolism. Terbinafine (250 mg/d) is also effective for onychomycosis. Therapy with terbinafine is continued for 6 weeks for fingernail infections and 12 weeks for toenail infections. Terbinafine has fewer drug-drug interactions, but caution should be used when patients are on multiple medications.

TINEA VERSICOLOR

Tinea versicolor is caused by a non-dermatophyte, dimorphic fungus, *Malassezia furfur*, a normal inhabitant of the skin. The expression of infection is promoted by heat and humidity. The typical lesions consist of oval scaly macules, papules, and patches concentrated on the chest, shoulders, and back but only rarely on the face or distal extremities. On dark skin, they often appear as hypopigmented areas, while on light skin, they are slightly erythematous or hyperpigmented. A KOH preparation from scaling lesions will demonstrate a confluence of short hyphae and round spores ("spaghetti and meatballs"). Lotions or shampoos containing sulfur, salicylic acid, or selenium sulfide will clear the infection if used daily for 1–2 weeks and then weekly thereafter. These preparations are irritating if left on the skin for more than 10 min; thus, they should be washed off completely. Treatment with some oral antifungal agents is also effective, but they do not provide lasting results, and they are not FDA-approved for this indication. Ketoconazole has been used as a single 400-mg dose; the patient waits 1 h, exercises to the point of sweating, then lets the skin dry. Itraconazole and fluconazole have also been used at various doses and frequencies. Griseofulvin is not effective, and terbenifine is not reliably effective for tinea versicolor.

CANDIDIASIS

Candidiasis is a fungal infection caused by a related group of yeasts, whose manifestations may be localized to the skin, or rarely, may be systemic and life-threatening. The causative organism is usually *Candida albicans*, but may also be *C. tropicalis*, *C. parapsilosis*, or *C. krusei*. These organisms are normal saprophytic inhabitants of the gastrointestinal tract but may overgrow (usually due to broad-spectrum antibiotic therapy) and cause disease at a number of cutaneous sites. Other predisposing factors include diabetes mellitus, chronic intertrigo, oral contraceptive use, and cellular immune deficiency. Candidiasis is a very common infection in HIV-infected individuals (Chap. 182). The oral cavity is commonly involved. Lesions may occur on the tongue or buccal mucosa (thrush) and appear as white plaques (see Fig. 52-12). Microscopic examination of scrapings demonstrate both pseudohyphae and yeast

forms. Fissured, macerated lesions at the corners of the mouth (perlèche) are often seen in individuals with poorly fitting dentures and may also be associated with candidal infection. Additionally, candidal infections have an affinity for sites that are chronically wet and macerated, including the skin around nails (onycholysis and paronychia) and in intertriginous areas. Intertriginous lesions are characteristically edematous, erythematous, and scaly, with scattered "satellite pustules." In males, there is often involvement of the penis and scrotum as well as the inner aspect of the thighs. In contrast to dermatophyte infections, candidal infections are frequently painful and accompanied by a marked inflammatory response. Diagnosis of candidal infection is based upon the clinical pattern and demonstration of yeast on KOH preparation or culture.

Rx CANDIDIASIS

Treatment involves removing any predisposing factors such as antibiotic therapy or chronic wetness and the use of appropriate topical or systemic antifungal agents. Effective topicals include nystatin or azoles (miconazole, clotrimazole, econazole, or ketoconazole). The associated inflammatory response accompanying candidal infection on glabrous skin can be treated with a mild glucocorticoid lotion or cream (2.5% hydrocortisone). Systemic therapy is usually reserved for immunosuppressed patients or individuals with chronic or recurrent disease who fail to respond to appropriate topical therapy. Oral agents approved for the treatment of candidiasis include itraconazole and fluconazole. Oral nystatin is only effective for candidiasis of the gastrointestinal tract. Griseofulvin and terbenifine are not effective.

WARTS

Warts are cutaneous neoplasms caused by papilloma viruses. More than 100 different human papilloma viruses (HPV) have been described. A typical wart, verruca vulgaris, is sessile, dome-shaped, and usually about a centimeter in diameter. Its surface is hyperkeratotic consisting of many small filamentous projections. The HPV that cause typical verruca vulgaris also cause typical plantar warts, flat warts (or verruca plana), and filiform warts. Plantar warts are endophytic and are covered by thick keratin. Paring of the wart will generally demonstrate a central core of keratinized debris and punctate bleeding points. Filiform warts are most commonly seen on the face, neck, and skin folds and present as papillomatous lesions on a narrow base. Flat warts are only slightly elevated and have a velvety, nonverrucous surface. They have a propensity for the face, arms, and legs and are often spread by shaving.

Genital warts begin as small papillomas that may grow to form large fungating lesions. In women, they may involve either the labia, perineum, or perianal skin. Additionally, the mucosa of the vagina, urethra, and anus can be involved, as well as the cervical epithelium. In men, the lesions often occur initially in the coronal sulcus but may be seen on the shaft of the penis, the scrotum, perianal skin, or in the urethra.

Appreciable evidence has accumulated that suggests HPV plays a role in the development of neoplasia of the uterine cervix and anogenital skin (Chap. 93). HPV types 16 and 18 have been most intensely studied and are the major risk factors for intraepithelial neoplasia and squamous cell carcinoma of the cervix, anus, vulva, and penis. The risk is higher in patients immunosuppressed after solid organ transplantation and in those infected with HIV. Recent evidence also implicates other types. Histologic examination of biopsies from affected sites may reveal changes associated with typical warts and/or features typical of intraepidermal carcinoma (Bowen's disease). Squamous cell carcinomas associated with HPV infections have also been observed in extragenital skin (Chap. 83). This is most commonly seen in patients immunosuppressed after organ transplantation. Patients on long-term immunosuppression should be monitored for the development of squamous cell carcinoma and other cutaneous malignancies.

Rx WARTS

Treatment of warts, other than anogenital warts, should be tempered by the observation that a majority of warts in normal individuals resolve spontaneously within 1–2 years. There are many modalities available to treat warts, but no single therapy is universally effective. Factors that influence the choice of therapy include the location of the wart, extent of disease, the age and immunologic status of the patient, and the patient's desire for therapy. Perhaps the most useful and convenient method for treating warts in almost any location is cryotherapy with liquid nitrogen. Equally effective for non-genital warts, but requiring much more patient compliance, is the use of keratolytic agents such as salicylic acid plasters or solutions. For genital warts, in-office application of a podophyllin solution is moderately effective but may be associated with marked local reactions. Prescription preparations of dilute, purified podophyllin are available for home use. Topical imiquimod, a potent inducer of local cytokine release, has also been approved for use in genital warts. Conventional and laser surgical procedures may be required for recalcitrant warts. Recurrence of warts appears to be common to all these modalities. A highly effective vaccine for selected types of HPV has been recently approved by the FDA, and its use will likely reduce the incidence of anogenital and cervical carcinoma.

HERPES SIMPLEX

See Chap. 172

HERPES ZOSTER

See Chap. 173

ACNE

ACNE VULGARIS

Acne vulgaris is a self-limited disorder primarily of teenagers and young adults, although perhaps 10–20% of adults may continue to experience some form of the disorder. The permissive factor for the expression of the disease in adolescence is the increase in sebum production by sebaceous glands after puberty. Small cysts, called *comedones*, form in hair follicles due to blockage of the follicular orifice by retention of keratinous material and sebum. The activity of bacteria (*Proprionobacterium acnes*) within the comedones releases free fatty acids from sebum, causes inflammation within the cyst, and results in rupture of the cyst wall. An inflammatory foreign-body reaction develops as result of extrusion of oily and keratinous debris from the cyst.

The clinical hallmark of acne vulgaris is the comedone, which may be closed (whitehead) or open (blackhead). Closed comedones appear as 1- to 2-mm pebbly white papules, which are accentuated when the skin is stretched. They are the precursors of inflammatory lesions of acne vulgaris. The contents of closed comedones are not easily expressed. Open comedones, which rarely result in inflammatory acne lesions, have a large dilated follicular orifice and are filled with easily expressible oxidized, darkened, oily debris. Comedones are usually accompanied by inflammatory lesions: papules, pustules, or nodules.

The earliest lesions seen in adolescence are generally mildly inflamed or noninflammatory comedones on the forehead. Subsequently, more typical inflammatory lesions develop on the cheeks, nose, and chin (Fig. 53-7). The most common location for acne is the face, but involvement of the chest and back is common. Most disease remains mild and does not lead to scarring. A small number of patients develop large inflam-

FIGURE 53-7 Acne vulgaris. An example of acne vulgaris with inflammatory papules, pustules, and comedones. (*Courtesy of Kalman Watsky, MD; with permission.*)

matory cysts and nodules, which may drain and result in significant scarring. Regardless of the severity, acne may affect a patient's quality of life. If adequately treated, this may be a transient effect. In the case of severe, scarring acne, the effects can be permanent and profound. Early therapeutic intervention in severe acne is essential.

Exogenous and endogenous factors can alter the expression of acne vulgaris. Friction and trauma (from headbands or chin straps of athletic helmets), application of comedogenic topical agents (cosmetics or hair preparations), or chronic topical exposure to certain industrial compounds may elicit or aggravate acne. Glucocorticoids, topical or systemic, may also elicit acne. Other systemic medications such as oral contraceptive pills, lithium, isoniazid, androgenic steroids, halogens, phenytoin, and phenobarbital may produce acneiform eruptions or aggravate preexisting acne. Genetic factors and polycystic ovary disease may also play a role.

℞ ACNE VULGARIS

Treatment of acne vulgaris is directed toward elimination of comedones by normalization of follicular keratinization, decreasing sebaceous gland activity, decreasing the population of *P. acnes*, and decreasing inflammation. Minimal to moderate, pauci-inflammatory disease may respond adequately to local therapy alone. Although areas affected with acne should be kept clean, overly vigorous scrubbing may aggravate acne due to mechanical rupture of comedones. Topical agents such as retinoic acid, benzoyl peroxide, or salicylic acid may alter the pattern of epidermal desquamation, preventing the formation of comedones and aiding in the resolution of preexisting cysts. Topical antibacterial agents such as azelaic acid, topical erythromycin (with or without zinc), or clindamycin are also useful adjuncts to therapy.

Patients with moderate to severe acne with a prominent inflammatory component will benefit from the addition of systemic therapy, such as tetracycline in doses of 250–500 mg bid, or doxycycline, 100 mg bid. Minocycline may also be useful. Such antibiotics appear to have an anti-inflammatory effect independent of their antibacterial effect. Female patients who do not respond to oral antibiotics may benefit from hormonal therapy. Women placed on oral contraceptives containing ethinyl estradiol and norgestimate have demonstrated improvement in their acne when compared to a placebo control.

Patients with severe nodulocystic acne unresponsive to the therapies discussed above may benefit from treatment with the synthetic retinoid, isotretinoin. Its dose is based on the patient's weight, and it is given once daily for 5 months. Results are excellent in appropriately selected patients. Its use is highly regulated due to its potential for severe adverse events, primarily teratogenicity. Additionally, patients receiving this medication develop extremely dry skin, cheilitis, and must be followed for development of hypertriglyceridemia. Recently there have also been concerns that it is associated with severe depression in some patients. The latter has not been proved. At present, prescribers must enroll in a program designed to prevent pregnancy and adverse events while patients are taking isotretinoin. These measures are imposed to ensure that all prescribers are familiar with the risks of isotretinoin; that all female patients have two negative pregnancy tests prior to initiating therapy and a negative pregnancy test prior to each refill; and that all patients have been warned about the risks associated with isotretinoin.

ACNE ROSACEA

Acne rosacea, commonly referred to as rosacea, is an inflammatory disorder predominantly affecting the central face. Those most often affected are Caucasians of northern European background, but it is seen in patients with dark skin also. It is seen almost exclusively in adults, only rarely affecting patients <30 years. Rosacea is more common in women, but those most severely affected are men. It is characterized by the presence of erythema, telangiectases, and superficial pustules (Fig. 53-8), but is not associated with the presence of comedones. Rosacea only rarely involves the chest or back.

FIGURE 53-8 Acne rosacea. Prominent facial erythema, telangiectasia, scattered papules, and small pustules are seen in this patient with acne rosacea. (*Courtesy of Robert Swerlick, MD; with permission.*)

There is a relationship between the tendency for facial flushing and the subsequent development of acne rosacea. Often, individuals with rosacea initially demonstrate a pronounced flushing reaction. This may be in response to heat, emotional stimuli, alcohol, hot drinks, or spicy foods. As the disease progresses, the flush persists longer and longer and may eventually become permanent. Papules, pustules, and telangiectases can become superimposed on the persistent flush. Rosacea of very long standing may lead to connective tissue overgrowth, particularly of the nose (rhinophyma). Rosacea may also be complicated by various inflammatory disorders of the eye, including keratitis, blepharitis, iritis, and recurrent chalazion. These ocular problems are potentially sight-threatening and warrant ophthalmologic evaluation.

℞ ACNE ROSACEA

Acne rosacea can be treated topically or systemically. Mild disease often responds to topical metronidazole or sodium sulfacetamide. More severe disease requires oral tetracyclines: tetracycline 250–500 mg bid, doxycycline 100 mg bid, or minocycline 50–100 mg bid. Residual telangiectasia may respond to laser therapy. Topical glucocorticoids, especially potent agents, should be avoided since chronic use of these preparations may elicit rosacea. Topical therapy of the skin is not effective treatment for ocular disease.

SKIN DISEASES AND SMALLPOX VACCINATION

Given the potential threat of a bioterrorism attack with smallpox, vaccinations against smallpox are available to the general public, although they are not recommended. Because of a higher incidence of adverse events associated with smallpox vaccination in patients with a history of certain skin diseases, including atopic dermatitis, eczema, and psoriasis, such vaccination is contraindicated in patients with these conditions in the absence of a bioterrorism attack and a real or potential exposure to smallpox. In the case of such exposure, the risk of smallpox infection outweighs the risk of adverse events from the vaccine (Chap. 214).

54 Skin Manifestations of Internal Disease

Jean L. Bolognia, Irwin M. Braverman

It is now a generally accepted concept in medicine that the skin can show signs of internal disease. Therefore, in textbooks of medicine one finds a chapter describing in detail the major systemic disorders that can be identified by cutaneous signs. The underlying assumption of such a chapter is that the clinician has been able to identify the disorder in the patient and needs only to read about it in the textbook. In reality, concise differential diagnoses and the identification of these disorders are actually difficult for the nondermatologist because he or she is not well versed in the recognition of cutaneous lesions or their spectrum of presentations. Therefore, the authors of this chapter have decided to cover this particular topic of cutaneous medicine not by discussing individual disorders but by describing and discussing the various presenting clinical signs and symptoms that indicate the presence of these disorders. Concise differential diagnoses will be generated in which the significant diseases will be briefly discussed and distinguished from the more common disorders that have no significance for internal diseases. The latter disorders are reviewed in table form and always need to be excluded when considering the former. For a detailed description of individual diseases, the reader should consult a dermatologic text.

PAPULOSQUAMOUS SKIN LESIONS

(Table 54-1) When an eruption is characterized by elevated lesions, papules (<1 cm), or plaques (>1 cm), in association with scale, it is referred to as a *papulosquamous lesion*. The most common papulosquamous diseases—*psoriasis*, *tinea*, *pityriasis rosea*, and *lichen planus*—are primary cutaneous disorders (Chap. 53). When psoriatic lesions are accompanied by arthritis, the possibility of psoriatic arthritis or *Reiter's disease* should be considered. A history of oral ulcers, conjunctivitis, uveitis, and/or urethritis points to the latter diagnosis. Lithium, beta blockers, HIV or streptococcal infections, and a rapid taper of systemic glucocorticoids are known to exacerbate psoriasis.

Whenever the diagnosis of pityriasis rosea or lichen planus is made, it is important to review the patient's medications because the eruption can be treated by simply discontinuing the offending agent. Pityriasis rosea–like drug eruptions are seen most commonly with beta blockers, angiotensin-converting enzyme (ACE) inhibitors, gold, and metronidazole, while the drugs that can produce a lichenoid eruption include thiazides, antimalarials, gold, quinidine, phenothiazines, sulfonylureas, and ACE inhibitors. In some populations, there is a higher prevalence of hepatitis C viral infection in patients with lichen planus. Lichen planus–like lesions are also observed in chronic graft-versus-host disease.

TABLE 54-1 SELECTED CAUSES OF PAPULOSQUAMOUS SKIN LESIONS

1. Primary cutaneous disorders
   a. Psoriasis[a]
   b. Tinea[a]
   c. Pityriasis rosea[a]

   b. Cutaneous T cell lymphoma
   c. Secondary syphilis
   d. Reiter's disease
   e. Sarcoidosis[d]

[a]Discussed in detail in Chap. 53.
[b]Associated with chronic sun exposure and exposure to arsenic.
[c]See also Red Lesions in "Papulonodular Skin Lesions."
[d]See also Red-Brown Lesions in "Papulonodular Skin Lesions."

In its early stages, *cutaneous T cell lymphoma* (CTCL) may be confused with eczema or psoriasis, but it often fails to respond to the appropriate therapy for those inflammatory diseases. CTCL can develop within lesions of large-plaque parapsoriasis and is suggested by an increase in the thickness of the lesions. The diagnosis of CTCL is established by skin biopsy in which collections of atypical T lymphocytes are found in the epidermis and dermis. As the disease progresses, cutaneous tumors and lymph node involvement may appear.

In *secondary syphilis* there are scattered red-brown papules with thin scale. The eruption often involves the palms and soles and can resemble pityriasis rosea. Associated findings are helpful in making the diagnosis and include annular plaques on the face, nonscarring alopecia, condyloma lata (broad-based and moist), and mucous patches as well as lymphadenopathy, malaise, fever, headache, and myalgias. The interval between the primary chancre and the secondary stage is usually 4–8 weeks, and spontaneous resolution without appropriate therapy is seen.

ERYTHRODERMA

(Table 54-2) *Erythroderma* is the term used when the majority of the skin surface is erythematous (red in color). There may be associated scale, erosions, or pustules as well as shedding of the hair and nails. Potential systemic manifestations include fever, chills, hypothermia, reactive lymphadenopathy, peripheral edema, hypoalbuminemia, and high-output cardiac failure. The major etiologies of erythroderma are (1) cutaneous diseases such as psoriasis and dermatitis (Table 54-3); (2) drugs; (3) systemic diseases, most commonly CTCL; and (4) idiopathic. In the first three groups, the location and description of the initial lesions, prior to the development of the erythroderma, aid in the diagnosis. For example, a history of red scaly plaques on the elbows and knees would point to psoriasis. It is also important to examine the skin carefully for a migration of the erythema and associated secondary changes such as pustules or erosions. Migratory waves of erythema studded with superficial pustules are seen in *pustular psoriasis*.

Drug-induced erythroderma (exfoliative dermatitis) may begin as an exanthematous (morbilliform) eruption (Chap. 56) or may arise as diffuse erythema. A number of drugs can produce an erythroderma, including penicillins, sulfonamides, carbamazepine, phenytoin, gold, allopurinol, and zalcitabine. Fever and peripheral eosinophilia often accompany the eruption, and there may also be facial swelling, hepatitis, and allergic interstitial nephritis; this constellation is frequently referred to as *drug reaction with eosinophilia and systemic symptoms* (DRESS). In addition, reactions to anticonvulsants can lead to a pseudolymphoma syndrome (with adenopathy and circulating atypical lymphocytes), while reactions to allopurinol may be accompanied by gastrointestinal bleeding.

The most common malignancy that is associated with erythroderma is CTCL; in some series, up to 25% of the cases of erythroderma were due to CTCL. The patient may progress from isolated plaques and tumors, but more commonly the erythroderma is present throughout the course of the disease (Sézary syndrome). In the Sézary syndrome, there are circulating atypical T lymphocytes, pruritus, and lymphadenopathy. In cases of erythroderma where there is no apparent cause (idiopathic), longitudinal follow-up is mandatory to monitor for the possible development of CTCL. There have been isolated case reports of erythroderma secondary to some solid tumors—lung, liver, prostate, thyroid, and colon—but it is usually in a late stage of the disease.

TABLE 54-2 CAUSES OF ERYTHRODERMA

1. Primary cutaneous disorders

   b. Dermatitis [atopic, contact >> seborrheic or stasis (with autosensitization)][a]
   c. Pityriasis rubra pilaris
2. Drugs
3. Systemic diseases
   a. Cutaneous T cell lymphoma
   b. Lymphoma
4. Idiopathic

[a]Discussed in detail in Chap. 53.

TABLE 54-3 ERYTHRODERMA (PRIMARY CUTANEOUS DISORDERS)

	Initial Lesions	Location of Initial Lesions	Other Findings	Diagnostic Aids	Treatment
Psoriasis[a]	Pink-red, silvery scale, sharply demarcated	Elbows, knees, scalp, presacral area	Nail dystrophy, arthritis, pustules	Skin biopsy	Topical glucocorticoids, vitamin D; UV-B (narrowband); oral retinoid and/or PUVA; MTX, cyclosporine, anti-TNF agents
Dermatitis[a]					
Atopic	Acute: Erythema, fine scale, crust, indistinct borders Chronic: Lichenification (increased skin markings)	Antecubital and popliteal fossae, neck, hands	Pruritus Family history of atopy, including asthma, allergic rhinitis or conjunctivitis, and atopic dermatitis Exclude secondary infection with *S. aureus* Exclude superimposed irritant or allergic contact dermatitis	Skin biopsy	Topical glucocorticoids, tacrolimus, pimecrolimus, tar, and antipruritics; oral antihistamines; open wet dressings; UV-B ± UV-A; PUVA; oral/IM glucocorticoids; MTX; cyclosporine Topical or oral antibiotics
Contact	Local: Erythema, crusting, vesicles, and bullae	Depends on offending agent	Irritant—onset often within hours Allergic—delayed-type hypersensitivity; lag time of 48 h	Patch testing	Remove irritant or allergen; topical glucocorticoids; oral antihistamines; oral/IM glucocorticoids
	Systemic: Erythema, fine scale, crust	Generalized	Patient has history of allergic contact dermatitis to topical agent and then receives systemic medication that is structurally related, e.g., ethylenediamine (topical), aminophylline (IV)	Patch testing	Same as local
Seborrheic (rare)	Pink-red, greasy scale	Scalp, nasolabial folds, eyebrows, intertriginous zones	Flares with stress, HIV infection Associated with Parkinson's disease	Skin biopsy	Topical glucocorticoids and imidazoles
Stasis (with autosensitization)	Erythema, crusting, excoriations	Lower extremities	Pruritus, lower extremity edema History of venous ulcers, thrombophlebitis, and/or cellulitis Exclude cellulitis Exclude superimposed contact dermatitis, e.g., topical neomycin	Skin biopsy	Topical glucocorticoids; open wet dressings; leg elevation; pressure stockings
Pityriasis rubra pilaris	Orange-red, perifollicular papules	Generalized, but characteristic "skip" areas of normal skin	Wax-like keratoderma Exclude cutaneous T cell lymphoma	Skin biopsy	Isotretinoin or acitretin; methotrexate

[a]Discussed in detail in Chap. 53.

Note: PUVA, *p*soralens + *u*ltraviolet *A* irradiation; UV-B, *u*ltraviolet *B*; UV-A, *u*ltraviolet *A*; MTX, methotrexate; TNF, tumor necrosis factor.

ALOPECIA

(Table 54-4) The two major forms of alopecia are scarring and nonscarring. In *scarring alopecia* there are associated fibrosis, inflammation, and loss of hair follicles. A smooth scalp with a decreased number of follicular openings is usually observed clinically, but in some cases the changes are seen only in biopsy specimens from the affected areas. In *nonscarring alopecia* the hair shafts are gone, but the hair follicles are preserved, explaining the reversible nature of nonscarring alopecia.

The most common causes of nonscarring alopecia include *telogen effluvium*, *androgenetic alopecia*, *alopecia areata*, *tinea capitis*, and some cases of *traumatic alopecia* (Table 54-5). In women with androgenetic alopecia, an elevation in circulating levels of androgens may be seen as a result of ovarian or adrenal gland dysfunction. When there are signs of virilization, such as a deepened voice and enlarged clitoris, the possibility of an ovarian or adrenal gland tumor should be considered.

Exposure to various drugs can also cause diffuse hair loss, usually by inducing a telogen effluvium. An exception is the anagen effluvium observed with antimitotic agents such as daunorubicin. Alopecia is a side effect of the following drugs: warfarin, heparin, propylthiouracil, carbimazole, vitamin A, isotretinoin, acitretin, lithium, beta blockers, colchicine, and amphetamines. Fortunately, spontaneous regrowth usually follows discontinuation of the offending agent.

Less commonly, nonscarring alopecia is associated with *lupus erythematosus* and *secondary syphilis*. In systemic lupus there are two forms of alopecia—one is scarring secondary to discoid lesions (see below) and the other is nonscarring. The latter form may be diffuse and involve the entire

TABLE 54-4 CAUSES OF ALOPECIA

I. Nonscarring alopecia
- A. Primary cutaneous disorders
  - 1. Telogen effluvium
  - 2. Androgenetic alopecia
  - 3. Alopecia areata
  - 4. Tinea capitis
  - 5. Traumatic alopecia[a]
- B. Drugs

II. Scarring alopecia
- A. Primary cutaneous disorders
  - 1. Cutaneous lupus (chronic discoid)
  - 2. Lichen planus
  - 3. Folliculitis decalvans
  - 4. Linear scleroderma (morphea)
  - 5. Central centrifugal cicatricial alopecia
- B. Systemic diseases
  - 1. Lupus erythematosus
  - 2. Sarcoidosis
  - 3. Cutaneous metastases

[a]Most patients with trichotillomania, pressure-induced alopecia.

TABLE 54-5 NONSCARRING ALOPECIA (PRIMARY CUTANEOUS DISORDERS)

	Clinical Characteristics	Pathogenesis	Treatment
Telogen effluvium	Diffuse shedding of normal hairs Follows either major stress (high fever, severe infection) or change in hormones (post partum) Reversible without treatment	Stress causes the normally asynchronous growth cycles of individual hairs to become synchronous; therefore, large numbers of growing (anagen) hairs simultaneously enter the dying (telogen) phase	Observation; discontinue any drugs that have alopecia as a side effect; must exclude underlying metabolic causes, e.g., hypothyroidism, hyperthyroidism
Androgenetic alopecia (male pattern; female pattern)	Miniaturization of hairs along the midline of the scalp Recession of the anterior scalp line in men and some women	Increased sensitivity of affected hairs to the effects of testosterone Increased levels of circulating androgens (ovarian or adrenal source in women)	If no evidence of hyperandrogen state, then topical minoxidil; finasteride[a]; hair transplant
Alopecia areata	Well-circumscribed, circular areas of hair loss, 2–5 cm in diameter In extensive cases, coalescence of lesions and/or involvement of other hair-bearing surfaces of the body Pitting of the nails	The germinative zones of the hair follicles are surrounded by T lymphocytes Occasional associated diseases: hyperthyroidism, hypothyroidism, vitiligo, Down syndrome	Topical anthralin; intralesional glucocorticoids; topical contact sensitizers
Tinea	Varies from scaling with minimal hair loss to discrete patches with "black dots" (broken hairs) to boggy plaque with pustules (kerion)	Invasion of hairs by dermatophytes, most commonly *Trichophyton tonsurans*	Oral griseofulvin or terbinafine plus 2.5% selenium sulfide or ketoconazole shampoo; examine family members
Traumatic alopecia[b]	Broken hairs Irregular outline	Traction with curlers, rubber bands, braiding Exposure to heat or chemicals (e.g., hair straighteners) Mechanical pulling (trichotillomania)	Discontinuation of offending hair style or chemical treatments; trichotillomania may require hair clipping and observation of shaved hairs or biopsy for diagnosis, possibly followed by psychotherapy

[a]To date, FDA-approved for men.

[b]May also be scarring.

scalp, or it may be localized to the frontal scalp, eventually resulting in multiple short hairs ("lupus hairs"). Scattered, poorly circumscribed patches of alopecia with a "moth-eaten" appearance are a manifestation of the secondary stage of syphilis. Diffuse thinning of the hair is also associated with hypothyroidism and hyperthyroidism (Table 54-4).

Scarring alopecia is more frequently the result of a primary cutaneous disorder such as *lichen planus*, *folliculitis decalvans*, *chronic cutaneous (discoid) lupus*, or *linear scleroderma* (*morphea*) than it is a sign of systemic disease. Although the scarring lesions of *discoid lupus* can be seen in patients with systemic lupus, in the majority of cases the disease process is limited to the skin. Less common causes of scarring alopecia include *sarcoidosis* (see "Papulonodular Skin Lesions," below) and *cutaneous metastases*.

In the early phases of discoid lupus, lichen planus, and folliculitis decalvans, there are circumscribed areas of alopecia. Fibrosis and subsequent loss of follicles are observed primarily in the center of the individual lesions, while the inflammatory process is most prominent at the periphery. The areas of active inflammation in discoid lupus are erythematous with scale, whereas the areas of previous inflammation are often hypopigmented with a rim of hyperpigmentation. In lichen planus the peripheral perifollicular macules are usually violet-colored. Complete examination of the skin and oral mucosa combined with a biopsy and direct immunofluorescence microscopy will aid in distinguishing these two entities. The peripheral active lesions in folliculitis decalvans are follicular pustules; these patients can develop a reactive arthritis.

FIGURATE SKIN LESIONS

(Table 54-6) In *figurate eruptions*, the lesions form rings and arcs that are usually erythematous but can be skin-colored to brown. Most commonly, they are due to primary cutaneous diseases such as *tinea*, *urticaria*, *erythema annulare centrifugum*, and *granuloma annulare* (Chaps. 53 and 55). An underlying systemic illness is found in a second, less common group of migratory annular erythemas. It includes *erythema gyratum repens*, *erythema migrans*, *erythema marginatum*, and *necrolytic migratory erythema*.

In erythema gyratum repens, one sees numerous mobile concentric arcs and wavefronts that resemble the grain in wood. A search for an underlying malignancy is mandatory in a patient with this eruption. Erythema migrans is the cutaneous manifestation of Lyme disease, which is caused by the spirochete *Borrelia burgdorferi*. In the initial stage (3–30 days after tick bite), a single annular lesion is usually seen, which can expand to ≥10 cm in diameter. Within several days, approximately half the patients develop multiple smaller erythematous lesions at sites distant from the bite. Associated symptoms include fever, headache, photophobia, myalgias, arthralgias, and malar rash. Erythema marginatum is seen in patients with rheumatic fever, primarily on the trunk. Lesions are pink-red in color, flat to mildly elevated, and transient.

There are additional cutaneous diseases that present as annular eruptions but lack an obvious migratory component. Examples include *CTCL*, *subacute cutaneous lupus*, *secondary syphilis*, and *sarcoidosis* (see "Papulonodular Skin Lesions," below).

ACNE

(Table 54-7) In addition to *acne vulgaris* and *acne rosacea*, the two major forms of acne (Chap. 53), there are drugs and systemic diseases that can lead to acneiform eruptions (Table 54-7).

TABLE 54-6 CAUSES OF FIGURATE SKIN LESIONS

I. Primary cutaneous disorders
- A. Tinea
- B. Urticaria (≥90% of cases)
- C. Erythema annulare centrifugum
- D. Granuloma annulare
- E. Psoriasis

[a]Migratory erythema with erosions; favors lower extremities and girdle area.

TABLE 54-7 CAUSES OF ACNEIFORM ERUPTIONS

I. Primary cutaneous disorders
  A. Acne vulgaris
  B. Acne rosacea
II. Drugs, e.g., anabolic steroids, glucocorticoids, lithium, iodides, EGFR[a] inhibitors
III. Systemic diseases
  A. Increased androgen production
    1. Adrenal origin, e.g., Cushing's disease, 21-hydroxylase deficiency
    2. Ovarian origin, e.g., polycystic ovary syndrome
  B. Cryptococcosis, disseminated
  C. Dimorphic fungi
  D. Behçet's disease

[a]EGFR, epidermal growth factor receptor.

Patients with the *carcinoid syndrome* have episodes of flushing of the head, neck, and sometimes the trunk. Resultant skin changes of the face, in particular telangiectasias, may mimic the clinical appearance of acne rosacea.

PUSTULAR LESIONS

Acneiform eruptions (see "Acne," above) and *folliculitis* represent the most common pustular dermatoses. An important consideration in the evaluation of follicular pustules is a determination of the associated pathogen, e.g., normal flora, *Staphylococcus aureus*, *Pseudomonas aeruginosa* ("hot tub" folliculitis), *Malassezia*, dermatophytes (Majocchi's granuloma). Noninfectious forms of folliculitis include HIV-associated eosinophilic folliculitis and folliculitis secondary to drugs such as glucocorticoids and lithium. Administration of high-dose systemic glucocorticoids can result in a widespread eruption of follicular pustules on the trunk, characterized by lesions in the same stage of development. With regard to underlying systemic diseases, nonfollicular-based pustules are a characteristic component of pustular psoriasis and can be seen in septic emboli of bacterial or fungal origin (see "Purpura," below).

TELANGIECTASIAS

(Table 54-8) In order to distinguish the various types of telangiectasias, it is important to examine the shape and configuration of the dilated blood vessels. *Linear telangiectasias* are seen on the face of patients with *actinically damaged skin* and *acne rosacea,* and they are found on the legs of patients with *venous hypertension* and *essential telangiectasia*. Patients with an unusual form of *mastocytosis* (telangiectasia macularis eruptiva perstans) and the *carcinoid syndrome* (see "Acne," above) also have linear telangiectasias. Lastly, linear telangiectasias are found in areas of cutaneous inflammation. For example, lesions of discoid lupus frequently have telangiectasias within them.

TABLE 54-8 CAUSES OF TELANGIECTASIAS

    2. Scleroderma
    3. Dermatomyositis
    4. Hereditary hemorrhagic telangiectasia
  E. Papular
    1. Hereditary hemorrhagic telangiectasia
  F. Spider angioma
    1. Cirrhosis

[a]Becoming less common.

Poikiloderma is a term used to describe a patch of skin with (1) reticulated hypo- and hyperpigmentation, (2) wrinkling secondary to epidermal atrophy, and (3) telangiectasias. Poikiloderma does not imply a single disease entity—although becoming less common, it is seen in skin damaged by *ionizing radiation* as well as in patients with autoimmune connective tissue diseases, primarily *dermatomyositis* (DM), and rare genodermatoses (e.g., Kindler syndrome).

In *scleroderma*, the dilated blood vessels have a unique configuration and are known as *mat telangiectasias*. The lesions are broad macules that usually measure 2–7 mm in diameter but occasionally are larger. Mats have a polygonal or oval shape, and their erythematous color may be uniform or the result of delicate telangiectasias. The most common locations for mat telangiectasias are the face, oral mucosa, and hands—peripheral sites that are prone to intermittent ischemia. The CREST (*c*alcinosis cutis, *R*aynaud's phenomenon, *e*sophageal dysmotility, *s*clerodactyly, and *t*elangiectasia) variant of scleroderma (Chap. 316) is associated with a chronic course and anticentromere antibodies. Mat telangiectasias are an important clue to the diagnosis of the CREST syndrome as well as systemic scleroderma, for they may be the only cutaneous finding.

Periungual telangiectasias are pathognomonic signs of the three major autoimmune connective tissue diseases—*lupus erythematosus*, *scleroderma*, and *DM*. They are easily visualized by the naked eye and occur in at least two-thirds of these patients. In both DM and lupus there is associated nailfold erythema, and in DM the erythema is often accompanied by "ragged" cuticles and fingertip tenderness. Under 10× magnification, the blood vessels in the nailfolds of lupus patients are tortuous and resemble "glomeruli," whereas in scleroderma and DM there is a loss of capillary loops and those that remain are markedly dilated.

In *hereditary hemorrhagic telangiectasia* (Osler-Rendu-Weber disease), the lesions usually appear during adulthood and are most commonly seen on the mucous membranes, face, and distal extremities, including under the nails. They represent arteriovenous (AV) malformations of the dermal microvasculature, are dark red in color, and are usually slightly elevated. When the skin is stretched over an individual lesion, an eccentric punctum with radiating legs is seen. Although the degree of systemic involvement varies in this autosomal dominant disease (due to mutations in either the endoglin or activin receptor–like kinase gene), the major symptoms are recurrent epistaxis and gastrointestinal bleeding. The fact that these mucosal telangiectasias are actually AV communications helps to explain their tendency to bleed.

HYPOPIGMENTATION

(Table 54-9) Disorders of hypopigmentation are often classified as either diffuse or localized. The classic example of *diffuse hypopigmentation* is *oculocutaneous albinism* (OCA). The most common forms are due to mutations in the tyrosinase gene (type I) or the *P* gene (type II); patients with type IA OCA have a total lack of enzyme activity. At birth, different forms of OCA can appear similar—white hair, gray-blue eyes, and pink-white skin. However, the patients with no tyrosinase activity maintain this phenotype, whereas those with decreased activity will acquire some pigmentation of the eyes, hair, and skin as they age. The degree of pigment formation is also a function of racial background, and the pigmentary dilution is readily apparent when patients are compared to their first-degree relatives. The ocular findings in OCA correlate with the degree of hypopigmentation and include decreased visual acuity, nystagmus, photophobia, and a lack of normal binocular vision.

The differential diagnosis of *localized hypomelanosis* includes the following primary cutaneous disorders: *idiopathic guttate hypomelanosis*, *postinflammatory hypopigmentation*, *tinea (pityriasis) versicolor*, *vitiligo*, *chemical leukoderma*, *nevus depigmentosus* (see below), and *piebaldism* (Table 54-9). In this group of diseases, the areas of involvement are macules or patches with a decrease or absence of pigmentation. Patients with vitiligo also have an increased incidence of several autoimmune disorders, including hypothyroidism, Graves' disease, pernicious anemia, Addison's disease, uveitis, alopecia areata, chronic mucocutaneous candidiasis, and the polyglandular autoimmune syndromes (types I and II). Diseases of the thyroid gland are the most frequently associated disorders, occurring in up to 30% of patients with

[d]Giant lysosomal granules and recurrent infections.

vitiligo. Circulating autoantibodies are often found, and the most common ones are antithyroglobulin, antimicrosomal, and antithyroid-stimulating hormone receptor antibodies.

There are four systemic diseases that should be considered in a patient with skin findings suggestive of vitiligo—*Vogt-Koyanagi-Harada syndrome*, *scleroderma*, *onchocerciasis*, and *melanoma-associated leukoderma*. A history of aseptic meningitis, nontraumatic uveitis, tinnitus, hearing loss, and/or dysacusis points to the diagnosis of the Vogt-Koyanagi-Harada syndrome. In these patients, the face and scalp are the most common locations of pigment loss. The vitiligo-like leukoderma seen in patients with scleroderma has a clinical resemblance to idiopathic vitiligo that has begun to repigment as a result of treatment; that is, perifollicular macules of normal pigmentation are seen within areas of depigmentation. The basis of this leukoderma is unknown; there is no evidence of inflammation in areas of involvement, but it can resolve if the underlying connective tissue disease becomes inactive. In contrast to idiopathic vitiligo, melanoma-associated leukoderma often begins on the trunk, and its appearance should prompt a search for metastatic disease. It is also seen in patients undergoing immunotherapy for melanoma, with cytotoxic T lymphocytes presumably recognizing cell surface antigens common to melanoma cells and melanocytes.

There are two systemic disorders (neurocristopathies) that may have the cutaneous findings of piebaldism (Table 54-10). They are *Shah-Waardenburg syndrome* and *Waardenburg syndrome*. A possible explanation for both disorders is an abnormal embryonic migration or survival of two neural crest–derived elements, one of them being melanocytes and the other myenteric ganglion cells (leading to Hirschsprung disease in Shah-Waardenburg syndrome) or auditory nerve cells (Waardenburg syndrome). The latter syndrome is characterized by congenital sensorineural hearing loss, dystopia canthorum (lateral displacement of the inner canthi but normal interpupillary distance), heterochromic irises, and a broad nasal root, in addition to the piebaldism. Patients with Waardenburg syndrome have been shown to have mutations in three genes including two (*PAX-3* and *MITF*) that encode DNA-binding proteins, while patients with Hirschsprung disease plus white spotting have mutations in one of three genes—endothelin 3, endothelin B receptor, and *SOX-10*.

In *tuberous sclerosis*, the earliest cutaneous sign is an ash leaf spot. These lesions are often present at birth and are usually multiple; however, detection may require Wood's lamp examination, especially in fair-skinned individuals. The pigment within them is reduced but not absent. The average size is 1–3 cm, and the common shapes are polygonal and lance-ovate. Examination of the patient for additional cutaneous signs such as multiple angiofibromas of the face (adenoma sebaceum), ungual and gingival fibromas, fibrous plaques of the forehead, and connective tissue nevi (shagreen patches) is recommended. It is important to remember that an ash leaf spot on the scalp will result in *poliosis*, which is a circumscribed patch of gray-white hair. Internal manifestations include seizures, mental retardation, central nervous system (CNS) and retinal hamartomas, renal angiomyolipomas, and cardiac rhabdomyomas. The latter can be detected in up to 60% of children (<18 years) with tuberous sclerosis by echocardiography.

Nevus depigmentosus is a stable, well-circumscribed hypomelanosis that is present at birth. There is usually a single oval or rectangular lesion, but occasionally the nevus has a segmental or whorled pattern (also referred to as *linear nevoid hypopigmentation*). It is important to distinguish this more common entity from ash leaf spots of tuberous sclerosis, especially when there are multiple lesions. In *hypomelanosis of Ito*, swirls and streaks of hypopigmentation run parallel to one another in a pattern that resembles a marble cake. Lesions may progress or regress with time, and in up to a third of patients, associated abnormalities are found involving the musculoskeletal system (asymmetry), the CNS (seizures and mental retardation), and the eyes (strabismus and hypertelorism). Chromosomal mosaicism has been detected in these patients, lending support to the hypothesis that the pattern is the result of the migration of two clones of primordial melanocytes, each with a different pigment potential.

Localized areas of decreased pigmentation are commonly seen as a result of cutaneous inflammation (Table 54-10) and have been observed in the skin overlying active lesions of sarcoidosis (see "Papulonodular Skin Lesions," below) as well as in CTCL. Cutaneous infections also present as disorders of hypopigmentation, and in *tuberculoid leprosy* there are a few asymmetric patches of hypomelanosis that have associated anesthesia, anhidrosis, and alopecia. Biopsy specimens of the palpable border show dermal granulomas that contain rare, if any, *Mycobacterium leprae* organisms.

HYPERPIGMENTATION

(Table 54-11) Disorders of hyperpigmentation are also divided into two groups—localized and diffuse. The localized forms are due to an epidermal alteration, a proliferation of melanocytes, or an increase in pigment production. Both seborrheic keratoses and acanthosis nigricans belong to the first group. *Seborrheic keratoses* are common lesions, but in one rare clinical setting they are a sign of systemic disease, and that setting is the sudden appearance of multiple lesions, often with an inflammatory base and in association with acrochordons (skin tags) and acanthosis nigricans. This is termed the *sign of Leser-Trélat* and alerts the clinician to search for an internal malignancy. *Acanthosis nigricans* can also be a reflection of an internal malignancy, most commonly of the gastrointestinal tract, and it appears as velvety hyperpigmentation, primarily in flexural areas. In the majority of patients, acanthosis nigricans is associated with obesity and insulin resistance, but it may be a reflection of an endocrinopathy such as acromegaly, Cushing's syndrome, polycystic ovary syndrome, or insulin-resistant diabetes mellitus (type A, type B, and lipoatrophic forms).

A proliferation of melanocytes results in the following pigmented lesions: *lentigo*, *melanocytic nevus*, and *melanoma* (Chap. 83). In an adult, the majority of lentigines are related to sun exposure, which explains their distribution. However, in the Peutz-Jeghers and LEOPARD [*l*entigines; *E*CG abnormalities, primarily conduction defects; *o*cular hypertelorism; *p*ulmonary stenosis and subaortic valvular stenosis; *a*bnormal genitalia (cryptorchidism, hypospadias); *r*etardation of growth; and *d*eafness (sensorineural)] syndromes, lentigines do serve

TABLE 54-10 HYPOPIGMENTATION (PRIMARY CUTANEOUS DISORDERS, LOCALIZED)

	Clinical Characteristics	Wood's Lamp Examination (UV-A; Peak = 365 nm)	Skin Biopsy Specimen	Pathogenesis	Treatment
Idiopathic guttate hypomelanosis	Common; acquired; 1–4 mm in diameter Shins and extensor forearms	Less enhancement than vitiligo	Abrupt decrease in epidermal melanin content	Possible somatic mutations as a reflection of aging; UV exposure	None
Postinflammatory hypopigmentation	Can develop within active lesions, as in subacute lupus, or after the lesion fades, as in dermatitis	Depends on particular disease Usually less enhancement than in vitiligo	Type of inflammatory infiltrate depends on specific disease	Block in transfer of melanin from melanocytes to keratinocytes could be secondary to edema or decrease in contact time Destruction of melanocytes if inflammatory cells attack basal layer	Treat underlying inflammatory disease
Tinea (pityriasis) versicolor	Common disorder Upper trunk and neck Shawl-like distribution Young adults Macules have fine white scale when scratched	Golden fluorescence	Hyphae and budding yeast in stratum corneum	Invasion of stratum corneum by the yeast *Malassezia* Yeast is lipophilic and produces C_9 and C_{11} dicarboxylic acids, which in vitro inhibit tyrosinase	Selenium sulfide 2.5%; topical imidazoles; oral imidazoles or triazoles
Vitiligo	Acquired; progressive Symmetric areas of complete pigment loss Periorificial—around mouth, nose, eyes, nipples, umbilicus, anus Other areas—flexor wrists, extensor distal extremities Segmental form is less common—unilateral, dermatomal-like	More apparent Chalk-white	Absence of melanocytes Mild inflammation	Possible autoimmune phenomenon that results in destruction of melanocytes—cellular and/or humoral Alternative hypothesis is self-destruction of melanocytes and circulating antibodies or cytotoxic T cells as a secondary phenomenon	Topical glucocorticoids; topical calcineurin inhibitors; UV-B; PUVA; transplants; depigmentation if widespread
Chemical leukoderma	Similar appearance to vitiligo Often begins on hands Satellite lesions in areas not exposed to chemicals	More apparent Chalk-white	Decreased number or absence of melanocytes	Exposure to chemicals that selectively destroy melanocytes, in particular phenols and catechols (germicides; adhesives) Release of cellular antigens and activation of circulating lymphocytes may explain satellite phenomenon	Avoid exposure to offending agent, then treat as vitiligo
Piebaldism	Autosomal dominant Congenital, stable White forelock Areas of hypomelanosis contain normally pigmented and hyperpigmented macules of various sizes Symmetric involvement of central forehead, ventral trunk, and mid regions of upper and lower extremities	Enhancement of leukoderma and hyperpigmented macules	Hypomelanotic areas—few to no melanocytes	Defect in migration of melanoblasts from neural crest to ventral skin or failure of melanoblasts to survive or differentiate in these areas Mutations within the c-*kit* proto-oncogene that encodes the tyrosine kinase receptor for stem cell growth factor	None; occasionally transplants

Note: PUVA, *p*soralens +*u*ltraviolet *A* irradiation; UV-B, *u*ltraviolet *B*.

as a clue to systemic disease. In *LEOPARD syndrome*, hundreds of lentigines develop during childhood and are scattered over the entire surface of the body. The lentigines in patients with *Peutz-Jeghers syndrome* are located primarily around the nose and mouth, on the hands and feet, and within the oral cavity. While the pigmented macules on the face may fade with age, the oral lesions persist. However, similar intraoral lesions are also seen in Addison's disease and as a normal finding in darkly pigmented individuals. Patients with this autosomal dominant syndrome (due to mutations in a novel serine threonine kinase gene) have multiple benign polyps of the gastrointestinal tract, testicular tumors, and an increased risk of developing gastrointestinal (primarily colon), pancreatic, and gynecologic cancers.

In the Carney complex, numerous lentigines are also seen, but in association with cardiac myxomas. This autosomal dominant disorder is also known as the *LAMB* (*l*entigines, *a*trial myxomas, *m*ucocutaneous myxomas, and *b*lue nevi) *syndrome* or *NAME* [*n*evi, *a*trial myxoma, *m*yxoid neurofibroma, and *e*phelides (freckles)] *syndrome*. These patients can also have evidence of endocrine overactivity in the form of Cushing's syndrome, acromegaly, or sexual precocity.

The third type of localized hyperpigmentation is due to a local increase in pigment production, and it includes *ephelides* and café au lait macules (CALM). The latter are most commonly associated with two disorders—neurofibromatosis (NF) and McCune-Albright syndrome. *CALM* are flat, uniformly brown in color (usually two shades darker than uninvolved skin), and can vary in size from 0.5–12 cm. Approximately 80–90% of adult patients with *type I NF* will have six or more CALM measuring ≥1.5 cm in diameter. Additional findings are discussed in the section on neurofibromas (see "Papulonodular Skin Le-

sions," below). In comparison with NF, the CALM in patients with *McCune-Albright syndrome* [polyostotic fibrous dysplasia with precocious puberty in females due to mosaicism for an activating mutation in a G protein ($G_s\alpha$) gene] are usually larger, more irregular in outline, and tend to respect the midline. CALM have also been associated with pulmonary stenosis (Watson syndrome), tuberous sclerosis, the LEOPARD syndrome, and multiple endocrine neoplasia (MEN), but a few such lesions can be found in normal individuals.

In incontinentia pigmenti, dyskeratosis congenita, and bleomycin pigmentation, the areas of localized hyperpigmentation form a pattern—swirled in the first, reticulated in the second, and flagellate in the third. In *dyskeratosis congenita*, atrophic reticulated hyperpigmentation is seen on the neck, trunk, and thighs and is accompanied by nail dystrophy, pancytopenia, and leukoplakia of the oral and anal mucosae. The latter often develops into squamous cell carcinoma. In addition to the flagellate pigmentation (linear streaks) on the trunk, patients receiving bleomycin often have hyperpigmentation overlying the elbows, knees, and small joints of the hand.

Localized hyperpigmentation is seen as a side effect of several other *systemic medications*, including those that produce fixed drug reactions [nonsteroidal anti-inflammatory drugs (NSAIDs), sulfonamides, barbiturates, and tetracyclines] and those that can complex with melanin (antimalarials) or iron (minocycline). Fixed drug eruptions recur in the exact same location as circular areas of erythema that can become bullous and then resolve as brown macules. The eruption usually appears within hours of administration of the offending agent, and common locations include the genitalia, extremities, and perioral region. Chloroquine and hydroxychloroquine produce gray-brown to blue-black discoloration of the shins, hard palate, and face, while blue macules (often misdiagnosed as bruises) can be seen on the lower extremities and in sites of inflammation with prolonged minocycline administration. Estrogen in oral contraceptives can induce melasma—symmetric brown patches on the face, especially the cheeks, upper lip, and forehead. Similar changes are seen in pregnancy and in patients receiving phenytoin.

In the diffuse forms of hyperpigmentation, the darkening of the skin may be of equal intensity over the entire body or may be accentuated in sun-exposed areas. The causes of diffuse hyperpigmentation can be divided into four major groups—endocrine, metabolic, autoimmune, and drugs. The endocrinopathies that frequently have associated hyperpigmentation include *Addison's disease*, *Nelson syndrome*, and *ectopic ACTH syndrome*. In these diseases, the increased pigmentation is diffuse but is accentuated in the palmar creases, sites of friction, scars, and the oral mucosa. An overproduction of the pituitary hormones α-MSH (melanocyte-stimulating hormone) and ACTH can lead to an increase in melanocyte activity. These peptides are products of the proopiomelanocortin gene and exhibit homology; e.g., α-MSH and ACTH share 13 amino acids. A minority of the patients with Cushing's disease or hyperthyroidism have generalized hyperpigmentation.

The metabolic causes of hyperpigmentation include *porphyria cutanea tarda* (PCT), *hemochromatosis*, *vitamin B_{12} deficiency*, *folic acid deficiency*, *pellagra*, *malabsorption*, and *Whipple's disease*. In patients with PCT (see "Vesicles/Bullae," below), the skin darkening is seen in sun-exposed areas and is a reflection of the photoreactive properties of porphyrins. The increased level of iron in the skin of patients with hemochromatosis stimulates melanin pigment production and leads to the classic bronze color. Patients with pellagra have a brown discoloration of the skin, especially in sun-exposed areas, as a result of nicotinic acid (niacin) deficiency. In the areas of increased pigmentation, there is a thin varnish-like scale. These changes are also seen in patients who are vitamin B_6 deficient, have functioning carcinoid tumors (increased consumption of niacin), or take isoniazid. Approximately 50% of the patients with Whipple's disease have an associated generalized hyperpigmentation in association with diarrhea, weight loss, arthritis, and lymphadenopathy. A diffuse slate-blue color is seen in patients with melanosis secondary to metastatic melanoma. Although there is a debate as to whether the color is due to single-cell metastases in the dermis or to a widespread deposition of melanin resulting from the high concentration of circulating melanin precursors, there is more evidence to support the latter.

Of the autoimmune diseases associated with diffuse hyperpigmentation, *biliary cirrhosis* and *scleroderma* are the most common, and occasionally both disorders are seen in the same patient. The skin is dark brown in color, especially in sun-exposed areas. In biliary cirrhosis the hyperpigmentation is accompanied by pruritus, jaundice, and xanthomas, whereas in scleroderma it is accompanied by sclerosis of the extremities, face, and, less commonly, the trunk. Additional clues to the diagnosis of scleroderma are telangiectasias, calcinosis cutis, Raynaud's phenomenon, and distal ulcerations (see "Telangiectasias," above). The differential diagnosis of cutaneous sclerosis with hyperpigmentation includes the POEMS [*p*olyneuropathy; *o*rganomegaly (liver, spleen, lymph nodes); *e*ndocrinopathies (impotence, gynecomastia); *M*-protein; and *s*kin changes] syndrome. The skin changes include hyperpigmentation, skin thickening, hypertrichosis, and angiomas.

Diffuse hyperpigmentation that is due to drugs or metals can result from one of several mechanisms—induction of melanin pigment formation, complexing of the drug or its metabolites to melanin, and deposits of the drug in the dermis. Busulfan, cyclophosphamide, 5-fluorouracil,

and inorganic arsenic induce pigment production. Complexes containing melanin or hemosiderin plus the drug or its metabolites are seen in patients receiving chlorpromazine and minocycline. The sun-exposed skin as well as the conjunctivae of patients on long-term, high-dose chlorpromazine can become blue-gray in color. Patients taking minocycline may develop a diffuse blue-gray, muddy appearance in sun-exposed areas in addition to pigmentation of the mucous membranes, teeth, nails, bones, and thyroid. Administration of amiodarone can result in both a phototoxic eruption (exaggerated sunburn) and/or a brown or blue-gray discoloration of sun-exposed skin. Biopsy specimens of the latter show yellow-brown granules in dermal macrophages, which represent intralysosomal accumulations of lipids, amiodarone, and its metabolites. Actual deposits of a particular drug or metal in the skin are seen with silver (argyria), where the skin appears blue-gray in color; gold (chrysiasis), where the skin has a brown to blue-gray color; and clofazimine, where the skin appears reddish brown. The associated hyperpigmentation is accentuated in sun-exposed areas, and discoloration of the eye is seen with gold (sclerae) and clofazimine (conjunctivae).

VESICLES/BULLAE

(Table 54-12) Depending on their size, cutaneous blisters are referred to as *vesicles* (<0.5 cm) or *bullae* (>0.5 cm). The primary blistering disorders include *pemphigus vulgaris*, *pemphigus foliaceus*, *pemphigus erythematosus*, *paraneoplastic pemphigus*, *bullous pemphigoid*, *gestational pemphigoid*, *cicatricial pemphigoid*, *epidermolysis bullosa acquisita*, *linear IgA bullous dermatosis*, and *dermatitis herpetiformis* (Chap. 55).

Vesicles and bullae are also seen in *contact dermatitis*, both allergic and irritant forms (Chap. 53). When there is a linear arrangement of vesicular lesions, an exogenous cause should be suspected. Bullous disease secondary to the ingestion of drugs can take one of several forms, including phototoxic eruptions, isolated bullae, Stevens-Johnson syndrome (SJS), and toxic epidermal necrolysis (TEN) (Chap. 56). Clinically, phototoxic eruptions resemble an exaggerated sunburn with diffuse erythema and bullae in sun-exposed areas. The most commonly associated drugs are doxycycline, sulfonamides, thiazides, NSAIDs, and psoralens. The development of a phototoxic eruption is dependent on the doses of both the drug and ultraviolet (UV)-A irradiation.

[a]Intraepidermal.
[b]Subepidermal.
[c]Associated with gluten enteropathy.
[d]Associated with inflammatory bowel disease.
[e]Also systemic.
[f]In adults, associated with renal failure and immunocompromised state.

Toxic epidermal necrolysis is characterized by bullae that arise on widespread areas of erythema and then slough. This results in large areas of denuded skin. The associated morbidity, such as sepsis, and mortality are relatively high and are a function of the extent of epidermal necrosis. In addition, these patients may also have involvement of the mucous membranes and intestinal tract. Drugs are the primary cause of TEN, and the most common offenders are phenytoin, barbiturates, carbamazepine, sulfonamides, penicillins, and NSAIDs. Severe acute graft-versus-host disease (grade 4) can also resemble TEN.

In *erythema multiforme* (EM), the primary lesions are pink-red macules and edematous papules, the centers of which may become vesicular. The clue to the diagnosis of EM, as opposed to a morbilliform exanthem, is the development of a "dusky" violet color or petechiae in the center of the lesions. Target or iris lesions are also characteristic of EM and arise as a result of active centers and borders in combination with centrifugal spread. However, iris lesions need not be present to make the diagnosis of EM.

EM has been subdivided into two major groups: (1) EM minor due to herpes simplex virus (HSV); and (2) EM major due to HSV, *Mycoplasma pneumoniae,* or rarely drugs. Involvement of the mucous membranes (oral, nasal, ocular, and genital) is seen more commonly in the latter form. Hemorrhagic crusts of the lips are characteristic of EM major and SJS as well as herpes simplex, pemphigus vulgaris, and paraneoplastic pemphigus. Fever, malaise, myalgias, sore throat, and cough may precede or accompany the eruption. The lesions of EM usually resolve over 3–6 weeks but may be recurrent, especially when due to HSV. In addition to HSV (in which lesions appear 7–12 days after the viral eruption), EM can also follow vaccinations, radiation therapy, and exposure to environmental toxins.

Induction of SJS is most often due to drugs, especially sulfonamides, phenytoin, barbiturates, penicillins, and carbamazepine. Widespread dusky macules and significant mucosal involvement are characteristic of SJS, and the cutaneous lesions may or may not develop epidermal detachment. If the latter occurs, by definition, it is limited to <10% of the body surface area (BSA). Greater involvement leads to the diagnosis of SJS/TEN overlap (10–30% BSA) or TEN (>30% BSA).

In addition to primary blistering disorders and hypersensitivity reactions, bacterial and viral infections can lead to vesicles and bullae. The most common infectious agents are HSV (Chap. 172), varicella-zoster virus (Chap. 173), and *S. aureus* (Chap. 129).

Staphylococcal scalded-skin syndrome (SSSS) and *bullous impetigo* are two blistering disorders associated with staphylococcal (phage group II) infection. In SSSS, the initial findings are redness and tenderness of the central face, neck, trunk, and intertriginous zones. This is followed by short-lived flaccid bullae and a slough or exfoliation of the superficial epidermis. Crusted areas then develop, characteristically around the mouth. SSSS is distinguished from TEN by the following features: younger age group (primarily infants), more superficial site of blister formation, no oral lesions, shorter course, less morbidity and mortality, and an association with staphylococcal exfoliative toxin ("exfoliatin"), not drugs. A rapid diagnosis of SSSS versus TEN can be made by a frozen section of the blister roof or exfoliative cytology of the blister contents. In SSSS the site of staphylococcal infection is usually extracutaneous (conjunctivitis, rhinorrhea, otitis media, pharyngitis, tonsillitis), and the cutaneous lesions are sterile, whereas in bullous impetigo the skin lesions are the site of infection. Impetigo is more localized than SSSS and usually presents with honey-colored crusts. Occasionally, superficial purulent blisters also form. *Cutaneous emboli* from gram-negative infections may present as isolated bullae, but the base of the lesion is purpuric or necrotic, and it may develop into an ulcer (see "Purpura," below).

Several metabolic disorders are associated with blister formation, including diabetes mellitus, renal failure, and porphyria. Local hypoxia secondary to decreased cutaneous blood flow can also produce blisters, which explains the presence of bullae over pressure points in comatose patients (coma bullae). In *diabetes mellitus*, tense bullae with clear viscous fluid arise on normal skin. The lesions can be as large as 6 cm in diameter and are located on the distal extremities. There are several types of porphyria, but the most common form with cutaneous findings is *PCT*. In sun-exposed areas (primarily the face and hands), the skin is very fragile, and trauma leads to erosions and tense vesicles. These lesions then heal with scarring and formation of milia; the latter are firm, 1- to 2-mm white or yellow papules that represent epidermoid inclusion cysts. Associated findings can include hypertrichosis of the lateral malar region (men) or face (women) and, in sun-exposed areas, hyperpigmentation and firm sclerotic plaques. An elevated level of urinary uroporphyrins confirms the diagnosis and is due to a decrease in uroporphyrinogen decarboxylase activity. Precipitating agents include alcohol, iron, chlorinated hydrocarbons, hepatitis C infection, and hepatomas.

The differential diagnosis of PCT includes (1) *porphyria variegata*—the skin signs of PCT plus the systemic findings of acute intermittent porphyria; it has a diagnostic plasma porphyrin fluorescence emission at 626 nm; (2) *drug-induced* pseudoporphyria—the clinical and histologic findings are similar to PCT, but porphyrins are normal; etiologic agents include naproxen, furosemide, tetracycline, and nalidixic acid; (3) *bullous dermatosis of hemodialysis*—the same appearance as PCT, but porphyrins are usually normal or occasionally borderline elevated; patients have chronic renal failure and are on hemodialysis; (4) PCT associated with hepatomas, hepatic carcinomas, and hemodialysis; and (5) *epidermolysis bullosa acquisita* (Chap. 55).

EXANTHEMS

(Table 54-13) Exanthems are characterized by an acute generalized eruption. The two most common presentations are erythematous macules and papules (morbilliform) and confluent blanching erythema (scarlatiniform). *Morbilliform* eruptions are usually due to either drugs or viral infections. For example, up to 5% of the patients receiving penicillins, sulfonamides, phenytoin, or gold will develop a maculopapular eruption. Accompanying signs may include pruritus, fever, eosinophilia, and transient lymphadenopathy. Similar maculopapular eruptions are seen in the classic childhood viral exanthems, including (1) *rubeola* (measles)—a prodrome of coryza, cough, and conjunctivitis followed by Koplik's spots on the buccal mucosa; the eruption begins behind the ears, at the hairline, and on the forehead and then spreads down the body, often becoming confluent; (2) *rubella*—the eruption begins on the forehead and face and then spreads down the body; it resolves in the same order and is associated with retroauricular and suboccipital lymphadenopathy; and (3) *erythema infectiosum* (fifth disease)—erythema of the cheeks is followed by a reticulated pattern on extremities; it is secondary to a parvovirus B19 infection, and an associated arthritis is seen in adults.

[a]CMV, cytomegalovirus.

Both measles and rubella are seen in unvaccinated young adults, and an atypical form of measles is seen in adults immunized with either killed measles vaccine or killed vaccine followed in time by live vaccine. In contrast to classic measles, the eruption of atypical measles begins on the palms, soles, wrists, and knuckles, and the lesions may become purpuric. The patient with atypical measles can have pulmonary involvement and be quite ill. Rubelliform and roseoliform eruptions are also associated with *Epstein-Barr virus* (5–15% of patients), *echovirus*, *coxsackievirus*, *cytomegalovirus*, and *adenovirus* infections. Detection of specific IgM antibodies or fourfold elevations in IgG antibodies allows the proper diagnosis. Occasionally, a maculopapular drug eruption is a reflection of an underlying viral infection. For example, about 95% of the patients with infectious mononucleosis who are given ampicillin will develop a rash.

Of note, early in the course of infections with *Rickettsia* and meningococcus, prior to the development of purpura, the lesions may be erythematous macules and papules. This is also the case in chickenpox prior to the development of vesicles. Maculopapular eruptions are associated with early *HIV infection*, early secondary *syphilis*, *typhoid fever*, and *acute graft-versus-host disease*. In the last, lesions frequently begin on the palms and soles; the macular rose spots of typhoid fever involve primarily the anterior trunk.

The prototypic *scarlatiniform* eruption is seen in *scarlet fever* and is due to an erythrotoxin produced by group A β-hemolytic streptococcal infections, most commonly pharyngitis. This eruption is characterized by diffuse erythema, which begins on the neck and upper trunk, and red follicular puncta. Additional findings include a white strawberry tongue (white coating with red papillae) followed by a red strawberry tongue (red tongue with red papillae); petechiae of the palate; a facial flush with circumoral pallor; linear petechiae in the antecubital fossae; and desquamation of the involved skin, palms, and soles 5–20 days after onset of the eruption. A similar desquamation of the palms and soles is seen in toxic shock syndrome (TSS), Kawasaki's disease, and after severe febrile illnesses. Certain strains of staphylococci also produce an erythrotoxin that leads to the same clinical findings as in streptococcal scarlet fever, except that the anti-streptolysin O or -DNase B titers are not elevated.

In *toxic shock syndrome*, staphylococcal (phage group I) infections produce an exotoxin (TSST-1) that causes the fever and rash, as well as enterotoxins. Initially, the majority of cases were reported in menstruating women who were using tampons. However, other sites of infection, including wounds and vaginitis, can lead to TSS. The diagnosis of TSS is based on clinical criteria (Chap. 129), and three of these involve mucocutaneous sites (diffuse erythema of the skin, desquamation of the palms and soles 1–2 weeks after onset of illness, and involvement of the mucous membranes). The latter is characterized as hyperemia of the vagina, oropharynx, or conjunctivae. Similar systemic findings have been described in *streptococcal toxic shock–like syndrome* (Chap. 130), and although an exanthem is seen less often than in TSS due to a staphylococcal infection, the underlying infection is often in the soft tissue.

The cutaneous eruption in *Kawasaki's disease* (mucocutaneous lymph node syndrome) (Chap. 319) is polymorphous, but the two most common forms are morbilliform and scarlatiniform. Additional mucocutaneous findings include bilateral conjunctival injection; erythema and edema of the hands and feet followed by desquamation; and diffuse erythema of the oropharynx, red strawberry tongue, and erosions with crusting on the lips. This clinical picture can resemble TSS and scarlet fever, but clues to the diagnosis of Kawasaki's disease are cervical lymphadenopathy, lip erosions, and thrombocytosis. The most serious associated systemic finding in this disease is coronary aneurysm secondary to arteritis. Aneurysms may lead to sudden death, primarily within the first 30 days of the illness. Scarlatiniform eruptions are also seen in the early phase of SSSS (see "Vesicles/Bullae," above) and as reactions to drugs.

URTICARIA

(Table 54-14) *Urticaria* (hives) are transient lesions that are composed of a central wheal surrounded by an erythematous halo. Individual lesions are round, oval, or figurate and are often pruritic. Acute and chronic urticaria has a wide variety of allergic etiologies and reflect edema in the dermis. Urticarial lesions can also be seen in patients with mastocytosis (urticaria pigmentosa), hyperthyroidism, and systemic-onset juvenile idiopathic arthritis (Still's disease). In both juvenile- and adult-onset Still's disease, the lesions coincide with the fever spike, are transient, and are due to dermal infiltrates of neutrophils.

The common *physical urticarias* include dermographism, solar urticaria, cold urticaria, and cholinergic urticaria. Patients with *dermographism* exhibit linear wheals following minor pressure or scratching of the skin. It is a common disorder, affecting ~5% of the population. *Solar urticaria* characteristically occurs within minutes of sun exposure and is a skin sign of one systemic disease—erythropoietic protoporphyria. In addition to the urticaria, these patients have subtle pitted scarring of the nose and hands. *Cold urticaria* is precipitated by exposure to the cold, and therefore exposed areas are usually affected. In some patients, the disease is associated with abnormal circulating proteins—more commonly cryoglobulins and less commonly cryofibrinogens or cold agglutinins. Additional systemic symptoms include wheezing and syncope, thus explaining the need for these patients to avoid swimming in cold water. *Cholinergic urticaria* is precipitated by heat, exercise, or emotion and is characterized by small wheals with relatively large flares. It is occasionally associated with wheezing.

Whereas urticarias are the result of dermal edema, subcutaneous edema leads to the clinical picture of *angioedema*. Sites of involvement include the eyelids, lips, tongue, larynx, and gastrointestinal tract as well as the subcutaneous tissue. Angioedema occurs alone or in combination with urticaria, including urticarial vasculitis and the physical urticarias. Both acquired and hereditary (autosomal dominant) forms of angioedema occur (Chap. 311), and in the latter, urticaria is rarely, if ever, seen.

Urticarial vasculitis is an immune complex disease that may be confused with simple urticaria. In contrast to simple urticaria, individual lesions tend to last longer than 24 h and usually develop central petechiae that can be observed even after the urticarial phase has resolved. The patient may also complain of burning rather than pruritus. On biopsy, there is a leukocytoclastic vasculitis of the small blood vessels. Although many cases of urticarial vasculitis are idiopathic in origin, it can be a reflection of an underlying systemic illness such as lupus erythematosus, Sjögren's syndrome, or hereditary complement deficiency. There is a spectrum of urticarial vasculitis that ranges from purely cutaneous to multisystem involvement. The most common systemic signs and symptoms are arthralgias and/or arthritis, nephritis, and crampy abdominal pain, with asthma and chronic obstructive lung disease seen less often. Hypocomplementemia occurs in one- to two-thirds of patients, even in the idiopathic cases. Urticarial vasculitis can also be seen in patients with *hepatitis B* and *hepatitis C* infections, *serum sickness*, and *serum sickness–like illnesses*.

PAPULONODULAR SKIN LESIONS

(Table 54-15) In the *papulonodular diseases*, the lesions are elevated above the surface of the skin and may coalesce to form plaques. The location, consistency, and color of the lesions are the keys to their diagnosis; this section is organized on the basis of color.

WHITE LESIONS

In *calcinosis cutis* there are firm white to white-yellow papules with an irregular surface. When the contents are expressed, a chalky white material is seen. *Dystrophic calcification* is seen at sites of previous inflammation or damage to the skin. It develops in acne scars as well as on the distal extremities of patients with scleroderma and in the subcutaneous tissue and intermuscular fascial planes in DM. The latter is more extensive and is more commonly seen in children. An elevated calcium phosphate product, most commonly due to secondary hyperparathyroidism in the setting of renal failure, can lead to nodules of *metastatic calcinosis cutis*, which tend to be subcutaneous and periarticular. These patients can also develop calcification of muscular arteries and subsequent ischemic necrosis (calciphylaxis).

SKIN-COLORED LESIONS

There are several types of skin-colored lesions, including epidermoid inclusion cysts, lipomas, rheumatoid nodules, neurofibromas, angiofibromas, neuromas, and adnexal tumors such as tricholemmomas. Both *epidermoid inclusion cysts* and *lipomas* are very common mobile subcutaneous nodules—the former are rubbery and drain cheeselike material (sebum and keratin) if incised. Lipomas are firm and somewhat lobulated on palpation. When extensive facial epidermoid inclusion cysts develop during childhood or there is a family history of such lesions, the patient should be examined for other signs of Gardner syndrome, including osteomas and desmoid tumors. *Rheumatoid nodules* are firm, 0.5- to 4-cm nodules that tend to localize around pressure points, especially the elbows. They are seen in ~20% of patients with rheumatoid arthritis and 6% of patients with Still's disease. Biopsies of the nodules show palisading granulomas. Similar lesions that are smaller and shorter-lived are seen in rheumatic fever.

Neurofibromas (benign Schwann cell tumors) are soft papules or nodules that exhibit the "button-hole" sign, that is, they invaginate into the skin with pressure in a manner similar to a hernia. Single lesions are seen in normal individuals, but multiple neurofibromas, usually in combination with six or more CALM measuring >1.5 cm (see "Hyperpigmentation," above), axillary freckling, and multiple Lisch nodules, are seen in von Recklinghausen's disease (NF type I; Chap. 375). In some patients the neurofibromas are localized and unilateral due to somatic mosaicism.

Angiofibromas are firm, pink to skin-colored papules that measure from 3 mm to a few centimeters in diameter. When multiple lesions are located on the central cheeks (adenoma sebaceum), the patient has tuberous sclerosis or MEN syndrome, type 1. The former is an autosomal disorder due to mutations in two different genes, and the associated findings are discussed in the section on ash leaf spots as well as in Chap. 375.

Neuromas (benign proliferations of nerve fibers) are also firm, skin-colored papules. They are more commonly found at sites of amputation and as rudimentary supernumerary digits. However, when there are multiple neuromas on the eyelids, lips, distal tongue, and/or oral mucosa, the patient should be investigated for other signs of the MEN syndrome, type 2b. Associated findings include marfanoid habitus, protuberant lips, intestinal ganglioneuromas, and medullary thyroid carcinoma (>75% of patients; Chap. 345).

Adnexal tumors are derived from pluripotent cells of the epidermis that can differentiate toward hair, sebaceous, apocrine, or eccrine glands or remain undifferentiated. *Basal cell carcinomas* (BCCs) are examples of adnexal tumors that have little or no evidence of differentiation. Clinically, they are translucent papules with rolled borders, telangiectasias, and central erosion. BCCs commonly arise in sun-damaged skin of the head and neck as well as the upper trunk. When a patient has multiple BCCs, especially prior to age 30, the possibility of the nevoid basal cell carcinoma syndrome should be raised. It is inherited as an autosomal

TABLE 54-15 PAPULONODULAR SKIN LESIONS ACCORDING TO COLOR GROUPS

Note: MEN, multiple endocrine neoplasia.

dominant trait and is associated with jaw cysts, palmar and plantar pits, frontal bossing, medulloblastomas, and calcification of the falx cerebri and diaphragma sellae. *Tricholemmomas* are also skin-colored adnexal tumors but differentiate toward hair follicles and can have a wartlike appearance. The presence of multiple tricholemmomas on the face and cobblestoning of the oral mucosa points to the diagnosis of Cowden disease (multiple hamartoma syndrome) due to mutations in the *PTEN* gene. Internal organ involvement (in decreasing order of frequency) includes fibrocystic disease and carcinoma of the breast, adenomas and carcinomas of the thyroid, and gastrointestinal polyposis. Keratoses of the palms, soles, and dorsal aspect of the hands are also seen.

PINK LESIONS

The cutaneous lesions associated with primary systemic *amyloidosis* are often pink in color and translucent. Common locations are the face, especially the periorbital and perioral regions, and flexural areas. On biopsy, homogeneous deposits of amyloid are seen in the dermis and in the walls of blood vessels; the latter lead to an increase in vessel wall fragility. As a result, petechiae and purpura develop in clinically normal skin as well as in lesional skin following minor trauma, hence the term *pinch purpura*. Amyloid deposits are also seen in the striated muscle of the tongue and result in macroglossia.

Even though specific mucocutaneous lesions are rarely seen in secondary amyloidosis and are present in only ~30% of the patients with primary amyloidosis, a rapid diagnosis of systemic amyloidosis can be made by an examination of abdominal subcutaneous fat. By special staining, deposits are seen around blood vessels or individual fat cells in 40–50% of patients. There are also three forms of amyloidosis that are limited to the skin and that should not be construed as cutaneous lesions of systemic amyloidosis. They are macular amyloidosis (upper back), lichenoid amyloidosis (usually lower extremities), and nodular amyloidosis. In macular and lichenoid amyloidosis, the deposits are composed of altered epidermal keratin. Recently, macular and lichenoid amyloidosis have been associated with MEN syndrome, type 2a.

Patients with *multicentric reticulohistiocytosis* also have pink-colored papules and nodules on the face and mucous membranes as well as on the extensor surface of the hands and forearms. They have a polyarthritis that can mimic rheumatoid arthritis clinically. On histologic examination, the papules have characteristic giant cells that are not seen in biopsies of rheumatoid nodules. Pink to skin-colored papules that are firm, 2–5 mm in diameter, and often in a linear arrangement are seen in patients with *papular mucinosis*. This disease is also referred to as *generalized lichen myxedematosus* or *scleromyxedema*. The latter name comes from the brawny induration of the face and extremities that may accompany the papular eruption. Biopsy specimens of the papules show localized mucin deposition, and serum protein electrophoresis and/or immunofixation electrophoresis demonstrates a monoclonal spike of IgG, usually with a λ light chain.

YELLOW LESIONS

Several systemic disorders are characterized by yellow-colored cutaneous papules or plaques—hyperlipidemia (xanthomas), gout (tophi), diabetes (necrobiosis lipoidica), pseudoxanthoma elasticum, and Torre syndrome (sebaceous tumors). Eruptive xanthomas are the most common form of *xanthomas* and are associated with hypertriglyceridemia (types I, III, IV, and V). Crops of yellow papules with erythematous halos occur primarily on the extensor surfaces of the extremities and the buttocks, and they spontaneously involute with a fall in serum triglycerides. Increased β-lipoproteins (primarily types II and III) result in one or more of the following types of xanthoma: xanthelasma, tendon xanthomas, and plane xanthomas. Xanthelasma are found on the eyelids, whereas tendon xanthomas are frequently associated with the Achilles and extensor finger tendons; plane xanthomas are flat and favor the palmar creases, face, upper trunk, and scars. Tuberous xanthomas are frequently associated with hypertriglyceridemia, but they are also seen in patients with hypercholesterolemia (type II) and are found most frequently over the large joints or hand. Biopsy specimens of xanthomas show collections of lipid-containing macrophages (foam cells).

Patients with several disorders, including biliary cirrhosis, can have a secondary form of hyperlipidemia with associated tuberous and planar xanthomas. However, patients with myeloma have *normolipemic flat xanthomas*. This latter form of xanthoma may be ≥12 cm in diameter and is most frequently seen on the upper trunk or side of the neck. It is important to note that the most common setting for eruptive xan-

thomas is uncontrolled diabetes mellitus. The least specific sign for hyperlipidemia is xanthelasma, because at least 50% of the patients with this finding have normal lipid profiles.

In *tophaceous gout* there are deposits of monosodium urate in the skin around the joints, particularly those of the hands and feet. Additional sites of *tophi* formation include the helix of the ear and the olecranon and prepatellar bursae. The lesions are firm, yellow in color, and occasionally discharge a chalky material. Their size varies from 1 mm to 7 cm, and the diagnosis can be established by polarization of the aspirated contents of a lesion. Lesions of *necrobiosis lipoidica* are found primarily on the shins (90%), and patients can have diabetes mellitus or develop it subsequently. Characteristic findings include a central yellow color, atrophy (transparency), telangiectasias, and an erythematous border. Ulcerations can also develop within the plaques. Biopsy specimens show necrobiosis of collagen, granulomatous inflammation, and obliterative endarteritis.

In *pseudoxanthoma elasticum* (PXE) there is an abnormal deposition of calcium on the elastic fibers of the skin, eye, and blood vessels. In the skin, the flexural areas such as the neck, axillae, antecubital fossae, and inguinal area are the primary sites of involvement. Yellow papules coalesce to form reticulated plaques that have an appearance similar to that of plucked chicken skin. In severely affected skin, hanging, redundant folds develop. Biopsy specimens of involved skin show swollen and irregularly clumped elastic fibers with deposits of calcium. In the eye, the calcium deposits in Bruch's membrane lead to angioid streaks and choroiditis; in the arteries of the heart, kidney, gastrointestinal tract, and extremities, the deposits lead to angina, hypertension, gastrointestinal bleeding, and claudication, respectively. Long-term administration of D-penicillamine can lead to PXE-like skin changes as well as elastic fiber alterations in internal organs.

Adnexal tumors that have differentiated toward sebaceous glands include sebaceous adenoma, sebaceous carcinoma, and sebaceous hyperplasia. Except for sebaceous hyperplasia, which is commonly seen on the face, these tumors are fairly rare. Patients with Torre syndrome have one or more *sebaceous adenoma(s)*, and they can also have sebaceous carcinomas and sebaceous hyperplasia as well as keratoacanthomas. The internal manifestations of Torre syndrome include *multiple* carcinomas of the gastrointestinal tract (primarily colon) as well as cancers of the larynx, genitourinary tract, and endometrium.

RED LESIONS

Cutaneous lesions that are red in color have a wide variety of etiologies; in an attempt to simplify their identification, they will be subdivided into papules, papules/plaques, and subcutaneous nodules. Common red papules include *arthropod bites* and *cherry hemangiomas*; the latter are small, bright-red, dome-shaped papules that represent benign proliferation of capillaries. In patients with AIDS, the development of multiple red hemangioma-like lesions points to bacillary angiomatosis, and biopsy specimens show clusters of bacilli that stain positive with the Warthin-Starry stain; the pathogens have been identified as *Bartonella henselae* and *B. quintana*. Disseminated visceral disease is seen primarily in immunocompromised hosts but can occur in immunocompetent individuals.

Multiple *angiokeratomas* are seen in Fabry disease, an X-linked recessive lysosomal storage disease that is due to a deficiency of α-galactosidase A. The lesions are red to red-blue in color and can be quite small in size (1–3 mm), with the most common location being the lower trunk. Associated findings include chronic renal failure, peripheral neuropathy, and corneal opacities (cornea verticillata). Electron photomicrographs of angiokeratomas and clinically normal skin demonstrate lamellar lipid deposits in fibroblasts, pericytes, and endothelial cells that are diagnostic of this disease. Widespread acute eruptions of erythematous papules are discussed in the section on exanthems.

There are several infectious diseases that present as erythematous papules or nodules in a lymphocutaneous or sporotrichoid pattern, i.e., in a linear arrangement along the lymphatic channels. The two most common etiologies are *Sporothrix schenckii* (sporotrichosis) and *M. marinum* (mycobacteria other than tuberculosis; atypical mycobacteria). The organisms are introduced as a result of trauma, and a primary inoculation site is often seen in addition to the lymphatic nodules. Additional causes include *Nocardia*, *Leishmania*, and other dimorphic fungi; culture of lesional tissue will aid in the diagnosis.

The diseases that are characterized by erythematous plaques with scale are reviewed in the papulosquamous section, and the various forms of dermatitis are discussed in the section on erythroderma. Additional disorders in the differential diagnosis of red papules/plaques include *erysipelas*, *polymorphous light eruption* (PMLE), *cutaneous lymphoid hyperplasia* (lymphocytoma cutis), *cutaneous lupus*, *lymphoma cutis*, and *leukemia cutis*. The first three diseases represent primary cutaneous disorders. PMLE is characterized by erythematous papules and plaques in a primarily sun-exposed distribution—dorsum of the hand, extensor forearm, and upper trunk. Lesions follow exposure to UV-B and/or UV-A, and in northern latitudes PMLE is most severe in the late spring and early summer. A process referred to as "hardening" occurs with continued UV exposure, and the eruption fades, but in temperate climates it will recur in the spring. PMLE must be differentiated from cutaneous lupus, and this is accomplished by histologic examination and direct immunofluorescence of the lesions. Cutaneous lymphoid hyperplasia (pseudolymphoma) is a *benign* polyclonal proliferation of lymphocytes in the skin that presents as infiltrated pink-red to red-purple papules and plaques; it must be distinguished from lymphoma cutis.

Several types of red plaques are seen in patients with systemic *lupus*, including (1) erythematous urticarial plaques across the cheeks and nose in the classic butterfly rash; (2) erythematous discoid lesions with fine or "carpet-tack" scale, telangiectasias, central hypopigmentation, peripheral hyperpigmentation, follicular plugging, and atrophy located on the face, scalp, external ears, arms, and upper trunk; and (3) psoriasiform or annular lesions of subacute lupus with hypopigmented centers located primarily on the extensor arms and upper trunk. Additional cutaneous findings include (1) a violaceous flush on the face and V of the neck; (2) urticarial vasculitis (see "Urticaria," above); (3) lupus panniculitis (see below); (4) diffuse alopecia; (5) alopecia secondary to discoid lesions; (6) periungual telangiectasias and erythema; (7) EM-like lesions that may become bullous; and (8) distal ulcerations secondary to Raynaud's phenomenon, vasculitis, or livedoid vasculopathy. Patients with only discoid lesions usually have the form of lupus that is limited to the skin. However, 2–10% of these patients eventually develop systemic lupus. Direct immunofluorescence of involved skin shows deposits of IgG or IgM and C3 in a granular distribution along the dermal-epidermal junction.

In *lymphoma cutis* there is a proliferation of malignant lymphocytes or histiocytes in the skin, and the clinical appearance resembles that of cutaneous lymphoid hyperplasia—infiltrated pink-red to red-purple papules and plaques. Lymphoma cutis can occur anywhere on the surface of the skin, whereas the sites of predilection for lymphocytomas include the malar ridge, tip of the nose, and earlobes. Patients with non-Hodgkin lymphomas have specific cutaneous lesions more often than those with Hodgkin disease, and occasionally, the skin nodules precede the development of extracutaneous non-Hodgkin lymphoma or represent the only site of involvement (e.g., primary cutaneous B cell lymphoma). Arcuate lesions are sometimes seen in lymphoma and lymphocytoma cutis as well as in CTCL. *Adult T cell leukemia/lymphoma* that develops in association with HTLV-1 infection is characterized by cutaneous plaques, hypercalcemia, and circulating CD25+ lymphocytes. *Leukemia cutis* has the same appearance as lymphoma cutis, and specific lesions are seen more commonly in monocytic leukemias than in lymphocytic or granulocytic leukemias. Cutaneous chloromas (granulocytic sarcomas) may precede the appearance of circulating blasts in acute myelogeneous leukemia and, as such, represent a form of aleukemic leukemia cutis.

Common causes of erythematous subcutaneous nodules include inflamed epidermoid inclusion cysts, acne cysts, and furuncles. *Panniculitis*, an inflammation of the fat, also presents as subcutaneous nodules and is frequently a sign of systemic disease. There are several forms of panniculitis, including erythema nodosum, erythema induratum/nodular vasculitis, lupus profundus, lipodermatosclerosis, α_1-antitrypsin deficiency, factitial, and fat necrosis secondary to pancreatic disease. Except for erythema nodosum, these lesions may break down and ulcerate or

heal with a scar. The shin is the most common location for the nodules of erythema nodosum, whereas the calf is the most common location for lesions of erythema induratum. In erythema nodosum the nodules are initially red but then develop a blue color as they resolve. Patients with erythema nodosum but no underlying systemic illness can still have fever, malaise, leukocytosis, arthralgias, and/or arthritis. However, the possibility of an underlying illness should be excluded, and the most common associations are streptococcal infections, upper respiratory viral infections, sarcoidosis, and inflammatory bowel disease in addition to drugs (oral contraceptives, sulfonamides, penicillins, bromides, iodides). Less common associations include bacterial gastroenteritis (*Yersinia*, *Salmonella*) and coccidioidomycosis followed by tuberculosis, histoplasmosis, brucellosis, and infections with *Chlamydophila pneumoniae* or *Chlamydia trachomatis, M. pneumoniae,* or hepatitis B virus.

Erythema induratum and nodular vasculitis share a similar histology and were thought to represent the clinical spectrum of a single entity; subsequently they have been separated, with the latter usually idiopathic and the former associated with the presence of *M. tuberculosis* DNA by polymerase chain reaction (PCR) within skin lesions. The lesions of lupus profundus are found primarily on the upper arms and buttocks (sites of abundant fat) and are seen in both the cutaneous and systemic forms of lupus. The overlying skin may be normal, erythematous, or have the changes of discoid lupus. The subcutaneous fat necrosis that is associated with pancreatic disease is presumably secondary to circulating lipases and is seen in patients with pancreatic carcinoma as well as in patients with acute and chronic pancreatitis. In this disorder there may be an associated arthritis, fever, and inflammation of visceral fat. Histologic examination of deep incisional biopsy specimens will aid in the diagnosis of the particular type of panniculitis.

Subcutaneous erythematous nodules are also seen in *cutaneous polyarteritis nodosa* (PAN) and as a manifestation of *systemic vasculitis*, e.g., systemic PAN, allergic granulomatosis, or Wegener's granulomatosis (Chap. 319). Cutaneous PAN presents with painful subcutaneous nodules and ulcers within a red-purple, netlike pattern of livedo reticularis. The latter is due to slowed blood flow through the superficial horizontal venous plexus. The majority of lesions are found on the lower extremity, and while arthralgias and myalgias may accompany cutaneous PAN, there is no evidence of systemic involvement. In both the cutaneous and systemic forms of vasculitis, skin biopsy specimens of the associated nodules will show the changes characteristic of a vasculitis; the size of the vessel involved will depend on the particular disease.

RED-BROWN LESIONS

The cutaneous lesions in *sarcoidosis* (Chap. 322) are classically red to red-brown in color, and with diascopy (pressure with a glass slide) a yellow-brown residual color is observed that is secondary to the granulomatous infiltrate. The waxy papules and plaques may be found anywhere on the skin, but the face is the most common location. Usually there are no surface changes, but occasionally the lesions will have scale. Biopsy specimens of the papules show "naked" granulomas in the dermis, i.e., granulomas surrounded by a minimal number of lymphocytes. Other cutaneous findings in sarcoidosis include annular lesions with an atrophic or scaly center, papules within scars, hypopigmented macules and papules, alopecia, acquired ichthyosis, erythema nodosum, and lupus pernio (see below).

The differential diagnosis of sarcoidosis includes foreign-body granulomas produced by chemicals such as beryllium and zirconium, late secondary syphilis, and *lupus vulgaris*. Lupus vulgaris is a form of cutaneous tuberculosis that is seen in previously infected and sensitized individuals. There is often underlying active tuberculosis elsewhere, usually in the lungs or lymph nodes. At least 90% of the lesions occur in the head and neck area and are red-brown plaques with a yellow-brown color on diascopy. Secondary scarring and squamous cell carcinomas can develop within the plaques. Cultures or PCR analysis of the lesions should be done because it is rare for the acid-fast stain to show bacilli within the dermal granulomas.

Sweet's syndrome is characterized by red to red-brown plaques and nodules that are frequently painful and occur primarily on the head, neck, and upper extremities. The patients also have fever, neutrophilia, and a dense dermal infiltrate of neutrophils in the lesions. In ~10% of the patients there is an associated malignancy, most commonly acute myelogenous leukemia. Sweet's syndrome has also been reported with lymphoma, myeloma, myelodysplastic syndromes, and solid tumors (primarily of the genitourinary tract) as well as drugs (e.g., *all-trans*-retinoic acid). The differential diagnosis includes neutrophilic eccrine hidradenitis and atypical forms of pyoderma gangrenosum. Extracutaneous sites of involvement include joints, muscles, eye, kidney (proteinuria, occasionally glomerulonephritis), and lung (neutrophilic infiltrates). The idiopathic form of Sweet's syndrome is seen more often in women, following a respiratory tract infection.

A generalized distribution of red-brown macules and papules is seen in the form of mastocytosis known as *urticaria pigmentosa* (Chap. 311). Each lesion represents a collection of mast cells in the dermis, with hyperpigmentation of the overlying epidermis. Stimuli such as rubbing cause these mast cells to degranulate, and this leads to the formation of localized urticaria (Darier's sign). Additional symptoms can result from mast cell degranulation and include headache, flushing, diarrhea, and pruritus. Mast cells also infiltrate various organs such as the liver, spleen, and gastrointestinal tract, and accumulations of mast cells in the bones may produce either osteosclerotic or osteolytic lesions on radiographs. In the majority of these patients, however, the internal involvement remains indolent. A subtype of chronic cutaneous small-vessel vasculitis, *erythema elevatum diutinum* (EED), also presents with papules that are red-brown in color. The papules coalesce into plaques on the extensor surfaces of knees, elbows, and the small joints of the hand. Flares of EED have been associated with streptococcal infections.

BLUE LESIONS

Lesions that are blue in color are the result of either vascular ectasias and tumors or melanin pigment in the dermis. *Venous lakes* (ectasias) are compressible dark-blue lesions that are found commonly in the head and neck region. *Venous malformations* are also compressible blue papulonodules and plaques that can occur anywhere on the body, including the oral mucosa. When there are multiple rather than single congenital lesions, the patient may have the blue rubber bleb syndrome or Mafucci's syndrome. Patients with the blue rubber bleb syndrome also have vascular anomalies of the gastrointestinal tract that may bleed, whereas patients with Mafucci's syndrome have associated dyschondroplasia and osteochondromas. *Blue nevi* (moles) are seen when there are collections of pigment-producing nevus cells in the dermis. These benign papular lesions are dome-shaped and occur most commonly on the dorsum of the hand or foot or in the head and neck region.

VIOLACEOUS LESIONS

Violaceous papules and plaques are seen in *lupus pernio*, *lymphoma cutis*, and *cutaneous lupus*. Lupus pernio is a particular type of sarcoidosis that involves the tip and alar rim of the nose as well as the earlobes, with lesions that are violaceous in color rather than red-brown. This form of sarcoidosis is associated with involvement of the upper respiratory tract. The plaques of lymphoma cutis and cutaneous lupus may be red or violaceous in color and were discussed above.

PURPLE LESIONS

Purple-colored papules and plaques are seen in vascular tumors, such as *Kaposi's sarcoma* (Chap. 182) and *angiosarcoma*, and when there is extravasation of red blood cells into the skin in association with inflammation, as in *palpable purpura* (see "Purpura," below). Patients with congenital or acquired AV fistulas and venous hypertension can develop purple papules on the lower extremities that can resemble Kaposi's sarcoma clinically and histologically; this condition is referred to as pseudo-Kaposi sarcoma (acral angiodermatitis). Angiosarcoma is found most commonly on the scalp and face of elderly patients or within areas of chronic lymphedema and presents as purple papules and plaques. In the head and neck region the tumor often extends beyond the clinically defined borders and may be accompanied by facial edema.

BROWN AND BLACK LESIONS

Brown- and black-colored papules are reviewed in "Hyperpigmentation," above.

CUTANEOUS METASTASES

These are discussed last because they can have a wide range of colors. Most commonly they present as either firm, skin-colored subcutaneous nodules or firm, red to red-brown papulonodules. The lesions of lymphoma cutis range from pink-red to plum in color, whereas metastatic melanoma can be pink, blue, or black in color. Cutaneous metastases develop from hematogenous or lymphatic spread and are most often due to the following primary carcinomas: in men, lung, colon, melanoma, and oral cavity; and in women, breast, melanoma, and lung. These metastatic lesions may be the initial presentation of the carcinoma, especially when the primary site is the lung, kidney, or ovary.

PURPURA

(Table 54-16) *Purpura* are seen when there is an extravasation of red blood cells into the dermis and, as a result, the lesions do not blanch with pressure. This is in contrast to those erythematous or violet-colored lesions that are due to localized vasodilatation—they do blanch with pressure. Purpura (≥3 mm) and petechiae (≤2 mm) are divided into two major groups, palpable and nonpalpable. The most frequent causes of *nonpalpable* petechiae and purpura are primary cutaneous disorders such as *trauma*, *solar* (*actinic*) *purpura*, and *capillaritis*. Less common causes are *steroid purpura* and *livedoid vasculopathy* (see "Ulcers," below). Solar purpura are seen primarily on the extensor forearms, while steroid purpura secondary topotent topical glucocorticoids or endogenous or exogenous Cushing's syndrome can be more widespread. In both cases there is alteration of the supporting connective tissue that surrounds the dermal blood vessels. In contrast, the petechiae that result from capillaritis are found primarily on the lower extremities. In capillaritis there is an extravasation of erythrocytes as a result of perivascular lymphocytic inflammation. The petechiae are bright red, 1–2 mm in size, and scattered within annular or coin-shaped yellow-brown macules. The yellow-brown color is caused by hemosiderin deposits within the dermis.

TABLE 54-16 CAUSES OF PURPURA

- I. Primary cutaneous disorders
  - A. Nonpalpable
    - 1. Trauma
    - 2. Solar purpura
    - 3. Steroid purpura
    - 4. Capillaritis
    - 5. Livedoid vasculopathy[a]
- II. Systemic diseases
  - A. Nonpalpable
    - 1. Clotting disturbances
      - a. Thrombocytopenia (including ITP)
      - b. Abnormal platelet function
      - c. Clotting factor defects
    - 2. Vascular fragility
      - a. Amyloidosis
      - b. Ehlers-Danlos syndrome
      - c. Scurvy
    - 3. Thrombi
      - a. Disseminated intravascular coagulation
      - b. Monoclonal cryoglobulinemia
      - c. Heparin-induced thrombocytopenia and thrombosis
      - d. Thrombotic thrombocytopenic purpura
      - e. Warfarin reaction
    - 4. Emboli
      - a. Cholesterol
      - b. Fat
    - 5. Possible immune complex
      - a. Gardner-Diamond syndrome (autoerythrocyte sensitivity)
      - b. Waldenström's hypergammaglobulinemic purpura
  - B. Palpable
    - 1. Vasculitis
      - a. Cutaneous small-vessel vasculitis
      - b. Polyarteritis nodosa
    - 2. Emboli[b]
      - a. Acute meningococcemia
      - b. Disseminated gonococcal infection
      - c. Rocky Mountain spotted fever
      - d. Ecthyma gangrenosum

[a]Also associated with systemic diseases.
[b]Bacterial, fungal, or parasitic.
Note: ITP, idiopathic thrombocytopenic purpura.

Systemic causes of nonpalpable purpura fall into several categories, and those secondary to clotting disturbances and vascular fragility will be discussed first. The former group includes *thrombocytopenia* (Chap. 109), *abnormal platelet function* as is seen in uremia, and *clotting factor defects*. The initial site of presentation for thrombocytopenia-induced petechiae is the distal lower extremity. Capillary fragility leads to nonpalpable purpura in patients with systemic *amyloidosis* (see "Papulonodular Skin Lesions," above), disorders of collagen production such as *Ehlers-Danlos syndrome*, and *scurvy*. In scurvy there are flattened corkscrew hairs with surrounding hemorrhage on the lower extremities, in addition to gingivitis. Vitamin C is a cofactor for lysyl hydroxylase, an enzyme involved in the posttranslational modification of procollagen that is necessary for cross-link formation.

In contrast to the previous group of disorders, the purpura seen in the following group of diseases are associated with thrombi formation within vessels. It is important to note that these thrombi are demonstrable in skin biopsy specimens. This group of disorders includes disseminated intravascular coagulation (DIC), monoclonal cryoglobulinemia, thrombotic thrombocytopenic purpura, and reactions to warfarin and heparin (heparin-induced thrombocytopenia and thrombosis). DIC is triggered by several types of infection (gram-negative, gram-positive, viral, and rickettsial) as well as by tissue injury and neoplasms. Widespread purpura and hemorrhagic infarcts of the distal extremities are seen. Similar lesions are found in purpura fulminans, which is a form of DIC associated with fever and hypotension that occurs more commonly in children following an infectious illness such as varicella, scarlet fever, or an upper respiratory tract infection. In both disorders, hemorrhagic bullae can develop in involved skin.

Monoclonal cryoglobulinemia is associated with multiple myeloma, Waldenström's macroglobulinemia, lymphocytic leukemia, and lymphoma. Purpura, primarily of the lower extremities, and hemorrhagic infarcts of the fingers and toes are seen in these patients. Exacerbations of disease activity can follow cold exposure or an increase in serum viscosity. Biopsy specimens show precipitates of the cryoglobulin within dermal vessels. Similar deposits have been found in the lung, brain, and renal glomeruli. Patients with *thrombotic thrombocytopenic purpura* can also have hemorrhagic infarcts as a result of intravascular thromboses. Additional signs include thrombocytopenic purpura, fever, and microangiopathic hemolytic anemia (Chap. 101).

Administration of *warfarin* can result in painful areas of erythema that become purpuric and then necrotic with an adherent black eschar; the condition is referred to as warfarin-induced necrosis. This reaction is seen more often in women and in areas with abundant subcutaneous fat—breasts, abdomen, buttocks, thighs, and calves. The erythema and purpura develop between the third and tenth day of therapy, most likely as a result of a transient imbalance in the levels of anticoagulant and procoagulant vitamin K–dependent factors. Continued therapy does not exacerbate preexisting lesions, and patients with an inherited or acquired deficiency of protein C are at increased risk for this particular reaction as well as for purpura fulminans.

Purpura secondary to *cholesterol emboli* are usually seen on the lower extremities of patients with atherosclerotic vascular disease. They often follow anticoagulant therapy or an invasive vascular procedure such as an arteriogram but also occur spontaneously from disintegration of atheromatous plaques. Associated findings include livedo reticularis, gangrene, cyanosis, and ischemic ulcerations. Multiple step sections of the biopsy specimen may be necessary to demonstrate the cholesterol clefts within the vessels. Petechiae are also an important sign of *fat embolism* and occur primarily on the upper body 2–3 days after a major injury. By using special fixatives, the emboli can be demonstrated in biopsy specimens of the petechiae. Emboli of tumor or thrombus are seen in patients with atrial myxomas and marantic endocarditis.

In the *Gardner-Diamond syndrome* (autoerythrocyte sensitivity), female patients develop large ecchymoses within areas of painful, warm erythema. Intradermal injections of autologous erythrocytes or phos-

phatidyl serine derived from the red cell membrane can reproduce the lesions in some patients; however, there are instances where a reaction is seen at an injection site of the forearm but not in the midback region. The latter has led some observers to view Gardner-Diamond syndrome as a cutaneous manifestation of severe emotional stress. More recently, the possibility of platelet dysfunction (as assessed via aggregation studies) has been raised. *Waldenström's hypergammaglobulinemic purpura* is a chronic disorder characterized by petechiae on the lower extremities. There are circulating complexes of IgG–anti-IgG molecules, and exacerbations are associated with prolonged standing or walking.

Palpable purpura are further subdivided into vasculitic and embolic. In the group of vasculitic disorders, cutaneous small-vessel vasculitis, also known as *leukocytoclastic vasculitis* (LCV), is the one most commonly associated with palpable purpura (Chap. 319). Underlying etiologies include drugs (e.g., antibiotics), infections (e.g., hepatitis C virus), and autoimmune connective tissue diseases. *Henoch-Schönlein purpura* is a subtype of acute LCV that is seen primarily in children and adolescents following an upper respiratory infection. The majority of lesions are found on the lower extremities and buttocks. Systemic manifestations include fever, arthralgias (primarily of the knees and ankles), abdominal pain, gastrointestinal bleeding, and nephritis. Direct immunofluorescence examination shows deposits of IgA within dermal blood vessel walls. In *polyarteritis nodosa*, specific cutaneous lesions result from a vasculitis of arterial vessels or there may be an associated LCV. The arteritis leads to ischemia of the skin, and this explains the irregular outline of the purpura (see below).

Several types of infectious emboli can give rise to palpable purpura. These embolic lesions are usually *irregular* in outline as opposed to the lesions of LCV, which are *circular* in outline. The irregular outline is indicative of a cutaneous infarct, and the size corresponds to the area of skin that received its blood supply from that particular arteriole or artery. The palpable purpura in LCV are circular because the erythrocytes simply diffuse out evenly from the postcapillary venules as a result of inflammation. Infectious emboli are most commonly due to gram-negative cocci (meningococcus, gonococcus), gram-negative rods (Enterobacteriaceae), and gram-positive cocci (*Staphylococcus*). Additional causes include *Rickettsia* and, in immunocompromised patients, *Candida* and opportunistic fungi.

The embolic lesions in *acute meningococcemia* are found primarily on the trunk, lower extremities, and sites of pressure, and a gunmetal-gray color often develops within them. Their size varies from 1 mm to several centimeters, and the organisms can be cultured from the lesions. Associated findings include a preceding upper respiratory tract infection, fever, meningitis, DIC, and, in some patients, a deficiency of the terminal components of complement. In *disseminated gonococcal infection* (arthritis-dermatitis syndrome), a small number of papules and vesicopustules with central purpura or hemorrhagic necrosis are found on the distal extremities. Additional symptoms include arthralgias, tenosynovitis, and fever. To establish the diagnosis, a Gram stain of these lesions should be performed. *Rocky Mountain spotted fever* is a tick-borne disease that is caused by *R. rickettsii*. A several-day history of fever, chills, severe headache, and photophobia precedes the onset of the cutaneous eruption. The initial lesions are erythematous macules and papules on the wrists, ankles, palms, and soles. With time, the lesions spread centripetally and become purpuric.

Lesions of *ecthyma gangrenosum* begin as edematous, erythematous papules or plaques and then develop central purpura and necrosis. Bullae formation also occurs in these lesions, and they are frequently found in the girdle region. The organism that is classically associated with ecthyma gangrenosum is *Pseudomonas aeruginosa*, but other gram-negative rods such as *Klebsiella*, *Escherichia coli*, and *Serratia* can produce similar lesions. In immunocompromised hosts, the list of potential pathogens is expanded to include *Candida* and opportunistic fungi.

ULCERS

The approach to the patient with a cutaneous ulcer is outlined in Table 54-17. Peripheral vascular diseases of the extremities are reviewed in Chap. 243, as is Raynaud's phenomenon.

TABLE 54-17 CAUSES OF CUTANEOUS ULCERS

[d]Favors plantar surface of the foot.
Note: TEN, toxic epidermal necrolysis.

Livedoid vasculopathy (livedoid vasculitis; atrophie blanche) represents a combination of a vasculopathy plus intravascular thrombosis. Purpuric lesions and livedo reticularis are found in association with *painful* ulcerations of the lower extremities. These ulcers are often slow to heal, but when they do, irregularly shaped white scars are formed. The majority of cases are secondary to venous hypertension, but possible underlying illnesses include cryofibrinogenemia and disorders of hypercoagulability, e.g., the antiphospholipid syndrome (Chaps. 111 and 313).

In *pyoderma gangrenosum*, the border of the ulcers has a characteristic appearance of an undermined necrotic violaceous edge and a peripheral erythematous halo. The ulcers often begin as pustules that then expand rather rapidly to a size as large as 20 cm. Although these lesions are most commonly found on the lower extremities, they can arise anywhere on the surface of the body, including sites of trauma (pathergy). An estimated 30–50% of cases are idiopathic, and the most common associated disorders are ulcerative colitis and Crohn's disease. Less commonly, pyoderma gangrenosum is associated with seropositive rheumatoid arthritis, acute and chronic myelogenous leukemia, hairy cell leukemia, and myelofibrosis. Additional findings in these patients, even those with idiopathic disease, are cutaneous anergy and a monoclonal gammopathy, usually IgA. Because the histology of pyoderma gangrenosum may be nonspecific (dermal infiltrate of neutrophils when in untreated state), the diagnosis is usually made clinically and includes excluding less common causes of similar-appearing ulcers such as necrotizing vasculitis, Meleney's ulcer (synergistic infection at a site of trauma or surgery), dimorphic fungi, cutaneous amebiasis, spider bites, and factitial. In the myeloproliferative disorders, the ulcers may be more superficial with a pustulobullous border, and these lesions provide a connection between classic pyoderma gangrenosum and acute febrile neutrophilic dermatosis (Sweet's syndrome).

FEVER AND RASH

The major considerations in a patient with a fever and a rash are inflammatory diseases versus infectious diseases. In the hospital setting,

the most common scenario is a patient who has a drug rash plus a fever secondary to an underlying infection. However, it should be emphasized that a drug reaction can lead to both a cutaneous eruption and a fever ("drug fever"), especially in the setting of DRESS. Additional inflammatory diseases that are often associated with a fever include pustular psoriasis, erythroderma, and Sweet's syndrome. Lyme disease, secondary syphilis, and viral and bacterial exanthems (see "Exanthems," above) are examples of infectious diseases that produce a rash and a fever. Lastly, it is important to determine whether or not the cutaneous lesions represent septic emboli (see "Purpura," above). Such lesions usually have evidence of ischemia in the form of purpura, necrosis, or impending necrosis (gunmetal-gray color). In the patient with thrombocytopenia, however, purpura can be seen in inflammatory reactions such as morbilliform drug eruptions and infectious lesions.

55 Immunologically Mediated Skin Diseases

Kim B. Yancey, Thomas J. Lawley

A number of immunologically mediated skin diseases and immunologically mediated systemic disorders with cutaneous manifestations are now recognized as distinct entities with consistent clinical, histologic, and immunopathologic findings. Many of these disorders are due to autoimmune mechanisms. Clinically, they are characterized by morbidity (pain, pruritus, disfigurement) and in some instances by mortality (largely due to loss of epidermal barrier function and/or secondary infection). The major features of the more common immunologically mediated skin diseases are summarized in this chapter (Table 55-1), as are the systemic disorders with cutaneous manifestations.

AUTOIMMUNE CUTANEOUS DISEASES

PEMPHIGUS VULGARIS

Pemphigus refers to a group of autoantibody-mediated intraepidermal blistering diseases characterized by loss of cohesion between epidermal cells (a process termed *acantholysis*). Manual pressure to the skin of these patients may elicit the separation of the epidermis (Nikolsky's sign). This finding, while characteristic of pemphigus, is not specific to this group of disorders and is also seen in toxic epidermal necrolysis, Stevens-Johnson syndrome, and a few other skin diseases.

Pemphigus vulgaris (PV) is a mucocutaneous blistering disease that predominates in patients >40 years. PV typically begins on mucosal surfaces; it often progresses to a mucocutaneous disease in which fragile, flaccid blisters rupture to produce extensive denudation of the skin (Fig. 55-1). PV typically involves the mouth, scalp, face, neck, axilla, groin, and trunk. PV may be associated with severe skin pain; some patients experience pruritus as well. Lesions usually heal without scarring, except at sites complicated by secondary infection or mechanically induced dermal wounds. Postinflammatory

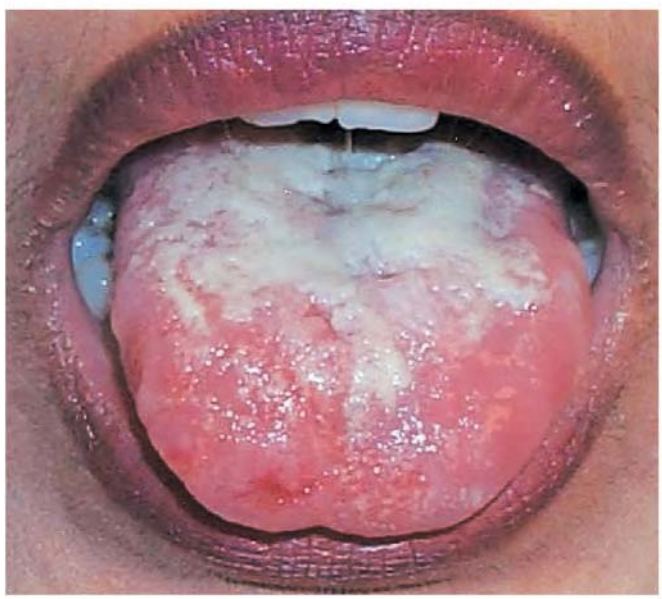
TABLE 55-1 IMMUNOLOGICALLY MEDIATED BLISTERING DISEASES

Disease	Clinical	Histology	Immunopathology	Autoantigens[a]
Pemphigus foliaceus	Crusts and shallow erosions on scalp, central face, upper chest, and back	Acantholytic blister formed in superficial layer of epidermis	Cell surface deposits of IgG on keratinocytes	Dsg1
Pemphigus vulgaris	Flaccid blisters, denuded skin, oromucosal lesions	Acantholytic blister formed in suprabasal layer of epidermis	Cell surface deposits of IgG on keratinocytes	Dsg3 (plus Dsg1 in patients with skin involvement)
Paraneoplastic pemphigus	Painful stomatitis with papulosquamous or lichenoid eruptions that progress to blisters	Acantholysis, keratinocyte necrosis and vacuolar interface dermatitis	Cell surface deposits of IgG and C3 on keratinocytes and (variably) similar immunoreactants in epidermal BMZ	Plakin protein family members and desmosomal cadherins (see text for details)
Bullous pemphigoid	Large tense blisters on flexor surfaces and trunk	Subepidermal blister with eosinophil-rich infiltrate	Linear band of IgG and/or C3 in epidermal BMZ	BPAG1, BPAG2
Pemphigoid gestationis	Pruritic, urticarial plaques, rimmed by vesicles and bullae on the trunk and extremities	Teardrop-shaped, subepidermal blisters in dermal papillae; eosinophil-rich infiltrate	Linear band of C3 in epidermal BMZ	BPAG2 (plus BPAG1 in some patients)
Linear IgA disease	Pruritic small papules on extensor surfaces; occasionally larger, arciform blisters	Subepidermal blister with neutrophil-rich infiltrate	Linear band of IgA in epidermal BMZ	BPAG2 (see text for specific details)
Cicatricial pemphigoid	Erosive and/or blistering lesions of mucous membranes and possibly the skin; scarring of some sites	Subepidermal blister that may or may not include a leukocytic infiltrate	Linear band of IgG, IgA, and/or C3 in epidermal BMZ	BPAG2, laminin 5, or others
Epidermolysis bullosa acquisita	Blisters, erosions, scars, and milia on sites exposed to trauma; widespread, inflammatory, tense blisters may be seen initially	Subepidermal blister that may or may not include a leukocytic infiltrate	Linear band of IgG and/or C3 in epidermal BMZ	Type VII collagen
Dermatitis herpetiformis	Extremely pruritic small papules and vesicles on elbows, knees, buttocks, and posterior neck	Subepidermal blister with neutrophils in dermal papillae	Granular deposits of IgA in dermal papillae	Epidermal transglutaminase

[a]Autoantigens bound by these patients' autoantibodies are defined as follows: Dsg1, desmoglein 1; Dsg3, desmoglein 3; BPAG1, bullous pemphigoid antigen 1; BPAG2, bullous pemphigoid antigen 2.

Note: BMZ, basement membrane zone.

A



B

FIGURE 55-1 Pemphigus vulgaris. *A.* Pemphigus vulgaris demonstrating flaccid bullae that are easily ruptured, resulting in multiple erosions and crusted plaques. ***B.*** Pemphigus vulgaris almost invariably involves the oral mucosa and may present with erosions involving the gingiva, buccal mucosa, palate, posterior pharynx, or the tongue. (***B,*** *Courtesy of Robert Swerlick, MD; with permission.*)

hyperpigmentation is usually present at sites of healed lesions for some time.

Biopsies of early lesions demonstrate intraepidermal vesicle formation secondary to loss of cohesion between epidermal cells (i.e., acantholytic blisters). Blister cavities contain acantholytic epidermal cells, which appear as round homogeneous cells containing hyperchromatic nuclei. Basal keratinocytes remain attached to the epidermal basement membrane, hence blister formation is within the suprabasal portion of the epidermis. Lesional skin may contain focal collections of intraepidermal eosinophils within blister cavities; dermal alterations are slight, often limited to an eosinophil-predominant leukocytic infiltrate. Direct immunofluorescence microscopy of lesional or intact patient skin shows deposits of IgG on the surface of keratinocytes; deposits of complement components are typically found in lesional but not uninvolved skin. Deposits of IgG on keratinocytes are derived from circulating autoantibodies directed against cell-surface autoantigens. Such circulating autoantibodies can be demonstrated in 80–90% of PV patients by indirect immunofluorescence microscopy; monkey esophagus is the optimal substrate for these studies. Patients with PV have IgG autoantibodies directed against *desmogleins* (Dsgs), transmembrane desmosomal glycoproteins that belong to the cadherin family of calcium-dependent adhesion molecules. Such autoantibodies can be precisely quantitated by enzyme-linked immunosorbent assay (ELISA). Patients with early PV (i.e., mucosal disease) have only IgG autoantibodies directed against Dsg3; patients with advanced PV (i.e., mucocutaneous disease) have IgG autoantibodies directed against both Dsg3 and Dsg1. Experimental studies have shown that autoantibodies from patients with PV are pathogenic (i.e., responsible for blister formation) and that their titer correlates with disease activity. Recent studies have shown that the anti-Dsg autoantibody profile in these patients' sera as well as the tissue distribution of Dsg3 and Dsg1 determine the site of blister formation in patients with pemphigus. Coexpression of Dsg3 and Dsg1 by epidermal cells protects against pathogenic IgG directed against either cadherin but not pathogenic autoantibodies directed against both.

PV can be life-threatening. Prior to the availability of glucocorticoids, the mortality ranged from 60–90%; the current mortality is ~5%. Common causes of morbidity and mortality are infection and complications of treatment with glucocorticoids. Bad prognostic factors include advanced age, widespread involvement, and the requirement for high doses of glucocorticoids (with or without other immunosuppressive agents) for control of disease. The course of PV in individual patients is variable and difficult to predict. Some patients achieve remission, while others may require long-term treatment or succumb to complications of their disease or its treatment. The mainstay of treatment is systemic glucocorticoids. Patients with moderate to severe PV are usually started on prednisone, 1 mg/kg per day. If new lesions continue to appear after 1–2 weeks of treatment, the dose may need to be increased. Many regimens combine an immunosuppressive agent with systemic glucocorticoids for control of PV. The most frequently used are azathioprine (2–2.5 mg/kg per day), mycophenolate mofetil (20–35 mg/kg per day), or cyclophosphamide (1–2 mg/kg per day). Patients with severe, treatment-resistant disease may derive benefit from plasmapheresis [six high-volume exchanges (i.e., 2–3 liters per exchange) over ~2 weeks], IV immunoglobulin (2 g/kg over 3–5 days every 6–8 weeks), or rituximab (375 mg/m^2 per week × 4). It is important to bring severe or progressive disease under control quickly to lessen the severity and/or duration of this disorder.

PEMPHIGUS FOLIACEUS

Pemphigus foliaceus (PF) is distinguished from PV by several features. In PF, acantholytic blisters are located high within the epidermis, usually just beneath the stratum corneum. Hence PF is a more superficial blistering disease than PV. The distribution of lesions in the two disorders is much the same, except that in PF mucous membranes are almost always spared. Patients with PF rarely demonstrate intact blisters but rather exhibit shallow erosions associated with erythema, scale, and crust formation. Mild cases of PF resemble severe seborrheic dermatitis; severe PF may cause extensive exfoliation. Sun exposure (ultraviolet irradiation) may be an aggravating factor. *Fogo selvagem* (FS), an endemic form of PF thought to develop as a consequence of environmental stimuli (e.g., insect bites), is found in south central rural Brazil as well as selected sites in Latin America and Tunisia.

Patients with PF have immunopathologic features in common with PV. Specifically, direct immunofluorescence microscopy of perilesional skin demonstrates IgG on the surface of keratinocytes. Similarly, patients with PF have circulating IgG autoantibodies directed against the surface of keratinocytes. Guinea pig esophagus is the optimal substrate for indirect immunofluorescence microscopy studies of sera from patients with PF. In PF, autoantibodies are directed against Dsg1, a 160-kDa desmosomal cadherin. As noted for PV, the autoantibody profile in patients with PF (i.e., anti-Dsg1 IgG) and the tissue distribution of this autoantigen (i.e., expression in oral mucosa that is compensated by coexpression of Dsg3) is thought to account for the distribution of lesions in this disease.

Although pemphigus has been associated with several autoimmune diseases, its association with thymoma and/or myasthenia gravis is particularly notable. To date, >30 cases of thymoma and/or myasthenia gravis have been reported in association with pemphigus, usually

with PF. Patients may also develop pemphigus as a consequence of drug exposure; drug-induced pemphigus usually resembles PF rather than PV. Drugs containing a thiol group in their chemical structure (e.g., penicillamine, captopril, enalapril) are most commonly associated with drug-induced pemphigus. Nonthiol drugs linked to pemphigus include penicillins, cephalosporins, and piroxicam. It has been suggested that thiol- and nonthiol-containing drugs induce pemphigus via biochemical and immunologic mechanisms, respectively. Hence, the better prognosis upon drug withdrawal in cases of pemphigus induced by thiol-containing medications. Some cases of drug-induced pemphigus are durable and require treatment with systemic glucocorticoids and/or immunosuppressive agents.

PF is generally a less severe disease than PV and carries a better prognosis. Localized disease can sometimes be treated with topical or intralesional glucocorticoids; more active cases can usually be controlled with systemic glucocorticoids. Patients with severe, treatment-resistant disease may require more aggressive interventions as described above for patients with severe PV.

PARANEOPLASTIC PEMPHIGUS

Paraneoplastic pemphigus (PNP) is an autoimmune acantholytic mucocutaneous disease associated with an occult or confirmed neoplasm. Patients with PNP typically show painful mucosal erosive lesions in association with papulosquamous and/or lichenoid eruptions that often progress to blisters. Palm and sole involvement is common in these patients and raises the possibility that prior reports of neoplasia-associated erythema multiforme actually may have represented unrecognized cases of PNP. Biopsies of lesional skin from these patients show varying combinations of acantholysis, keratinocyte necrosis, and vacuolar-interface dermatitis. Direct immunofluorescence microscopy of patient skin shows deposits of IgG and complement on the surface of keratinocytes and (variably) similar immunoreactants in the epidermal basement membrane zone. Patients with PNP have IgG autoantibodies against cytoplasmic proteins that are members of the plakin family (e.g., desmoplakins I and II, bullous pemphigoid antigen 1, envoplakin, periplakin, and plectin) and cell-surface proteins that are members of the cadherin family (e.g., Dsg3 and Dsg1). Passive transfer studies have shown that autoantibodies from patients with PNP are pathogenic.

The predominant neoplasms associated with PNP are non-Hodgkin's lymphoma, chronic lymphocytic leukemia, thymoma, spindle cell tumors, Waldenström's macroglobulinemia, and Castleman's disease; the latter is particularly common among children with PNP. In addition to severe skin lesions, many patients with PNP develop life-threatening bronchiolitis obliterans. PNP is generally resistant to conventional therapies (i.e., those used to treat PV); rare patients may improve (or even remit) following ablation or removal of underlying neoplasms.

BULLOUS PEMPHIGOID

Bullous pemphigoid (BP) is a polymorphic autoimmune subepidermal blistering disease usually seen in the elderly. Initial lesions may consist of urticarial plaques; most patients eventually display tense blisters on either normal-appearing or erythematous skin (Fig. 55-2). The lesions are usually distributed over the lower abdomen, groin, and flexor surface of the extremities; oral mucosal lesions are found in some patients. Pruritus may be nonexistent or severe. As lesions evolve, tense blisters tend to rupture and be replaced by erosions with or without surmounting crust. Nontraumatized blisters heal without scarring. The major histocompatibility complex class II allele HLA-DQβ1*0301 is prevalent in patients with BP. Despite isolated reports, several studies have shown that patients with BP do not have an increased incidence of malignancy in comparison with appropriately age- and gender-matched controls.

Biopsies of early lesional skin demonstrate subepidermal blisters and histologic features that roughly correlate with the clinical character of the particular lesion under study. Lesions on normal-appearing skin generally show a sparse perivascular leukocytic infiltrate with some eosinophils; conversely, biopsies of inflammatory lesions typically show an eosinophil-rich infiltrate at sites of vesicle formation and in perivascular areas. In addition to eosinophils, cell-rich lesions also contain mononuclear cells and neutrophils. It is not possible to distinguish BP from other subepidermal blistering diseases by routine histologic techniques alone.

FIGURE 55-2 Bullous pemphigoid with tense vesicles and bullae on erythematous, urticarial bases. (*Courtesy of the Yale Resident's Slide Collection; with permission.*)

Direct immunofluorescence microscopy of normal-appearing perilesional skin from patients with BP shows linear deposits of IgG and/or C3 in the epidermal basement membrane. The sera of ~70% of these patients contain circulating IgG autoantibodies that bind the epidermal basement membrane of normal human skin in indirect immunofluorescence microscopy. IgG from an even higher percentage of patients shows reactivity to the epidermal side of 1 *M* NaCl split skin [an alternative immunofluorescence microscopy test substrate used to distinguish circulating IgG anti-basement membrane autoantibodies in patients with BP from those in patients with similar, yet different, subepidermal blistering diseases (see below)]. In BP, circulating autoantibodies recognize 230- and 180-kDa hemidesmosome-associated proteins in basal keratinocytes [i.e., bullous pemphigoid antigen (BPAG)1 and BPAG2, respectively]. Autoantibodies against BPAG2 are thought to deposit in situ, activate complement, produce dermal mast cell degranulation, and generate granulocyte-rich infiltrates that cause tissue damage and blister formation.

BP may persist for months to years, with exacerbations or remissions. Although extensive involvement may result in widespread erosions and compromise cutaneous integrity, the mortality rate is relatively low. Nonetheless, deaths may occur in elderly and/or debilitated patients. The mainstay of treatment is systemic glucocorticoids. Patients with local or minimal disease can sometimes be controlled with topical glucocorticoids alone; patients with more extensive lesions generally respond to systemic glucocorticoids either alone or in combination with immunosuppressive agents. Patients will usually respond to prednisone, 0.75–1 mg/kg per day. In some instances, azathioprine (2–2.5 mg/kg per day), mycophenolate mofetil (20–35 mg/kg per day), or cyclophosphamide (1–2 mg/kg per day) are necessary adjuncts.

PEMPHIGOID GESTATIONIS

Pemphigoid gestationis (PG), also known as *herpes gestationis*, is a rare, nonviral, subepidermal blistering disease of pregnancy and the puerperium. PG may begin during any trimester of pregnancy or present shortly after delivery. Lesions are usually distributed over the abdomen, trunk, and extremities; mucous membrane lesions are rare. Skin lesions in these patients may be quite polymorphic and consist of erythematous urticarial papules and plaques, vesiculopapules, and/or frank bullae. Lesions are almost always very pruritic. Severe exacerbations of PG frequently occur after delivery, typically within 24–48 h. PG tends to recur in subsequent pregnancies, often beginning earlier during such gesta-

tions. Brief flare-ups of disease may occur with resumption of menses and may develop in patients later exposed to oral contraceptives. Occasionally, infants of affected mothers demonstrate transient skin lesions.

Biopsies of early lesional skin show teardrop-shaped subepidermal vesicles forming in dermal papillae in association with an eosinophil-rich leukocytic infiltrate. Differentiation of PG from other subepidermal bullous diseases by light microscopy is difficult. However, direct immunofluorescence microscopy of perilesional skin from PG patients reveals the immunopathologic hallmark of this disorder—linear deposits of C3 in epidermal basement membrane. These deposits develop as a consequence of complement activation produced by low titer IgG anti-basement membrane autoantibodies directed against BPAG2, the same hemidesmosome-associated protein that is targeted by autoantibodies in patients with BP—a subepidermal bullous disease that resembles PG clinically, histologically, and immunopathologically.

The goals of therapy in patients with PG are to prevent the development of new lesions, relieve intense pruritus, and care for erosions at sites of blister formation. Many patients require treatment with moderate doses of daily glucocorticoids (i.e., 20–40 mg prednisone) at some point in their course. Mild cases (or brief flare-ups) may be controlled by vigorous use of potent topical glucocorticoids. Infants born of mothers with PG appear to be at increased risk of being slightly premature or "small for dates." Current evidence suggests that there is no difference in the incidence of uncomplicated live births in PG patients treated with systemic glucocorticoids and in those managed more conservatively. If systemic glucocorticoids are administered, newborns are at risk for development of reversible adrenal insufficiency.

DERMATITIS HERPETIFORMIS

Dermatitis herpetiformis (DH) is an intensely pruritic, papulovesicular skin disease characterized by lesions symmetrically distributed over extensor surfaces (i.e., elbows, knees, buttocks, back, scalp, and posterior neck) (see Fig. 52-8). Primary lesions in this disorder consist of papules, papulovesicles, or urticarial plaques. Because pruritus is prominent, patients may present with excoriations and crusted papules but no observable primary lesions. Patients sometimes report that their pruritus has a distinctive burning or stinging component; the onset of such local symptoms reliably heralds the development of distinct clinical lesions 12–24 h later. Almost all DH patients have an associated, usually subclinical, gluten-sensitive enteropathy (Chap. 288), and >90% express the HLA-B8/DRw3 and HLA-DQw2 haplotypes. DH may present at any age, including childhood; onset in the second to fourth decades is most common. The disease is typically chronic.

Biopsy of early lesional skin reveals neutrophil-rich infiltrates within dermal papillae. Neutrophils, fibrin, edema, and microvesicle formation at these sites are characteristic of early disease. Older lesions may demonstrate nonspecific features of a subepidermal bulla or an excoriated papule. Because the clinical and histologic features of this disease can be variable and resemble other subepidermal blistering disorders, the diagnosis is confirmed by direct immunofluorescence microscopy of normal-appearing perilesional skin. Such studies demonstrate granular deposits of IgA (with or without complement components) in the papillary dermis and along the epidermal basement membrane zone. IgA deposits in the skin are unaffected by control of disease with medication; however, these immunoreactants may diminish in intensity or disappear in patients maintained for long periods on a strict gluten-free diet (see below). Patients with DH have granular deposits of IgA in their epidermal basement membrane zone and should be distinguished from individuals with linear IgA deposits at this site (see below).

Although most DH patients do not report overt gastrointestinal symptoms or have laboratory evidence of malabsorption, biopsies of small bowel usually reveal blunting of intestinal villi and a lymphocytic infiltrate in the lamina propria. As is true for patients with celiac disease, this gastrointestinal abnormality can be reversed by a gluten-free diet. Moreover, if maintained, this diet alone may control the skin disease and eventuate in clearance of IgA deposits from these patients' epidermal basement membrane zone. Subsequent gluten exposure in such patients alters the morphology of their small bowel, elicits a flare-up of their skin disease, and is associated with the reappearance of IgA in their epidermal basement membrane zone. As in patients with celiac disease, dietary gluten sensitivity in patients with DH is associated with IgA anti-endomysial autoantibodies that target tissue transglutaminase. Recent studies suggest that patients with DH also have high-avidity IgA autoantibodies against epidermal transglutaminase 3 and that the latter is co-localized with granular deposits of IgA in the papillary dermis of DH patients. Patients with DH also have an increased incidence of thyroid abnormalities, achlorhydria, atrophic gastritis, and antigastric parietal cell autoantibodies. These associations likely relate to the high frequency of the HLA-B8/DRw3 haplotype in these patients, since this marker is commonly linked to autoimmune disorders. The mainstay of treatment of DH is dapsone, a sulfone. Patients respond rapidly (24–48 h) to dapsone (50–200 mg/d) but require careful pretreatment evaluation and close follow-up to ensure that complications are avoided or controlled. All patients on >100 mg/d dapsone will have some hemolysis and methemoglobinemia. These are expected pharmacologic side effects of this agent. Gluten restriction can control DH and lessen dapsone requirements; this diet must rigidly exclude gluten to be of maximal benefit. Many months of dietary restriction may be necessary before a beneficial result is achieved. Good dietary counseling by a trained dietitian is essential.

LINEAR IgA DISEASE

Linear IgA disease, once considered a variant form of dermatitis herpetiformis, is actually a separate and distinct entity. Clinically, these patients may resemble individuals with DH, BP, or other subepidermal blistering diseases. Lesions typically consist of papulovesicles, bullae, and/or urticarial plaques predominantly on central or flexural sites. Oral mucosal involvement occurs in some patients. Severe pruritus resembles that seen in patients with DH. Patients with linear IgA disease do not have an increased frequency of the HLA-B8/DRw3 haplotype or an associated enteropathy and hence are not candidates for treatment with a gluten-free diet.

The histologic alterations in early lesions may be virtually indistinguishable from those in DH. However, direct immunofluorescence microscopy of normal-appearing perilesional skin reveals linear deposits of IgA (and often C3) in the epidermal basement membrane zone. Most patients with linear IgA disease demonstrate circulating IgA anti-basement membrane autoantibodies directed against neoepitopes in the proteolytically processed extracellular domain of BPAG2. These patients generally respond to treatment with dapsone, 50–200 mg/d.

EPIDERMOLYSIS BULLOSA ACQUISITA

EBA is a rare, noninherited, polymorphic, chronic, subepidermal blistering disease. (The inherited form is discussed in Chap. 357.) Patients with classic or noninflammatory EBA have blisters on noninflamed skin, atrophic scars, milia, nail dystrophy, and oral lesions. Because lesions generally occur at sites exposed to minor trauma, classic EBA is considered to be a mechanobullous disease. Other patients with EBA have widespread inflammatory, scarring, and bullous lesions that resemble severe BP. Inflammatory EBA may evolve into the classic, noninflammatory form of this disease. Rare patients present with lesions that predominate on mucous membranes. The HLA-DR2 haplotype is found with increased frequency in EBA patients. Recent studies suggest that EBA is often associated with inflammatory bowel disease (especially Crohn's disease).

The histology of lesional skin varies depending on the character of the lesion being studied. Noninflammatory bullae show subepidermal blisters with a sparse leukocytic infiltrate and resemble those in patients with porphyria cutanea tarda. Inflammatory lesions consist of neutrophil-rich subepidermal blisters. EBA patients have continuous deposits of IgG (and frequently C3 as well as other complement components) in a linear pattern within the epidermal basement membrane zone. Ultrastructurally, these immunoreactants are found in the sublamina densa region in association with anchoring fibrils. Approximately 50% of EBA patients have demonstrable circulating IgG anti-basement membrane autoantibodies directed against type VII collagen—the collagen species that comprises anchoring fibrils. Such IgG autoantibodies bind the dermal side of 1 *M* NaCl split skin (in contrast to IgG autoantibodies in patients with BP). Recent studies have shown that passive transfer of

experimental or patient IgG directed against type VII collagen can produce lesions in mice that clinically, histologically, and immunopathologically resemble those seen in patients with inflammatory EBA.

Treatment of EBA is generally unsatisfactory. Some patients with inflammatory EBA may respond to systemic glucocorticoids, either alone or in combination with immunosuppressive agents. Other patients (especially those with neutrophil-rich inflammatory lesions) may respond to dapsone. The chronic, noninflammatory form of this disease is largely resistant to treatment, although some patients may respond to cyclosporine, azathioprine, or IV immunoglobulin (IVIg).

CICATRICIAL PEMPHIGOID

Cicatricial pemphigoid (CP) is a rare, acquired, subepithelial immunobullous disease characterized by erosive lesions of mucous membranes and skin that result in scarring of at least some sites of involvement. Common sites of involvement include the oral mucosa (especially the gingiva) and conjunctiva; other sites that may be affected include the nasopharyngeal, laryngeal, esophageal, and anogenital mucosa. Skin lesions (present in about one-third of patients) tend to predominate on the scalp, face, and upper trunk and generally consist of a few scattered erosions or tense blisters on an erythematous or urticarial base. CP is typically a chronic and progressive disorder. Serious complications may arise as a consequence of ocular, laryngeal, esophageal, or anogenital lesions. Erosive conjunctivitis may result in shortened fornices, symblephara, ankyloblepharon, entropion, corneal opacities, and (in severe cases) blindness. Similarly, erosive lesions of the larynx may cause hoarseness, pain, and tissue loss that, if unrecognized and untreated, may eventuate in complete destruction of the airway. Esophageal lesions may result in stenosis and/or strictures that may place patients at risk for aspiration. Strictures may also complicate anogenital involvement.

Biopsies of lesional tissue generally demonstrate subepithelial vesiculobullae and a mononuclear leukocytic infiltrate. Neutrophils and eosinophils may be seen in biopsies of early lesions; older lesions may demonstrate a scant leukocytic infiltrate and fibrosis. Direct immunofluorescence microscopy of perilesional tissue typically demonstrates deposits of IgG, IgA, and/or C3 in the epidermal basement membrane of these patients. Because many of these patients show no evidence of circulating anti-basement membrane autoantibodies, testing of perilesional skin is important diagnostically. Although CP was once thought to be a single nosologic entity, it is now largely regarded as a disease phenotype that may develop as a consequence of an autoimmune reaction against a variety of different molecules in epidermal basement membrane (e.g., BPAG2, laminin 5, type VII collagen, and other antigens yet to be completely defined). Recent studies suggest that CP patients with anti-laminin 5 autoantibodies have an increased relative risk for cancer. Treatment of CP is largely dependent upon sites of involvement. Due to potentially severe complications, patients with ocular, laryngeal, esophageal, and/or anogenital involvement require aggressive systemic treatment with dapsone, prednisone, or the latter in combination with another immunosuppressive agent (e.g., azathioprine, mycophenolate mofetil, or cyclophosphamide) or IVIg. Less threatening forms of the disease may be managed with topical or intralesional glucocorticoids.

AUTOIMMUNE SYSTEMIC DISEASES WITH PROMINENT CUTANEOUS FEATURES

DERMATOMYOSITIS

The cutaneous manifestations of dermatomyositis (Chap. 383) are often distinctive but at times may resemble those of systemic lupus erythematosus (SLE) (Chap. 313), scleroderma (Chap. 316), or other overlapping connective tissue diseases (Chap. 316). The extent and severity of cutaneous disease may or may not correlate with the extent and severity of the myositis. The cutaneous manifestations of dermatomyositis are similar whether the disease appears in children or the elderly, except that calcification of subcutaneous tissue is a common late sequela in childhood dermatomyositis.

The cutaneous signs of dermatomyositis may precede or follow the development of myositis by weeks to years. Cases lacking muscle involvement (i.e., dermatomyositis sine myositis) have also been reported. The most common manifestation is a purple-red discoloration of the upper eyelids, sometimes associated with scaling ("heliotrope" erythema; Fig. 55-3) and periorbital edema. Erythema on the cheeks and nose in a "butterfly" distribution may resemble the malar eruption of SLE. Erythematous or violaceous scaling patches are common on the upper anterior chest, posterior neck, scalp, and the extensor surfaces of the arms, legs, and hands. Erythema and scaling may be particularly prominent over the elbows, knees, and the dorsal interphalangeal joints. Approximately one-third of patients have violaceous, flat-topped papules over the dorsal interphalangeal joints that are pathognomonic of dermatomyositis (Gottron's sign or Gottron's papules; Fig. 55-4). These lesions can be contrasted with the erythema and scaling on the dorsum of the fingers in some patients with SLE, which spares the skin over the interphalangeal joints. Periungual telangiectasia may be prominent. Lacy or reticulated erythema may be associated with fine scaling on the extensor surfaces of the thighs and upper arms. Other patients, particularly those with long-standing disease, develop areas of hypopigmentation, hyperpigmentation, mild atrophy, and telangiectasia known as *poikiloderma*. Poikiloderma is rare in both SLE and scleroderma and thus can serve as a clinical sign that distinguishes dermatomyositis from these two diseases. Cutaneous changes may be similar in scleroderma and dermatomyositis and may include thickening and binding down of the skin of the hands (sclerodac-

tyly) as well as Raynaud's phenomenon. However, the presence of severe muscle disease, Gottron's papules, heliotrope erythema, and poikiloderma serve to distinguish patients with dermatomyositis. Skin biopsy of erythematous, scaling lesions of dermatomyositis may reveal only mild nonspecific inflammation but sometimes may show changes indistinguishable from those found in SLE, including epidermal atrophy, hydropic degeneration of basal keratinocytes, edema of the upper dermis, and a mild mononuclear cell infiltrate. Direct immunofluorescence microscopy of lesional skin is usually negative, although granular deposits of immunoglobulin(s) and complement in the epidermal basement membrane zone have been described in some patients. Treatment should be directed at the systemic disease. Topical glucocorticoids are sometimes useful; patients should avoid exposure to ultraviolet irradiation and use photoprotective measures such as broad-spectrum sunscreens.

LUPUS ERYTHEMATOSUS

The cutaneous manifestations of lupus erythematosus (LE) (Chap. 313) can be divided into acute, subacute, and chronic types. *Acute cutaneous LE* is characterized by erythema of the nose and malar eminences in a "butterfly" distribution (Fig. 55-5). The erythema is often sudden in onset, accompanied by edema and fine scale, and correlated with systemic involvement. Patients may have widespread involvement of the face as well as erythema and scaling of the extensor surfaces of the extremities and upper chest. These acute lesions, while sometimes evanescent, usually last for days and are often associated with exacerbations of systemic disease. Skin biopsy of acute lesions may show only a sparse dermal infiltrate of mononuclear cells and dermal edema. In some instances, cellular infiltrates around blood vessels and hair follicles are notable, as is hydropic degeneration of basal cells of the epidermis. Direct immunofluorescence microscopy of lesional skin frequently reveals deposits of immunoglobulin(s) and complement in the epidermal basement membrane zone. Treatment is aimed at control of systemic disease; photoprotection in this, as well as in other forms of LE, is very important.

Subacute cutaneous lupus erythematosus (SCLE) is characterized by a widespread photosensitive, nonscarring eruption. Most of these patients have SLE in which renal and central nervous system involvement is mild or absent. SCLE may present as a papulosquamous eruption that resembles psoriasis or annular lesions that resemble those seen in erythema multiforme. In the papulosquamous form, discrete erythematous papules arise on the back, chest, shoulders, extensor surfaces of the arms, and the dorsum of the hands; lesions are uncommon on the face, flexor surfaces of the arms, and below the waist. These slightly scaling papules tend to merge into large plaques, some with a reticulate appearance. The annular form involves the same areas and presents with erythematous papules that evolve into oval, circular, or polycyclic lesions. The lesions of SCLE are more widespread but have less tendency for scarring than do lesions of discoid LE. Skin biopsy reveals a dense mononuclear cell infiltrate around hair follicles and blood vessels in the superficial dermis, combined with hydropic degeneration of basal cells in the epidermis. Direct immunofluorescence microscopy of lesional skin reveals deposits of immunoglobulin(s) in the epidermal basement membrane zone in about half these cases. A particulate pattern of IgG deposition throughout the epidermis has recently been associated with SCLE. Most SCLE patients have anti-Ro autoantibodies. Local therapy alone is usually unsuccessful. Most patients require treatment with aminoquinoline antimalarials. Low-dose therapy with oral glucocorticoids is sometimes necessary. Photoprotective measures against both ultraviolet B and A wavelengths are very important.

Discoid lupus erythematosus (DLE, also called *chronic cutaneous LE*) is characterized by discrete lesions, most often found on the face, scalp, and/or external ears. The lesions are erythematous papules or plaques with a thick, adherent scale that occludes hair follicles (follicular plugging). When the scale is removed, its underside shows small excrescences that correlate with the openings of hair follicles (so called "carpet tacking"), a finding relatively specific for DLE. Long-standing lesions develop central atrophy, scarring, and hypopigmentation but frequently have erythematous, sometimes raised borders (Fig. 55-6). These lesions persist for years and tend to expand slowly. Only 5–10% of patients with DLE meet the American Rheumatism Association criteria for SLE. However, typical discoid lesions are frequently seen in patients with SLE. Biopsy of DLE lesions shows hyperkeratosis, follicular plugging, atrophy of the epidermis, hydropic degeneration of basal keratinocytes, and a mononuclear cell infiltrate adjacent to epidermal, adnexal, and microvascular basement membranes. Direct immunofluorescence microscopy demonstrates immunoglobulin(s) and complement deposits at the basement membrane zone in ~90% of cases. Treatment is focused on control of local cutaneous disease and consists mainly of photoprotection and topical or intralesional glucocorticoids. If local therapy is ineffective, use of aminoquinoline antimalarials may be indicated.

SCLERODERMA AND MORPHEA

The skin changes of scleroderma (Chap. 316) usually begin on the hands, feet, and face, with episodes of recurrent nonpitting edema. Sclerosis of the skin begins distally on the fingers (sclerodactyly) and spreads proximally, usually accompanied by resorption of bone of the fingertips, which may have punched out ulcers, stellate scars, or areas of hemorrhage (Fig. 55-7). The fingers may actually shrink in size and become sausage-shaped, and since the fingernails are usually unaffected, the nails may curve over the end of the fingertips. Periungual telangiectases are usually present, but periungual erythema is rare. In advanced cases, the extremities show contractures and calcinosis cutis. Facial involvement includes a smooth, unwrinkled brow, taut skin over the nose,

FIGURE 55-6 Discoid lupus erythematosus. Violaceous, hyperpigmented, atrophic plaques, often with evidence of follicular plugging, which may result in scarring, are characteristic of discoid lupus erythematosus (also called chronic cutaneous lupus erythematosus).

shrinkage of tissue around the mouth, and perioral radial furrowing (Fig. 55-8). Matlike telangiectases are often present, particularly on the face and hands. Involved skin feels indurated, smooth, and bound to underlying structures; hyperpigmentation and hypopigmentation are also often present. Raynaud's phenomenon, i.e., cold-induced blanching, cyanosis, and reactive hyperemia, is present in almost all patients and can precede development of scleroderma by many years. The combination of calcinosis cutis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia has been termed the *CREST syndrome*. Anticentromere antibodies have been reported in a very high percentage of patients with the CREST syndrome but in only a small minority of patients with scleroderma. Skin biopsy reveals thickening of the dermis and homogenization of collagen bundles. Direct immunofluorescence microscopy of lesional skin is usually negative.

Morphea is characterized by localized thickening and sclerosis of skin, usually affecting young adults or children. Morphea begins as erythematous or flesh-colored plaques that become sclerotic, develop central hypopigmentation, and demonstrate an erythematous border. In most cases, patients have one or a few lesions, and the disease is termed *localized morphea*. In some patients, widespread cutaneous lesions may occur, without systemic involvement. This form is called *generalized morphea*. Most patients with morphea do not have autoantibodies. Skin

FIGURE 55-7 Scleroderma showing acral sclerosis and focal digital ulcers.

FIGURE 55-8 Scleroderma often eventuates in development of an expressionless, mask-like facies.

biopsy of morphea is indistinguishable from that of scleroderma. Linear scleroderma is a limited form of disease that presents in a linear, bandlike distribution and tends to involve deep as well as superficial layers of skin. Scleroderma and morphea are usually quite resistant to therapy. For this reason, physical therapy to prevent joint contractures and to maintain function is employed and is often helpful.

Diffuse fasciitis with eosinophilia is a clinical entity that can sometimes be confused with scleroderma. There is usually the sudden onset of swelling, induration, and erythema of the extremities frequently following significant physical exertion. The proximal portions of extremities (arms, forearms, thighs, legs) are more often involved than are the hands and feet. While the skin is indurated, it is usually not bound down as in scleroderma; contractures may occur early secondary to fascial involvement. The latter may also cause muscle groups to be separated and veins to appear depressed. These skin findings are accompanied by peripheral blood eosinophilia, increased erythrocyte sedimentation rate, and sometimes hypergammaglobulinemia. Deep biopsy of affected areas of skin reveals inflammation and thickening of the deep fascia overlying muscle. An inflammatory infiltrate composed of eosinophils and mononuclear cells is usually found. Patients with eosinophilic fasciitis appear to be at increased risk to develop bone marrow failure or other hematologic abnormalities. While the ultimate course of eosinophilic fasciitis is uncertain, many patients respond favorably to treatment with prednisone in doses ranging from 40–60 mg/d.

The *eosinophilia-myalgia syndrome*, a disorder reported in epidemic numbers in 1989 and linked to ingestion of L-tryptophan manufactured by a single company in Japan, is a multisystem disorder characterized by debilitating myalgias and absolute eosinophilia in association with varying combinations of arthralgias, pulmonary symptoms, and peripheral edema. In a later phase (i.e., 3–6 months after initial symptoms), these patients often develop localized sclerodermatous skin changes, weight loss, and/or neuropathy (Chap. 316). The precise cause of this syndrome, which may resemble other sclerotic skin conditions, is unknown. However, the implicated lots of L-tryptophan contained the contaminant 1,1-ethylidene bis[tryptophan]. This contaminant may be pathogenic or a marker for another substance that provokes the disorder.

56 Cutaneous Drug Reactions

Jean-Claude Roujeau, Robert S. Stern, Bruce U. Wintroub

Cutaneous reactions are among the most frequent adverse reactions to drugs. Every physician will see patients suffering from them. Most are benign, but a few can be life-threatening. Prompt recognition of severe reactions, drug withdrawal, and appropriate therapeutic interventions can minimize toxicity. This chapter focuses on adverse cutaneous reactions to drugs other than topical agents; it covers their incidence, patterns, and pathogenesis and provides some practical guidelines on treatment, assessment of causality, and future utilization of drugs.

USE OF PRESCRIPTION DRUGS IN THE UNITED STATES

In the United States more than 3 billion prescriptions for over 60,000 drug products, which include more than 2000 different active agents, are dispensed annually. Hospital inpatients alone annually receive about 120 million courses of drug therapy, and half of adult Americans receive prescription drugs on a regular outpatient basis. Many additional patients use over-the-counter medicines that may cause adverse cutaneous reactions.

INCIDENCE OF CUTANEOUS REACTIONS

Several large cohort studies established that acute cutaneous reaction to drugs affected about 3% of hospital inpatients. Reactions usually occur a few days to 4 weeks after initiation of therapy.

Many drugs of common use are associated with a 1–2% rate of "rashes" during premarketing clinical trials. The risk is often higher when medications are used in general unselected populations. The rate may reach 3–7% for amoxicillin, sulfamethoxazole, and many anticonvulsants (Table 56-1). It may be even higher with anti-HIV agents.

In addition to acute eruptions, a variety of skin diseases can be induced or exacerbated by prolonged utilization of drugs, e.g., pruritus, pigmentation, nail or hair disorders, psoriasis, and pemphigus. These chronic drug reactions are not frequent, but neither their incidence nor their impact on public health has been evaluated.

In a series of 48,005 inpatients over a 20-year period, morbilliform rash (91%) and urticaria (6%) were the most frequent skin reactions. Severe reactions are actually too rare to be detected in such cohorts. Their incidence has been estimated to be in the range of 1 in 10,000 to 1 in 1 million users. Even though they are rare, severe cutaneous reactions to drugs have an important impact on health and on the risk-versus-benefit evaluation of medicines because of significant mortality and sequelae.

TABLE 56-1 CUTANEOUS REACTIONS TO DRUGS RECEIVED BY AT LEAST 1000 PATIENTS (BCDSP)[a]

Drug	Reactions, No.	Recipients, No.	Rate, %	95% Confidence Interval
Amoxicillin	63	1225	5.1	3.9–6.4
Ampicillin	215	4763	4.5	3.9–5.1
Co-trimoxazole	46	1235	3.7	2.7–4.8
Semisynthetic penicillins	41	1436	2.9	2.0–3.7
Red blood cells	67	3386	2.0	1.5–2.4
Penicillin G	68	4204	1.6	1.2–2.0
Cephalosporins	27	1781	1.5	0.9–2.1
Gentamicin	13	1277	1.0	0.5–1.6

Some populations are at increased risks of drug reactions: patients with collagen vascular diseases, bone marrow graft recipients, and those with acute Epstein-Barr virus infection. It has also been established that HIV infection increases the risk of drug allergy (Chap. 182). This was true for many drugs but has been evaluated mainly with sulfamethoxazole. Up to 40% of HIV-infected patients had skin reactions when treated with high doses, and about 15% reacted to the same dosage that induced 3–5% eruptions in non-HIV-infected populations. How HIV promotes allergy to certain medications has not yet been explained.

PATHOGENESIS OF DRUG REACTIONS

Untoward cutaneous responses to drugs can arise as a result of immunologic or nonimmunologic mechanisms. A variety of adverse reactions result from mechanisms that do not involve an immunologic process. Drug reactions are a public health problem because of their frequent occurrence, occasional severity, and impact on the use of medications. The skin is among the organs most often affected by adverse drug reactions. The list of conditions that can be triggered by medications includes nearly all dermatologic diseases. Many of these adverse reactions result from mechanisms that do not involve an immunologic process. Obvious examples are pigmentary changes related to accumulation in the dermis of amiodarone, antimalarials, minocycline, quinolones, alteration of hair follicles by cytostatics, and lipodystrophy associated with metabolic effects of anti-HIV medications. These side effects are mostly toxic, predictable, and often can be avoided at least in part by simple preventive measures.

IMMUNOLOGIC DRUG REACTIONS

For most acute drug eruptions, benign or severe, accumulated data suggest an immunologic basis. In the last 10 years drug-specific T cell clones were derived from the blood lymphocytes or from skin lesions of patients with a variety of drug allergies. Since these clones had been obtained after several stimulations in vitro with the drug, their relevance to explain the original manifestations of allergy can be questioned. Regardless, these T cell clones brought definite evidence that drugs can be recognized as antigens by human T cells, and that these T cells play a role in drug allergy. Specific clones were obtained with penicillin G, amoxicillin, cephalosporins, sulfamethoxazole, phenobarbital, carbamazepine, lamotrigine, i.e., many of the medications that are frequently a cause of drug eruptions. Both CD4 and CD8 clones were often obtained, whatever the clinical type of eruption.

Some clones produced a T_H0 profile of cytokines (simultaneous release of IL-4 and IFN-γ). A T_H2 orientation was frequent in CD4+ clones while CD8+ clones were usually T_H1 and often cytotoxic. Drug presentation to T cell was MHC-restricted, usually as expected by HLA class II for CD4+ cells and by HLA class I for CD8. But there were also less classic situations like HLA class II restricted cytotoxic CD4 clones. With many drugs, an original observation was that the drug could be presented to the TCR and activate a specific clone without prior processing by the antigen-presenting cell and through a noncovalent binding to the MHC or its embedded peptide. Actually, some specific TCR could recognize sulfamethoxazole presented either in covalent or

noncovalent bound form, but the former was the exception and the latter the rule. Since the noncovalent binding is reminiscent of the pharmacologic interaction between a drug and its receptor, the denomination of pharmoco-immune (p-i) concept has been proposed.

Once a drug has induced an immune response, the final phenotype of the reaction probably depends on the nature of effectors: cytotoxic (CD8+) T cells in blistering reactions, chemokines for reactions mediated by neutrophils or eosinophils, and collaboration with B cells for production of specific antibodies for urticarial reactions.

Immediate Reactions Immediate reactions depend on the release of mediators of inflammation by tissue mast cells or circulating basophilic leukocytes. These mediators include histamine, leukotrienes, prostaglandins, platelet-activating factor, enzymes, and proteoglycans. Drugs can trigger mediator release either directly ("anaphylactoid" reaction) or through IgE-specific antibodies. These reactions are usually manifest in the skin and gastrointestinal, respiratory, and cardiovascular systems (Chap. 311). Primary symptoms and signs include pruritus, urticaria, nausea, vomiting, cramps, bronchospasm, and laryngeal edema—and, occasionally, anaphylactic shock with hypotension and death. They occur within minutes of drug exposure. Nonsteroidal anti-inflammatory drugs (NSAIDs), including aspirin, and radiocontrast media are frequent causes of pharmacologically mediated anaphylactoid reactions, which can occur on first exposure. Penicillins and myorelaxants used in general anesthesia are the most frequent causes of IgE-dependent reactions to drugs, which require prior sensitization. Release of mediators is triggered when polyvalent drug protein conjugates cross-link IgE molecules fixed to sensitized cells. Certain routes of administration favor different clinical patterns (e.g., gastrointestinal effects from oral route, circulatory effects from intravenous route).

Immune Complex–Dependent Reactions Because the use of nonhuman sera is now uncommon, this mechanism is rarely relevant to adverse reactions seen today. Serum sickness is produced by tissue deposition of circulating immune complexes with consumption of complement. It is characterized by fever, arthritis, nephritis, neuritis, edema, and an urticarial, papular, or purpuric rash (Chap. 319). It was first described following administration of foreign sera; it may now occur with monoclonal antibodies. In classic serum sickness, symptoms develop 6 days or more after exposure to a drug, the latent period representing the time needed to synthesize antibody. Cephalosporin administration in febrile children may be associated with a clinically similar "serum sickness–like" reaction. The real mechanism of this reaction is unknown but is unrelated to complement activation.

Cutaneous or systemic vasculitis, a relatively rare cutaneous complication of drugs, may also be a result of immune complex deposition (Chap. 319).

Delayed Hypersensitivity Delayed hypersensitivity mechanisms directed by drug-specific T cells are probably the most important mechanisms in the etiology of the most common drug eruptions—morbilliform exanthems—and also of rare and severe forms such as hypersensitivity syndrome, acute generalized exanthematous pustulosis (AGEP), Stevens-Johnson syndrome (SJS), and toxic epidermal necrolysis (TEN). Drug-specific T cells have been detected in these types of drug eruptions.

Contrary to what has been believed for years, the antigen is more often the native drug itself than its metabolites. It remains to better understand why the stimulation of T cells by medications leads to reactions that are clinically so diverse. Some answers were provided by the study of effector cells obtained at the site of skin lesions. Drug-specific cytotoxic T cells have been detected in the skin lesions of fixed drug eruptions and of TEN. In TEN, blisters that result from accumulation of interstitial fluid under the necrotic epidermis contain T lymphocytes that are able to kill autologous lymphocytes and keratinocytes in a drug-specific, HLA-restricted, and perforin/granzyme-mediated pathway.

Drug-specific clones producing CXCL8, a neutrophil-attracting chemokine, were obtained from skin tests of patients with AGEP, a neutrophil-mediated drug reaction.

One may therefore assume that the final pattern of drug eruptions results both from the nature of effectors—cytotoxic T cells in blistering reactions, chemokines in reactions mediated by neutrophils or eosinophils—and from the intensity of stimulation and response.

Genetic Factors and Cutaneous Drug Reactions Specific genetically determined defects in the ability of an individual to detoxify toxic reactive drug metabolites predispose such individuals to the development of drug toxicity. It has also been suspected that a slow acetylator phenotype increases the risk of rash from sulfonamides. However, in two large prospective cohorts of HIV-infected patients treated with sulfonamides, no association of drug eruption with acetylation genotype was found.

Recent literature shows that genetic factors may be important predictors of severe drug reactions. Hypersensitivity to the anti-HIV medication abacavir was strongly associated with HLA B*5701. In Taiwan, within a homogeneous Han Chinese population, a 100% association was observed between SJS or TEN related to carbamazepine and HLA B*1502. In the same population, another 100% association was found between SJS, TEN, or hypersensitivity syndrome/drug reaction with eosinophilia and systemic symptoms (DRESS) related to allopurinol and HLA B*5801. These observations have important theoretical implications. By pointing to HLA genes, they strongly support a key role for immune mechanisms. However, the strong associations found in Taiwan have not been observed in other countries with more heterogenous populations. Therefore, widespread practical applications of these findings are not yet possible.

CLINICAL PRESENTATION OF CUTANEOUS DRUG REACTIONS

NONIMMUNE CUTANEOUS REACTIONS

Exacerbation or Induction of Dermatologic Diseases A variety of agents can exacerbate preexisting diseases or sometimes induce a disease that may or may not disappear after withdrawal of the inducing medication. For example, NSAIDs, lithium, beta blockers, and angiotensin-converting enzyme (ACE) inhibitors can exacerbate plaque psoriasis, while antimalarials can worsen pustular psoriasis. Acne may be induced by glucocorticoids, androgens, and lithium. Minocycline and thiazide diuretics may exacerbate subacute systemic lupus erythematosus, and pemphigus can be induced by D-penicillamine, captopril, and other ACE inhibitors. The hypothesis that a drug may be responsible should always be considered, especially in cases with atypical clinical presentation, unusual age of onset, or unexpected evolution.

Photosensitivity Eruptions Photosensitivity eruptions are usually most marked in sun-exposed areas but may extend to sun-protected areas. The mechanism is almost always phototoxicity. Phototoxic reactions resemble sunburn and can occur with first exposure to a drug. Their severity depends on the tissue level of the drug, its efficiency as a photosensitizer, and the extent of exposure to the activating wavelengths of ultraviolet light (Chap. 57).

Common orally administered photosensitizing drugs include many fluoroquinolones and cycline antibiotics. Other drugs less frequently encountered are chlorpromazine, thiazides, and several NSAIDs (ibuprofen, naproxen, piroxicam). Because UV-A and visible light, which trigger these reactions, are not easily absorbed by nonopaque sunscreens and are transmitted through window glass, photosensitivity reactions may be difficult to block.

Photosensitivity reactions abate with removal of either the drug or ultraviolet radiation, use of high-potency sunscreens that block UV-A light, and treating the reaction as one would a sunburn. Rarely, individuals develop persistent reactivity to light, necessitating long-term avoidance of sun exposure.

Pigmentation Changes Drugs, either systemic or topical, may cause a variety of pigmentary changes in the skin. Oral contraceptives may induce melasma. Long-term minocycline or pefloxacin may cause blue-gray pigmentation, while amiodarone causes a more purple coloration. Long-term high-dose phenothiazine results in gray-brown pigmentation of sun-exposed areas. Numerous cancer chemothera-

peutic agents may be associated with pigmentation, e.g., bleomycin, busulfan, daunorubicin, cyclophosphamide, hydroxyurea, and methotrexate. Pigmentation changes may also occur in mucous membranes (busulfan), nails (zidovudine), hair, and teeth.

Warfarin Necrosis of Skin This rare reaction usually occurs between the third and tenth days of therapy with warfarin derivatives, usually in women. The more common sites are breasts, thighs, and buttocks. Lesions are sharply demarcated, erythematous, indurated, and purpuric and may resolve or progress to form large, irregular, hemorrhagic bullae with eventual necrosis and slow-healing eschar formation.

Development of the syndrome is unrelated to drug dose, and the course is not altered by discontinuation of the drug after onset of the eruption. Warfarin reactions are associated with protein C deficiency. Warfarin anticoagulation in heterozygotes for protein C deficiency causes a precipitous fall in circulating levels of protein C, permitting hypercoagulability and thrombosis in the cutaneous microvasculature, with consequent areas of necrosis. Similar reactions have been associated with heparin. Heparin-induced necrosis may have clinically similar features but is probably due to heparin-induced platelet aggregation with subsequent occlusion of blood vessels.

Warfarin-induced cutaneous necrosis is treated with vitamin K and heparin. Treatment with protein C concentrates may also be helpful.

Drug-Induced Hair Disorders • ***DRUG-INDUCED HAIR LOSS*** Medications may affect hair follicles at two different phases of their cycle. *Anagen effluvium* occurs within days of drug administration, whereas in *telogen effluvium*, the delay is 2–4 months. Both present as diffuse nonscarring alopecia most often reversible after discontinuation of the responsible agent.

The prevalence and severity of alopecia depend on the drug as well as on individual predisposition. A considerable number of drugs have been reported to induce hair loss. These include antineoplastic agents (alkylating agents, bleomycin, vinca alkaloids, platinum compounds), anticonvulsants (carbamazepine, valproate), antihypertensive drugs (beta blockers), antidepressants, antithyroid drugs, interferons (IFNs), oral contraceptives, and hypolipidemics.

HIRSUTISM Hirsutism is an excessive growth of coarse hair with masculine characteristics in a female, most often on the lateral aspects of face and back. Hirsutism results from androgenic stimulation of hormone-sensitive hair follicles.

Anabolic steroids, oral contraceptives of the nonsteroid progesterone type, testosterone, and corticotropin can induce hirsutism.

HYPERTRICHOSIS Hypertrichosis differs from hirsutism by being located mainly on the forehead and temporal regions. It is usually reversible. Drugs responsible for hypertrichosis include anti-inflammatory drugs, glucocorticoids, vasodilators (diazoxide, minoxidil), diuretics (acetazolamide), anticonvulsants (phenytoin), immunosuppressive agents, psoralens, and zidovudine.

Changes in hair color or structure are uncommon adverse effects from medications. Hair discoloration may occur with chloroquine, IFN-α, chemotherapeutic agents, and tyrosine kinase inhibitors. Changes in hair structure have been observed in patients given EGFR inhibitors.

Drug-Induced Nail Disorders These usually involve several or all 20 nails and need months to resolve after withdrawal of the offending agent. The pathogenesis is most often toxic. Drug-induced nail changes include Beau's line (transversal depression of the nail plate), onycholysis (detachment of the distal part of the nail plate), onychomadesis (detachment of the proximal part of the nail plate), pigmentation, and paronychia (inflammation of periungual skin).

ONYCHOLYSIS Onycholysis may occur as a consequence of phototoxic reactions, particularly with tetracyclines, fluoroquinolones, phenothiazines, and psoralens, as well as in persons taking NSAIDs, captopril, retinoids, sodium valproate, and many chemotherapeutic agents such as anthracyclines or taxanes including paclitaxel and docetaxel. The risk of onycholysis in patients receiving cytotoxic drugs can be increased by exposure to sunlight.

ONYCHOMADESIS Onychomadesis is caused by temporary arrest of nail matrix mitotic activity. Common drugs reported to induce onychomadesis include carbamazepine, lithium, retinoids, and chemotherapeutic agents such as cyclophosphamide and vincristine.

PARONYCHIA Paronychia and multiple pyogenic granuloma with progressive and painful periungual abscess of fingers and toes are a side effect of systemic retinoids, lamivudine, indinavir, and anti-EGFR monoclonal antibodies (cetuximab, gefitinib).

NAIL DISCOLORATION Some drugs, including anthracyclines, taxanes, fluorouracil, and zidovudine, may induce nail bed hyperpigmentation through melanocyte stimulation. It appears to be reversible and dose-dependent.

Pruritus Pruritus is a common symptom of most drug eruptions, but it may also occur without skin lesions as the only manifestation of drug intolerance. Severe pruritus may occur in up to 50% of African patients treated with antimalarials and lead to poor compliance. It is much rarer in Caucasians.

IMMUNE CUTANEOUS REACTIONS: BENIGN

Maculopapular Eruptions Morbilliform or maculopapular eruptions are the most common of all drug-induced reactions, often start on the trunk or areas of pressure or trauma, and consist of erythematous macules and papules that are frequently symmetric and may become confluent. Involvement of mucous membranes is unusual, with the exception of scaly lips; the eruption may be associated with moderate to severe pruritus and fever. Diagnosis is rarely assisted by laboratory testing. Skin biopsy is useless because it shows normal skin or very mild and nonspecific changes. A viral exanthem is the principal differential diagnostic consideration, especially in children. Absence of enanthems, absence of symptoms in ears, nose, and throat and upper respiratory tract, and polymorphism of the skin lesions support a drug rather than a viral eruption.

Maculopapular reactions usually develop within 1 week of initiation of therapy and last less than 2 weeks. Occasionally these eruptions may decrease or fade with continued use of the responsible drug. Since the eruption may also worsen, the suspect drug should be discontinued unless it is essential. Oral antihistamines, emollients, and soothing baths may help relieve pruritus. Short courses of potent topical glucocorticoids can reduce inflammation and symptoms. Systemic glucocorticoid treatment is rarely indicated.

Urticaria/Angioedema *Urticaria* is the second most frequent type of cutaneous reaction to drugs. However, "drug allergy" explains no more than 10–20% of acute urticaria cases. It is a skin reaction characterized by pruritic, red wheals of varying size. Individual lesions rarely last more than 24 h. Deep edematous dermal and subcutaneous tissues are known as *angioedema*. Angioedema may involve mucous membranes. Urticaria and angioedema may be part of a life-threatening anaphylactic reaction.

Drug-induced urticaria may be caused by three mechanisms: an IgE-dependent mechanism, circulating immune complexes (serum sickness), and nonimmunologic activation of effector pathways. IgE-dependent urticarial reactions usually occur within 36 h of drug exposure but can occur within minutes. Immune complex–induced urticaria associated with serum sickness usually occurs 6–12 days after first exposure. In this syndrome, the urticarial eruption may be accompanied by fever, hematuria, arthralgias, hepatic dysfunction, and neurologic symptoms.

Certain drugs, such as NSAIDs, ACE inhibitors, angiotensin II antagonists, and radiographic dyes, may induce urticarial reactions, angioedema, and anaphylaxis in the absence of drug-specific antibody. Although ACE inhibitors, aspirin, penicillin, and blood products are the most frequent causes of urticarial eruptions, urticaria has been observed in association

with nearly all drugs. Drugs may also cause chronic urticaria, which lasts more than 6 weeks. Aspirin frequently exacerbates this problem.

The treatment of urticaria or angioedema depends on the severity of the reaction and the rate at which it is evolving. In severe cases, with respiratory or cardiovascular compromise, epinephrine is the mainstay of therapy, but its effect is reduced in patients using beta blockers. Treatment with systemic glucocorticoids, sometimes administered IV, is helpful. In addition to drug withdrawal, for patients with only cutaneous symptoms and without symptoms of angioedema or anaphylaxis, oral antihistamines are usually sufficient.

Fixed Drug Eruptions These reactions are characterized by one or more sharply demarcated, erythematous lesions, sometimes leading to a blister. Hyperpigmentation results after resolution of the acute inflammation. With rechallenge, the lesion recurs in the same (i.e., fixed) location. Lesions often involve the lips, hands, legs, face, genitalia, and oral mucosa and cause a burning sensation. Most patients have multiple lesions. Fixed drug eruptions have been associated with phenolphthalein, sulfonamides, cyclines, dipyrone, NSAIDs, and barbiturates. Patch testing has been used in Europe to help establish the etiology.

IMMUNE CUTANEOUS REACTIONS: SEVERE

Vasculitis Cutaneous necrotizing vasculitis often presents as palpable purpuric lesions that may be generalized or limited to the lower extremities or other dependent areas (Chap. 319). Urticarial lesions, ulcers, and hemorrhagic blisters also occur. Vasculitis may involve other organs, including the liver, kidney, brain, and joints. Drugs are an infrequent cause of vasculitis. Infection and collagen vascular disease are responsible for the majority of cases.

Propylthiouracil induces a cutaneous vasculitis that is accompanied by leukopenia and splenomegaly. Direct immunofluorescent changes in these lesions suggest immune-complex deposition. Drugs implicated in vasculitis include allopurinol, thiazides, sulfonamides, other antimicrobials, and several NSAIDs. The presence of eosinophils in the perivascular infiltrate of skin biopsy may indicate a higher probability of a drug etiology.

Pustular Eruptions AGEP is a rare reaction pattern, often associated with exposure to drugs. Usually beginning on the face or intertriginous areas, small nonfollicular pustules overlying erythematous and edematous skin may coalesce and lead to superficial ulceration. Differentiating this eruption from TEN in its initial stages may be difficult. A skin biopsy is important and shows scattered pustules in the upper part of the epidermis instead of the full-thickness necrosis that characterizes TEN. Fever is present with elevated neutrophil counts, and sepsis is often suspected. Acute pustular psoriasis is the principal differential diagnostic consideration. AGEP often begins within a few days of initiating drug treatment, most notably antibiotics. For other associated drugs, diltiazem, chloroquine, hydroxychloroquine or terbinafine, AGEP begins later: 7–14 days after initiation of treatment.

Hypersensitivity Syndrome Initially described with phenytoin, hypersensitivity syndrome—a multiorgan drug-induced reaction—is also known as *DRESS* and *drug-induced hypersensitivity syndrome* (*DIHS*). It presents as a widespread erythematous eruption that may become purpuric or lichenoid and is accompanied by many of the following features: fever, facial and periorbital edema, tender generalized lymphadenopathy, leukocytosis (often with atypical lymphocytes and eosinophils), hepatitis, and sometimes nephritis or pneumonitis. The cutaneous reaction usually begins 2–8 weeks after the drug is started and lasts longer than mild eruptions after drug cessation. Symptoms may persist for several weeks, especially hepatitis. The eruption recurs with rechallenge, and cross-reactions among aromatic anticonvulsants, including phenytoin, carbamazepine, and barbiturates, are frequent. Other drugs causing this syndrome include lamotrigine, minocycline, dapsone, allopurinol, and sulfonamides, as well as abacavir and zalcitabine in HIV-infected patients. Reactivation of herpes viruses, especially of herpes virus 6, has been reported to be frequent in this syndrome. The role of virus infection is still unclear; it may contribute to long-lasting manifestations such as hepatitis or encephalitis. Mortality as high as 10% has been reported. In life-threatening situations such as pneumonitis or nephritis, systemic glucocorticoids (prednisone, 0.5–1.0 mg/kg) seem to reduce symptoms. Topical high-potency glucocorticoids may also be helpful. In all cases, rapid withdrawal of the suspected drug is required.

Stevens-Johnson Syndrome and Toxic Epidermal Necrolysis *SJS* and *TEN* are terms that, most believe, describe the same usually drug-induced disorder, which is characterized by blisters and epidermal detachment resulting from epidermal necrosis in the absence of substantial dermal inflammation. The term *SJS* is now used to describe cases with blisters developing on dusky or purpuric macules in which total body surface area blistering and eventual detachment is <10%. The term *SJS/TEN* is used to describe cases with 10–30% detachment, and *TEN* is used to describe cases with >30% detachment. Erythema multiforme major is now considered by most to be different from SJS, characterized by typical "target" lesions and resulting from a reaction to infection, most commonly from herpes simplex virus.

Patients with SJS, SJS/TEN, or TEN initially present with acute symptoms, painful skin lesions, fever >39°C (102.2°F), sore throat, and visual impairment resulting from mucous membrane and ocular lesions. Intestinal and pulmonary involvements are associated with a poor prognosis, as are a greater extent of epidermal detachment and older age. About 10% and 30% of SJS- and TEN-affected persons die from their disease, respectively. Drugs that most commonly cause SJS or TEN are anti-infectious sulfonamides, nevirapine, allopurinol, lamotrigine, aromatic anticonvulsants, and oxicam NSAIDs. At this time SJS or TEN have no treatment of proven efficacy. The best results come from early diagnosis, immediate discontinuation of any suspected drug, and supportive therapy, paying close attention to ocular complications, often in burn units or intensive care units.

DRUGS OF SPECIAL INTEREST

ALLOPURINOL

Together with sulfonamides and antiepileptics, allopurinol is one of the "usual suspects" that induce frequently mild maculopapular eruptions (in at least 3% of users) and may also cause more severe reactions including hypersensitivity/DRESS and SJS/TEN. Because of increasing utilization it is one of the most frequent causes of life-threatening reactions.

ANTI-HIV MEDICATIONS

In clinical trials, combinations of highly active antiretroviral treatments were frequently associated with ≥10% "drug eruptions." Two drugs, nevirapine and abacavir, have been associated with specific risks.

Nevirapine has both a high risk of maculopapular eruptions and a very high risk (about 1 in 1000) of SJS or TEN. Progressive escalation of daily doses has been shown to decrease the risk of mild eruption but does not abrogate the risk of severe reactions.

Abacavir is associated with a 4–5% risk of a hypersensitivity reaction, which is remarkable because of the association of symptoms suggesting a type I reaction (dyspnea, diarrhea, low blood pressure, shock on rechallenge) and signs of delayed hypersensitivity (rash, late onset, hepatitis). The risk is lower in patients of African ancestry and strongly correlated with HLAB*5701.

PENICILLIN

The utilization rate of penicillin has decreased markedly since it has been the subject of many investigations and a model for "drug allergy." Incidence of cutaneous reactions is about 1%. About 85% of cutaneous reactions to penicillin are morbilliform, and about 10% are urticaria or angioedema. Anaphylaxis and serum sickness appear to be due to IgE antibodies in serum.

Delayed reactions, mainly maculopapular eruptions, are much more common with aminopenicillins, involving 4–7% of users. The question of cross-reactivity between β-lactam antibiotics and prevent-

ing the risk of anaphylaxis is discussed below ("Management of a Patient with a Drug Eruption").

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

Most NSAIDs, including aspirin, cause immediate allergy-like symptoms in susceptible individuals. Approximately 1% of persons experience urticaria or angioedema, and about half as many (0.5%) experience rhinosinusitis and asthma.

Urticaria/angioedema may be delayed up to 24 h and may occur at any age. The rhinosinusitis-asthma syndrome generally develops within 1 h of drug administration. Recurrences are frequent and can be complicated by nasal and sinus infection, polyposis, bloody discharge, and nasal eosinophilia. In many individuals with this syndrome, asthma that can be life-threatening eventually ensues whenever NSAIDs are subsequently ingested. Proof of the association of symptoms and NSAID use requires either clear-cut history of symptoms following drug ingestion or an oral challenge. That procedure must be conducted only in a hospital setting by experienced personnel. Cross-reactivity between NSAIDs that inhibit cyclooxygenase (COX) 1 is common, while reactivity to COX-2 inhibitors is less frequent. The reaction is pharmacologic, and patients who are sensitive to NSAIDs cannot be identified by assessment of IgE antibody to aspirin, lymphocyte sensitization, or in vitro immunologic testing.

Other reactions can also occur with NSAIDs, including phototoxicity with many agents, a pattern of pseudoporphyria being often related to naproxen, hypersensitivity/DRESS (oxicam derivatives, COX-2 inhibitors), and SJS or TEN (phenylbutazone, oxicam derivatives, diclofenac).

RADIOCONTRAST MEDIA

Large numbers of patients are exposed to radiocontrast agents. High-osmolality radiocontrast media were about five times more likely to induce urticaria (1%) or anaphylaxis than were newer low-osmolality media. Severe reactions are rare with either type of contrast media. About one-third of those with mild reactions to previous exposure re-react on re-exposure. In most cases, these reactions are probably not immunologic. Pretreatment with prednisone and diphenhydramine reduces reaction rates. Persons with a reaction to a high-osmolality contrast media should be given low-osmolality media if later contrast studies are required.

ANTICONVULSANTS

Along with sulfonamide antibiotics, phenobarbital, phenytoin, and carbamazepine among the older anticonvulsants, and lamotrigine among the newer, are associated with many types of severe reactions and a high incidence of less severe reactions, particularly in children. These drugs have among the highest risk of SJS, TEN, and hypersensitivity syndrome in immunologically normal patients. The aromatic anticonvulsants can induce a pseudolymphoma syndrome and induce gingival hyperplasia.

SULFONAMIDES

Antibacterial sulfonamides have a rather high risk of causing cutaneous eruptions and are among the drugs most frequently implicated in SJS and TEN. The combination of sulfamethoxazole and trimethoprim frequently induces adverse cutaneous reactions in patients with AIDS (Chap. 182). Desensitization is often successful in AIDS patients with morbilliform eruptions but is not recommended in AIDS patients who manifested erythroderma or a bullous reaction in response to their earlier sulfonamide exposure.

Reaction rates are much lower with nonantibiotic sulfonamides, including diuretics or antidiabetic agents. Cross-reactivity between antibiotic and nonantibiotic sulfonamides is, at most, infrequent.

VANCOMYCIN

Vancomycin causes two unusual but recognizable cutaneous reactions: linear IgA bullous dermatosis (a transient blistering eruption) and *red man syndrome*. Red man syndrome occurs during rapid IV infusion of vancomycin. This is thought to be a histamine-related anaphylactoid reaction characterized by flushing, diffuse maculopapular eruption, hypotension, and, in rare cases, cardiac arrest.

AGENTS USED IN CANCER CHEMOTHERAPY

Since many agents used in cancer chemotherapy inhibit cell division, rapidly proliferating elements of the skin, including hair, mucous membranes, and appendages, are sensitive to their effects. As a result, stomatitis and alopecia are among the most frequent dose-dependent side effects of chemotherapy. Various nail abnormalities have been described: onycholysis, dystrophy, Beau's lines, white lines, and pigmentation. Sterile cellulitis and phlebitis and ulceration of pressure areas occur with many of these agents. Also reported is acral erythema, which begins with dysesthesia followed by redness and a painful edematous eruption of the palms and soles; it is caused by cytarabine, doxorubicin, methotrexate, and 5-fluorouracil. Urticaria, angioedema, and exfoliative dermatitis also have been seen, as has local and diffuse hyperpigmentation.

Hypersensitivity to carboplatin or cisplatin is not rare (with an incidence of 10–20%) among patients receiving multiple treatments with these drugs. It is probably IgE mediated. Moderate to severe reactions including respiratory distress and hypotension are also observed in 10–20% of patients receiving paclitaxel regardless of premedication with glucocorticoids and histamine H(1) and H(2) antagonists.

GLUCOCORTICOIDS

Both systemic and topical glucocorticoids cause a variety of skin changes, including acneiform eruptions, atrophy, striae, and other stigmata of Cushing's syndrome, and in sufficiently high doses can retard wound healing. Patients using glucocorticoids are at higher risk for bacterial, yeast, and fungal skin infections that may be misinterpreted as drug eruptions but are instead drug side effects. Allergy to glucocorticoids may also occur either as contact dermatitis to topical formulations or as systemic reactions, including anaphylaxis.

BIOLOGIC THERAPIES

These include cytokines and monoclonal antibodies.

Injection-site reactions are the most frequent adverse event. The severity varies from mild redness to deep inflammation and necrosis. In most cases the treatment can be continued and the severity of reactions will decrease with time.

Like all foreign proteins, monoclonal antibodies may induce urticaria, angioedema, anaphylactic reactions, and serum sickness.

Alopecia is a common complication of IFN-α. A nonspecific highly pruritic "dermatitis" is frequent in patients receiving IFN and ribavirin for hepatitis C.

Induction or exacerbation of various immune-mediated disorders, especially lupus erythematosus, has been reported with many biologicals (interleukin 2, IFN-α, anti–tumor necrosis factor α).

Granulocyte colony-stimulating factor may induce various neutrophilic dermatoses, including Sweet's syndrome and pyoderma gangrenosum, and can exacerbate psoriasis.

Cetuximab is a member of a new family of antineoplastic agents that inhibit the EGF receptor. These molecules induce acneiform eruptions after a mean interval of 10 days in a majority of patients. The severity of the eruption was shown to correlate with a better anticancer effect. Systemic antibiotics and topical anti-acne treatments are helpful.

Although not usually classified as adverse drug reactions, skin infections and skin cancer could become a major concern with long-term use of immune-modifying biologicals.

ANTIMALARIAL AGENTS

Antimalarial agents are used as therapy for several skin diseases, including the skin manifestations of lupus and polymorphous light eruption, but they can also induce cutaneous reactions. The most frequent is pruritus, which occurs in up to 50% of African patients receiving chloroquine and may be severe enough to lead to discontinuation of treatment.

Pigmentation disturbances, including black pigmentation of the face, mucous membranes, and pretibial and subungual areas, occur

TABLE 56-2 CLINICAL AND LABORATORY FINDINGS ASSOCIATED WITH MORE SERIOUS DRUG-INDUCED CUTANEOUS CLINICAL FINDINGS

Cutaneous
Confluent erythema
Facial edema or central facial involvement
Skin pain
Palpable purpura
Skin necrosis
Blisters or epidermal detachment
Positive Nikolsky's sign
Mucous membrane erosions
Urticaria
Swelling of tongue
General
High fever [temperature >40°C (>104°F)]
Enlarged lymph nodes
Arthralgias or arthritis
Shortness of breath, wheezing, hypotension
Laboratory results
Eosinophil count >1000/μL
Lymphocytosis with atypical lymphocytes
Abnormal liver function tests

Source: Adapted from Roujeau and Stern.

with antimalarials. Quinacrine (mepacrine) causes generalized, cutaneous yellow discoloration. Less frequent reactions include pustular eruptions (AGEP) and hypersensitivity/DRESS.

MANAGEMENT OF A PATIENT WITH A DRUG ERUPTION

There are four main questions to be answered when seeing an eruption:

1. Is it a severe eruption or the onset of a form that may become severe?
2. Is it a drug reaction?
3. Which drug(s) are suspected, and which should be withdrawn?
4. What is recommended for future use of drugs?

EARLY DIAGNOSIS OF SEVERE ERUPTIONS

Many patients who experience a severe skin reaction complain that the diagnosis has been delayed, sometimes for several days. Initially, most eruptions look nonspecific. Of special importance is the rapid recognition of reactions that may become serious or life-threatening. Table 56-2 lists clinical and laboratory features that, if present, suggest the reaction may be serious. Table 56-3 provides key features of the most serious adverse cutaneous reactions. Intensity of symptoms and rapid progression of signs should raise the suspicion of a severe eruption. Any doubt should lead to consultation with a dermatologist and/or referral of the patient to a specialized center.

CONFIRMATION OF DRUG REACTION

The probability of drug etiology varies with the pattern of the reaction. Only fixed drug eruptions are always drug-induced. Maculopapular eruptions are usually viral in children and drug-induced in adults. Among severe reactions, attribution to drugs varies from 10–20% for anaphylaxis and vasculitis to 70–90% for AGEP, DRESS, SJS, or TEN. Skin biopsy helps in characterizing the reaction but does not indicate drug causality. Blood counts and liver and renal function tests are important for evaluating organ involvement. The association of mild elevation of liver enzymes and high eosinophil count is frequent but not specific for a drug reaction. Blood tests that could identify an alternative cause, antinuclear antibody tests, and serology or polymerase chain reaction for infections may be of great importance for final assessment of etiology.

WHICH DRUG(S) TO SUSPECT AND WITHDRAW

Most cases of drug eruptions occur during the first course of treatment with a new medication, after a delay that varies with the type of reaction. A notable exception is IgE-mediated urticaria and anaphylaxis that need presensitization and develop a few minutes to a few hours after rechallenge. Characteristic time lags between onset of treatment and reaction are 4–14 days for maculopapular eruptions, 7–21 days for SJS/TEN, and 14–48 days for DRESS. Medications introduced for the first time in the relevant time frame are prime suspects. Two other important elements to suspect causality at this stage are (1) previous experience with the drug in the population and (2) alternative etiologic candidates.

TABLE 56-3 CLINICAL FEATURES OF SELECTED SEVERE CUTANEOUS REACTIONS OFTEN INDUCED BY DRUGS

Diagnosis	Mucosal Lesions	Typical Skin Lesions	Frequent Signs and Symptoms	Alternative Causes Not Related to Drugs
Stevens-Johnson syndrome	Erosions usually at ≥two sites	Small blisters on dusky purpuric macules or atypical targets; rare areas of confluence; detachment ≤10% of body surface area	Most cases involve fever	10–20% cause not determined
Toxic epidermal necrolysis[a]	Erosions usually at ≥two sites	Individual lesions like those seen in Stevens-Johnson syndrome; confluent erythema; outer layer of epidermis separates readily from basal layer with lateral pressure; large sheet of necrotic epidermis; total detachment of >30% of body surface area	Nearly all cases involve fever, "acute skin failure," leukopenia	10–20% cause not determined
Hypersensitivity syndrome	Infrequent	Severe exanthematous rash (may become purpuric), exfoliative dermatitis	30–50% of cases involve fever, lymphadenopathy, hepatitis, nephritis, carditis, eosinophilia, atypical lymphocytes	Cutaneous lymphoma
Acute generalized exanthematous pustulosis	About 20% erosions mouth, tongue	Initially nonfollicular small pustules overlying edematous erythema, sometimes leading to superficial ulcers	Fever, burning, pruritus, facial swelling, leukocytosis, hypocalcemia	Infection
Serum sickness or reactions resembling serum sickness	Absent	Morbilliform lesions, sometimes with urticaria	Fever, arthralgias	Infection
Anticoagulant-induced necrosis	Infrequent	Erythema then purpura and necrosis, especially of fatty areas	Pain in affected areas	Disseminated intravascular coagulopathy, septicemia
Angioedema	Often involved	Urticaria or swelling of central part of face	Respiratory distress, cardiovascular collapse	Insect stings, foods

[a]Overlap of Stevens-Johnson syndrome and toxic epidermal necrolysis with features of both and attachment of 10 to 30% of body surface area may occur.

Source: Adapted from Roujeau and Stern.

The decision to continue or discontinue any medication will depend on the severity of the reaction, the severity of the primary disease, degree of suspicion of causality, and feasibility of an alternative safer treatment. In many instances when a decision of "treating through" an eruption has been made, the rash disappears in a few days. This was seen in patients with AIDS treated for opportunistic infections with antibacterial sulfonamides. The decision to treat through an eruption should, however, remain the exception and withdrawal of every suspect drug the general rule. On the other hand, drugs that are not suspected and are important for the patient, e.g., antidiabetic or antihypertensive agents, generally should not be withdrawn. This approach prevents reluctance to future utilization of these agents.

RECOMMENDATION FOR FUTURE USE OF DRUGS

The aims are (1) to prevent the recurrence of the drug eruption and (2) not to compromise future treatments by contraindicating otherwise useful medications.

Begin with thorough assessment of drug causality. Drug causality is evaluated based on timing of the reaction, evaluation of other possible causes, effect of drug withdrawal or continuation, and knowledge of medications that have been associated with the observed reaction. Combination of these criteria leads to considering the causality as definite, probable, possible, or unlikely.

A drug with "unlikely" causality or that has been continued when the reaction improved or reintroduced without a reaction can be administered safely.

A drug with a "definite" or "probable" causality should be contraindicated, and a warning card given to the patient.

A drug with a "possible" causality may be submitted to further investigations depending on the expected need for future treatment.

The usefulness of drug tests is still debated. Many in vitro tests have been developed. They include lymphocyte proliferation assays, measuring the production of cytokines by patient lymphocytes in presence of medication, lymphocyte toxicity tests, and basophil degranulation assays. The predictive value of these tests has not been validated in any large series of affected patients, and these tests are research and not clinical tools.

In patients with history suggesting immediate IgE-mediated reactions to penicillin, skin testing with major and minor determinants of penicillins or cephalosporins has proved useful for identifying patients at risk of anaphylactic reactions to these agents. However, skin tests themselves carry a small risk of anaphylaxis. Negative skin tests do not totally rule out IgE-mediated reactivity, but the risk of anaphylaxis in response to penicillin administration in patients with negative skin tests is about 1% while about two-thirds of patients with a positive skin test experience an allergic response on rechallenge.

For patients with late drug reactions, the clinical usefulness of skin tests is more questionable. At least one of a combination of several tests (prick, patch, and intradermal) is positive in 50–70% of patients with a reaction "definitely" attributed to a single medication. This low sensitivity probably contributes to the fact that readministration of drugs that had been tested negative resulted in up to 17% eruptions.

CROSS-SENSITIVITY

Because of the possibility of cross-sensitivity among chemically related drugs, many physicians recommend avoidance of not only the medication that induced the reaction but also all drugs of the same group.

There are two types of cross-sensitivity. Reactions that depend on a pharmacologic interaction may recur with all drugs that target the same pathway, whether structurally similar or not. This is the case with angioedema caused by NSAIDs and ACE inhibitors. In this situation, the risk of recurrence varies from drug to drug in a particular class; however, avoidance of all drugs in the class is usually recommended. The other cross-sensitivity manifests in the risk that structurally related drugs are cross-recognized by the immune system. This is a real problem with aromatic antiepileptics (barbiturates, phenytoin, carbamazepine), with up to 50% reaction to a second drug in patients who reacted to one. For other drugs, in vitro as well as in vivo data have suggested that cross-reactivity existed only between compounds with very similar chemical structures. Sulfamethoxazole-specific lymphocytes may occasionally recognize a few other antibacterial sulfonamides but not diuretics, antidiabetic drugs, or anti-COX2 NSAIDs with a sulfonamide group.

Recent data suggest that although the risk of a drug eruption to another drug was increased in persons with a prior reaction, "cross-sensitivity" was probably not the explanation. As an example, persons with a history of an allergic-like reaction to penicillin were at higher risk to develop a reaction to antibacterial sulfonamides than to cephalosporin.

These data suggest that the list of drugs to avoid after a drug reaction should be limited to the causative one(s) and to a few very similar medications.

Because of growing evidence that some severe cutaneous reactions to drugs are associated with HLA genes, it is probably wise to recommend that first-degree family members of patients with severe cutaneous reactions also should avoid these causative medications.

Desensitization can be considered in those with history of reaction to a medication that must be used again. Efficacy of such procedures has been demonstrated in cases of immediate reaction to penicillin and positive skin tests, anaphylactic reactions to platinum chemotherapy, and delayed reactions to sulfonamides in patients with AIDS. Various protocols are available, including oral and parenteral approaches. Oral desensitization appears to have a lower risk of serious anaphylactic reactions. However, desensitization carries the risk of anaphylaxis regardless of how it is performed. After desensitization, many patients experience non-life-threatening reactions during therapy with the culprit drug.

REPORTING

Any severe reaction to drugs should be notified to a regulatory agency or to pharmaceutical companies. Because severe reactions are too rare to be detected in premarketing clinical trials, spontaneous reports are of critical importance for early detection of unexpected life-threatening events. To be useful, the report should contain enough details to permit ascertainment of severity and drug causality. This permits recognition of similar cases that may be reported from several different sources.

David R. Bickers

SOLAR RADIATION

Sunlight is the most visible and obvious source of comfort in the environment. The sun provides the beneficial effects of warmth and vitamin D synthesis; however, acute and chronic sun exposure also have pathologic consequences. Few effects of sun exposure beyond those affecting the skin have been identified, but cutaneous exposure to sunlight is the major cause of human skin cancer and can exert immunosuppressive effects as well.

The sun's energy reaching the earth's surface is limited to components of the ultraviolet (UV), the visible, and portions of the infrared spectra. The cutoff at the short end of the UV is at ~290 nm; this is due primarily to stratospheric ozone formed by highly energetic ionizing radiation, thereby preventing penetration to the earth's surface of the shorter, more energetic, potentially more harmful wavelengths of solar radiation. Indeed, concern about destruction of the ozone layer by chlorofluorocarbons released into the atmosphere has led to international agreements to reduce production of these chemicals.

Measurements of solar flux indicate that there is a twentyfold regional variation in the amount of energy at 300 nm that reaches the earth's surface. This variability relates to seasonal effects; the path of sunlight transmission through ozone and air; the altitude (4% increase for each 300 m of elevation); the latitude (increasing intensity with decreasing latitude); and the amount of cloud cover, fog, and pollution.

The major components of the photobiologic action spectrum capable of affecting human skin include the UV and visible wavelengths between 290 and 700 nm. In addition, the wavelengths beyond 700 nm in the infrared spectrum primarily emit heat and under certain circumstances may exacerbate the pathologic effects of energy in the UV and visible spectra.

The UV spectrum reaching the earth represents <10% of total incident solar energy and is arbitrarily divided into two major segments, UV-B and UV-A, comprising the wavelengths from 290–400 nm. UV-B consists of wavelengths between 290 and 320 nm. This portion of the photobiologic action spectrum is the most efficient in producing redness or erythema in human skin and hence is sometimes known as the "sunburn spectrum." UV-A represents those wavelengths between 320 and 400 nm and is ~1000-fold less efficient in producing skin redness than is UV-B.

The wavelengths between 400 and 700 nm are visible to the human eye. The photon energy in the visible spectrum is not capable of damaging human skin in the absence of a photosensitizing chemical. Without the absorption of energy by a molecule there can be no photosensitivity. Thus the *absorption spectrum* of a molecule is defined as the range of wavelengths absorbed by it, whereas the *action spectrum* for an effect of incident radiation is defined as the range of wavelengths that evoke the response.

Photosensitivity occurs when a photon-absorbing chemical (chromophore) present in the skin absorbs incident energy, becomes excited, and transfers the absorbed energy to various structures or to oxygen.

UV RADIATION (UVR) AND SKIN STRUCTURE AND FUNCTION

Skin consists of two major compartments: the outer epidermis, a stratified squamous epithelium, and the underlying dermis rich in matrix proteins such as collagen and elastin. Both of these compartments are susceptible to damage from sun exposure. The epidermis and the dermis contain several chromophores capable of absorbing incident solar energy including nucleic acids, proteins, and lipids. The outermost epidermal layer, the stratum corneum, is a major absorber of UV-B, and <10% of incident UV-B wavelengths penetrate through the epidermis to the dermis. Approximately 3% of radiation below 300 nm, 20% of radiation below 360 nm, and 33% of short visible radiation reaches the basal cell layer in untanned human skin. In contrast, UV-A readily penetrates to the dermis and is capable of altering structural and matrix proteins that contribute to photoaging of chronically sun-exposed skin, particularly in individuals of light complexion.

Molecular Targets for UVR-Induced Skin Effects Epidermal DNA, predominantly in keratinocytes and in Langerhans cells (LCs), which are dendritic antigen-presenting cells, absorbs UV-B and undergoes structural changes including the formation of cyclobutane dimers and 6,4-photoproducts. These structural changes are potentially mutagenic and can be repaired by mechanisms that result in their recognition and excision and the reestablishment of normal base sequences. The efficient repair of these structural aberrations is crucial, since individuals with defective DNA repair are at high risk for the development of cutaneous cancer. For example, patients with xeroderma pigmentosum (XP), an autosomal recessive disorder, are characterized by variably deficient repair of UV-induced photoproducts, and their skin phenotype often manifests the dry, leathery appearance of prematurely photoaged skin as well as basal cell and squamous cell carcinomas and melanoma in the first two decades of life. Studies in mice using knockout gene technology have verified the importance of functional genes regulating these repair pathways in preventing the development of UV-induced cancer. Furthermore, incorporation of a bacterial DNA repair enzyme, T4N5 endonuclease, into liposomes in a product applied to skin of patients with XP selectively removes cyclobutane pyrimidine dimers and reduces the degree of solar damage and skin cancer. DNA damage in LCs may contribute to the known immunosuppressive effects of UV-B (see "Immunologic Effects," below).

Cutaneous Optics and Chromophores Chromophores are endogenous or exogenous chemical components that can absorb physical energy. Endogenous chromophores are of two types: (1) chemicals that are normal components of skin, including nucleic acids, proteins, lipids, and 7-dehydrocholesterol, the precursor of vitamin D; and (2) chemicals, such as porphyrins, synthesized elsewhere in the body that circulate in the bloodstream and diffuse into the skin. Normally, only trace amounts of porphyrins are present in the skin, but in selected diseases known as the porphyrias (Chap. 352), increased amounts are released into the circulation from the bone marrow and the liver and are transported to the skin, where they absorb incident energy both in the Soret band, around 400 nm (short visible), and to a lesser extent in the red portion of the visible spectrum (580–660 nm). This results in the generation of reactive oxygen species that can mediate structural damage to the skin, manifest as erythema, edema, urticaria, or blister formation.

Acute Effects of Sun Exposure The acute effects of skin exposure to sunlight include sunburn and vitamin D synthesis. Molecular targets for UVR in addition to DNA include molecular oxygen leading to the generation of reactive oxygen species (ROS), cell membranes, and urocanic acid.

SUNBURN This painful skin condition is caused predominantly by UV-B. Generally speaking, an individual's ability to tolerate sunlight is inversely proportional to the degree of melanin pigmentation. Melanin, a complex tyrosine polymer, is synthesized in specialized epidermal dendritic cells known as melanocytes and is packaged into *melanosomes* that are transferred via dendritic process into *keratinocytes*, thereby providing photoprotection and simultaneously darkening the skin. Sun-induced melanogenesis is a consequence of increased tyrosinase activity in melanocytes that in turn is a consequence of a human gene, the melanocortin1 receptor (*MCIR*), that accounts for the wide variation in human skin and hair color. Human *MCIR* encodes a 317-amino-acid G-coupled receptor (melanocortin receptor) that binds α-melanocyte-stimulating hormone. This leads to increased intracellular cyclic AMP and protein kinase A, followed by increased transcription of microphthalmia transcription factor

TABLE 57-1 SKIN TYPE AND SUNBURN SENSITIVITY (FITZPATRICK CLASSIFICATION)

Type	Description
I	Always burn, never tan
II	Always burn, sometimes tan
III	Sometimes burn, sometimes tan
IV	Sometimes burn, always tan
V	Never burn, sometimes tan
VI	Never burn, always tan

(MITF) that regulates melanogenesis. *MCIR* mutations account for population differences in skin color, ability to tan, and cancer susceptibility. The Fitzpatrick classification of human skin is a function of the efficiency of the epidermal-melanin unit and can usually be ascertained by asking an individual two questions: (1) Do you burn after sun exposure? and (2) Do you tan after sun exposure? The answers to these questions permit division of the population into six skin types varying from type I (always burn, never tan) to type VI (never burn, always tan) (Table 57-1).

Sunburn is due to vasodilatation of dermal blood vessels. There is a lag in time between skin exposure to sunlight and the development of visible redness (usually 4–12 h), suggesting that an epidermal chromophore causes delayed production and/or release of vasoactive mediator(s), or cytokines, that diffuse to the dermal vasculature to evoke vasodilatation.

The action spectrum for sunburn erythema includes the UV-B and UV-A. Photons in the UV-B are at least 1000-fold more efficient than photons in the UV-A in evoking the response. However, UV-A may contribute to sunburn erythema at midday when much more UV-A than UV-B is present in the solar spectrum. UV-induced activation of nuclear factor-κB (NF-κB)-dependent gene transactivation can augment release of several proinflammatory cytokines including interleukin (IL) 1B, 1L-6, IL-8, vascular endothelial growth factor, prostaglandin E_2, and tumor necrosis factor α. Local accumulation of these cytokines occurs in sunburned skin, providing chemotactic factors that attract neutrophils and macrophages. It is of interest that nonsteroidal anti-inflammatory drugs (NSAIDs) can reduce sunburn erythema, perhaps by blocking I-κB kinase 2, the enzyme essential for nuclear translocation of cytosolic NF-κB.

VITAMIN D PHOTOCHEMISTRY Cutaneous exposure to UV-B causes photolysis of epidermal 7-dehydrocholesterol converting it to pre-vitamin D_3, which then undergoes a temperature-dependent isomerization to form the stable hormone vitamin D_3. This compound then diffuses to the dermal vasculature and circulates systemically where it is converted to the functional hormone 1,25-dihydroxyvitamin D_3[1,25$(OH)_2D_3$]. Vitamin D metabolites from the circulation or those produced in the skin itself can augment epidermal differentiation signaling. Controversy exists regarding the importance of sun exposure in vitamin D homeostasis. At present, it is important to emphasize that the use of sunscreens does not substantially diminish vitamin D levels. Since aging also substantially decreases the ability of human skin to photocatalytically produce vitamin D_3, the widespread use of sunscreens that filter out UV-B has led to concern that vitamin D deficiency may become a significant clinical problem in the elderly.

Chronic Effects of Sun Exposure: Nonmalignant The clinical features of photodamaged sun-exposed skin consist of wrinkling, blotchiness, and telangiectasia and a roughened, irregular, "weather-beaten" leathery appearance. Whether this photoaging represents accelerated chronologic aging or a separate and distinct process is not clear.

Within chronically sun-exposed epidermis, there is thickening (acanthosis) and morphologic heterogeneity within the basal cell layer. Higher but irregular melanosome content may be present in some keratinocytes, indicating prolonged residence of the cells in the basal cell layer. These structural changes may help to explain the leathery texture and the blotchy discoloration of sun-damaged skin.

UV-A is important in the pathogenesis of photoaging in human skin, and ROS are likely involved. The dermis and its connective tissue matrix are the major site for sun-associated chronic damage, manifest as solar elastosis, a massive increase in thickened irregular masses of abnormal elastic fibers. Collagen fibers are also abnormally clumped in the deeper dermis of sun-damaged skin. The chromophore(s), the action spectra, and the specific biochemical events orchestrating these changes are only partially understood, although UV-A seems to be primarily involved. Chronologically aged, sun-protected skin and photoaged skin share important molecular features including connective tissue damage and elevated matrix metalloproteinases (MMPs). MMPs are enzymes involved in the degradation of the extracellular matrix, and UV-A induces MMP-1 and MMP-3 mRNA expression, leading to enhanced collagen breakdown. In addition, UV-A reduces type I procollagen mRNA expression.

Chronic Effects of Sun Exposure: Malignant One of the major known consequences of chronic skin exposure to sunlight is nonmelanoma skin cancer. The two types of nonmelanoma skin cancer are *basal cell carcinoma* (BCC) and *squamous cell carcinoma* (SCC; Chap. 83). There are three major steps for cancer induction: initiation, promotion, and progression. Exposure of human skin to sunlight results in *initiation*, a step whereby structural (mutagenic) changes in DNA evoke an irreversible alteration in the target cell (*keratinocyte*) that begins the tumorigenic process. Exposure to a tumor initiator such as UV-B is believed to be a necessary but not sufficient step in the malignant process, since initiated skin cells not exposed to tumor promoters do not generally develop tumors. The second stage in tumor development is *promotion*, a multistep process whereby chronic exposure to sunlight evokes epigenetic changes that culminate in the clonal expansion of initiated cells and cause the development, over many years, of premalignant growths known as *actinic keratoses*, a minority of which may progress to form skin cancer. Based on extensive studies it seems clear that UV-B is a *complete carcinogen*, meaning that it can act as both a tumor initiator and a promoter.

The third and final step in the malignant process is *malignant conversion* of benign precursors into malignant lesions, a process thought to require additional genetic alterations in already transformed cells. Skin carcinogenesis is thought to be caused by the accumulation of mutations in the tumor-suppressor gene *p53* as a result of UV-induced DNA damage. Indeed both human and murine UV-induced skin cancers have unique *p53* mutations (C → T and CC → TT transitions) that are present in the majority of these lesions. Studies have shown that sunscreens can substantially reduce the frequency of these signature mutations in *p53* and can dramatically inhibit the induction of tumors. The *p53* mutations are present in sun-exposed normal human skin, in actinic keratoses, and in nonmelanoma skin cancers including BCC and SCC.

BCCs also manifest mutations in the tumor-suppressor gene known as *patched*, which results in activation of hedgehog signaling, and enhanced activity of *smoothened*, which in turn causes downstream activation of transcription factors that augment cell proliferation. Thus, these tumors can manifest mutations in both p53 and in *patched*.

Sun exposure causes nonmelanoma cancers and melanoma of the skin, although the evidence is far more direct for its role in nonmelanoma (BCC and SCC) than in melanoma. Approximately 80% of nonmelanoma skin cancers develop on exposed body areas, including the face, the neck, and the hands. Major risk factors include male sex, childhood sun exposures, older age, fair skin, and residence at latitudes closer to the equator. Whites of darker complexions (e.g., Hispanics) have one-tenth the risk of developing such cancers compared to fair-skinned individuals. Blacks are at substantially reduced risk for all forms of skin cancer. More than 1.3 million individuals in the United States develop nonmelanoma skin cancer annually, and the lifetime risk for a fair-skinned individual to develop such a neoplasm is estimated at ~15%. A consensus exists that the incidence of nonmelanoma skin cancer in the population is increasing at the rate of 2–3% per year, for unknown reasons. One potential explanation is the widespread use of indoor tanning. It is esti-

mated that 30 million people tan indoors in the United States annually, including >2 million adolescents.

The relationship of sun exposure to melanoma development is less clear-cut, but suggestive evidence supports an association. The strongest risk factors for melanoma include positive family history for melanoma, multiple dysplastic nevi, and prior melanoma. Melanomas occasionally develop by the teenage years, indicating that the latent period for tumor growth is less than that of nonmelanoma skin cancer. Melanomas are among the most rapidly increasing of all human malignancies (Chap. 83). Epidemiologic studies of immigrant populations of similar ethnic stock indicate that individuals born in one area or who migrate to the same locale before age 10 have higher age-specific melanoma rates than individuals arriving later. It is thus reasonable to conclude that life in a sunny climate from birth or early childhood increases the risk of melanoma. In general, risk does not correlate with cumulative sun exposure but may relate to the duration and extent of exposure in childhood. Epidemiologic studies have shown that indoor tanning is a risk factor for melanoma.

Meta-analysis of 17 case-control studies in patients with melanoma concluded that the protective effect of sunscreens against this type of tumor could not be substantiated, but this is likely due to failure to control for confounding factors such as sunscreen stability and frequency of application. Since no prospective studies are available to address this issue, it seems reasonable to recommend that patients at risk for melanoma utilize photoprotection such as sun avoidance, high sun protective factor (SPF) sunscreens, and protective clothing.

Immunologic Effects Exposure to solar radiation causes local (inhibition of immune responses to antigens applied at the irradiated site) and systemic (inhibition of immune responses to antigens applied at remote unirradiated sites) immunosuppression. The action spectrum for UV-induced immunosuppression closely mimics the absorption spectrum of DNA. Pyrimidine dimers in LCs may inhibit antigen presentation. The absorption spectrum of epidermal urocanic acid closely mimics the action spectrum for UV-B-induced immunosuppression. *Trans-cis* isomerization of urocanic acid in the stratum corneum leads to its systemic absorption and consequent immunosuppressive effects. Furthermore administration of modest doses of UV-B to human skin reduces the degree of allergic sensitization to the potent contact allergen, dinitrochlorobenzene. This is associated with ROS-induced depletion of epidermal LCs.

Higher doses of UV-radiation evoke diminished immunologic responses to antigens introduced either epicutaneously or intracutaneously at sites distant from the irradiated site. These suppressed responses are also associated with the induction of antigen-specific suppressor T lymphocytes and may be mediated by as yet undefined factors that are released from epidermal cells at the irradiated site. One important consequence of chronic sun exposure and the concomitant immunosuppression is enhanced risk of skin cancer. Perhaps the most graphic demonstration of the role of immunosuppression in enhancing the risk of nonmelanoma skin cancer has come from studies of patients receiving organ transplantation who are on chronic immunosuppressive antirejection drug regimens. More than 50% of transplant patients develop BCCs and SCCs, and these cancers are the most common malignancy arising in immunosuppressed solid-organ transplant recipients. Human papilloma viruses (HPVs) may also play a role in the increased risk of SCCs in these patients since tumors display an HPV DNA carriage rate of almost 80%. These patients require close periodic monitoring and rigorous photoprotection using sunscreens, protective clothing, and sun avoidance.

PHOTOSENSITIVITY DISEASES

The diagnosis of photosensitivity requires a careful history to define the duration of the signs and symptoms, the length of time between exposure to sunlight and the development of subjective complaints, and visible changes in the skin. The age of onset can also be a helpful clue; for example, the acute photosensitivity of erythropoietic protoporphyria almost always begins in childhood, whereas the chronic photosensitivity of porphyria cutanea tarda (PCT) typically begins in the fourth and fifth decades. A history of exposure to topical and systemic drugs and chemicals may provide important clues. Many classes of drugs can cause photosensitivity on the basis of either phototoxicity or photoallergy. Fragrances such as musk ambrette that were previously present in numerous cosmetic products are also potent photosensitizers.

TABLE 57-2 CLASSIFICATION OF PHOTOSENSITIVITY DISEASES

Type	Disease
Genetic	Erythropoietic porphyria
	Erythropoietic protoporphyria
	Porphyria cutanea tarda—familial
	Variegate porphyria
	Hepatoerythropoietic porphyria
	Albinism
	Xeroderma pigmentosum
	Rothmund-Thompson disease
	Bloom syndrome
	Cockayne's disease
	Kindler syndrome
	Phenylketonuria
Metabolic	Porphyria cutanea tarda—sporadic
	Hartnup disease
	Kwashiorkor
	Pellagra
	Carcinoid syndrome
Phototoxic	
Internal	Drugs
External	Drugs, plants, food
Photoallergic	
Immediate	Solar urticaria
Delayed	Drug photoallergy
	Persistent light reaction/chronic actinic dermatitis
Neoplastic and degenerative	Photoaging
	Actinic keratosis
	Melanoma and nonmelanoma skin cancer
Idiopathic	Polymorphous light eruption
	Hydroa aestivale

Examination of the skin may also offer important clues. Anatomic areas that are naturally protected from direct sunlight such as the hairy scalp, the upper eyelids, the retroauricular areas, and the infranasal and submental regions may be spared, whereas exposed areas show characteristic features of the pathologic process. These anatomic localization patterns are often helpful, but not infallible, in making the diagnosis. For example, airborne contact sensitizers that are blown onto the skin may produce dermatitis that can be difficult to distinguish from photosensitivity, despite the fact that such material may trigger skin reactivity in areas shielded from direct sunlight.

Many dermatologic conditions may be caused or aggravated by sunlight (Table 57-2). The role of light in evoking these responses may be dependent on genetic abnormalities ranging from well-described defects in DNA repair that occur in XP to the inherited abnormalities in heme synthesis that characterize the porphyrias. In certain photosensitivity diseases, the chromophore has been identified, whereas in the majority, the energy-absorbing agent is unknown.

Polymorphous Light Eruption After sunburn, the most common type of photosensitivity disease is *polymorphous light eruption* (PLE), the mechanism of which is unknown. Many affected individuals never seek medical attention because the condition is often transient, becoming manifest each spring with initial sun exposure but then sub-

siding spontaneously with continuing exposure, a phenomenon known as "hardening." The major manifestations of PLE include pruritic (often intensely so) erythematous papules that may coalesce into plaques in a patchy distribution on exposed areas of the trunk and forearms. The face is usually less seriously involved.

The diagnosis can be confirmed by skin biopsy and by performing phototest procedures in which skin is exposed to multiple erythema doses of UV-A and UV-B. The action spectrum for PLE is usually within these portions of the solar spectrum.

Treatment of this PLE includes the use of sunscreens and the induction of hardening by the cautious administration of artificial UV-B (broad-band or narrow-band) and/or UV-A radiation for 2–3 weeks prior to initial sun exposure.

Phototoxicity and Photoallergy These photosensitivity disorders are related to the topical or systemic administration of drugs and other chemicals. Both reactions require the absorption of energy by a drug or chemical resulting in the production of an excited-state photosensitizer that can transfer its absorbed energy to a bystander molecule or to molecular oxygen, thereby generating tissue-destructive chemical species, including ROS.

Phototoxicity is a nonimmunologic reaction caused by drugs and chemicals, a few of which are listed in Table 57-3. The usual clinical manifestations include erythema resembling a sunburn reaction that quickly desquamates, or "peels," within several days. In addition, edema, vesicles, and bullae may occur.

Photoallergy is much less common and is distinct in that this is an immunopathologic process. The excited-state photosensitizer may create highly unstable haptenic free radicals that bind covalently to macromolecules to form a functional antigen capable of evoking a delayed hypersensitivity response. Some of the drugs and chemicals that produce photoallergy are listed in Table 57-4. The clinical manifestations typically differ from those of phototoxicity in that an intensely pruritic eczematous dermatitis tends to predominate and evolves into lichenified, thickened, "leathery" changes in sun-exposed areas. A small subset (perhaps 5–10%) of patients with photoallergy may develop a persistent exquisite hypersensitivity to light even when the offending drug or chemical is identified and eliminated, a condition known as *persistent light reaction*.

A very uncommon type of persistent photosensitivity is known as *chronic actinic dermatitis*. These patients are typically elderly men with a long history of preexisting allergic contact dermatitis or photosensitivity. They are usually exquisitely sensitive to UV-B, UV-A, and visible wavelengths.

Diagnostic confirmation of phototoxicity and photoallergy can often be obtained using phototest procedures. In patients with suspected phototoxicity, determining the minimal erythema dose (MED) while the patient is exposed to a suspected agent and then repeating the MED after discontinuation of the agent may provide a clue to the causative drug or chemical. Photopatch testing can be performed to confirm the diagnosis of photoallergy. This is a simple variant of ordinary patch testing in which a series of known photoallergens is applied to the skin in duplicate and one set is irradiated with a suberythema dose of UV-A. Development of eczematous changes at sites exposed to sensitizer and light is a positive result. The characteristic abnormality in patients with persistent light reaction is a diminished threshold to erythema evoked by UV-B. Patients with chronic actinic dermatitis usually manifest a broad spectrum of UV hyperresponsiveness and require meticulous photoprotection including avoiding sun exposure, high (>30) SPF sunscreens, and in severe cases systemic immunosuppression, preferably with azathioprine (1–2 mg/kg per day).

The management of drug photosensitivity involves first and foremost the elimination of exposure to the chemical agents responsible for the reaction and minimization of sun exposure. The acute symptoms of phototoxicity may be ameliorated by cool, moist compresses, topical glucocorticoids, and systemically administered NSAIDs. In severely affected individuals, a rapidly tapered course of systemic glucocorticoids may be useful. Judicious use of analgesics may be necessary.

Photoallergic reactions require a similar management approach. Furthermore, patients with persistent light reaction and chronic actinic dermatitis must be meticulously protected against light exposure. In selected patients in whom chronic systemic high-dose glucocorticoids pose unacceptable risks, it may be necessary to employ immunosuppressive drugs such as azathioprine, cyclophosphamide, cyclosporine, or mycophenolate mofetil.

Porphyria The porphyrias (Chap. 352) are a group of diseases that have in common inherited or acquired derangements in the synthesis of heme. Heme is an iron-chelated tetrapyrrole or porphyrin, and the nonmetal chelated porphyrins are potent photosensitizers that absorb light intensely in both the short (400–410 nm) and the long (580–650 nm) portions of the visible spectrum.

Heme cannot be reutilized and must be continuously synthesized, and the two body compartments with the largest capacity for its production are the bone marrow and the liver. Accordingly, the porphyrias originate in one or the other of these organs, with the end result of excessive endogenous production of potent photosensitizing porphyrins. The porphyrins circulate in the bloodstream and diffuse into the skin, where they absorb solar energy, become photoexcited, generate ROS, and evoke cutaneous photosensitivity. The mechanism of porphyrin photosensitization is known to be photodynamic, or oxygen-dependent, and is mediated by ROS such as singlet oxygen and superoxide anions.

Porphyria cutanea tarda is the most common type of human porphyria and is associated with decreased activity of the enzyme uroporphyrinogen decarboxylase associated with a number of gene mutations. There are two basic types of PCT: (1) the sporadic or acquired type, generally seen in individuals ingesting ethanol or receiving estrogens; and (2) the inherited type, in which there is autosomal dominant transmission of deficient enzyme activity. Both forms are associated with increased hepatic iron stores.

In both types of PCT, the predominant feature is a chronic photosensitivity characterized by increased fragility of sun-exposed skin, particularly areas subject to repeated trauma such as the dorsa of the hands, the

forearms, the face, and the ears. The predominant skin lesions are vesicles and bullae that rupture, producing moist erosions, often with a hemorrhagic base, that heal slowly with crusting and purplish discoloration of the affected skin. Hypertrichosis, mottled pigmentary change, and scleroderma-like induration are associated features. Biochemical confirmation of the diagnosis can be obtained by measurement of urinary porphyrin excretion, plasma porphyrin assay, and by assay of erythrocyte and/or hepatic uroporphyrinogen decarboxylase. Multiple mutations of the uroporphyrinogen decarboxylase gene have been identified in human populations, including exon skipping and base substitutions. Some patients with PCT have associated mutations in the *HFE* gene linked to hemochromatosis. This could contribute to the iron overload seen in PCT, although iron status as measured by serum ferritin, iron levels, and transferrin saturation is no different from that in PCT patients without *HFE* mutations. Prior hepatitis C virus infection appears to be an independent risk factor for PCT.

Treatment of PCT consists of repeated phlebotomies to diminish the excessive hepatic iron stores and/or intermittent low doses of the antimalarial drugs chloroquine and hydroxychloroquine. Long-term remission of the disease can be achieved if the patient eliminates exposure to porphyrinogenic agents.

Erythropoietic protoporphyria originates in the bone marrow and is due to a decrease in the mitochondrial enzyme ferrochelatase secondary to numerous gene mutations. The major clinical features include an acute photosensitivity characterized by subjective burning and stinging of exposed skin that often develops during or just after exposure. There may be associated skin swelling and, after repeated episodes, a waxlike scarring.

The diagnosis is confirmed by demonstration of elevated levels of free erythrocyte protoporphyrin. Detection of increased plasma protoporphyrin helps to differentiate lead poisoning and iron-deficiency anemia, in both of which elevated erythrocyte protoporphyrin levels occur in the absence of cutaneous photosensitivity and of elevated plasma protoporphyrin levels.

Treatment consists of reducing sun exposure and the oral administration of the carotenoid β-carotene, which is an effective scavenger of free radicals. This drug increases tolerance to sun exposure in many affected individuals, although it has no effect on deficient ferrochelatase.

An algorithm for managing patients with photosensitivity is illustrated in Fig. 57-1.

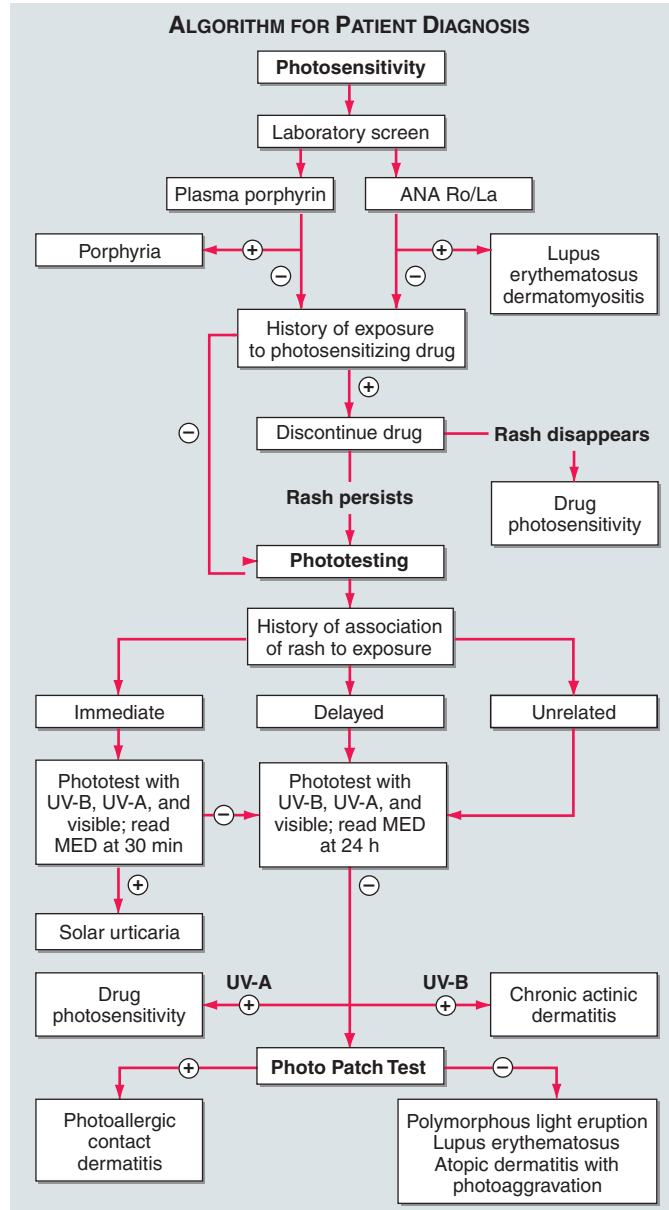

FIGURE 57-1 An algorithm for the diagnosis of a patient with photosensitivity.

PHOTOPROTECTION

Since photosensitivity of the skin results from exposure to sunlight, it follows that absolute avoidance of the sun would eliminate these disorders. Unfortunately, contemporary life-styles make this an impractical alternative for most individuals, and this has led to a search for better approaches to photoprotection.

Natural photoprotection is provided by structural proteins in the epidermis, particularly keratins and melanin. The amount of melanin and its distribution in cells is genetically regulated, and individuals of darker complexion (skin types IV–VI) are at decreased risk for the development of acute sunburn and cutaneous malignancy.

Other forms of photoprotection include clothing and sunscreens. Clothing constructed of tightly woven sun-protective fabrics, irrespective of color, affords substantial protection. Wide-brimmed hats, long sleeves, and trousers all reduce direct exposure. Sunscreens are now considered to be over-the-counter drugs and category I ingredients are recognized by the U.S. Food and Drug Administration (FDA) as monographed and safe and effective. These are listed in Table 57-5. Sunscreens are rated for their photoprotective effect by their SPF. The SPF is simply a ratio of the time required to produce sunburn erythema with and without sunscreen application. The monograph stipulates that sunscreens must be rated on a scale ranging from minimal (SPF ⩽2 and ⩾12) to moderate (SPF ⩽12 and ⩾30) to high (SPF ≥30, labeled as 30+). No SPF number >30 can be placed on the label.

In addition to light absorption, a critical determinant of the sustained photoprotective effect of sunscreens is their water-resistance.

TABLE 57-5 FDA CATEGORY 1 MONOGRAPHED SUNSCREEN INGREDIENTS[a]

Ingredients	Maximum Concentration, %
p-Aminobenzoic acid (PABA)	15
Avobenzone	3
Cinoxate	3
Dioxybenzone (benzophenone-8)	3
Ecamsule[b]	15
Homosalate	15
Menthyl anthranilate	5

Padimate O (octyl dimethyl PABA)	8
Phenylbenzimidazole sulfonic acid	4
Sulisobenzone (benzophenone-4)	10
Titanium dioxide	25
Trolamine salicylate	12
Zinc oxide	25

[a]FDA, U.S. Food and Drug Administration.
[b]Recently approved by the FDA.

The FDA monograph has also defined strict testing criteria for sunscreens making this claim.

Some degree of photoprotection can also be achieved by limiting the time of exposure during the day. Since the majority of an individual's total lifetime sun exposure may occur by the age of 18, it is important to educate parents and young children about the hazards of sunlight. Simply eliminating exposure at midday will substantially reduce lifetime UV-B exposure.

PHOTOTHERAPY AND PHOTOCHEMOTHERAPY

UV can also be used therapeutically. The administration of UV-B alone or in combination with topically applied agents can induce remissions of psoriasis and atopic dermatitis.

Photochemotherapy in which topically applied or systemically administered psoralens are combined with UV-A (PUVA) is also effective in treating psoriasis and in the early stages of cutaneous T cell lymphoma and vitiligo. Psoralens are tricyclic furocoumarins that, when intercalated into DNA and exposed to UV-A, form adducts with pyrimidine bases and eventually form DNA cross-links. These structural changes are thought to decrease DNA synthesis and relate to the improvement that occurs in psoriasis. The reason that PUVA photochemotherapy is effective in cutaneous T cell lymphoma is not clear.

In addition to its effects on DNA, PUVA photochemotherapy also stimulates epidermal thickening and melanin synthesis; the latter provides the rationale for its use in the depigmenting disease vitiligo. Oral 8-methoxypsoralen and UV-A appear to be most effective in this regard, but as many as 100 treatments extending over 12–18 months may be required to promote satisfactory repigmentation.

Not surprisingly the major side effects of long-term UV-B phototherapy and PUVA photochemotherapy mimic those seen in individuals with chronic sun exposure and include skin dryness, actinic keratoses, and an increased risk of skin cancer. Despite these risks, the therapeutic index of these modalities continues to be excellent.

58 Anemia and Polycythemia

John W. Adamson, Dan L. Longo

HEMATOPOIESIS AND THE PHYSIOLOGIC BASIS OF RED CELL PRODUCTION

Hematopoiesis is the process by which the formed elements of the blood are produced. The process is regulated through a series of steps beginning with the pluripotent hematopoietic stem cell. Stem cells are capable of producing red cells, all classes of granulocytes, monocytes, platelets, and the cells of the immune system. The precise molecular mechanism—either intrinsic to the stem cell itself, or through the action of extrinsic factors—by which the stem cell becomes committed to a given lineage is not fully defined. However, experiments in mice suggest that erythroid cells come from a common erythroid/megakaryocyte progenitor that does not develop in the absence of expression of the GATA-1 and FOG-1 (friend of GATA-1) transcription factors (Chap. 68). Following lineage commitment, hematopoietic progenitor and precursor cells come increasingly under the regulatory influence of growth factors and hormones. For red cell production, erythropoietin (EPO) is the regulatory hormone. EPO is required for the maintenance of committed erythroid progenitor cells that, in the absence of the hormone, undergo programmed cell death (*apoptosis*). The regulated process of red cell production is *erythropoiesis*, and its key elements are illustrated in Fig. 58-1.

In the bone marrow, the first morphologically recognizable erythroid precursor is the pronormoblast. This cell can undergo 4–5 cell divisions that result in the production of 16–32 mature red cells. With increased EPO production, or the administration of EPO as a drug, early progenitor cell numbers are amplified and, in turn, give rise to increased numbers of erythrocytes. The regulation of EPO production itself is linked to O_2 availability.

In mammals, O_2 is transported to tissues bound to the hemoglobin contained within circulating red cells. The mature red cell is 8 μm in diameter, anucleate, discoid in shape, and extremely pliable in order to traverse the microcirculation successfully; its membrane integrity is maintained by the intracellular generation of ATP. Normal red cell production results in the daily replacement of 0.8–1% of all circulating red cells in the body, since the average red cell lives 100–120 days. The organ responsible for red cell production is called the *erythron*. The erythron is a dynamic organ made up of a rapidly proliferating pool of marrow erythroid precursor cells and a large mass of mature circulating red blood cells. The size of the red cell mass reflects the balance of red cell production and destruction. The physiologic basis of red cell production and destruction provides an understanding of the mechanisms that can lead to anemia.

The physiologic regulator of red cell production, the glycoprotein hormone EPO, is produced and released by peritubular capillary lining cells within the kidney. These cells are highly specialized epithelial-like cells. A small amount of EPO is produced by hepatocytes. The

e10 Atlas of Skin Manifestations of Internal Disease

Thomas J. Lawley, Stephen F. Templeton

In the practice of medicine, virtually every clinician encounters patients with skin disease. Physicians of all specialties face the daily task of determining the nature and clinical implication of dermatologic disease. In patients with skin eruptions and rashes, the physician must confront the question of whether the cutaneous process is confined to the skin, representing a pure dermatologic event, or whether it is a manifestation of internal disease relating to the patient's overall medical condition. Evaluation and accurate diagnosis of skin lesions are also critical given the marked rise in both melanoma and nonmelanoma skin cancer. Dermatologic conditions can be classified and categorized in many different ways, and in this Atlas, a selected group of inflammatory skin eruptions and neoplastic conditions are grouped in the following manner: (A) common skin diseases and lesions, (B) nonmelanoma skin cancer, (C) melanoma and pigmented lesions, (D) infectious disease and the skin, (E) immunologically mediated skin disease, and (F) skin manifestations of internal disease.

COMMON SKIN DISEASES AND LESIONS

(Figs. e10-1 to e10-19) In this section, several common inflammatory skin diseases and benign neoplastic and reactive lesions are presented. While most of these dermatoses usually present as a predominantly dermatologic process, underlying systemic associations may be made in some settings. Atopic dermatitis is often present in patients with an atopic diathesis, including asthma and sinusitis. Psoriasis ranges from limited patches on the elbows and knees to severe erythrodermic involvement and associated psoriatic arthritis. Some patients with alopecia areata may have an underlying thyroid abnormality requiring screening. Finally, even acne vulgaris, one of the most common inflammatory dermatoses, can be associated with a systemic process such as polycystic ovarian syndrome.

NONMELANOMA SKIN CANCER

(Figs. e10-20 to e10-27) In more fair-skinned ethnic populations, nonmelanoma skin cancer is increasing at an alarming rate. Basal cell carcinoma is the most common cancer in humans and is strongly linked to ultraviolet radiation. Squamous cell carcinoma, including keratoacanthoma-type squamous cell carcinoma, is the second most common skin cancer in most ethnic populations and is also most commonly linked to ultraviolet radiation. Less common cutaneous malignancies include cutaneous T cell lymphoma (mycosis fungoides) and carcinoma and lymphoma metastatic to skin.

FIGURE e10-27 Actinic keratoses consist of hyperkeratotic erythematous papules and patches on sun-exposed skin. They arise in middle-aged to older adults and have some potential for malignant transformation. *(Courtesy of Robert Swerlick, MD; with permission.)*

MELANOMA AND BENIGN PIGMENTED LESIONS

(Figs. e10-28 to e10-33) As the prognosis of melanoma is primarily related to microscopic depth of invasion, and early detection with surgical treatment can be curative in a high percentage of patients, it is essential that all clinicians acquire some facility in evaluating pigmented lesions. Three of the clinicopathologic subtypes of melanoma, superficial spreading, lentigo maligna, and acral lentiginous melanoma, typically display features noted in the "ABCD rule." *A*symmetry—one half of the lesion varies from the other half. *B*order irregularity—the circumferential border exhibits an irregular, sometimes jagged appearance. *C*olor—there is uneven coloration and tone to the pigmented lesion with varying shades of brown, black, red, and white within different areas of the lesion. *D*iameter—is typically >6 mm. The more uncommon subtype, nodular melanoma, may not manifest all these features but present as a more symmetric, evenly pigmented or amelanotic lesion. Dysplastic (atypical) melanocytic nevi may occur as solitary or multiple lesions as well as in the setting of familial melanoma. They display some degree of asymmetry, border irregularity, and color variation. Ordinary nevi may be acquired or congenital and are quite common.

FIGURE e10-28 Nevus. Nevi are benign proliferations of nevomelanocytes characterized by regularly shaped hyperpigmented macules or papules of a uniform color.

FIGURE e10-29 Dysplastic nevi are irregularly pigmented and shaped nevomelanocytic lesions which may be associated with familial melanoma.

FIGURE e10-32 Nodular melanoma most commonly manifests itself as a rapidly growing, often ulcerated or crusted black nodule. *(Courtesy of S. Wright Caughman, MD; with permission.)*

FIGURE e10-33 Acral lentiginous melanoma is more common in blacks, Asians, and Hispanics and occurs as an enlarging hyperpigmented macule or plaque on the palms or soles. Lateral pigment diffusion is present.

INFECTIOUS DISEASE AND THE SKIN

(Figs. e10-34 to e10-59) One of the roles of the skin is to function as a barrier from the outside world. In this capacity, exposure to infectious agents occurs, and bacterial, viral, fungal, and parasitic infections may result. In addition the skin may be secondarily involved and provide diagnostic clues to systemic infections such as meningococcemia, Rocky Mountain spotted fever, Lyme disease, and septic emboli. Most sexually transmitted bacterial and viral diseases exhibit cutaneous involvement, and examples include primary and secondary syphilis, chancroid, genital herpes simplex, and condyloma accuminatum.

FIGURE e10-34 Erysipelas is a streptococcal infection of the superficial dermis and consists of well-demarcated, erythematous, edematous, warm plaques.

IMMUNOLOGICALLY MEDIATED SKIN DISEASE

(Figs. e10-60 to e10-71) Immunologically mediated skin disease may be largely localized to skin and mucous membranes and manifest with blisters and erosions such as pemphigus, pemphigoid, and dermatitis herpetiformis. In diseases such as systemic lupus erythematosus, dermatomyositis, and vasculitis, skin manifestations are often only one element of a widespread process.

SKIN MANIFESTATIONS OF INTERNAL DISEASE

(Figs. e10-72 to e10-79) While many systemic diseases also have cutaneous manifestations, there are some well recognized dermatologic markers of internal disease, and some are demonstrated in this section. Many of these dermatologic markers may precede, accompany, or follow diagnosis of systemic disease. Acanthosis nigricans is a prototypical dermatologic process often occurring in association with underlying systemic abnormalities, most commonly obesity and insulin resistance. It may also be associated with other endocrine disorders and several rare genetic syndromes. Malignant acanthosis nigricans may occur in association with several malignancies, especially adenocarcinoma of the gastrointestinal tract, lung, and breast. Other markers of internal disease in this section include pretibial myxedema, which is associated with thyroid disease, and Sweet's syndrome, which may be associated with hematologic malignancies, solid tumors, or inflammatory bowel disease. The skin is also involved in many systemic inflammatory diseases such as sarcoidosis, rheumatoid arthritis, and lupus erythematosus.

fundamental stimulus for EPO production is the availability of O_2 for tissue metabolic needs. Impaired O_2 delivery to the kidney can result from a decreased red cell mass (*anemia*), impaired O_2 loading of the hemoglobin molecule or a high O_2 affinity mutant hemoglobin (*hypoxemia*), or, rarely, impaired blood flow to the kidney (renal artery stenosis). EPO governs the day-to-day production of red cells, and ambient levels of the hormone can be measured in the plasma by sensitive immunoassays—the normal level being 10–25 U/L. When the hemoglobin concentration falls below 100–120 g/L (10–12 g/dL), plasma EPO levels increase in proportion to the severity of the anemia (Fig. 58-2). In circulation, EPO has a half-clearance time of 6–9 h. EPO acts by binding to specific receptors on the surface of marrow erythroid precursors, inducing them to proliferate and to mature. With EPO stimulation, red cell production can increase four- to fivefold within a 1- to 2-week period but only in the presence of adequate nutrients, especially iron. The functional capacity of the erythron, therefore, requires normal renal production of EPO, a functioning erythroid marrow, and an adequate supply of substrates for hemoglobin synthesis. A defect in any of these key components can lead to anemia. Generally, anemia is recognized in the laboratory when a patient's hemoglobin level or hematocrit is reduced below an expected value (the normal range). The likelihood and severity of anemia are defined based on the deviation of the patient's hemoglobin/hematocrit from values expected for age- and sex-matched normal subjects. The hemoglobin concentration in adults has a Gaussian distribution. The mean hematocrit value for adult males is 47% (± SD 7) and that for adult females is 42% (± 5). Any single hematocrit or hemoglobin value carries with it a likelihood of associated anemia. Thus, a hematocrit of ≤39% in an adult male or <35% in an adult female has only about a 25% chance of being normal. Suspected low hemoglobin or hematocrit values are more easily interpreted if previous values for the same patient are known for comparison. The World Health Organization (WHO) defines anemia as a hemoglobin level < 130 g/L (13 g/dL) in men and <120 g/L (12 g/dL) in women.

The critical elements of erythropoiesis—EPO production, iron availability, the proliferative capacity of the bone marrow, and effective maturation of red cell precursors—are used for the initial classification of anemia (see below).

ANEMIA

CLINICAL PRESENTATION OF ANEMIA

Signs and Symptoms Anemia is most often recognized by abnormal screening laboratory tests. Patients less commonly present with advanced anemia and its attendant signs and symptoms. Acute anemia is nearly always due to blood loss or hemolysis. If blood loss is mild, enhanced O_2 delivery is achieved through changes in the O_2-hemoglobin dissociation curve mediated by a decreased pH or increased CO_2 (*Bohr effect*). With acute blood loss, hypovolemia dominates the clinical picture and the hematocrit and hemoglobin levels do not reflect the volume of blood lost. Signs of vascular instability appear with acute losses of 10–15% of the total blood volume. In such patients, the issue is not anemia but hypotension and decreased organ perfusion. When >30% of the blood volume is lost suddenly, patients are unable to compensate with the usual mechanisms of vascular contraction and changes in regional blood flow. The patient prefers to remain supine and will show postural hypotension and tachycardia. If the volume of blood lost is >40% (i.e., >2 L in the average-sized adult), signs of hypovolemic shock including confusion, dyspnea, diaphoresis, hypotension, and tachycardia appear (Chap. 101). Such patients have significant deficits in vital organ perfusion and require immediate volume replacement.

With acute hemolytic disease, the signs and symptoms depend on the mechanism that leads to red cell destruction. Intravascular hemolysis with release of free hemoglobin may be associated with acute back pain, free hemoglobin in the plasma and urine, and renal failure. Symptoms associated with more chronic or progressive anemia depend on the age of the patient and the adequacy of blood supply to critical organs. Symptoms associated with moderate anemia include fatigue, loss of stamina, breathlessness, and tachycardia (particularly with physical exertion). However, because of the intrinsic compensatory mechanisms that govern the O_2-hemoglobin dissociation curve, the gradual onset of anemia—particularly in young patients—may not be associated with signs or symptoms until the anemia is severe [hemoglobin <70–80 g/L (7–8 g/dL)]. When anemia develops over a period of days or weeks, the total blood volume is normal to slightly increased and changes in cardiac output and regional blood flow help compensate for the overall loss in O_2-carrying capacity. Changes in the position of the O_2-hemoglobin dissociation curve account for some of the compensatory response to anemia. With chronic anemia, intracellular levels of 2,3-bisphosphoglycerate rise, shifting the dissociation curve to the right and facilitating O_2 unloading. This compensatory mechanism can only maintain normal tissue O_2 delivery in the face of a 20–30 g/L (2–3 g/dL) deficit in hemoglobin concentration. Finally, further protection of O_2 delivery to vital organs is achieved by the shunting of blood away from organs that are relatively rich in blood supply, particularly the kidney, gut, and skin.

Certain disorders are commonly associated with anemia. Chronic inflammatory states (e.g., infection, rheumatoid arthritis) are associated with mild to moderate anemia, whereas lymphoproliferative disorders, such as chronic lymphocytic leukemia and certain other B cell neoplasms, may be associated with autoimmune hemolysis.

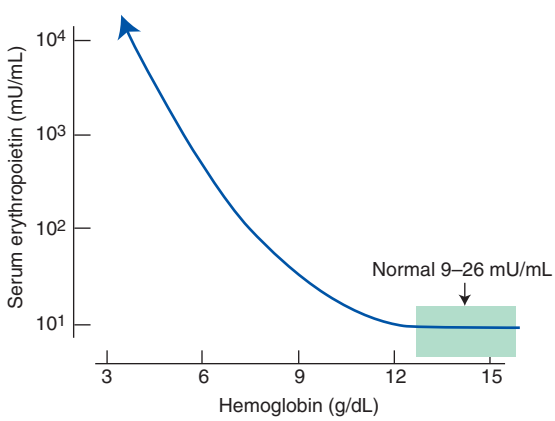

FIGURE 58-2 Erythropoietin levels in response to anemia. When the hemoglobin level falls to 120 g/L (12 g/dL), plasma erythropoietin levels increase logarithmically. In the presence of renal disease or chronic inflammation, EPO levels are typically lower than expected for a particular level of anemia. As individuals age, the level of EPO needed to sustain normal hemoglobin levels appears to increase. (*From Hillman et al.*)

APPROACH TO THE PATIENT: Anemia

The evaluation of the patient with anemia requires a careful history and physical examination. Nutritional history related to drugs or alcohol intake and family history of anemia should always be assessed. Certain geographic backgrounds and ethnic origins are associated with an increased likelihood of an inherited disorder of the hemoglobin molecule or intermediary metabolism. Glucose-6-phosphate dehydrogenase (G6PD) deficiency and certain hemoglobinopathies are seen more commonly in those of Middle Eastern or African origin, including African Americans who have a high frequency of G6PD deficiency. Other information that may be useful includes exposure to certain toxic agents or drugs and symptoms related to other disorders commonly associated with anemia. These include symptoms and signs such as bleeding, fatigue, malaise, fever, weight loss, night sweats, and other systemic symptoms. Clues to the mechanisms of anemia may be provided on physical examination by findings of infection, blood in the stool, lymphadenopathy, splenomegaly, or petechiae. Splenomegaly and lymphade-

nopathy suggest an underlying lymphoproliferative disease, while petechiae suggest platelet dysfunction. Past laboratory measurements may be helpful to determine a time of onset.

In the anemic patient, physical examination may demonstrate a forceful heartbeat, strong peripheral pulses, and a systolic "flow" murmur. The skin and mucous membranes may be pale if the hemoglobin is <80–100 g/L (8–10 g/dL). This part of the physical examination should focus on areas where vessels are close to the surface such as the mucous membranes, nail beds, and palmar creases. If the palmar creases are lighter in color than the surrounding skin when the hand is hyperextended, the hemoglobin level is usually <80 g/L (8 g/dL).

LABORATORY EVALUATION Table 58-1 lists the tests used in the initial workup of anemia. A routine complete blood count (CBC) is required as part of the evaluation and includes the hemoglobin, hematocrit, and red cell indices: the mean cell volume (MCV) in femtoliters, mean cell hemoglobin (MCH) in picograms per cell, and mean concentration of hemoglobin per volume of red cells (MCHC) in grams per liter (non-SI: grams per deciliter). The red cell indices are calculated as shown in Table 58-2, and the normal variations in the hemoglobin and hematocrit with age are shown in Table 58-3. A number of physiologic factors affect the CBC including age, sex, pregnancy, smoking, and altitude. High-normal hemoglobin values may be seen in men and women who live at altitude or smoke heavily. Hemoglobin elevations due to smoking reflect normal compensation due to the displacement of O_2 by CO in hemoglobin binding. Other important information is provided by the reticulocyte count and measurements of iron supply including *serum iron*, *total iron-binding capacity* (TIBC; an indirect measure of the transferrin level), and *serum ferritin*. Marked alterations in the red cell indices usually reflect disorders of maturation or iron deficiency. A careful evaluation of the peripheral blood smear

TABLE 58-2 RED BLOOD CELL INDICES

Index	Normal Value
Mean cell volume (MCV) = (hematocrit × 10)/(red cell count × 10^6)	90 ± 8 fL
Mean cell hemoglobin (MCH) = (hemoglobin × 10)/(red cell count × 10^6)	30 ± 3 pg
Mean cell hemoglobin concentration = (hemoglobin × 10)/hematocrit, or MCH/MCV	33 ± 2%

TABLE 58-3 CHANGES IN NORMAL HEMOGLOBIN/HEMATOCRIT VALUES WITH AGE AND PREGNANCY

Age/Sex	Hemoglobin g/dL	Hematocrit %
At birth	17	52
Childhood	12	36
Adolescence	13	40
Adult man	16 (±2)	47 (±6)
Adult woman (menstruating)	13 (±2)	40 (±6)
Adult woman (postmenopausal)	14 (±2)	42 (±6)
During pregnancy	12 (±2)	37 (±6)

is important, and clinical laboratories often provide a description of both the red and white cells, a white cell differential count, and the platelet count. In patients with severe anemia and abnormalities in red blood cell morphology and/or low reticulocyte counts, a bone marrow aspirate or biopsy may be important to assist in the diagnosis. Other tests of value in the diagnosis of specific anemias are discussed in chapters on specific disease states.

The components of the CBC also help in the classification of anemia. *Microcytosis* is reflected by a lower than normal MCV (<80), whereas high values (>100) reflect *macrocytosis*. The MCH and MCHC reflect defects in hemoglobin synthesis (*hypochromia*). Automated cell counters describe the red cell volume distribution width (RDW). The MCV (representing the peak of the distribution curve) is insensitive to the appearance of small populations of macrocytes or microcytes. An experienced laboratory technician will be able to identify minor populations of large or small cells or hypochromic cells before the red cell indices change.

Peripheral Blood Smear The peripheral blood smear provides important information about defects in red cell production. As a complement to the red cell indices, the blood smear also reveals variations in cell size (*anisocytosis*) and shape (*poikilocytosis*). The degree of anisocytosis usually correlates with increases in the RDW or the range of cell sizes. Poikilocytosis suggests a defect in the maturation of red cell precursors in the bone marrow or fragmentation of circulating red cells. The blood smear may also reveal *polychromasia*—red cells that are slightly larger than normal and grayish blue in color on the Wright-Giemsa stain. These cells are reticulocytes that have been prematurely released from the bone marrow, and their color represents residual amounts of ribosomal RNA. These cells appear in circulation in response to EPO stimulation or to architectural damage of the bone marrow (fibrosis, infiltration of the marrow by malignant cells, etc.) that results in their disordered release from the marrow. The appearance of nucleated red cells, Howell-Jolly bodies, target cells, sickle cells, and others may provide clues to specific disorders (Figs. 58-3 to 58-11).

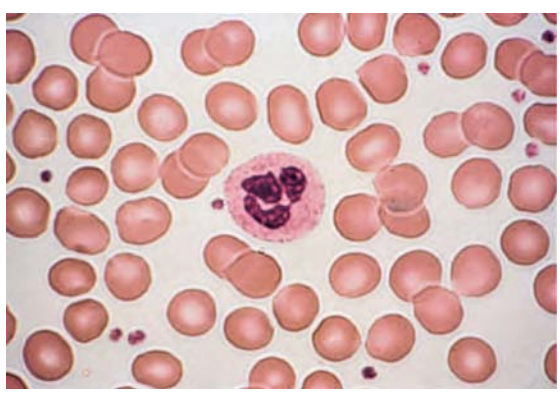

FIGURE 58-3 Normal blood smear (Wright's stain). High-power field showing normal red cells, a neutrophil, and a few platelets. (*From Hillman et al.*)

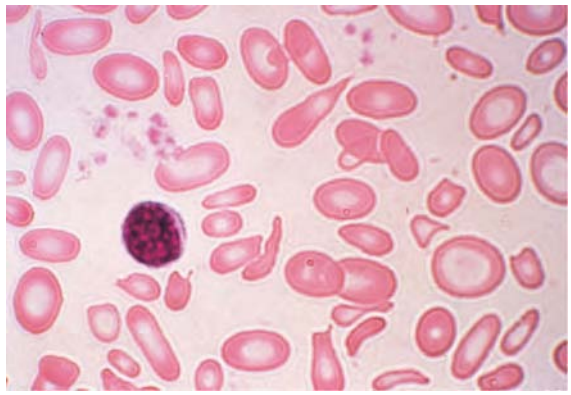

FIGURE 58-4 Severe iron-deficiency anemia. Microcytic and hypochromic red cells smaller than the nucleus of a lymphocyte associated with marked variation in size (anisocytosis) and shape (poikilocytosis). (*From Hillman et al.*)

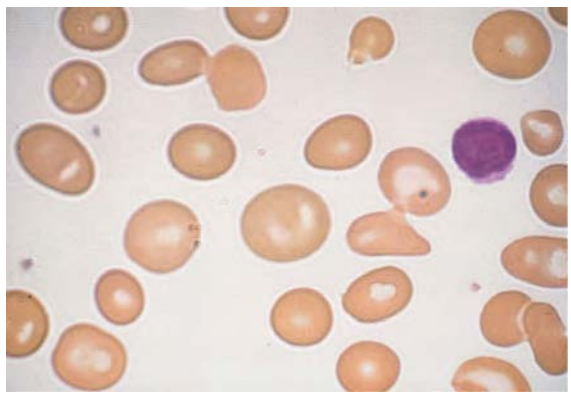

FIGURE 58-5 Macrocytosis. Red cells are larger than a small lymphocyte and well hemoglobinized. Often macrocytes are oval-shaped (macroovalocytes).

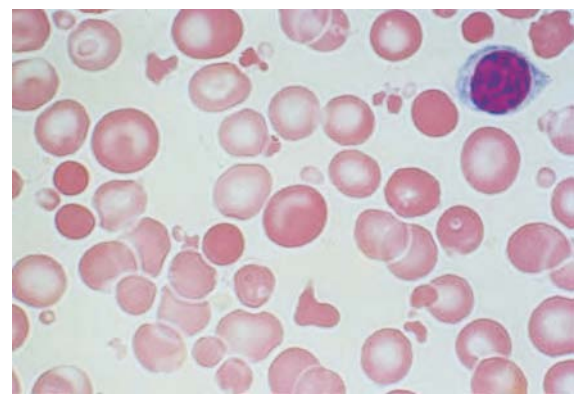

FIGURE 58-9 Red cell fragmentation. Red cells may become fragmented in the presence of foreign bodies in the circulation such as mechanical heart valves or in the setting of thermal injury. (*From Hillman et al.*)

Reticulocyte Count An accurate reticulocyte count is key to the initial classification of anemia. Normally, reticulocytes are red cells that have been recently released from the bone marrow. They are identified by staining with a supravital dye that precipitates the ribosomal RNA (Fig. 58-12). These precipitates appear as blue or black punctate spots. This residual RNA is metabolized over the first 24–36 h of the reticulocyte's lifespan in circulation. Normally, the reticulocyte count ranges from 1–2% and reflects the daily replacement of 0.8–1.0% of the circulating red cell population. A reticulocyte count provides a reliable measure of red cell production.

In the initial classification of anemia, the patient's reticulocyte count is compared with the expected reticulocyte response. In general, if the EPO and erythroid marrow responses to moderate anemia [hemoglobin < 100 g/L (10 g/dL)] are intact, the red cell production rate increases to two to three times normal within 10 days following the onset of anemia. In the face of established anemia, a reticulocyte response less than two to three times normal indicates an inadequate marrow response.

In order to use the reticulocyte count to estimate marrow response, two corrections are necessary. The first correction adjusts

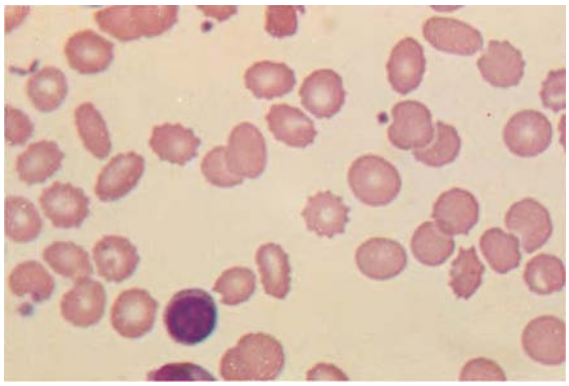

FIGURE 58-10 Uremia. The red cells in uremia may acquire numerous, regularly spaced, small spiny projections. Such cells, called burr cells or echinocytes, are readily distinguishable from irregularly spiculated acanthocytes shown in Fig. 58-11.

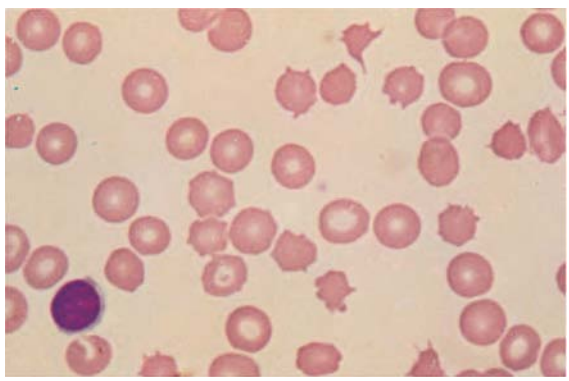

FIGURE 58-11 Spur cells. Spur cells are recognized as distorted red cells containing several irregularly distributed thornlike projections. Cells with this morphologic abnormality are also called acanthocytes. (*From Hillman et al.*)

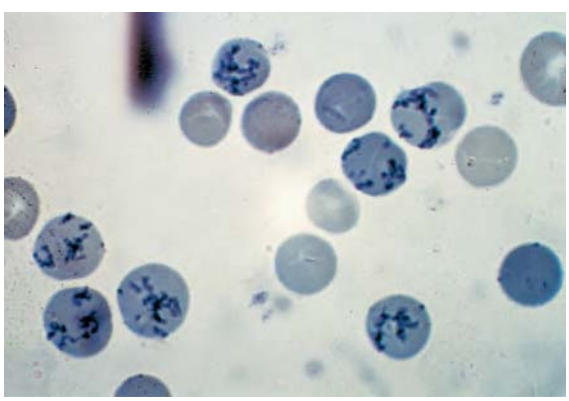

FIGURE 58-12 Reticulocytes. Methylene blue stain demonstrates residual RNA in newly made red cells. (*From Hillman et al.*)

the reticulocyte count based on the reduced number of circulating red cells. With anemia, the percentage of reticulocytes may be increased while the absolute number is unchanged. To correct for this effect, the reticulocyte percentage is multiplied by the ratio of the patient's hemoglobin or hematocrit to the expected hemoglobin/hematocrit for the age and gender of the patient (Table 58-4). This provides an estimate of the reticulocyte count corrected for anemia. In order to convert the corrected reticulocyte count to an index of marrow production, a further correction is required, depending on whether some of the reticulocytes in circulation have been released from the marrow prematurely. For this second correction, the peripheral blood smear is examined to see if there are polychromatophilic macrocytes present. These cells, representing

TABLE 58-4 CALCULATION OF RETICULOCYTE PRODUCTION INDEX

Correction #1 for anemia:
This correction produces the corrected reticulocyte count
In a person whose reticulocyte count is 9%, hemoglobin 7.5 g/dL, hematocrit 23%, the absolute reticulocyte count = 9 × (7.5/15) [or × (23/45)]= 4.5%
Correction #2 for longer life of prematurely released reticulocytes in the blood:
This correction produces the reticulocyte production index
In a person whose reticulocyte count is 9%, hemoglobin 7.5 gm/dL, hematocrit 23%, the reticulocyte production index

$$= 9 \times \frac{(7.5/15)(\text{hemoglobin correction})}{2\ (\text{maturation time correction})} = 2.25$$

prematurely released reticulocytes, are referred to as "shift" cells, and the relationship between the degree of shift and the necessary shift correction factor is shown in Fig. 58-13. The correction is necessary because these prematurely released cells survive as reticulocytes in circulation for >1 day, thereby providing a falsely high estimate of daily red cell production. If polychromasia is increased, the reticulocyte count, already corrected for anemia, should be divided again by a factor of 2 to account for the prolonged reticulocyte maturation time. The second correction factor varies from 1–3 depending on the severity of anemia. In general, a correction of 2 is commonly used. An appropriate correction is shown in Table 58-4. If polychromatophilic cells are not seen on the blood smear, the second correction is not required. The now doubly corrected reticulocyte count is the *reticulocyte production index*, and it provides an estimate of marrow production relative to normal.

Premature release of reticulocytes is normally due to increased EPO stimulation. However, if the integrity of the bone marrow release process is lost through tumor infiltration, fibrosis, or other disorders, the appearance of nucleated red cells or polychromatophilic macrocytes should still invoke the second reticulocyte correction. The shift correction should always be applied to a patient with anemia and a very high reticulocyte count to provide a true index of effective red cell production. Patients with severe chronic hemolytic anemia may increase red cell production as much as six- to sevenfold. This measure alone, therefore, confirms the fact that the patient has an appropriate EPO response, a normally functioning bone marrow, and sufficient iron available to meet the de-

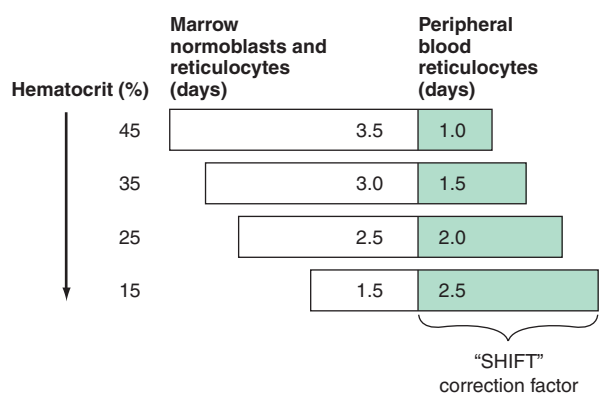

FIGURE 58-13 Correction of the reticulocyte count. In order to use the reticulocyte count as an indicator of effective red cell production, the reticulocyte number must be corrected based on the level of anemia and the circulating life span of the reticulocytes. Erythroid cells take ~4.5 days to mature. At normal hematocrit levels, they are released to the circulation with ~1 day left as reticulocytes. However, with different levels of anemia, erythroid cells are released from the marrow prematurely. Most patients come to clinical attention with hematocrits in the mid-20s and thus a correction factor of 2 is commonly used because the observed reticulocytes will live for 2 days in the circulation before losing their RNA.

TABLE 58-5 NORMAL MARROW RESPONSE TO ANEMIA

Hematocrit	Production Index	Reticulocytes (incl corrections)	Marrow M:E Ratio
45	1	1	3:1
35	2.0–3.0	4.8%/3.8/2.5	2:1–1:1
25	3.0–5.0	14%/8/4.0	1:1–1:2
15	3.0–5.0	30%/10/4.0	1:1–1:2

mands for new red cell formation. Table 58-5 demonstrates the normal marrow response to anemia. If the reticulocyte production index is <2 in the face of established anemia, a defect in erythroid marrow proliferation or maturation must be present.

Tests of Iron Supply and Storage The laboratory measurements that reflect the availability of iron for hemoglobin synthesis include the serum iron, the TIBC, and the percent transferrin saturation. The percent transferrin saturation is derived by dividing the serum iron level (× 100) by the TIBC. The normal serum iron ranges from 9–27 µmol/L (50–150 µg/dL), while the normal TIBC is 54–64 µmol/L (300–360 µg/dL); the normal transferrin saturation ranges from 25–50%. A diurnal variation in the serum iron leads to a variation in the percent transferrin saturation. The serum ferritin is used to evaluate total-body iron stores. Adult males have serum ferritin levels that average ~100 µg/L, corresponding to iron stores of ~1 g. Adult females have lower serum ferritin levels averaging 30 µg/L, reflecting lower iron stores (300 mg). A serum ferritin level of 10–15 µg/L represents depletion of body iron stores. However, ferritin is also an acute-phase reactant and, in the presence of acute or chronic inflammation, may rise severalfold above baseline levels. As a rule, a serum ferritin > 200 µg/L means there is at least some iron in tissue stores.

Bone Marrow Examination A bone marrow aspirate and smear or a needle biopsy may be useful in the evaluation of some patients with anemia. In patients with hypoproliferative anemia and normal iron status, a bone marrow is indicated. Marrow examination can diagnose primary marrow disorders such as myelofibrosis, a red cell maturation defect, or an infiltrative disease (Figs. 58-14 to 58-16). The increase or decrease of one cell lineage (myeloid vs. erythroid) compared to another is obtained by a differential count of nucleated cells in a bone marrow smear [the myeloid/erythroid (M/E) ratio]. A patient with a hypoproliferative anemia (see below) and a reticulocyte production index < 2 will demonstrate an M/E ratio of 2 or 3:1. In contrast, patients with hemolytic disease and a production index > 3 will have an M/E ratio of at least 1:1. Maturation disorders are identified from the discrepancy between the M/E ratio and the reticulocyte production index (see below). Either the marrow smear or biopsy can be stained for the presence of iron stores or iron in developing red cells. The storage iron is in the form of ferritin or *hemosiderin*. On carefully prepared bone marrow smears, small ferritin granules can normally be seen under oil immersion in 20–40% of developing erythroblasts. Such cells are called *sideroblasts*.

OTHER LABORATORY MEASUREMENTS Additional laboratory tests may be of value in confirming specific diagnoses. **For details of these tests and how they are applied in individual disorders, see Chaps. 98 to 102.**

DEFINITION AND CLASSIFICATION OF ANEMIA

Initial Classification of Anemia The functional classification of anemia has three major categories. These are: (1) marrow production defects (*hypoproliferation*), (2) red cell maturation defects (*ineffective erythropoiesis*), and (3) decreased red cell survival (*blood loss/hemolysis*). The classification is shown in Fig. 58-17. A hypoproliferative anemia is typically seen with a low reticulocyte production index together with little or no change in red cell morphology (a normocytic, normochromic anemia) (Chap. 98). Maturation disorders typically have a slight to moderately elevated reticulocyte production index that is accompanied by either macrocytic (Chap. 100) or microcytic (Chaps. 98, 99) red cell indices. Increased red blood cell destruction secondary to hemolysis results in an increase in the reticulocyte production index to at least three times normal (Chap. 101), provided sufficient iron is available. Hemorrhagic anemia does not typically result in production indices of more than 2.0–2.5 times normal because of the limitations placed on expansion of the erythroid marrow by iron availability.

In the first branch point of the classification of anemia, a reticulocyte production index > 2.5 indicates that hemolysis is most likely. A reticulocyte production index < 2 indicates either a hypoproliferative anemia or maturation disorder. The latter two possibilities can often

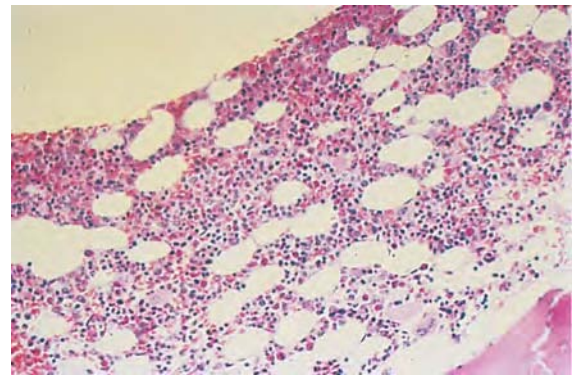

FIGURE 58-14 Normal bone marrow. This is a low-power view of a section of a normal bone marrow biopsy stained with hematoxylin and eosin (H&E). Note that the nucleated cellular elements account for ~40–50% and the fat (clear areas) accounts for ~50–60% of the area. (*From Hillman et al.*)

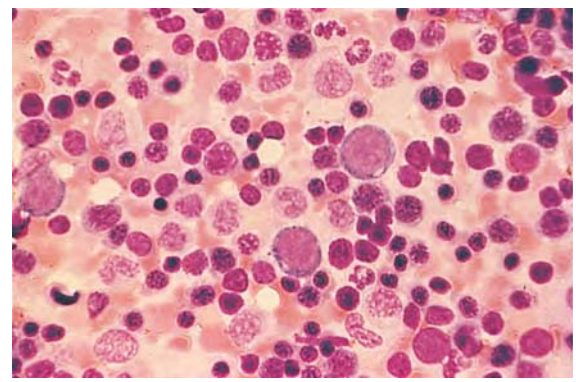

FIGURE 58-15 Erythroid hyperplasia. This marrow shows an increase in the fraction of cells in the erythroid lineage as might be seen when a normal marrow compensates for acute blood loss or hemolysis. The M/E ratio is about 1:1. (*From Hillman et al.*)

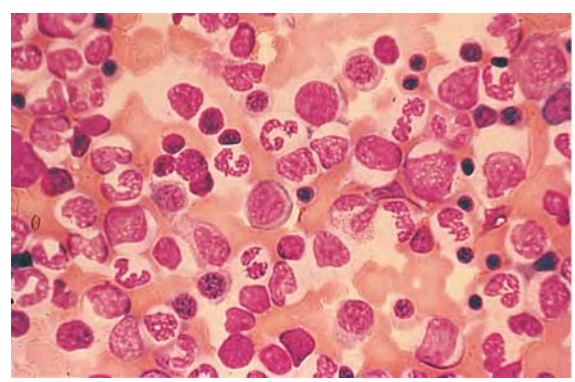

FIGURE 58-16 Myeloid hyperplasia. This marrow shows an increase in the fraction of cells in the myeloid or granulocytic lineage as might be seen in a normal marrow responding to infection. The M/E ratio is >3:1. (*From Hillman et al.*)

be distinguished by the red cell indices, by examination of the peripheral blood smear, or by a marrow examination. If the red cell indices are normal, the anemia is almost certainly hypoproliferative in nature. Maturation disorders are characterized by ineffective red cell production and a low reticulocyte production index. Bizarre red cell shapes—macrocytes or hypochromic microcytes—are seen on the peripheral blood smear. With a hypoproliferative anemia, no erythroid hyperplasia is noted in the marrow, whereas patients with ineffective red cell production have erythroid hyperplasia and an M/E ratio < 1:1.

Hypoproliferative Anemias At least 75% of all cases of anemia are hypoproliferative in nature. A hypoproliferative anemia reflects absolute or relative marrow failure in which the erythroid marrow has not proliferated appropriately for the degree of anemia. The majority of hypoproliferative anemias are due to mild to moderate iron deficiency or inflammation. A hypoproliferative anemia can result from marrow damage, iron deficiency, or inadequate EPO stimulation. The last may reflect impaired renal function, suppression of EPO production by inflammatory cytokines such as interleukin 1, or reduced tissue needs for O_2 from metabolic disease such as hypothyroidism. Only occasionally is the marrow unable to produce red cells at a normal rate, and this is most prevalent in patients with renal failure. With diabetes mellitus or myeloma, the EPO deficiency may be more marked than would be predicted by the degree of renal insufficiency. In general, hypoproliferative anemias are characterized by normocytic, normochromic red cells, although microcytic, hypochromic cells may be observed with mild iron deficiency or long-standing chronic inflammatory disease. The key laboratory tests in distinguishing between the various forms of hypoproliferative anemia include the serum iron and iron-binding capacity, evaluation of renal and thyroid function, a marrow biopsy or aspirate to detect marrow damage or infiltrative disease, and serum ferritin to assess iron stores. Occasionally, an iron stain of the marrow will be needed to determine the pattern of iron distribution. Patients with the anemia of acute or chronic inflammation show a distinctive pattern of serum iron (low), TIBC (normal or low), percent transferrin saturation (low), and serum ferritin (normal or high). These changes in iron values are brought about by hepcidin, the iron regulatory hormone that is increased in inflammation (Chap. 98). A distinct pattern of results is noted in mild to moderate iron deficiency (low serum iron, high TIBC, low percent transferrin saturation, low serum ferritin) (Chap. 98). Marrow damage by drugs, such as the antiretrovirals used to treat HIV infection, infiltrative disease such as leukemia or lymphoma, or marrow aplasia can usually be diagnosed from the peripheral blood and bone marrow morphology. With infiltrative disease or fibrosis, a marrow biopsy is required.

Maturation Disorders The presence of anemia with an inappropriately low reticulocyte production index, macro- or microcytosis on smear, and abnormal red cell indices suggests a maturation disorder. Maturation disorders are divided into two categories: nuclear maturation defects, associated with macrocytosis and abnormal marrow development, and cytoplasmic maturation defects, associated with microcytosis and hypochromia usually from defects in hemoglobin synthesis. The inappropriately low reticulocyte production index is a reflection of the ineffective erythropoiesis that results from the destruction within the marrow of developing erythroblasts. Bone marrow examination shows erythroid hyperplasia.

Nuclear maturation defects result from vitamin B_{12} or folic acid deficiency, drug damage, or myelodysplasia. Drugs that interfere with cellular DNA metabolism, such as methotrexate or alkylating agents, can produce a nuclear maturation defect. Alcohol, alone, is also capable of producing macrocytosis and a variable degree of anemia, but this is usually associated with folic acid deficiency. Measurements of folic acid and vitamin B_{12} are key not only in identifying the specific vitamin deficiency but also because they reflect different pathogenetic mechanisms.

Cytoplasmic maturation defects result from severe iron deficiency or abnormalities in globin or heme synthesis. Iron deficiency occupies an unusual position in the classification of anemia. If the iron-deficiency anemia is mild to moderate, erythroid marrow proliferation is decreased and the anemia is classified as hypoproliferative. However, if the anemia is severe and prolonged, the erythroid marrow will become hyperplastic despite the inadequate iron supply, and the anemia will be classified as ineffective erythropoiesis with a cytoplasmic maturation defect. In either case, an inappropriately low reticulocyte production index, microcytosis, and a classic pattern of iron values make the diagnosis clear and easily distinguish iron deficiency from other cytoplasmic maturation defects such as the thalassemias. Defects in heme synthesis, in contrast to globin synthesis, are less common and may be acquired or inherited (Chap. 352). Acquired abnormalities are usually associated with myelodysplasia, may lead to either a macro- or microcytic anemia, and are frequently associated with mitochondrial iron loading. In these cases, iron is taken up by the mitochondria of the developing erythroid cell but not incorporated into heme. The iron-encrusted mitochondria surround the nucleus of the erythroid cell, forming a ring. Based on the distinctive finding of so-called ringed sideroblasts on the marrow iron stain, patients are diagnosed as having a sideroblastic anemia—almost always reflecting myelodysplasia. Again, studies of iron parameters are helpful in the differential diagnosis and management of these patients.

Blood Loss/Hemolytic Anemia In contrast to anemias associated with an inappropriately low reticulocyte production index, hemolysis is associated with red cell production indices ≥2.5 times normal. The stimulated erythropoiesis is reflected in the blood smear by the appearance of increased numbers of polychromatophilic macrocytes. A marrow examination is rarely indicated if the reticulocyte production index is increased appropriately. The red cell indices are typically normocytic or slightly macrocytic, reflecting the increased number of reticulocytes. Acute blood loss is not associated with an increased reticulocyte production index because of the time required to increase EPO production and, subsequently, marrow proliferation. Subacute blood loss may be associated with modest reticulocytosis. Anemia from chronic

blood loss presents more often as iron deficiency than with the picture of increased red cell production.

The evaluation of blood loss anemia is usually not difficult. Most problems arise when a patient presents with an increased red cell production index from an episode of acute blood loss that went unrecognized. The cause of the anemia and increased red cell production may not be obvious. The confirmation of a recovering state may require observations over a period of 2–3 weeks, during which the hemoglobin concentration will be seen to rise and the reticulocyte production index fall.

Hemolytic disease, while dramatic, is among the least common forms of anemia. The ability to sustain a high reticulocyte production index reflects the ability of the erythroid marrow to compensate for hemolysis and, in the case of extravascular hemolysis, the efficient recycling of iron from the destroyed red cells to support red cell production. With intravascular hemolysis, such as paroxysmal nocturnal hemoglobinuria, the loss of iron may limit the marrow response. The level of response depends on the severity of the anemia and the nature of the underlying disease process.

Hemoglobinopathies, such as sickle cell disease and the thalassemias, present a mixed picture. The reticulocyte index may be high but is inappropriately low for the degree of marrow erythroid hyperplasia (Chap. 99).

Hemolytic anemias present in different ways. Some appear suddenly as an acute, self-limited episode of intravascular or extravascular hemolysis, a presentation pattern often seen in patients with autoimmune hemolysis or with inherited defects of the Embden-Meyerhof pathway or the glutathione reductase pathway. Patients with inherited disorders of the hemoglobin molecule or red cell membrane generally have a lifelong clinical history typical of the disease process. Those with chronic hemolytic disease, such as hereditary spherocytosis, may actually present not with anemia but with a complication stemming from the prolonged increase in red cell destruction such as symptomatic bilirubin gallstones or splenomegaly. Patients with chronic hemolysis are also susceptible to aplastic crises if an infectious process interrupts red cell production.

The differential diagnosis of an acute or chronic hemolytic event requires the careful integration of family history, the pattern of clinical presentation and—whether the disease is congenital or acquired—by a careful examination of the peripheral blood smear. Precise diagnosis may require more specialized laboratory tests, such as hemoglobin electrophoresis or a screen for red cell enzymes. Acquired defects in red cell survival are often immunologically mediated and require a direct or indirect antiglobulin test or a cold agglutinin titer to detect the presence of hemolytic antibodies or complement-mediated red cell destruction.

℞ ANEMIA

An overriding principle is to initiate treatment of mild to moderate anemia only when a specific diagnosis is made. Rarely, in the acute setting, anemia may be so severe that red cell transfusions are required before a specific diagnosis is made. Whether the anemia is of acute or gradual onset, the selection of the appropriate treatment is determined by the documented cause(s) of the anemia. Often, the cause of the anemia may be multifactorial. For example, a patient with severe rheumatoid arthritis who has been taking anti-inflammatory drugs may have a hypoproliferative anemia associated with chronic inflammation as well as chronic blood loss associated with intermittent gastrointestinal bleeding. In every circumstance, it is important to evaluate the patient's iron status fully before and during the treatment of any anemia. **Transfusion is discussed in Chap. 107; iron therapy is discussed in Chap. 98; treatment of megaloblastic anemia is discussed in Chap. 100; treatment of other entities is discussed in their respective chapters (sickle cell anemia, Chap. 99; hemolytic anemias, Chap. 101; aplastic anemia and myelodysplasia, Chap. 102).**

Therapeutic options for the treatment of anemias have expanded dramatically during the past 25 years. Blood component therapy is available and safe. Recombinant EPO as an adjunct to anemia management has transformed the lives of patients with chronic renal failure on dialysis and made some improvements in the quality of life of anemic cancer patients receiving chemotherapy. Improvements in the management of sickle cell crises and sickle cell anemia have also taken place. Eventually, patients with inherited disorders of globin synthesis or mutations in the globin gene, such as sickle cell disease, may benefit from the successful introduction of targeted genetic therapy (Chap. 65).

POLYCYTHEMIA

Polycythemia is defined as an increase in circulating red blood cells above normal. This increase may be real or only apparent because of a decrease in plasma volume (spurious or relative polycythemia). The term *erythrocytosis* may be used interchangeably with polycythemia, but some draw a distinction between them; erythrocytosis implies documentation of increased red cell mass, whereas polycythemia refers to any increase in red cells. Often patients with polycythemia are detected through an incidental finding of elevated hemoglobin or hematocrit levels. Concern that the hemoglobin level may be abnormally high is usually triggered at 170 g/L (17 g/dL) for men and 150 g/L (15 g/dL) for women. Hematocrit levels >50% in men or >45% in women may be abnormal. Hematocrits >60% in men and >55% in women are almost invariably associated with an increased red cell mass.

Historic features useful in the differential diagnosis include smoking history; living at high altitude; or a history of congenital heart disease, peptic ulcer disease, sleep apnea, chronic lung disease, or renal disease.

Patients with polycythemia may be asymptomatic or experience symptoms related to the increased red cell mass or an underlying disease process that leads to increased red cell production. The dominant symptoms from increased red cell mass are related to hyperviscosity and thrombosis (both venous and arterial), because the blood viscosity increases logarithmically at hematocrits >55%. Manifestations range from digital ischemia to Budd-Chiari syndrome with hepatic vein thrombosis. Abdominal thromboses are particularly common. Neurologic symptoms such as vertigo, tinnitus, headache, and visual disturbances may occur. Hypertension is often present. Patients with *polycythemia vera* may have aquagenic pruritus and symptoms related to hepatosplenomegaly. Patients may have easy bruising, epistaxis, or bleeding from the gastrointestinal tract. Patients with hypoxemia may develop cyanosis on minimal exertion or have headache, impaired mental acuity, and fatigue.

The physical examination usually reveals a ruddy complexion. Splenomegaly favors polycythemia vera as the diagnosis (Chap. 103). The presence of cyanosis or evidence of a right-to-left shunt suggests congenital heart disease presenting in the adult, particularly tetralogy of Fallot or Eisenmenger syndrome (Chap. 229). Increased blood viscosity raises pulmonary artery pressure; hypoxemia can lead to increased pulmonary vascular resistance. Together these factors can produce cor pulmonale.

Polycythemia can be spurious (related to a decrease in plasma volume; Gaisbock's syndrome), primary, or secondary in origin. The secondary causes are all associated with increases in EPO levels: either a physiologically adapted appropriate elevation based on tissue hypoxia (lung disease, high altitude, CO poisoning, high-affinity hemoglobinopathy) or an abnormal overproduction (renal cysts, renal artery stenosis, tumors with ectopic EPO production). A rare familial form of polycythemia is associated with normal EPO levels but hyperresponsive EPO receptors due to mutations.

APPROACH TO THE PATIENT: Polycythemia

As shown in Fig. 58-18, the first step is to document the presence of an increased red cell mass using the principle of isotope dilution by administering ^{51}Cr-labeled autologous red blood cells to the patient and sampling blood radioactivity over a 2-h period. If the red

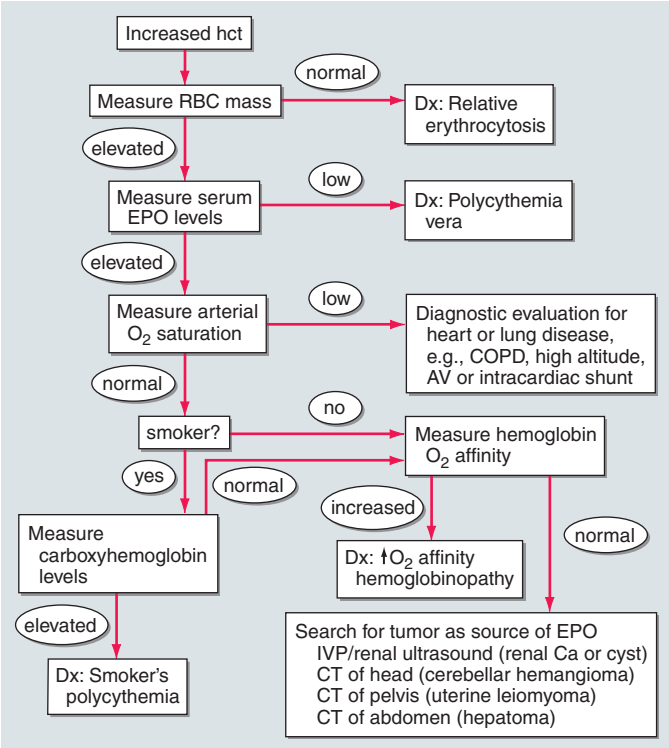

FIGURE 58-18 An approach to diagnosing patients with polycythemia. RBC, red blood cell; EPO, erythropoietin; COPD, chronic obstructive pulmonary disease; AV, atrioventricular; IVP, intravenous pyelogram; hct, hematocrit.

cell mass is normal (<36 mL/kg in men, <32 mL/kg in women), the patient has spurious polycythemia. If the red cell mass is increased (>36 mL/kg in men, >32 mL/kg in women), serum EPO levels should be measured. If EPO levels are low or unmeasurable, the patient most likely has polycythemia vera. Ancillary tests that support this diagnosis include elevated white blood cell count, increased absolute basophil count, and thrombocytosis. A mutation in *JAK-2* (Val617Phe), a key member of the cytokine intracellular signaling pathway, can be found in 70–95% of patients with polycythemia vera.

If serum EPO levels are elevated, one attempts to distinguish whether the elevation is a physiologic response to hypoxia or is related to autonomous production. Patients with low arterial O_2 saturation (<92%) should be further evaluated for the presence of heart or lung disease, if they are not living at high altitude. Patients with normal O_2 saturation who are smokers may have elevated EPO levels because of CO displacement of O_2. If carboxyhemoglobin (COHb) levels are high, the diagnosis is smoker's polycythemia. Such patients should be urged to stop smoking. Those who cannot stop smoking require phlebotomy to control their polycythemia. Patients with normal O_2 saturation who do not smoke either have an abnormal hemoglobin that does not deliver O_2 to the tissues (evaluated by finding elevated O_2-hemoglobin affinity) or have a source of EPO production that is not responding to the normal feedback inhibition. Further workup is dictated by the differential diagnosis of EPO-producing neoplasms. Hepatoma, uterine leiomyoma, and renal cancer or cysts are all detectable with abdominopelvic CT scans. Cerebellar hemangiomas may produce EPO, but they nearly always present with localizing neurologic signs and symptoms rather than polycythemia-related symptoms.

59 Bleeding and Thrombosis

Barbara A. Konkle

The human hemostatic system provides a natural balance between procoagulant and anticoagulant forces. The procoagulant forces include platelet adhesion and aggregation and fibrin clot formation; anticoagulant forces include the natural inhibitors of coagulation and fibrinolysis. Under normal circumstances, hemostasis is regulated to promote blood flow; however, it is also prepared to clot blood rapidly to arrest blood flow and prevent exsanguination. After bleeding is successfully halted, the system remodels the damaged vessel to restore normal blood flow. The major components of the hemostatic system, which function in concert, are (1) platelets and other formed elements of blood, such as monocytes and red cells; (2) plasma proteins (the coagulation and fibrinolytic factors and inhibitors); and (3) the vessel wall itself.

STEPS OF NORMAL HEMOSTASIS

PLATELET PLUG FORMATION

On vascular injury, platelets adhere to the site of injury, usually the denuded vascular intimal surface. Platelet adhesion is mediated primarily by von Willebrand factor (vWF), a large multimeric protein present in both plasma and in the extracellular matrix of the subendothelial vessel wall, which serves as the primary "molecular glue," providing sufficient strength to withstand the high levels of shear stress that would tend to detach them with the flow of blood. Platelet adhesion is also facilitated by direct binding to subendothelial collagen through specific platelet membrane collagen receptors.

Platelet adhesion results in subsequent platelet activation and aggregation. This process is enhanced and amplified by humoral mediators in plasma (e.g., epinephrine, thrombin); mediators released from activated platelets (e.g., adenosine diphosphate, serotonin); and vessel wall extracellular matrix constituents that come in contact with adherent platelets (e.g., collagen, vWF). Activated platelets undergo the release reaction, during which they secrete contents that further promote aggregation and inhibit the naturally anticoagulant endothelial cell factors. During platelet aggregation (platelet-platelet interaction), additional platelets are recruited from the circulation to the site of vascular injury, leading to the formation of an occlusive platelet thrombus. The platelet plug is anchored and stabilized by the developing fibrin mesh.

The platelet glycoprotein (Gp) IIb/IIIa ($\alpha_{IIb}\beta_3$) complex is the most abundant receptor on the platelet surface. Platelet activation converts the normally inactive GpIIb/IIIa receptor into an active receptor, enabling binding to fibrinogen and vWF. Because the surface of each platelet has about 50,000 GpIIb/IIIa fibrinogen binding sites, numerous activated platelets recruited to the site of vascular injury can rapidly form an occlusive aggregate by means of a dense network of intercellular fibrinogen bridges. Since this receptor is the key mediator of platelet aggregation, it has become an effective target for antiplatelet therapy.

FIBRIN CLOT FORMATION

Plasma coagulation proteins (*clotting factors*) normally circulate in plasma in their inactive forms. The sequence of coagulation protein reactions that culminate in the formation of fibrin was originally de-

scribed as a *waterfall* or a *cascade*. Two pathways of blood coagulation have been described in the past: the so-called extrinsic, or tissue factor, pathway and the so-called intrinsic, or contact activation, pathway. We now know that coagulation is normally initiated through tissue factor (TF) exposure and activation through the classic *extrinsic pathway*, but with critically important amplification through elements of the classic *intrinsic pathway*, as illustrated in Fig. 59-1. These reactions take place on phospholipid surfaces, usually the activated platelet surface. Coagulation testing in the laboratory can reflect other influences due to the artificial nature of the in vitro systems used (see below).

The immediate trigger for coagulation is vascular damage that exposes blood to TF that is constitutively expressed on the surfaces of subendothelial cellular components of the vessel wall, such as smooth-muscle cells and fibroblasts. TF is also present in circulating microparticles, presumably shed from cells including monocytes and platelets. TF binds the serine protease factor VIIa; the complex activates factor X to factor Xa. Alternatively, the complex can indirectly activate factor X by initially converting factor IX to factor IXa, which then activates factor X. The participation of factor XI in hemostasis is not dependent on its activation by factor XIIa but rather on its positive feedback activation by thrombin. Thus, factor XIa functions in the propagation and amplification, rather than in the initiation, of the coagulation cascade.

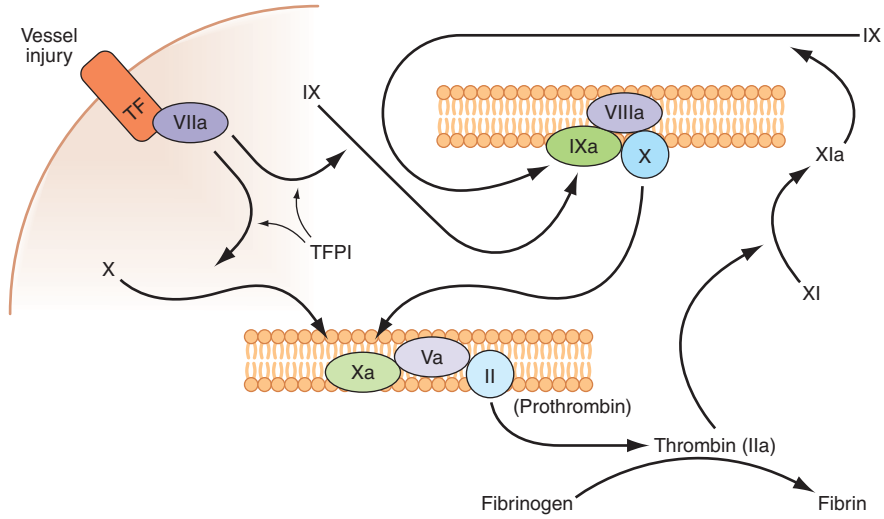

FIGURE 59-1 Coagulation is initiated by tissue factor (TF) exposure, which, with factor (F)VIIa, activates FIX and FX, which in turn, with FVIII and FV as cofactors, respectively, results in thrombin formation and subsequent conversion of fibrinogen to fibrin. Thrombin activates FXI, FVIII, and FV, amplifying the coagulation signal. Once the TF/FVIIa/FXa complex is formed, tissue factor pathway inhibitor (TFPI) inhibits the TF/FVIIa pathway, making coagulation dependent on the amplification loop through FIX/FVIII. Coagulation requires calcium (not shown) and takes place on phospholipid surfaces, usually the activated platelet membrane.

Factor Xa, which can be formed through the actions of either the tissue factor/factor VIIa complex or factor IXa (with factor VIIIa as a cofactor), converts prothrombin to thrombin, the pivotal protease of the coagulation system. The essential cofactor for this reaction is factor Va. Like the homologous factor VIIIa, factor Va is produced by thrombin-induced limited proteolysis of factor V. Thrombin is a multifunctional enzyme that converts soluble plasma fibrinogen to an insoluble fibrin matrix. Fibrin polymerization involves an orderly process of intermolecular associations (Fig. 59-2). Thrombin also activates factor XIII (fibrin-stabilizing factor) to factor XIIIa, which covalently cross-links and thereby stabilizes the fibrin clot.

The assembly of the clotting factors on activated cell membrane surfaces greatly accelerates their reaction rates and also serves to localize blood clotting to sites of vascular injury. The critical cell membrane components, acidic phospholipids, are not normally exposed on resting cell membrane surfaces. However, when platelets, monocytes, and endothelial cells are activated by vascular injury or inflammatory stimuli, the procoagulant head groups of the membrane anionic phospholipids become translocated to the surfaces of these cells or released as part of microparticles, making them available to support and promote the plasma coagulation reactions.

ANTITHROMBOTIC MECHANISMS

Several physiologic antithrombotic mechanisms act in concert to prevent clotting under normal circumstances. These mechanisms operate to preserve blood fluidity and limit blood clotting to specific focal sites of vascular injury. Endothelial cells have many antithrombotic effects. They produce prostacyclin, nitric oxide, and ectoADPase/CD39, which act to inhibit platelet binding, secretion, and aggregation. Endothelial cells produce anticoagulant factors including heparan proteoglycans, antithrombin, TF pathway inhibitor, and thrombomodulin. They also activate fibrinolytic mechanisms through the production of tissue plasminogen activator 1, urokinase, plasminogen activator inhibitor, and annexin-2. The sites of action of the major physiologic antithrombotic pathways are shown in Fig. 59-3.

Antithrombin (or antithrombin III) is the major plasma protease inhibitor of thrombin and the other clotting factors in coagulation. Antithrombin neutralizes thrombin and other activated coagulation factors by forming a complex between the active site of the enzyme and the reactive center of antithrombin. The rate of formation of these inactivating complexes increases by a factor of several thousand in the presence of heparin. Antithrombin inactivation of thrombin and other activated clotting factors occurs physiologically on vascular surfaces, where glycosaminoglycans, including heparan sulfates, are present to catalyze these reactions. Inherited quantitative or qualitative deficiencies of antithrombin lead to a lifelong predisposition to venous thromboembolism.

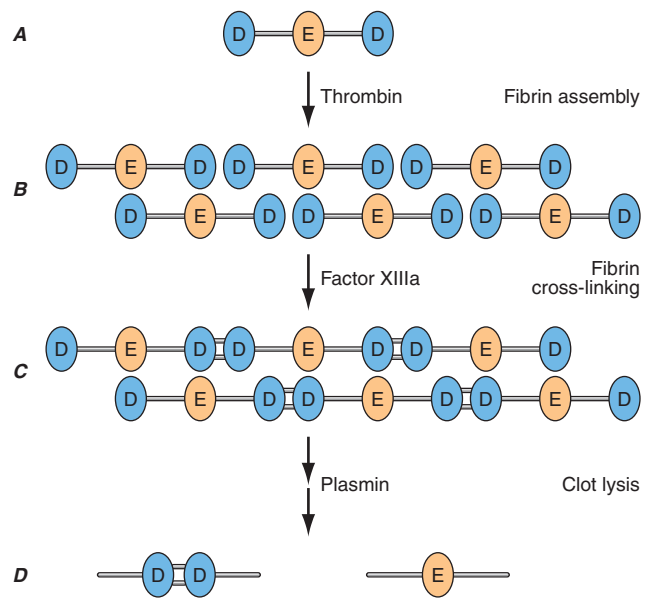

FIGURE 59-2 Fibrin formation and dissolution. *A.* Fibrinogen is a trinodular structure consisting of 2 D domains and 1 E domain. Thrombin activation results in an ordered lateral assembly of protofibrils ***(B)*** with noncovalent associations. FXIIIa cross-links the D domains on adjacent molecules ***(C).*** Fibrin and fibrinogen (not shown) lysis by plasmin occurs at discrete sites and results in intermediary fibrin(ogen) degradation products (not shown). D-Dimers are the product of complete lysis of fibrin, maintaining the cross-linked D domains.

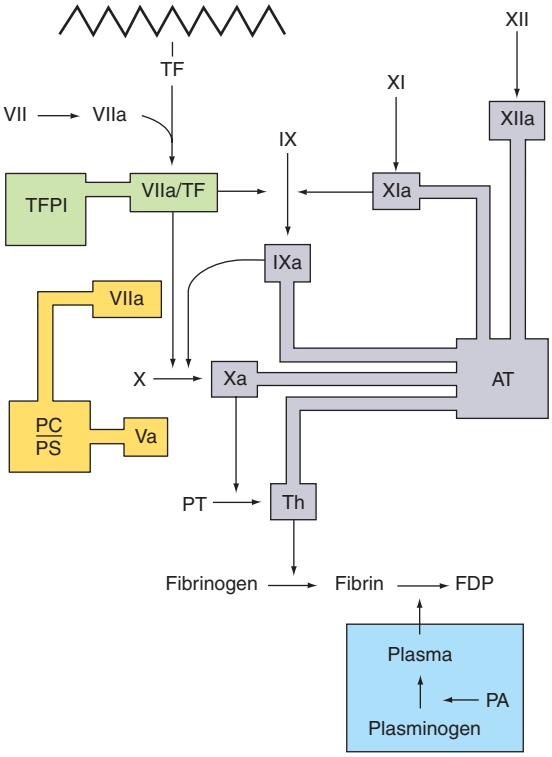

FIGURE 59-3 Sites of action of the four major physiologic antithrombotic pathways: antithrombin (AT); protein C/S (PC/PS); tissue factor pathway inhibitor (TFPI); and the fibrinolytic system, consisting of plasminogen, plasminogen activator (PA), and plasmin. PT, prothrombin; Th, thrombin; FDP, fibrin(ogen) degradation products. *[Modified from BA Konkle, AI Schafer, in DP Zipes et al (eds): Braunwald's Heart Disease, 7th ed. Philadelphia, Saunders, 2005.]*

Protein C is a plasma glycoprotein that becomes an anticoagulant when it is activated by thrombin. The thrombin-induced activation of protein C occurs physiologically on thrombomodulin, a transmembrane proteoglycan binding site for thrombin on endothelial cell surfaces. The binding of protein C to its receptor on endothelial cells places it in proximity to the thrombin-thrombomodulin complex, therefore enhancing its activation efficiency. Activated protein C acts as an anticoagulant by cleaving and inactivating activated factors V and VIII. This reaction is accelerated by a cofactor, protein S, which, like protein C, is a glycoprotein that undergoes vitamin K–dependent posttranslational modification. Quantitative or qualitative deficiencies of protein C or protein S, or resistance to the action of activated protein C by a specific mutation at its target cleavage site in factor Va (Factor V Leiden), lead to hypercoagulable states.

Tissue factor pathway inhibitor (TFPI) is a plasma protease inhibitor that regulates the TF-induced extrinsic pathway of coagulation. TFPI inhibits the TF/FVIIa/FXa complex, essentially turning off the TF/FVIIa initiation of coagulation, which then becomes dependent on the "amplification loop" via FXI and FVIII activation by thrombin. TFPI is bound to lipoprotein and can also be released by heparin from endothelial cells, where it is bound to glycosaminoglycans, and from platelets. The heparin-mediated release of TFPI may play a role in the anticoagulant effects of unfractionated and low-molecular-weight heparins.

THE FIBRINOLYTIC SYSTEM

Any thrombin that escapes the inhibitory effects of the physiologic anticoagulant systems is available to convert fibrinogen to fibrin. In response, the endogenous fibrinolytic system is then activated to dispose of intravascular fibrin and thereby maintain or reestablish the patency of the circulation. Just as thrombin is the key protease enzyme of the coagulation system, plasmin is the major protease enzyme of the fibrinolytic system, acting to digest fibrin to fibrin degradation products. The general scheme of fibrinolysis is shown in Fig. 59-4.

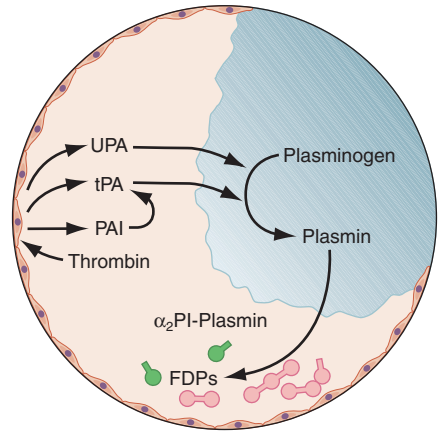

FIGURE 59-4 A schematic diagram of the fibrinolytic system. Tissue plasminogen activator (tPA) is released from endothelial cells, binds the fibrin clot, and activates plasminogen to plasmin. Excess fibrin is degraded by plasmin to distinct degradation products (FDPs). Any free plasmin is complexed with α_2-antiplasmin (α_2PI).

The plasminogen activators, tissue type plasminogen activator (tPA) and the urokinase type plasminogen activator (uPA), cleave the Arg560-Val561 bond of plasminogen to generate the active enzyme plasmin. The lysine-binding sites of plasmin (and plasminogen) permit it to bind to fibrin, so that physiologic fibrinolysis is "fibrin specific." Both plasminogen (through its lysine-binding sites) and tPA possess specific affinity for fibrin and thereby bind selectively to clots. The assembly of a ternary complex, consisting of fibrin, plasminogen, and tPA, promotes the localized interaction between plasminogen and tPA and greatly accelerates the rate of plasminogen activation to plasmin. Moreover, partial degradation of fibrin by plasmin exposes new plasminogen and tPA binding sites in carboxy-terminus lysine residues of fibrin fragments to enhance these reactions further. This creates a highly efficient mechanism to generate plasmin focally on the fibrin clot, which then becomes plasmin's substrate for digestion to fibrin degradation products.

Plasmin cleaves fibrin at distinct sites of the fibrin molecule leading to the generation of characteristic fibrin fragments during the process of fibrinolysis (Fig. 59-2). The sites of plasmin cleavage of fibrin are the same as those in fibrinogen. However, when plasmin acts on covalently cross-linked fibrin, D-dimers are released; hence, D-dimers can be measured in plasma as a relatively specific test of fibrin (rather than fibrinogen) degradation. D-Dimer assays can be used as sensitive markers of blood clot formation, and some have been validated for clinical use to exclude the diagnosis of deep venous thrombosis (DVT) and pulmonary embolism in selected populations.

Physiologic regulation of fibrinolysis occurs primarily at two levels: (1) plasminogen activator inhibitors (PAIs), specifically PAI1 and PAI2, inhibit the physiologic plasminogen activators; and (2) α_2 antiplasmin inhibits plasmin. PAI1 is the primary inhibitor of tPA and uPA in plasma. α_2 antiplasmin is the main inhibitor of plasmin in human plasma, inactivating any nonfibrin clot–associated plasmin.

APPROACH TO THE PATIENT: Bleeding and Thrombosis

CLINICAL PRESENTATION Disorders of hemostasis may be either inherited or acquired. A detailed personal and family history is key in determining the chronicity of symptoms and the likelihood of the disorder being inherited and it provides clues to underlying conditions that have contributed to the bleeding or thrombotic state. In addition, the history can give clues as to the etiology by determining (1) the bleeding (mucosal and/or joint) or thrombosis (arterial and/or venous) site, and (2) whether an underlying bleeding or clotting tendency was enhanced by another medical condition or the introduction of medications or dietary supplements.

History of Bleeding A history of bleeding is the most important predictor of bleeding risk. In evaluating a patient for a bleeding disorder, a history of at-risk situations, including the response to past surgeries, should be assessed. Does the patient have a history of spontaneous or trauma/surgery-induced bleeding? Spontaneous hemarthroses are a hallmark of moderate and severe factors VIII and IX deficiency and, in rare circumstances, of other clotting factor deficiencies. Mucosal bleeding symptoms are more suggestive of underlying platelet disorders or von Willebrand disease (vWD), termed *disorders of primary hemostasis or platelet plug formation*. Disorders affecting primary hemostasis are shown in Table 59-1.

The development of bruises (ecchymoses) after trauma is normal; however, an exaggerated response to trauma may be an indication of an underlying bleeding disorder. Ecchymoses presenting without known trauma, particularly on the trunk, and especially large ecchymoses, >2 in. in diameter, may be a sign of an underlying bleeding disorder. The introduction of medications or nutritional supplements with platelet inhibitory activity often enhance bruising and bleeding in a patient with an underlying bleeding disorder. Easy bruising can also be a sign of medical conditions in which there is no identifiable coagulopathy; instead, the conditions are caused by an abnormality of blood vessels or their supporting tissues. In Ehlers-Danlos syndrome there may be posttraumatic bleeding and a history of joint hyperextensibility. Cushing's syndrome, chronic steroid use, and aging result in changes in skin and subcutaneous tissue, and subcutaneous bleeding occurs in response to minor trauma. The latter has been termed *senile purpura*.

Epistaxis is a common symptom, particularly in children and in dry climates, and may not reflect an underlying bleeding disorder. However, it is the most common symptom in hereditary hemorrhagic telangiectasia and in boys with vWD. Clues that epistaxis is a symptom of an underlying bleeding disorder include lack of seasonal variation and bleeding that requires medical evaluation or treatment, including cauterization. Bleeding with eruption of primary teeth is seen in children with more severe bleeding disorders, such as moderate and severe hemophilia. It is uncommon in children with mild bleeding disorders. Patients with disorders of primary hemostasis (platelet adhesion) do have increased bleeding after dental cleanings and other procedures that involve gum manipulation.

Menorrhagia is defined quantitatively as a loss of >80 cc of blood per cycle, based on blood loss required to produce iron-deficiency anemia. A complaint of heavy menses is subjective and has a poor correlation with excessive blood loss. Predictors of menorrhagia include bleeding resulting in iron-deficiency anemia or a need for blood transfusion, excessive pad or tampon use, menses lasting longer than 8 days, passage of clots, bleeding through protection, or flooding at night. Menorrhagia is a common symptom in women with underlying bleeding disorders and is reported in the majority of women with vWD and factor XI deficiency and in symptomatic carriers of hemophilia A. Women with underlying bleeding disorders are more likely to have other bleeding symptoms, including bleeding after dental extractions, postoperative bleeding, and postpartum bleeding, and are much more likely to have menorrhagia beginning at menarche than women with menorrhagia due to other causes.

Postpartum hemorrhage is a common symptom in women with underlying bleeding disorders. This occurs most commonly in the first 48 h after delivery, but it may also be manifest by prolonged or excessive bleeding after discharge from the hospital. Women with a history of postpartum hemorrhage have a high risk of recurrence with subsequent pregnancies. Rupture of ovarian cysts with intra-abdominal hemorrhage has also been reported in women with underlying bleeding disorders.

Tonsillectomy is a major hemostatic challenge, as intact hemostatic mechanisms are essential to prevent excessive bleeding from the tonsillar bed. Bleeding may occur early after surgery or after approximately 7 days postoperatively, with loss of the eschar at the operative site. Similar delayed bleeding is seen after colonic polyp resection by cautery. Gastrointestinal (GI) bleeding and hematuria are usually due to underlying pathology and procedures to identify and treat the bleeding site should be undertaken, even in patients with known bleeding disorders. vWD, particularly types 2 and 3, has been associated with angiodysplasia of the bowel and GI bleeding.

TABLE 59-1 PRIMARY HEMOSTATIC (PLATELET PLUG) DISORDERS

- Defects of Platelet Adhesion
  - von Willebrand disease
  - Bernard-Soulier syndrome (absence of dysfunction of GpIb-IX-V)
- Defects of Platelet Aggregation
  - Glanzmann's thrombasthenia (absence or dysfunction of GpIIbIIIa)
  - Afibrinogenemia
- Defects of Platelet Secretion
  - Decreased cyclooxygenase activity
    - Drug-induced (aspirin, nonsteroidal anti-inflammatory agents)
    - Inherited
  - Granule storage pool defects
    - Inherited
    - Acquired
  - Nonspecific drug effects
  - Uremia
  - Platelet coating (e.g., paraprotein, penicillin)
- Defect of platelet coagulant activity
  - Scott's syndrome

Hemarthroses and spontaneous muscle hematomas are characteristic of moderate or severe congenital factor VIII or IX deficiency. They can also be seen in moderate and severe deficiencies of fibrinogen, prothrombin, and of factors V, VII, and X. Spontaneous hemarthroses occur rarely in other bleeding disorders except for severe vWD, with associated FVIII levels <5%. Muscle and soft tissue bleeds are also common in acquired FVIII deficiency. Bleeding into a joint results in severe pain and swelling, as well as loss of function, but is rarely associated with discoloration from bruising around the joint. Life-threatening sites of bleeding include bleeding into the oropharynx, where bleeding can obstruct the airway, into the central nervous system, and into the retroperitoneum. Central nervous system bleeding is the major cause of bleeding-related deaths in patients with severe congenital factor deficiencies.

Prohemorrhagic Effects of Medications and Dietary Supplements Aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) that inhibit cyclooxygenase 1 impair primary hemostasis and may exacerbate bleeding from another cause or even unmask a previously occult mild bleeding disorder such as vWD. All NSAIDs, however, can precipitate gastrointestinal bleeding, which may be more severe in patients with underlying bleeding disorders. The aspirin effect on platelet function as assessed by aggregometry can persist for up to 7 days, although it has frequently returned to normal by 3 days after the last dose. The effect of other NSAIDs is shorter, as the inhibitor effect is reversed when the drug is removed.

Many herbal supplements can impair hemostatic function (Table 59-2). Some have been more convincingly associated with a bleeding risk than others. Fish oil or concentrated omega 3 fatty acid supplements impair platelet activation. They alter platelet biochemistry to produce more PGI3, a more potent platelet inhibitor than prostacyclin (PGI2), and more thromboxane A3, a less potent platelet activator than thromboxane A2. In fact, diets naturally rich in omega 3 fatty acids can result in a prolonged bleeding time and abnormal platelet aggregation studies, but the actual associated bleeding risk is unclear. Vitamin E appears to inhibit protein kinase C–mediated platelet aggregation and nitric oxide production. In patients with unexplained bruising or bleeding, it is prudent to review any new medications or supplements and discontinue those that may be associated with bleeding.

Underlying Systemic Diseases That Cause or Exacerbate a Bleeding Tendency Acquired bleeding disorders are commonly secondary to, or associated with, systemic disease. The clinical evaluation of a patient with a bleeding tendency must therefore include a thorough

assessment for evidence of underlying disease. Bruising or mucosal bleeding may be the presenting complaint in liver disease, severe renal impairment, hypothyroidism, paraproteinemias or amyloidosis, and conditions causing bone marrow failure. All coagulation factors are synthesized in the liver and hepatic failure results in combined factor deficiencies. This is often compounded by thrombocytopenia from splenomegaly due to portal hypertension. Coagulation factors II, VII, IX, X and proteins C, S, and Z are dependent on vitamin K for posttranslational modification. Although Vitamin K is required in both procoagulant and anticoagulant processes, the phenotype of vitamin K deficiency or the warfarin effect on coagulation is bleeding.

The normal blood platelet count is 150,000–450,000/μL. Thrombocytopenia results from decreased production, increased destruction, and/or sequestration. Although the bleeding risk varies somewhat by the reason for the thrombocytopenia, bleeding rarely occurs in isolated thrombocytopenia at counts <50,000/μL and usually not until <10,000–20,000/μL. Coexisting coagulopathies, as seen in liver failure or disseminated coagulation; infection; platelet-inhibitory drugs; and underlying medical conditions can all increase the risk of bleeding in the thrombocytopenic patient. Most procedures can be performed in patients with a platelet count of 50,000/μL. The level needed for major surgery will depend on the type of surgery and the patients' underlying medical state, although a count of approximately 80,000/μL is likely sufficient.

History of Thrombosis The risk of thrombosis, like that of bleeding, is influenced by both genetic and environmental influences. The major risk factor for arterial thrombosis is atherosclerosis, while those for venous thrombosis are immobility, surgery, underlying medical conditions such as malignancy, medications such as hormonal therapy, obesity, and genetic predispositions. Factors that increase risks for venous and both venous and arterial thromboses are shown in Table 59-3.

The most important point in a history related to venous thrombosis is whether the thrombotic event was idiopathic (meaning there was no clear precipitating factor) or was a precipitated event. In patients without underlying malignancy, having an idiopathic event is the strongest predictor of recurrence of venous thromboembolism. In patients who have a vague history of thrombosis, a history of being treated with warfarin suggests a past DVT. Age is an important risk factor for venous thrombosis; the risk of DVT increases per decade, with an approximate incidence of 1/100,000 per year in early childhood to 1/200 per year among octogenarians. Family history is helpful in determining if there is a genetic predisposition and how strong that predisposition appears to be.

A genetic thrombophilia that confers a relatively small increased risk, such as being a heterozygote for the prothrombin G20210A or factor V Leiden mutation, may be a relatively minor determinant of

TABLE 59-3 RISK FACTORS FOR THROMBOSIS

Venous	Venous and Arterial
Inherited	Inherited
Factor V Leiden	Homocystinuria
Prothrombin G20210A	Dysfibrinogenemia
Antithrombin deficiency	
Protein C deficiency	Mixed (Inherited and acquired)
Protein S deficiency	Hyperhomocysteinemia
Elevated FVIII	
	Acquired
Acquired	Malignancy
Age	Antiphospholipid antibody syndrome
Previous thrombosis	Hormonal therapy
Immobilization	Polycythemia vera
Major surgery	Essential thrombocythemia
Pregnancy & puerperium	Paroxysmal nocturnal hemoglobinuria
Hospitalization	Thrombotic thrombocytopenic purpura
Obesity	Heparin-induced thrombocytopenia
Infection	Disseminated intravascular coagulation
APC resistance, nongenetic	
Unknown[a]	
Elevated factor II, IX, XI	
Elevated TAFI levels	
Low levels of TFPI	

[a]Unknown whether risk is inherited or acquired.

risk in an elderly individual undergoing a high risk surgical procedure. As shown in Fig. 59-5, a thrombotic event often has more than one contributing factor. Predisposing factors must be carefully assessed to determine the risk of recurrent thrombosis, and with consideration of the patient's bleeding risk, determine the length of anticoagulation. Similar consideration should be given to determining the need to test the patient and family members for genetic thrombophilias.

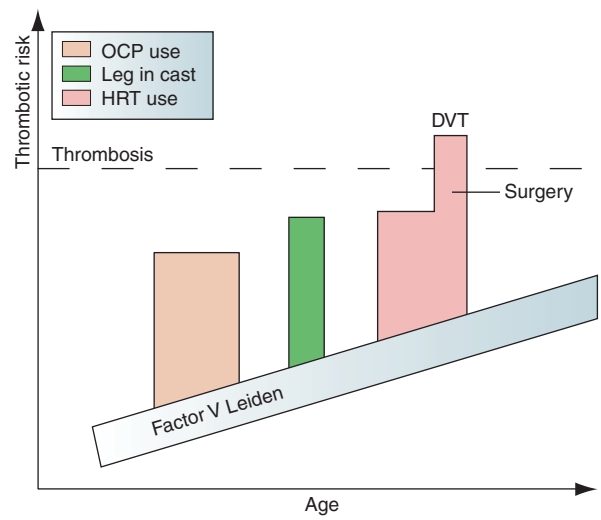

FIGURE 59-5 Thrombotic risk over time. Shown schematically is an individual's thrombotic risk over time. An underlying Factor V Leiden mutation provides a "theoretically" constant increased risk. The thrombotic risk increases with age and, intermittently, with oral contraceptive (OCP) or hormone replacement (HRT) use; other events may increase the risk further. At some point the cumulative risk may increase to the threshold for thrombosis and result in deep venous thrombosis (DVT). Note: The magnitude and duration of risk portrayed in the figure is meant for example only and may not precisely reflect the relative risk determined by clinical study. *[From BA Konkle, A Schafer, in DP Zipes et al (eds): Braunwald's Heart Disease, 7th ed. Philadelphia, Saunders, 2005; modified with permission from FR Rosendaal: Venous thrombosis: A multicausal disease. Lancet 353:1167, 1999.]*

LABORATORY EVALUATION Careful history taking and clinical examination are essential components in the assessment of bleeding and thrombotic risk. The use of laboratory tests of coagulation complement, but cannot substitute for, clinical assessment. No test provides a global assessment of hemostasis. The bleeding time has been used to assess bleeding risk; however, it does not predict bleeding risk with surgery and is not recommended for this indication. The PFA-100, an instrument that measures platelet-dependent coagulation under flow conditions, is more sensitive and specific for platelet disorders and vWD than the bleeding time; however, it is not sensitive enough to rule out underlying mild bleeding disorders. Also, it has not been evaluated prospectively to determine its utility in predicting bleeding risk, although such studies are underway.

For routine preoperative and preprocedure testing, an abnormal prothrombin time (PT) may detect liver disease or vitamin K deficiency that had not been previously appreciated. Studies have not confirmed the usefulness of an activated partial thromboplastin time (aPTT) in preoperative evaluations in patients with a negative bleeding history. The primary use of coagulation testing should be to confirm the presence and type of bleeding disorder in a patient with a suspicious clinical history.

Because of the nature of coagulation assays, proper sample acquisition and handling is critical to obtaining valid results. In patients with abnormal coagulation assays who have no bleeding history, repeat studies with attention to these factors frequently results in normal values. Most coagulation assays are performed in sodium citrate anticoagulated plasma that is recalcified for the assay. Because the anticoagulant is in liquid solution and needs to be added to blood in proportion to the plasma volume, incorrectly filled or inadequately mixed blood collection tubes will give erroneous results. Vacutainer tubes should be filled to >90% of the recommended fill, which is usually denoted by a line on the tube. An elevated hematocrit (>55%) can result in a false value due to a decreased plasma to anticoagulant ratio.

Screening Assays The most commonly used screening tests are the PT, aPTT, and platelet count. The PT assesses the factors I (fibrinogen), II (prothrombin), V, VII and X (Fig. 59-6). The PT measures the time for clot formation of the citrated plasma after recalcification and addition of thromboplastin, a mixture of TF and phospholipids. The sensitivity of the assay varies by the source of thromboplastin. To adjust for this variability, the overall sensitivity of different thromboplastins to reduction of the vitamin K–dependent clotting factors II, VII, IX, and X in anticoagulated patients is now expressed as the International Sensitivity Index (ISI). An inverse relationship exists between the ISI and thromboplastin sensitivity. The international normalized ratio (INR) is then determined based on the formula: $INR = (PT_{patient}/PT_{normal\ mean})^{ISI}$.

While the INR was developed to assess anticoagulation due to reduction of vitamin K–dependent coagulation factors, it is commonly used in the evaluation of patients with liver disease. This measure provides a system for comparing values from testing performed at different laboratories. However, as progressive liver failure is associated with variable changes in coagulation factors, the degree of prolongation of either the PT or the INR only roughly predicts the bleeding risk. Thrombin generation has been shown to be normal in many patients with mild to moderate liver dysfunction. As the PT only measures one aspect of hemostasis affected by liver dysfunction, we likely overestimate the bleeding risk of a mildly elevated INR in this setting.

The aPTT assesses the intrinsic and common coagulation pathways, factors XI, IX, VIII, X, V, II, fibrinogen, and also prekallikrein, high molecular weight kininogen and factor XII (Fig. 59-6). The aPTT reagent contains phospholipids derived from either animal or vegetable sources that function as a platelet substitute in the coagulation pathways and includes an activator of the intrinsic coagulation system, such as ellagic acid or the particulate activators kaolin, celite, or micronized silica.

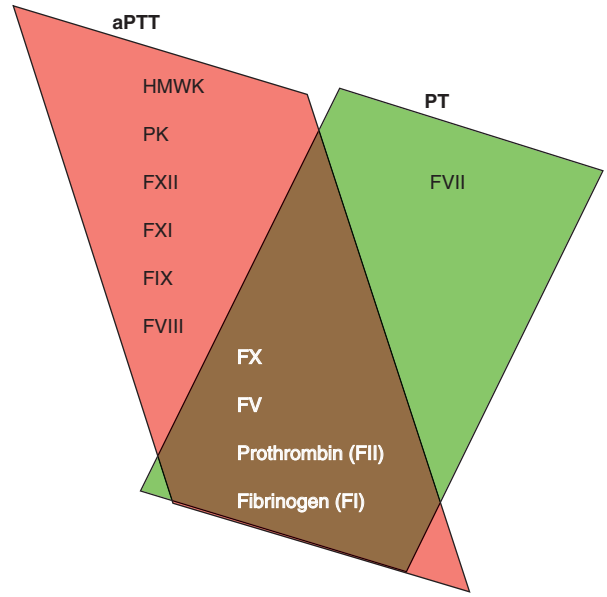

FIGURE 59-6 Coagulation factor activity tested in the activated partial thromboplastin time (aPTT) in red and prothrombin time (PT) in green, or both. HMWK, high-molecular-weight kininogen; PK, prekallikrein; F, factor.

The phospholipid composition of aPTT reagents varies, which influences the sensitivity of individual reagents to clotting factor deficiencies and to inhibitors such as heparin and lupus anticoagulants. Thus, aPTT results will vary from one laboratory to another, and the normal range in the laboratory where the testing occurs should be used in the interpretation. Local laboratories can relate their aPTT values to therapeutic heparin anticoagulation by correlating aPTT values with direct measurements of heparin activity (anti-Xa or protamine titration assays) in samples from heparinized patients, although correlation between these assays is often poor. The aPTT reagent will vary in sensitivity to individual factor deficiencies and usually becomes prolonged with individual factor deficiencies of 30–50%. The relationship between defects in secondary hemostasis (fibrin formation) and coagulation test abnormalities is shown in Table 59-4.

Mixing Studies Mixing studies are used to evaluate a prolonged aPTT or, less commonly PT, to distinguish between a factor deficiency and an inhibitor. In this assay, normal plasma and patient plasma are mixed in a 50:50 ratio, and the aPTT or PT is determined immediately and after incubation at 37°C for varying times, typically 30, 60, and/or 120 min. With isolated factor deficiencies, the aPTT will correct with mixing and stay corrected with incubation. With aPTT prolongation due to a lupus anticoagulant, the mixing and incubation will show no correction. In acquired neutralizing factor antibodies, such as an acquired factor VIII inhibitor, the initial assay may or may not correct immediately after mixing but will prolong or remain prolonged with incubation at 37°C. Failure to correct with mixing can also be due to the presence of other inhibitors or interfering substances such as heparin, fibrin split products, and paraproteins.

Specific Factor Assays Decisions to proceed with specific clotting factor assays will be influenced by the clinical situation and the results of coagulation screening tests. Precise diagnosis and effective management of inherited and acquired coagulation deficiencies necessitate quantitation of the relevant factors. When bleeding is severe, specific assays are often urgently required to guide appropriate therapy. Individual factor assays are usually performed as modifications of the mixing study, where the patient's plasma is

TABLE 59-4 HEMOSTATIC DISORDERS AND COAGULATION TEST ABNORMALITIES

- Prolonged activated partial thromboplastin time (aPTT)
  - No clinical bleeding – ↓ factors XII, high-molecular-weight kininogen, protein kinase
  - Variable, but usually mild, bleeding – ↓ factor XI, mild ↓ FVIII and FIX
  - Frequent, severe bleeding – severe deficiencies of FVIII and FIX
  - Heparin
- Prolonged prothrombin time (PT)
  - Factor VII deficiency
  - Vitamin K deficiency – early
  - Warfarin anticoagulation
- Prolonged aPTT and PT
  - Factor II, V or X deficiency
  - Vitamin K deficiency – late
  - Direct thrombin inhibitors
- Prolonged thrombin time
  - Heparin or heparin-like inhibitors
  - Mild or no bleeding – dysfibrinogenemia
  - Frequent, severe bleeding – afibrinogenemia
- Prolonged PT and/or aPTT not correct with mixing with normal plasma
  - Bleeding – specific factor inhibitor
  - No symptoms, or clotting and/or pregnancy loss – lupus anticoagulant
  - Disseminated intravascular coagulation
  - Heparin or direct thrombin inhibitor
- Abnormal clot solubility
  - Factor XIII deficiency
  - Inhibitors or defective cross-linking
- Rapid clot lysis
  - Deficiency of α_2-antiplasmin or plasminogen activator inhibitor 1
  - Treatment with fibrinolytic therapy

mixed with plasma deficient in the factor being studied. This will correct all factor deficiencies to >50%, thus making prolongation of clot formation due to a factor deficiency dependent on the factor missing from the added plasma.

Testing for Antiphospholipid Antibodies Antibodies to phospholipids (cardiolipin) or phospholipid-binding proteins (β_2-microglobulin and others) are detected by ELISA. When these antibodies interfere with phospholipid-dependent coagulation tests, they are termed *lupus anticoagulants*. The aPTT has variable sensitivity to lupus anticoagulants, depending in part on the aPTT reagents used. An assay utilizing a sensitive reagent has been termed an *LA-PTT*. The dilute Russell Viper Venom test (dRVVT) and the tissue thromboplastin time (TTI) are modifications of standard tests with the phospholipid reagent decreased, thus increasing the sensitivity to antibodies that interfere with the phospholipid component. The tests, however, are not specific for lupus anticoagulants, as factor deficiencies or other inhibitors also result in prolongation. Documentation of a lupus anticoagulant requires not only prolongation of a phospholipid-dependent coagulation test but also lack of correction when mixed with normal plasma and correction with the addition of activated platelet membranes or certain phospholipids, e.g., hexagonal phase.

Other Coagulation Tests The thrombin time and the reptilase time measure fibrinogen conversion to fibrin and are prolonged when the fibrinogen level is low (usually <80–100 mg/dL); qualitatively abnormal, as seen in inherited or acquired dysfibrinogenemias; or when fibrin/fibrinogen degradation products interfere. The thrombin time, but not the reptilase time, is prolonged in the presence of heparin. Measurement of anti-factor Xa plasma inhibitory activity is a test frequently used to assess low-molecular-weight heparin (LMWH) activity or as a direct measurement of unfractionated heparin (UFH) activity. Heparin in the patient sample inhibits the enzymatic conversion of an Xa-specific chromogenic substrate to colored product by factor Xa. Standard curves are created using multiple concentrations of UFH and LMWH and are used to calculate the concentration of anti-Xa activity in the patient plasma.

Laboratory Testing for Thrombophilia Laboratory assays to detect thrombophilic states include molecular diagnostic, immunologic and functional assays. These assays vary in their sensitivity and specificity for the condition being tested. Furthermore, acute thrombosis, acute illnesses, inflammatory conditions, pregnancy, and medications affect levels of many coagulation factors and their inhibitors. Antithrombin is decreased by heparin and in the setting of acute thrombosis. Protein C and S levels may be increased in the setting of acute thrombosis and are decreased by warfarin. Antiphospholipid antibodies are frequently transiently positive in acute illness. As thrombophilia evaluations are usually performed to assess the need to extend anticoagulation, testing should be performed in a steady state, remote from the acute event. In most instances warfarin anticoagulation can be stopped after the initial 3–6 months of treatment, and testing is performed at least 3 weeks later. Furthermore, sensitive markers of coagulation activation, notably the D-dimer assay and the thrombin generation test, hold promise as predictors, when elevated, of recurrent thrombosis when measured at least 1 month from discontinuation of warfarin, although further study is needed to better support this application.

Measures of Platelet Function The bleeding time has been used to assess bleeding risk; however, it has not been found to predict bleeding risk with surgery, and it is not recommended for use for this indication. The PFA-100 and similar instruments that measure platelet-dependent coagulation under flow conditions are generally more sensitive and specific for platelet disorders and vWD than the bleeding time; however, data are insufficient to support their use to predict bleeding risk or monitor response to therapy. When they are used in the evaluation of a patient with bleeding symptoms, abnormal results, as with the bleeding time, require specific testing, such as vWF assays and/or platelet aggregation studies. Since all of these "screening" assays may miss patients with mild bleeding disorders, further studies are needed to define their role in hemostasis testing.

For classic platelet aggregometry, various agonists are added to the patient's platelet-rich plasma, and platelet agglutination and aggregation are observed. Tests of platelet secretion in response to agonists can also be measured. These tests are affected by many factors, including numerous medications, and the association between minor defects in aggregation or secretion in these assays and bleeding risk is not clearly established.

60 Enlargement of Lymph Nodes and Spleen

Patrick H. Henry, Dan L. Longo

This chapter is intended to serve as a guide to the evaluation of patients who present with enlargement of the lymph nodes (*lymphadenopathy*) or the spleen (*splenomegaly*). Lymphadenopathy is a rather common clinical finding in primary care settings, whereas palpable splenomegaly is less so.

LYMPHADENOPATHY

Lymphadenopathy may be an incidental finding in patients being examined for various reasons, or it may be a presenting sign or symptom of the patient's illness. The physician must eventually decide whether the lymphadenopathy is a normal finding or one that requires further study, up to and including biopsy. Soft, flat, submandibular nodes (<1 cm) are often palpable in healthy children and young adults, and healthy adults may have palpable inguinal nodes of up to 2 cm, which are considered normal. Further evaluation of these normal nodes is not warranted. In contrast, if the physician believes the node(s) to be abnormal, then pursuit of a more precise diagnosis is needed.

APPROACH TO THE PATIENT: Lymphadenopathy

Lymphadenopathy may be a primary or secondary manifestation of numerous disorders, as shown in Table 60-1. Many of these disorders are infrequent causes of lymphadenopathy. In primary care practice, more than two-thirds of patients with lymphadenopathy have nonspecific causes or upper respiratory illnesses (viral or bacterial), and <1% have a malignancy. In one study, 84% of patients referred for evaluation of lymphadenopathy had a "benign" diagnosis. The remaining 16% had a malignancy (lymphoma or metastatic adenocarcinoma). Of the patients with benign lymphadenopathy, 63% had a nonspecific or reactive etiology (no causative agent found), and the remainder had a specific cause demonstrated, most commonly infectious mononucleosis, toxoplasmosis, or tuberculosis. Thus, the vast majority of patients with lymphadenopathy will have a nonspecific etiology requiring few diagnostic tests.

CLINICAL ASSESSMENT The physician will be aided in the pursuit of an explanation for the lymphadenopathy by a careful medical history, physical examination, selected laboratory tests, and perhaps an excisional lymph node biopsy.

The *medical history* should reveal the setting in which lymphadenopathy is occurring. Symptoms such as sore throat, cough, fever, night sweats, fatigue, weight loss, or pain in the nodes should be sought. The patient's age, sex, occupation, exposure to pets, sexual behavior, and use of drugs such as diphenylhydantoin are other important historic points. For example, children and young adults usually have benign (i.e., nonmalignant) disorders, such as viral or bacterial upper respiratory infections, infectious mononucleosis, toxoplasmosis, and, in some countries, tuberculosis, which account for the observed lymphadenopathy. In contrast, after age 50 the incidence of malignant disorders increases and that of benign disorders decreases.

The *physical examination* can provide useful clues such as the extent of lymphadenopathy (localized or generalized), size of nodes, texture, presence or absence of nodal tenderness, signs of inflammation over the node, skin lesions, and splenomegaly. A thorough ear, nose, and throat (ENT) examination is indicated in adult patients with cervical adenopathy and a history of tobacco use. Localized or regional adenopathy implies involvement of a single anatomic area. Generalized adenopathy has been defined as involvement of three or more noncontiguous lymph node areas. Many of the causes of lymphadenopathy (Table 60-1) can produce localized *or* generalized adenopathy, so this distinction is of limited utility in the differential diagnosis. Nevertheless, generalized lymphadenopathy is frequently associated with nonmalignant disorders such as infectious mononucleosis [Epstein-Barr virus (EBV) or cytomegalovirus (CMV)], toxoplasmosis, AIDS, other viral infections, systemic lupus erythematosus (SLE), and mixed connective tissue disease. Acute and chronic lymphocytic leukemias and malignant lymphomas also produce generalized adenopathy in adults.

The site of localized or regional adenopathy may provide a useful clue about the cause. Occipital adenopathy often reflects an infection of the scalp, and preauricular adenopathy accompanies conjunctival infections and cat-scratch disease. The most frequent site of regional adenopathy is the neck, and most of the causes are benign—upper respiratory infections, oral and dental lesions, infectious mononucleosis, other viral illnesses. The chief malignant causes include metastatic cancer from head and neck, breast, lung, and thyroid primaries. Enlargement of supraclavicular and scalene

TABLE 60-1 DISEASES ASSOCIATED WITH LYMPHADENOPATHY

1. Infectious diseases
   a. Viral—infectious mononucleosis syndromes (EBV, CMV), infectious hepatitis, herpes simplex, herpesvirus-6, varicella-zoster virus, rubella, measles, adenovirus, HIV, epidemic keratoconjunctivitis, vaccinia, herpesvirus-8
   b. Bacterial—streptococci, staphylococci, cat-scratch disease, brucellosis, tularemia, plague, chancroid, melioidosis, glanders, tuberculosis, atypical mycobacterial infection, primary and secondary syphilis, diphtheria, leprosy
   c. Fungal—histoplasmosis, coccidioidomycosis, paracoccidioidomycosis
   d. Chlamydial—lymphogranuloma venereum, trachoma
   e. Parasitic—toxoplasmosis, leishmaniasis, trypanosomiasis, filariasis
   f. Rickettsial—scrub typhus, rickettsialpox, Q fever
2. Immunologic diseases
   a. Rheumatoid arthritis
   b. Juvenile rheumatoid arthritis
   c. Mixed connective tissue disease
   d. Systemic lupus erythematosus
   e. Dermatomyositis
   f. Sjögren's syndrome
   g. Serum sickness
   h. Drug hypersensitivity—diphenylhydantoin, hydralazine, allopurinol, primidone, gold, carbamazepine, etc.
   i. Angioimmunoblastic lymphadenopathy
   j. Primary biliary cirrhosis
   k. Graft-vs.-host disease
   l. Silicone-associated
   m. Autoimmune lymphoproliferative syndrome
3. Malignant diseases
   a. Hematologic—Hodgkin's disease, non-Hodgkin's lymphomas, acute or chronic lymphocytic leukemia, hairy cell leukemia, malignant histiocytosis, amyloidosis
   b. Metastatic—from numerous primary sites
4. Lipid storage diseases—Gaucher's, Niemann-Pick, Fabry, Tangier
5. Endocrine diseases—hyperthyroidism
6. Other disorders
   a. Castleman's disease (giant lymph node hyperplasia)
   b. Sarcoidosis
   c. Dermatopathic lymphadenitis
   d. Lymphomatoid granulomatosis
   e. Histiocytic necrotizing lymphadenitis (Kikuchi's disease)
   f. Sinus histiocytosis with massive lymphadenopathy (Rosai-Dorfman disease)
   g. Mucocutaneous lymph node syndrome (Kawasaki's disease)
   h. Histiocytosis X
   i. Familial mediterranean fever
   j. Severe hypertriglyceridemia
   k. Vascular transformation of sinuses
   l. Inflammatory pseudotumor of lymph node
   m. Congestive heart failure

Note: EBV, Epstein-Barr virus; CMV, cytomegalovirus.

nodes is always abnormal. Because these nodes drain regions of the lung and retroperitoneal space, they can reflect lymphomas, other cancers, or infectious processes arising in these areas. Virchow's node is an enlarged left supraclavicular node infiltrated with metastatic cancer from a gastrointestinal primary. Metastases to supraclavicular nodes also occur from lung, breast, testis, or ovarian cancers. Tuberculosis, sarcoidosis, and toxoplasmosis are nonneoplastic causes of supraclavicular adenopathy. Axillary adenopathy is usually due to injuries or localized infections of the ipsilateral upper extremity. Malignant causes include melanoma or lymphoma and, in women, breast cancer. Inguinal lymphadenopathy is usually secondary to infections or trauma of the lower extremities and may accompany sexually transmitted diseases such as lymphogranuloma venereum, primary syphilis, genital herpes, or chancroid. These nodes may also be involved by lymphomas and metastatic cancer from primary lesions of the rectum, genitalia, or lower extremities (melanoma).

The size and texture of the lymph node(s) and the presence of pain are useful parameters in evaluating a patient with lymphadenopathy. Nodes <1.0 cm^2 in area (1.0 cm $\times$ 1.0 cm or less) are almost always secondary to benign, nonspecific reactive causes. In one retrospective analysis of younger patients (9–25 years) who had a lymph node biopsy, a maximum diameter of >2 cm served as one discriminant for predicting that the biopsy would reveal malignant or granulomatous disease. Another study showed that a lymph node size of 2.25 cm^2 (1.5 cm $\times$ 1.5 cm) was the best size limit for distinguishing malignant or granulomatous lymphadenopathy from other causes of lymphadenopathy. Patients with node(s) $\leq$1.0 cm^2 should be observed after excluding infectious mononucleosis and/or toxoplasmosis unless there are symptoms and signs of an underlying systemic illness.

The texture of lymph nodes may be described as soft, firm, rubbery, hard, discrete, matted, tender, movable, or fixed. Tenderness is found when the capsule is stretched during rapid enlargement, usually secondary to an inflammatory process. Some malignant diseases such as acute leukemia may produce rapid enlargement and pain in the nodes. Nodes involved by lymphoma tend to be large, discrete, symmetric, rubbery, firm, mobile, and nontender. Nodes containing metastatic cancer are often hard, nontender, and nonmovable because of fixation to surrounding tissues. The coexistence of splenomegaly in the patient with lymphadenopathy implies a systemic illness such as infectious mononucleosis, lymphoma, acute or chronic leukemia, SLE, sarcoidosis, toxoplasmosis, cat-scratch disease, or other less common hematologic disorders. The patient's story should provide helpful clues about the underlying systemic illness.

Nonsuperficial presentations (thoracic or abdominal) of adenopathy are usually detected as the result of a symptom-directed diagnostic workup. Thoracic adenopathy may be detected by routine chest radiography or during the workup for superficial adenopathy. It may also be found because the patient complains of a cough or wheezing from airway compression; hoarseness from recurrent laryngeal nerve involvement; dysphagia from esophageal compression; or swelling of the neck, face, or arms secondary to compression of the superior vena cava or subclavian vein. The differential diagnosis of mediastinal and hilar adenopathy includes primary lung disorders and systemic illnesses that characteristically involve mediastinal or hilar nodes. In the young, mediastinal adenopathy is associated with infectious mononucleosis and sarcoidosis. In endemic regions, histoplasmosis can cause unilateral paratracheal lymph node involvement that mimics lymphoma. Tuberculosis can also cause unilateral adenopathy. In older patients, the differential diagnosis includes primary lung cancer (especially among smokers), lymphomas, metastatic carcinoma (usually lung), tuberculosis, fungal infection, and sarcoidosis.

Enlarged intraabdominal or retroperitoneal nodes are usually malignant. Although tuberculosis may present as mesenteric lymphadenitis, these masses usually contain lymphomas or, in young men, germ cell tumors.

LABORATORY INVESTIGATION The laboratory investigation of patients with lymphadenopathy must be tailored to elucidate the etiology suspected from the patient's history and physical findings. One study from a family practice clinic evaluated 249 younger patients with "enlarged lymph nodes, not infected" or "lymphadenitis." No laboratory studies were obtained in 51%. When studies were performed, the most common were a complete blood count (CBC) (33%), throat culture (16%), chest x-ray (12%), or monospot test (10%). Only eight patients (3%) had a node biopsy, and half of those were normal or reactive. The CBC can provide useful data for the diagnosis of acute or chronic leukemias, EBV or CMV mononucleosis, lymphoma with a leukemic component, pyogenic infections, or immune cytopenias in illnesses such as SLE. Serologic studies may demonstrate antibodies specific to components of EBV, CMV, HIV, and other viruses; *Toxoplasma gondii*; *Brucella*; etc. If SLE is suspected, then antinuclear and anti-DNA antibody studies are warranted.

The chest x-ray is usually negative, but the presence of a pulmonary infiltrate or mediastinal lymphadenopathy would suggest tuberculosis, histoplasmosis, sarcoidosis, lymphoma, primary lung cancer, or metastatic cancer and demands further investigation.

A variety of imaging techniques (CT, MRI, ultrasound, color Doppler ultrasonography) have been employed to differentiate benign from malignant lymph nodes, especially in patients with head and neck cancer. CT and MRI are comparably accurate (65–90%) in the diagnosis of metastases to cervical lymph nodes. Ultrasonography has been used to determine the long (L) axis, short (S) axis, and a ratio of long to short axis in cervical nodes. An L/S ratio of <2.0 has a sensitivity and a specificity of 95% for distinguishing benign and malignant nodes in patients with head and neck cancer. This ratio has greater specificity and sensitivity than palpation or measurement of either the long or the short axis alone.

The indications for lymph node biopsy are imprecise, yet it is a valuable diagnostic tool. The decision to biopsy may be made early in a patient's evaluation or delayed for up to 2 weeks. Prompt biopsy should occur if the patient's history and physical findings suggest a malignancy; examples include a solitary, hard, nontender cervical node in an older patient who is a chronic user of tobacco; supraclavicular adenopathy; and solitary or generalized adenopathy that is firm, movable, and suggestive of lymphoma. If a primary head and neck cancer is suspected as the basis of a solitary, hard cervical node, then a careful ENT examination should be performed. Any mucosal lesion that is suspicious for a primary neoplastic process should be biopsied first. If no mucosal lesion is detected, an excisional biopsy of the largest node should be performed. Fine-needle aspiration should not be performed as the first diagnostic procedure. Most diagnoses require more tissue than such aspiration can provide, and it often delays a definitive diagnosis. Fine-needle aspiration should be reserved for thyroid nodules and for confirmation of relapse in patients whose primary diagnosis is known. If the primary physician is uncertain about whether to proceed to biopsy, consultation with a hematologist or medical oncologist should be helpful. In primary care practices, <5% of lymphadenopathy patients will require a biopsy. That percentage will be considerably larger in referral practices, i.e., hematology, oncology, or ENT.

Two groups have reported algorithms that they claim will identify more precisely those lymphadenopathy patients who should have a biopsy. Both reports were retrospective analyses in referral practices. The first study involved patients 9–25 years of age who had a node biopsy performed. Three variables were identified that predicted those young patients with peripheral lymphadenopathy who should undergo biopsy; lymph node size >2 cm in diameter and abnormal chest x-ray had positive predictive values, whereas recent ENT symp-

toms had negative predictive values. The second study evaluated 220 lymphadenopathy patients in a hematology unit and identified five variables [lymph node size, location (supraclavicular or nonsupraclavicular), age (>40 years or <40 years), texture (nonhard or hard), and tenderness] that were utilized in a mathematical model to identify those patients requiring a biopsy. Positive predictive value was found for age >40 years, supraclavicular location, node size >2.25 cm^2, hard texture, and lack of pain or tenderness. Negative predictive value was evident for age <40 years, node size <1.0 cm^2, nonhard texture, and tender or painful nodes. Ninety-one percent of those who required biopsy were correctly classified by this model. Since both of these studies were retrospective analyses and one was limited to young patients, it is not known how useful these models would be if applied prospectively in a primary care setting.

Most lymphadenopathy patients do not require a biopsy, and at least half require no laboratory studies. If the patient's history and physical findings point to a benign cause for lymphadenopathy, then careful follow-up at a 2- to 4-week interval can be employed. The patient should be instructed to return for reevaluation if the node(s) increase in size. Antibiotics are not indicated for lymphadenopathy unless strong evidence of a bacterial infection is present. Glucocorticoids should not be used to treat lymphadenopathy because their lymphotic effect obscures some diagnoses (lymphoma, leukemia, Castleman's disease) and they contribute to delayed healing or activation of underlying infections. An exception to this statement is the life-threatening pharyngeal obstruction by enlarged lymphoid tissue in Waldeyer's ring that is occasionally seen in infectious mononucleosis.

SPLENOMEGALY

STRUCTURE AND FUNCTION OF THE SPLEEN

The spleen is a reticuloendothelial organ that has its embryologic origin in the dorsal mesogastrium at about 5 weeks' gestation. It arises in a series of hillocks, migrates to its normal adult location in the left upper quadrant (LUQ), and is attached to the stomach via the gastrolienal ligament and to the kidney via the lienorenal ligament. When the hillocks fail to unify into a single tissue mass, accessory spleens may develop in around 20% of persons. The function of the spleen has been elusive. Galen believed it was the source of "black bile" or melancholia, and the word *hypochondria* (literally, beneath the ribs) and the idiom "to vent one's spleen" attest to the beliefs that the spleen had an important influence on the psyche and emotions. In humans its normal physiologic roles seem to be the following:

1. Maintenance of quality control over erythrocytes in the red pulp by removal of senescent and defective red blood cells. The spleen accomplishes this function through a unique organization of its parenchyma and vasculature (Fig. 60-1).
2. Synthesis of antibodies in the white pulp.
3. The removal of antibody-coated bacteria and antibody-coated blood cells from the circulation.

An increase in these normal functions may result in splenomegaly.

The spleen is composed of *red pulp* and *white pulp*, which are Malpighi's terms for the red blood–filled sinuses and reticuloendothelial cell–lined cords and the white lymphoid follicles arrayed within the red pulp matrix. The spleen is in the portal circulation. The reason for this is unknown but may relate to the fact that lower blood pressure allows less rapid flow and minimizes damage to normal erythrocytes. Blood flows into the spleen at a rate of about 150 mL/min through the splenic artery, which ultimately ramifies into central arterioles. Some blood goes from the arterioles to capillaries and then to splenic veins and out of the spleen, but the majority of blood from central arterioles flows into the macrophage-lined sinuses and cords. The blood entering the sinuses reenters the circulation through the splenic venules, but the blood entering the cords is subjected to an inspection of sorts.

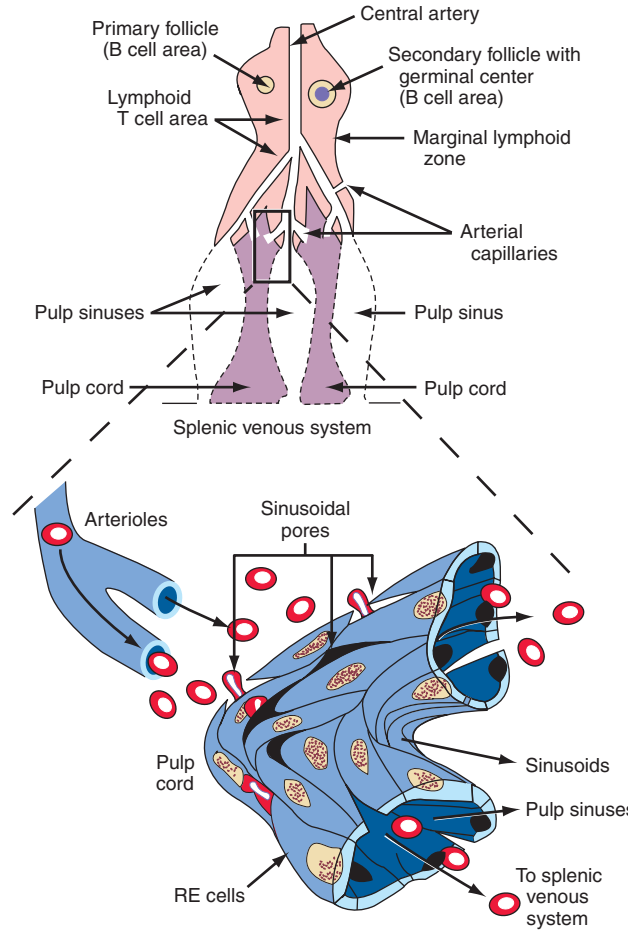

FIGURE 60-1 Schematic spleen structure. The spleen comprises many units of red and white pulp centered around small branches of the splenic artery, called *central arteries*. White pulp is lymphoid in nature and contains B cell follicles, a marginal zone around the follicles, and T cell–rich areas sheathing arterioles. The red pulp areas include pulp sinuses and pulp cords. The cords are dead ends. In order to regain access to the circulation, red blood cells must traverse tiny openings in the sinusoidal lining. Stiff, damaged, or old red cells cannot enter the sinuses. *(Top portion of figure from CA Janeway et al: Immunobiology, 5th ed., New York, Garland, 2001; bottom portion of figure from RS Hillman, KA Ault: Hematology in Clinical Practice, 4th ed. New York, McGraw-Hill, 2005.)*

In order to return to the circulation, the blood cells in the cords must squeeze through slits in the cord lining to enter the sinuses that lead to the venules. Old and damaged erythrocytes are less deformable and are retained in the cords, where they are destroyed and their components recycled. Red cell inclusion bodies such as parasites (Chap. 203 and e18), nuclear residua (Howell-Jolly bodies, Fig. 58-6), or denatured hemoglobin (Heinz bodies) are pinched off in the process of passing through the slits, a process called *pitting*. The culling of dead and damaged cells and the pitting of cells with inclusions appear to occur without significant delay since the blood transit time through the spleen is only slightly slower than in other organs.

The spleen is also capable of assisting the host in adapting to its hostile environment. It has at least three adaptive functions: (1) clearance of bacteria and particulates from the blood, (2) the generation of immune responses to certain pathogens, and (3) the generation of cellular components of the blood under circumstances in which the marrow is unable to meet the needs (i.e., extramedullary hematopoiesis). The latter adaptation is a recapitulation of the blood-forming function the spleen plays during gestation. In some animals, the spleen also serves a role in the vascular adaptation to stress because it stores red blood cells (often hemoconcentrated to higher hematocrits than normal) under normal

circumstances and contracts under the influence of β-adrenergic stimulation to provide the animal with an autotransfusion and improved oxygen-carrying capacity. However, the normal human spleen does not sequester or store red blood cells and does not contract in response to sympathetic stimuli. The normal human spleen contains approximately one-third of the total body platelets and a significant number of marginated neutrophils. These sequestered cells are available when needed to respond to bleeding or infection.

APPROACH TO THE PATIENT: Splenomegaly

CLINICAL ASSESSMENT The most common *symptoms* produced by diseases involving the spleen are pain and a heavy sensation in the LUQ. Massive splenomegaly may cause early satiety. Pain may result from acute swelling of the spleen with stretching of the capsule, infarction, or inflammation of the capsule. For many years it was believed that splenic infarction was clinically silent, which at times is true. However, Soma Weiss, in his classic 1942 report of the self-observations by a Harvard medical student on the clinical course of subacute bacterial endocarditis, documented that severe LUQ and pleuritic chest pain may accompany thromboembolic occlusion of splenic blood flow. Vascular occlusion, with infarction and pain, is commonly seen in children with sickle cell crises. Rupture of the spleen, from either trauma or infiltrative disease that breaks the capsule, may result in intraperitoneal bleeding, shock, and death. The rupture itself may be painless.

A palpable spleen is the major *physical sign* produced by diseases affecting the spleen and suggests enlargement of the organ. The normal spleen is said to weigh <250 g, decreases in size with age, normally lies entirely within the rib cage, has a maximum cephalocaudad diameter of 13 cm by ultrasonography or maximum length of 12 cm and/or width of 7 cm by radionuclide scan, and is usually not palpable. However, a palpable spleen was found in 3% of 2200 asymptomatic, male, freshman college students. Follow-up at 3 years revealed that 30% of those students still had a palpable spleen without any increase in disease prevalence. Ten-year follow-up found no evidence for lymphoid malignancies. Furthermore, in some tropical countries (e.g., New Guinea) the incidence of splenomegaly may reach 60%. Thus, the presence of a palpable spleen does not always equate with presence of disease. Even when disease is present, splenomegaly may not reflect the primary disease but rather a reaction to it. For example, in patients with Hodgkin's disease, only two-thirds of the palpable spleens show involvement by the cancer.

Physical examination of the spleen utilizes primarily the techniques of palpation and percussion. Inspection may reveal fullness in the LUQ that descends on inspiration, a finding associated with a massively enlarged spleen. Auscultation may reveal a venous hum or friction rub.

Palpation can be accomplished by bimanual palpation, ballotment, and palpation from above (Middleton maneuver). For bimanual palpation, which is at least as reliable as the other techniques, the patient is supine with flexed knees. The examiner's left hand is placed on the lower rib cage and pulls the skin toward the costal margin, allowing the fingertips of the right hand to feel the tip of the spleen as it descends while the patient inspires slowly, smoothly, and deeply. Palpation is begun with the right hand in the left lower quadrant with gradual movement toward the left costal margin, thereby identifying the lower edge of a massively enlarged spleen. When the spleen tip is felt, the finding is recorded as centimeters below the left costal margin at some arbitrary point, i.e., 10–15 cm, from the midpoint of the umbilicus or the xiphisternal junction. This allows other examiners to compare findings or the initial examiner to determine changes in size over time. Bimanual palpation in the right lateral decubitus position adds nothing to the supine examination.

Percussion for splenic dullness is accomplished with any of three techniques described by Nixon, Castell, or Barkun:

1. *Nixon's method*: The patient is placed on the right side so that the spleen lies above the colon and stomach. Percussion begins at the lower level of pulmonary resonance in the posterior axillary line and proceeds diagonally along a perpendicular line toward the lower midanterior costal margin. The upper border of dullness is normally 6–8 cm above the costal margin. Dullness >8 cm in an adult is presumed to indicate splenic enlargement.
2. *Castell's method*: With the patient supine, percussion in the lowest intercostal space in the anterior axillary line (8th or 9th) produces a resonant note if the spleen is normal in size. This is true during expiration or full inspiration. A dull percussion note on full inspiration suggests splenomegaly.
3. *Percussion of Traube's semilunar space*: The borders of Traube's space are the sixth rib superiorly, the left midaxillary line laterally, and the left costal margin inferiorly. The patient is supine with the left arm slightly abducted. During normal breathing, this space is percussed from medial to lateral margins, yielding a normal resonant sound. A dull percussion note suggests splenomegaly.

Studies comparing methods of percussion and palpation with a standard of ultrasonography or scintigraphy have revealed sensitivity of 56–71% for palpation and 59–82% for percussion. Reproducibility among examiners is better for palpation than percussion. Both techniques are less reliable in obese patients or patients who have just eaten. Thus, the physical examination techniques of palpation and percussion are imprecise at best. It has been suggested that the examiner perform percussion first and, if positive, proceed to palpation; if the spleen is palpable, then one can be reasonably confident that splenomegaly exists. However, not all LUQ masses are enlarged spleens; gastric or colon tumors and pancreatic or renal cysts or tumors can mimic splenomegaly.

The presence of an enlarged spleen can be more precisely determined, if necessary, by liver-spleen radionuclide scan, CT, MRI, or ultrasonography. The latter technique is the current procedure of choice for routine assessment of spleen size (normal = a maximum cephalocaudad diameter of 13 cm) because it has high sensitivity and specificity and is safe, noninvasive, quick, mobile, and less costly. Nuclear medicine scans are accurate, sensitive, and reliable but are costly, require greater time to generate data, and utilize immobile equipment. They have the advantage of demonstrating accessory splenic tissue. CT and MRI provide accurate determination of spleen size, but the equipment is immobile and the procedures are expensive. MRI appears to offer no advantage over CT. Changes in spleen structure such as mass lesions, infarcts, inhomogeneous infiltrates, and cysts are more readily assessed by CT, MRI, or ultrasonography. None of these techniques is very reliable in the detection of patchy infiltration (e.g., Hodgkin's disease).

DIFFERENTIAL DIAGNOSIS Many of the diseases associated with splenomegaly are listed in Table 60-2. They are grouped according to the presumed basic mechanisms responsible for organ enlargement:

1. Hyperplasia or hypertrophy related to a particular splenic function such as reticuloendothelial hyperplasia (work hypertrophy) in diseases such as hereditary spherocytosis or thalassemia syndromes that require removal of large numbers of defective red blood cells; immune hyperplasia in response to systemic infection (infectious mononucleosis, subacute bacterial endocarditis) or to immunologic diseases (immune thrombocytopenia, SLE, Felty's syndrome).
2. Passive congestion due to decreased blood flow from the spleen in conditions that produce portal hypertension (cirrhosis, Budd-Chiari syndrome, congestive heart failure).
3. Infiltrative diseases of the spleen (lymphomas, metastatic cancer, amyloidosis, Gaucher's disease, myeloproliferative disorders with extramedullary hematopoiesis).

TABLE 60-2 DISEASES ASSOCIATED WITH SPLENOMEGALY GROUPED BY PATHOGENIC MECHANISM

Enlargement Due to Increased Demand for Splenic Function

Reticuloendothelial system hyperplasia (for removal of defective erythrocytes)
- Spherocytosis
- Early sickle cell anemia
- Ovalocytosis
- Thalassemia major
- Hemoglobinopathies
- Paroxysmal nocturnal hemoglobinuria
- Pernicious anemia

Immune hyperplasia
- Response to infection (viral, bacterial, fungal, parasitic)
  - Infectious mononucleosis
  - AIDS
  - Viral hepatitis
  - Cytomegalovirus
  - Subacute bacterial endocarditis
  - Bacterial septicemia
  - Congenital syphilis
  - Splenic abscess
  - Tuberculosis
  - Histoplasmosis
  - Malaria
  - Leishmaniasis
  - Trypanosomiasis
  - Ehrlichiosis
- Disordered immunoregulation
  - Rheumatoid arthritis (Felty's syndrome)
  - Systemic lupus erythematosus
  - Collagen vascular diseases
  - Serum sickness
  - Immune hemolytic anemias
  - Immune thrombocytopenias
  - Immune neutropenias
  - Drug reactions
  - Angioimmunoblastic lymphadenopathy
  - Sarcoidosis
  - Thyrotoxicosis (benign lymphoid hypertrophy)
  - Interleukin 2 therapy

Extramedullary hematopoiesis
- Myelofibrosis
- Marrow damage by toxins, radiation, strontium
- Marrow infiltration by tumors, leukemias, Gaucher's disease

Enlargement Due to Abnormal Splenic or Portal Blood Flow

- Cirrhosis
- Hepatic vein obstruction
- Portal vein obstruction, intrahepatic or extrahepatic
- Cavernous transformation of the portal vein
- Splenic vein obstruction
- Splenic artery aneurysm
- Hepatic schistosomiasis
- Congestive heart failure
- Hepatic echinococcosis
- Portal hypertension (any cause including the above): "Banti's disease"

Infiltration of the Spleen

Intracellular or extracellular depositions
- Amyloidosis
- Gaucher's disease
- Niemann-Pick disease
- Tangier disease
- Hurler's syndrome and other mucopolysaccharidoses
- Hyperlipidemias

Benign and malignant cellular infiltrations
- Leukemias (acute, chronic, lymphoid, myeloid, monocytic)
- Lymphomas
- Hodgkin's disease
- Myeloproliferative syndromes (e.g., polycythemia vera, essential thrombocytosis)
- Angiosarcomas
- Metastatic tumors (melanoma is most common)
- Eosinophilic granuloma
- Histiocytosis X
- Hamartomas
- Hemangiomas, fibromas, lymphangiomas
- Splenic cysts

Unknown Etiology

- Idiopathic splenomegaly
- Berylliosis
- Iron-deficiency anemia

The differential diagnostic possibilities are much fewer when the spleen is "massively enlarged," palpable more than 8 cm below the left costal margin or its drained weight is ≥1000 g (Table 60-3). The vast majority of such patients will have non-Hodgkin's lymphoma, chronic lymphocytic leukemia, hairy cell leukemia, chronic myelogenous leukemia, myelofibrosis with myeloid metaplasia, or polycythemia vera.

LABORATORY ASSESSMENT The major laboratory abnormalities accompanying splenomegaly are determined by the underlying systemic illness. Erythrocyte counts may be normal, decreased (thalassemia major syndromes, SLE, cirrhosis with portal hypertension), or increased (polycythemia vera). Granulocyte counts may be normal, decreased (Felty's syndrome, congestive splenomegaly, leukemias), or increased (infections or inflammatory disease, myeloproliferative disorders). Similarly, the platelet count may be normal, decreased when there is enhanced sequestration or destruction of platelets in an enlarged spleen (congestive splenomegaly, Gaucher's disease, immune thrombocytopenia), or increased in the myeloproliferative disorders such as polycythemia vera.

The CBC may reveal cytopenia of one or more blood cell types, which should suggest *hypersplenism*. This condition is characterized by splenomegaly, cytopenia(s), normal or hyperplastic bone marrow, and a response to splenectomy. The latter characteristic is less precise because reversal of cytopenia, particularly granulocytopenia, is sometimes not sustained after splenectomy. The cytopenias result from increased destruction of the cellular elements secondary to reduced flow of blood through enlarged and congested cords (congestive splenomegaly) or to immune-mediated mechanisms. In hypersplenism, various cell types usually have normal morphology on the peripheral blood smear, although the red cells may be spherocytic due to loss of surface area during their longer transit through the enlarged spleen. The increased marrow production of red cells should be reflected as an increased reticulocyte production index, although the value may be less than expected due to increased sequestration of reticulocytes in the spleen.

The need for additional laboratory studies is dictated by the differential diagnosis of the underlying illness of which splenomegaly is a manifestation.

TABLE 60-3 DISEASES ASSOCIATED WITH MASSIVE SPLENOMEGALY[a]

Chronic myelogenous leukemia	Gaucher's disease
Lymphomas	Chronic lymphocytic leukemia
Hairy cell leukemia	Sarcoidosis
Myelofibrosis with myeloid metaplasia	Autoimmune hemolytic anemia
Polycythemia vera	Diffuse splenic hemangiomatosis

[a]The spleen extends greater than 8 cm below left costal margin and/or weighs more than 1000 g.

SPLENECTOMY

Splenectomy is infrequently performed for diagnostic purposes, especially in the absence of clinical illness or other diagnostic tests that suggest underlying disease. More often splenectomy is performed for symptom control in patients with massive splenomegaly, for disease control in patients with traumatic splenic rupture, or for correction of cytopenias in patients with hypersplenism or immune-mediated destruction of one or more cellular blood elements. Splenectomy is necessary for staging of patients with Hodgkin's disease only in those with clinical stage I or II disease in whom radiation therapy alone is contemplated as the treatment. Noninvasive staging of the spleen in Hodgkin's disease is not a sufficiently reliable basis for treatment decisions because one-third of normal-sized spleens will be involved with Hodgkin's disease and one-third of enlarged spleens will be tumor-free. Although splenectomy in chronic myelogenous leukemia does not affect the natural history of disease, removal of the massive spleen usually makes patients significantly more comfortable and simplifies their management by significantly reducing transfusion requirements. Splenectomy is an effective secondary or tertiary treatment for two chronic B cell leukemias, hairy cell leukemia and prolymphocytic leukemia, and for the very rare splenic mantle cell or marginal zone lymphoma. Splenectomy in these diseases may be associated with significant tumor regression in bone marrow and other sites of disease.

Similar regressions of systemic disease have been noted after splenic irradiation in some types of lymphoid tumors, especially chronic lymphocytic leukemia and prolymphocytic leukemia. This has been termed the *abscopal effect*. Such systemic tumor responses to local therapy directed at the spleen suggest that some hormone or growth factor produced by the spleen may affect tumor cell proliferation, but this conjecture is not yet substantiated. A common therapeutic indication for splenectomy is traumatic or iatrogenic splenic rupture. In a fraction of patients with splenic rupture, peritoneal seeding of splenic fragments can lead to *splenosis*—the presence of multiple rests of spleen tissue not connected to the portal circulation. This ectopic spleen tissue may cause pain or gastrointestinal obstruction, as in endometriosis. A large number of hematologic, immunologic, and congestive causes of splenomegaly can lead to destruction of one or more cellular blood elements. In the majority of such cases, splenectomy can correct the cytopenias, particularly anemia and thrombocytopenia. In a large series of patients seen in two tertiary care centers, the indication for splenectomy was diagnostic in 10% of patients, therapeutic in 44%, staging for Hodgkin's disease in 20%, and incidental to another procedure in 26%. Perhaps the only contraindication to splenectomy is the presence of marrow failure, in which the enlarged spleen is the only source of hematopoietic tissue.

The absence of the spleen has minimal long-term effects on the hematologic profile. In the immediate postsplenectomy period, leukocytosis (up to 25,000/μL) and thrombocytosis (up to 1×10^6/μL) may develop, but within 2–3 weeks, blood cell counts and survival of each cell lineage are usually normal. The chronic manifestations of splenectomy are marked variation in size and shape of erythrocytes (anisocytosis, poikilocytosis) and the presence of Howell-Jolly bodies (nuclear remnants), Heinz bodies (denatured hemoglobin), basophilic stippling, and an occasional nucleated erythrocyte in the peripheral blood. When such erythrocyte abnormalities appear in a patient whose spleen has not been removed, one should suspect splenic infiltration by tumor that has interfered with its normal culling and pitting function.

The most serious consequence of splenectomy is increased susceptibility to bacterial infections, particularly those with capsules such as *Streptococcus pneumoniae*, *Haemophilus influenzae*, and some gram-negative enteric organisms. Patients under age 20 years are particularly susceptible to overwhelming sepsis with *S. pneumoniae*, and the overall actuarial risk of sepsis in patients who have had their spleens removed is about 7% in 10 years. The case-fatality rate for pneumococcal sepsis in splenectomized patients is 50–80%. About 25% of patients without spleens will develop a serious infection at some time in their life. The frequency is highest within the first 3 years after splenectomy. About 15% of the infections are polymicrobial, and lung, skin, and blood are the most common sites. No increased risk of viral infection has been noted in patients who have no spleen. The susceptibility to bacterial infections relates to the inability to remove opsonized bacteria from the bloodstream and a defect in making antibodies to T cell–independent antigens such as the polysaccharide components of bacterial capsules. Pneumococcal vaccine (23-valent polysaccharide vaccine) should be administered to all patients 2 weeks before elective splenectomy. The Advisory Committee on Immunization Practices recommends that even splenectomized patients receive pneumococcal vaccine with a repeat vaccination 5 years later. Efficacy has not been proven in this setting, and the recommendation discounts the possibility that administration of the vaccine may actually lower the titer of specific pneumococcal antibodies. A more effective pneumococcal conjugate vaccine that involves T cells in the response is now available (Prevenar, 7-valent). The vaccine to *Neisseria meningitidis* should also be given to patients in whom elective splenectomy is planned. Although efficacy data for *Haemophilus influenzae* type b vaccine are not available for older children or adults, it may be given to patients who have had a splenectomy.

Splenectomized patients should be educated to consider any unexplained fever as a medical emergency. Prompt medical attention with evaluation and treatment of suspected bacteremia may be life-saving. Routine chemoprophylaxis with oral penicillin can result in the emergence of drug-resistant strains and is not recommended.

In addition to an increased susceptibility to bacterial infections, splenectomized patients are also more susceptible to the parasitic disease babesiosis. The splenectomized patient should avoid areas where the parasite *Babesia* is endemic (e.g., Cape Cod, MA).

Surgical removal of the spleen is an obvious cause of hyposplenism. Patients with sickle cell disease often suffer from autosplenectomy as a result of splenic destruction by the numerous infarcts associated with sickle cell crises during childhood. Indeed, the presence of a palpable spleen in a patient with sickle cell disease after age 5 suggests a coexisting hemoglobinopathy, e.g., thalassemia or hemoglobin C. In addition, patients who receive splenic irradiation for a neoplastic or autoimmune disease are also functionally hyposplenic. The term *hyposplenism* is preferred to *asplenism* in referring to the physiologic consequences of splenectomy because asplenia is a rare, specific, and fatal congenital abnormality in which there is a failure of the left side of the coelomic cavity (which includes the splenic anlagen) to develop normally. Infants with asplenia have no spleens, but that is the least of their problems. The right side of the developing embryo is duplicated on the left so there is liver where the spleen should be, there are two right lungs, and the heart comprises two right atria and two right ventricles.

61 Disorders of Granulocytes and Monocytes

Steven M. Holland, John I. Gallin

Leukocytes, the major cells comprising inflammatory and immune responses, include neutrophils, T and B lymphocytes, natural killer (NK) cells, monocytes, eosinophils, and basophils. These cells have specific functions, such as antibody production by B lymphocytes or destruction of bacteria by neutrophils, but in no single infectious disease is the exact role of the cell types completely established. Thus, whereas neutrophils are classically thought to be critical to host defense against bacteria, they may also play important roles in defense against viral infections.

The blood delivers leukocytes to the various tissues from the bone marrow, where they are produced. Normal blood leukocyte counts are $4.3–10.8 \times 10^9$/L, with neutrophils representing 45–74% of the cells, bands 0–4%, lymphocytes 16–45%, monocytes 4–10%, eosinophils 0–7%, and basophils 0–2%. Variation among individuals and among different ethnic groups can be substantial with lower leukocyte numbers for certain African-American ethnic groups. The various leukocytes are derived from a common stem cell in the bone marrow. Three-

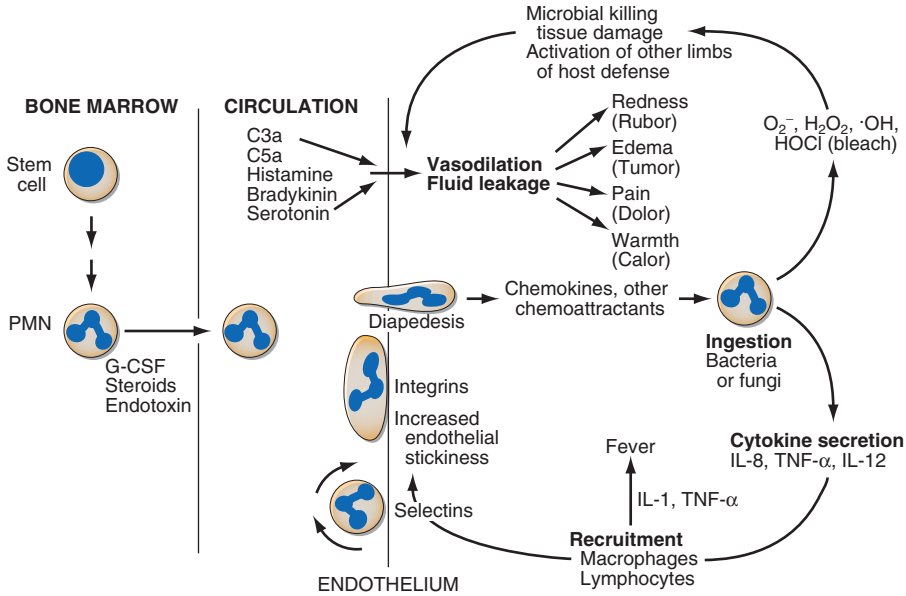

FIGURE 61-1 Schematic events in neutrophil production, recruitment, and inflammation. The four cardinal signs of inflammation (rubor, tumor, calor, dolor) are indicated, as are the interactions of neutrophils with other cells and cytokines. PMN, polymorphonuclear leukocytes; G-CSF, granulocyte colony-stimulating factor; IL, interleukin; TNF-α, tumor necrosis factor α.

fourths of the nucleated cells of bone marrow are committed to the production of leukocytes. Leukocyte maturation in the marrow is under the regulatory control of a number of different factors, known as colony-stimulating factors (CSFs) and interleukins (ILs). Because an alteration in the number and type of leukocytes is often associated with disease processes, total white blood count (WBC) (cells per μL) and differential counts are informative. This chapter focuses on neutrophils, monocytes, and eosinophils. **Lymphocytes and basophils are discussed in Chaps. 308 and 311, respectively.**

NEUTROPHILS

MATURATION

Important events in neutrophil life are summarized in Fig. 61-1. In normal humans, neutrophils are produced only in the bone marrow. The minimum number of stem cells necessary to support hematopoiesis is estimated to be 400–500 at any one time. Human blood monocytes, tissue macrophages, and stromal cells produce CSFs, hormones required for the growth of monocytes and neutrophils in the bone marrow. The hematopoietic system not only produces enough neutrophils (~1.3×10^{11} cells per 80-kg person per day) to carry out physiologic functions but also has a large reserve stored in the marrow, which can be mobilized in response to inflammation or infection. An increase in the number of blood neutrophils is called *neutrophilia*, and the presence of immature cells is termed a *shift to the left*. A decrease in the number of blood neutrophils is called *neutropenia*.

Neutrophils and monocytes evolve from pluripotent stem cells under the influence of cytokines and CSFs (Fig. 61-2). The proliferation phase through the metamyelocyte takes about 1 week, while the maturation phase from metamyelocyte to mature neutrophil takes another week. The myeloblast is the first recognizable precursor cell and is followed by the *promyelocyte*. The promyelocyte evolves when the classic lysosomal granules, called the *primary*, or *azurophil, granules* are produced. The primary granules contain hydrolases, elastase, myeloperoxidase, cathepsin G, cationic proteins, and bactericidal/permeability-increasing protein, which is important for killing gram-negative bacteria. Azurophil granules also contain *defensins*, a family of cysteine-rich polypeptides with broad antimicrobial activity against bacteria, fungi, and certain enveloped viruses. The promyelocyte divides to produce the *myelocyte*, a cell responsible for the synthesis of the *specific*, or *secondary, granules*, which contain unique (specific) constituents such as lactoferrin, vitamin B_{12}–binding protein, membrane components of the reduced nicotinamide-adenine dinucleotide phosphate (NADPH) oxidase required for hydrogen peroxide production, histaminase, and receptors for certain chemoattractants and adherence-promoting factors (CR3) as well as receptors for the basement membrane component, laminin. The secondary granules do not contain acid hydrolases and therefore are not classic lysosomes. Packaging of secondary granule contents during myelopoiesis is controlled by CCAAT/enhancer binding protein-ε. Secondary granule contents are readily released extracellularly, and their mobilization is important in modulating inflammation. During the final stages of maturation, no cell division occurs, and the cell passes through the metamyelocyte stage and then to the band neutrophil with a sausage-shaped nucleus (Fig. 61-3). As the band cell matures, the nucleus assumes a lobulated configuration. The nucleus of neutrophils normally contains up to four segments (Fig. 61-4). Excessive segmentation (more than five nuclear lobes) may be a manifestation of folate or vitamin B_{12} deficiency (see Fig. 100-4) and the congenital neutropenia syndrome of warts, hypogammaglobulinemia, infections, and myelokathexis (WHIM) described below. The Pelger-Hüet anomaly (Fig. 61-5), an infrequent dominant benign inherited trait, results in neutrophils with distinctive bilobed nuclei that must be distinguished from band forms. Acquired

Cell	Stage	Surface Markers[a]	Characteristics
	MYELOBLAST	CD33, CD13, CD15	Prominent nucleoli
	PROMYELOCYTE	CD33, CD13, CD15	Large cell Primary granules appear
	MYELOCYTE	CD33, CD13, CD15, CD14, CD11b	Secondary granules appear
	METAMYELOCYTE	CD33, CD13, CD15, CD14, CD11b	Kidney bean–shaped nucleus
	BAND FORM	CD33, CD13, CD15, CD14, CD11b CD10, CD16	Condensed, band–shaped nucleus
	NEUTROPHIL	CD33, CD13, CD15, CD14, CD11b CD10, CD16	Condensed, multilobed nucleus

[a]CD= Cluster Determinant; Nucleolus; Primary granule; Secondary granule.

FIGURE 61-2 Stages of neutrophil development shown schematically. G-CSF (granulocyte colony-stimulating factor) and GM-CSF (granulocyte-macrophage colony-stimulating factor) are critical to this process. Identifying cellular characteristics and specific cell-surface markers are listed for each maturational stage.

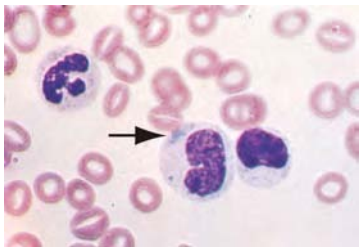

FIGURE 61-3 Neutrophil band with Döhle body. The neutrophil with a sausage-shaped nucleus in the center of the field is a band form. Döhle bodies are discrete, blue-staining nongranular areas found in the periphery of the cytoplasm of the neutrophil in infections and other toxic states. They represent aggregates of rough endoplasmic reticulum.

bilobed nuclei, pseudo Pelger-Huet anomaly, can occur with acute infections or in myelodysplastic syndromes. The physiologic role of the normal multilobed nucleus of neutrophils is unknown, but it may allow great deformation of neutrophils during migration into tissues at sites of inflammation.

In severe acute bacterial infection, prominent neutrophil cytoplasmic granules, called *toxic granulations*, are occasionally seen. Toxic granulations are immature or abnormally staining azurophil granules. Cytoplasmic inclusions, also called *Döhle bodies* (Fig. 61-3), can be seen during infection and are fragments of ribosome-rich endoplasmic reticulum. Large neutrophil vacuoles are often present in acute bacterial infection and probably represent pinocytosed (internalized) membrane.

Neutrophils are heterogeneous in function. Monoclonal antibodies have been developed that recognize only a subset of mature neutrophils. The meaning of neutrophil heterogeneity is not known.

The morphology of eosinophils and basophils is shown in Fig. 61-6.

MARROW RELEASE AND CIRCULATING COMPARTMENTS

Specific signals, including IL-1, tumor necrosis factor α (TNF-α), the CSFs, complement fragments, and chemokines, mobilize leukocytes from the bone marrow and deliver them to the blood in an unstimulated state. Under normal conditions, ~90% of the neutrophil pool is in the bone marrow, 2–3% in the circulation, and the remainder in the tissues (Fig. 61-7).

The circulating pool exists in two dynamic compartments: one freely flowing and one marginated. The freely flowing pool is about one-half the neutrophils in the basal state and is composed of those cells that are in the blood and not in contact with the endothelium. Marginated leukocytes are those that are in close physical contact with the endothelium (Fig. 61-8). In the pulmonary circulation, where an extensive capillary bed (~1000 capillaries per alveolus) exists, margination occurs because the capillaries are about the same size as a mature neutrophil. Therefore, neutrophil fluidity and deformability are necessary to make the transit through the pulmonary bed. Increased neutrophil rigidity and decreased deformability lead to augmented neutrophil trapping and margination in the lung. In contrast, in the systemic postcapillary venules, margination is mediated by the interaction of specific cell-surface molecules called *selectins*. Selectins are glycoproteins expressed on neutrophils and endothelial cells, among others, that cause a low-affinity interaction, resulting in "rolling" of the neutrophil along the endothelial surface. On neutrophils, the molecule L-selectin [cluster determinant (CD) 62L] binds to glycosylated proteins on endothelial cells [e.g., glycosylation-dependent cell adhesion molecule (GlyCAM1) and CD34]. Glycoproteins on neutrophils, most importantly sialyl-Lewis^x (SLe^x, CD15s), are targets for binding of selectins expressed on endothelial cells [E-selectin (CD62E) and P-selectin (CD62P)] and other leukocytes. In response to chemotactic stimuli from injured tissues (e.g., complement product C5a, leukotriene B_4, IL-8) or bacterial products [e.g., *N*-formylmethionyl-leucylphenylalanine (f-metleuphe)], neutrophil adhesiveness increases, and the cells "stick" to the endothelium through *integrins*. The integrins are leukocyte glycoproteins that exist as complexes of a common CD18 β chain with CD11a (LFA-1), CD11b (called Mac-1, CR3, or the C3bi receptor), and CD11c (called p150, 95 or CR4). CD11a/CD18 and CD11b/CD18 bind to specific endothelial receptors [intercellular adhesion molecules (ICAM) 1 and 2].

On cell stimulation, L-selectin is shed from neutrophils, and E-selectin increases in the blood, presumably because it is shed from endothelial cells; receptors for chemoattractants and opsonins are mobilized; and the phagocytes orient toward the chemoattractant source in the extravascular space, increase their motile activity (chemokinesis), and migrate directionally (chemotaxis) into tissues. The process of migration into tissues is called *diapedesis* and involves the crawling of neutrophils between postcapillary endothelial cells that open junctions between ad-

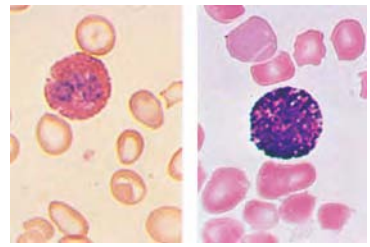

FIGURE 61-6 Normal eosinophil and basophil. The eosinophil contains large, bright orange granules and usually a bilobed nucleus. The basophil contains large purple-black granules that fill the cell and obscure the nucleus.

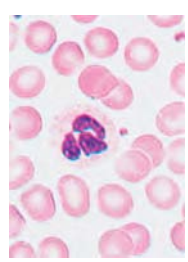

FIGURE 61-4 Normal granulocyte. The normal granulocyte has a segmented nucleus with heavy, clumped chromatin; fine neutrophilic granules are dispersed throughout the cytoplasm.

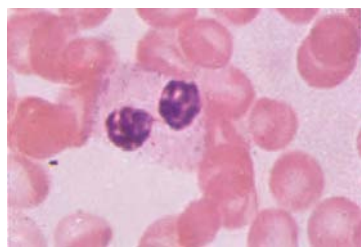

FIGURE 61-5 Pelger-Hüet anomaly. In this benign disorder, the majority of granulocytes are bilobed. The nucleus frequently has a spectacle-like, or "pince-nez," configuration.

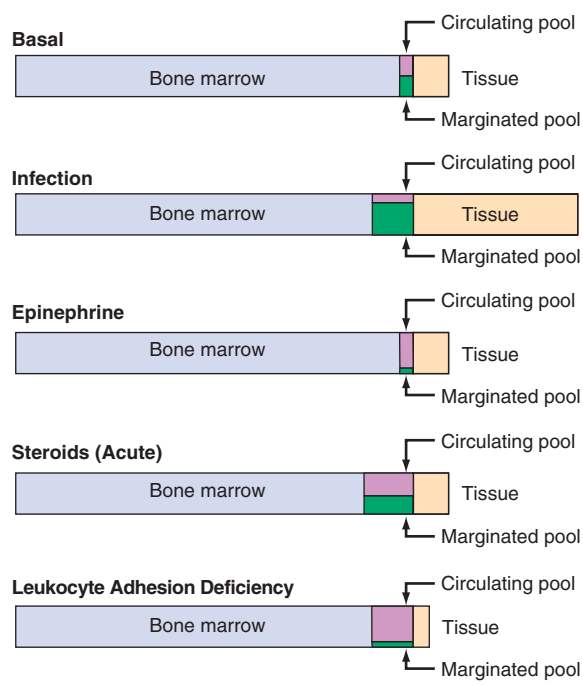

FIGURE 61-7 Schematic neutrophil distribution and kinetics between the different anatomic and functional pools.

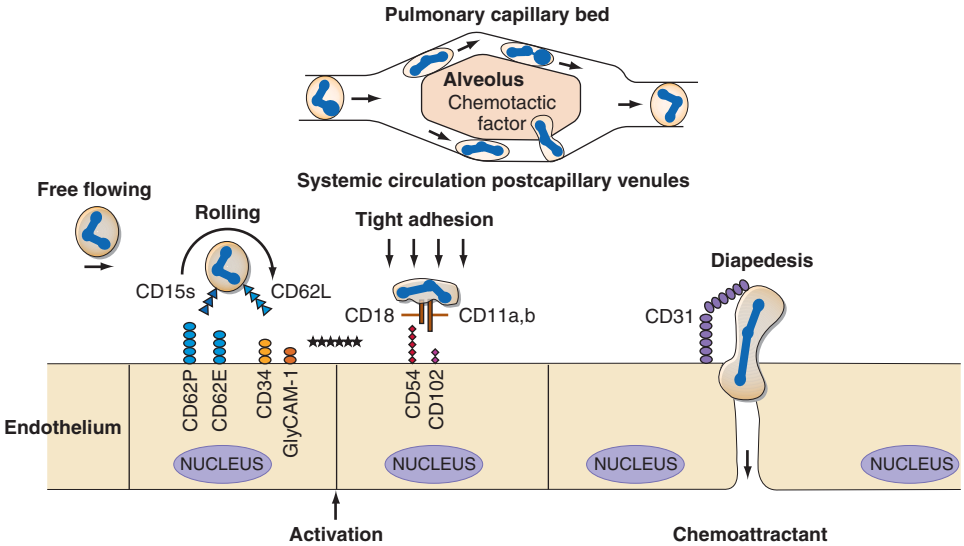

FIGURE 61-8 Neutrophil travel through the pulmonary capillaries is dependent on neutrophil deformability. Neutrophil rigidity (e.g., caused by C5a) enhances pulmonary trapping and response to pulmonary pathogens in a way that is not so dependent on cell-surface receptors. Intraalveolar chemotactic factors, such as those caused by certain bacteria (e.g., *Streptococcus pneumoniae*) lead to diapedesis of neutrophils from the pulmonary capillaries into the alveolar space. Neutrophil interaction with the endothelium of the systemic postcapillary venules is dependent on molecules of attachment. The neutrophil "rolls" along the endothelium using selectins: neutrophil CD15s (sialyl-Lewis^x) binds to CD62E (E-selectin) and CD62P (P-selectin) on endothelial cells; CD62L (L-selectin) on neutrophils binds to CD34 and other molecules (e.g., GlyCAM-1) expressed on endothelium. Chemokines or other activation factors stimulate integrin-mediated "tight adhesion": CD11a/CD18 (LFA-1) and CD11b/CD18 (Mac-1, CR3) bind to CD54 (ICAM-1) and CD102 (ICAM-2) on the endothelium. Diapedesis occurs between endothelial cells: CD31 (PECAM-1) expressed by the emigrating neutrophil interacts with CD31 expressed at the endothelial cell-cell junction.

jacent cells to permit leukocyte passage. Diapedesis involves platelet/endothelial cell adhesion molecule (PECAM) 1 (CD31), which is expressed on both the emigrating leukocyte and the endothelial cells. The endothelial responses (increased blood flow from increased vasodilation and permeability) are mediated by anaphylatoxins (e.g., C3a and C5a) as well as vasodilators such as histamine, bradykinin, serotonin, nitric oxide, vascular endothelial growth factor (VEGF), and prostaglandins E and I. Cytokines regulate some of these processes [e.g., TNF-α induction of VEGF, interferon (IFN) γ inhibition of prostaglandin E].

In the healthy adult, most neutrophils leave the body by migration through the mucous membrane of the gastrointestinal tract. Normally, neutrophils spend a short time in the circulation (half-life, 6–7 h). Senescent neutrophils are cleared from the circulation by macrophages in the lung and spleen. Once in the tissues, neutrophils release enzymes, such as collagenase and elastase, which help establish abscess cavities. Neutrophils ingest pathogenic materials that have been opsonized by IgG and C3b. Fibronectin and the tetrapeptide tuftsin also facilitate phagocytosis.

With phagocytosis comes a burst of oxygen consumption and activation of the hexose-monophosphate shunt. A membrane-associated NADPH oxidase, consisting of membrane and cytosolic components, is assembled and catalyzes the reduction of oxygen to superoxide anion, which is then converted to hydrogen peroxide and other toxic oxygen products (e.g., hydroxyl radical). Hydrogen peroxide + chloride + neutrophil myeloperoxidase generate hypochlorous acid (bleach), hypochlorite, and chlorine. These products oxidize and halogenate microorganisms and tumor cells and, when uncontrolled, can damage host tissue. Strongly cationic proteins, defensins, and probably nitric oxide also participate in microbial killing. Lactoferrin chelates iron, an important growth factor for microorganisms, especially fungi. Other enzymes, such as lysozyme and acid proteases, help digest microbial debris. After 1–4 days in tissues, neutrophils die. The apoptosis of neutrophils is also cytokine-regulated; granulocyte colony-stimulating factor (G-CSF) and IFN-γ prolong their life span. Under certain conditions, such as in delayed-type hypersensitivity, monocyte accumulation occurs within 6–12 h of initiation of inflammation. Neutrophils, monocytes, microorganisms in various states of digestion, and altered local tissue cells make up the inflammatory exudate, pus. Myeloperoxidase confers the characteristic green color to pus and may participate in turning off the inflammatory process by inactivating chemoattractants and immobilizing phagocytic cells.

Neutrophils respond to certain cytokines [IFN-γ, granulocyte-macrophage colony-stimulating factor (GM-CSF), IL-8] and produce cytokines and chemotactic signals [TNF-α, IL-8, macrophage inflammatory protein (MIP) 1] that modulate the inflammatory response. In the presence of fibrinogen, f-met leu phe or leukotriene B_4 induces IL-8 production by neutrophils, providing autocrine amplification of inflammation. *Chemokines* (*chemo*attractant cyto*kines*) are small proteins produced by many different cell types, including endothelial cells, fibroblasts, epithelial cells, neutrophils, and monocytes, that regulate neutrophil, monocyte, eosinophil, and lymphocyte recruitment and activation. Chemokines transduce their signals through heterotrimeric G protein–linked receptors that have seven cell membrane–spanning domains, the same type of cell-surface receptor that mediates the response to the classic chemoattractants f-metleuphe and C5a. Four major groups of chemokines are recognized based on the cysteine structure near the N terminus: C, CC, CXC, and CXXXC. The CXC cytokines such as IL-8 mainly attract neutrophils; CC chemokines such as MIP-1 attract lymphocytes, monocytes, eosinophils, and basophils; the C chemokine lymphotactin is T cell tropic; the CXXXC chemokine fractalkine attracts neutrophils, monocytes, and T cells. These molecules and their receptors not only regulate the trafficking and activation of inflammatory cells, but specific chemokine receptors serve as co-receptors for HIV infection (Chap. 182) and have a role in atherogenesis.

NEUTROPHIL ABNORMALITIES

A defect in the neutrophil life cycle can lead to dysfunction and compromised host defenses. Inflammation is often depressed, and the clinical result is often recurrent with severe bacterial and fungal infections. Aphthous ulcers of mucous membranes (gray ulcers without pus) and gingivitis and periodontal disease suggest a phagocytic cell disorder. Patients with congenital phagocyte defects can have infections within the first few days of life. Skin, ear, upper and lower respiratory tract, and bone infections are common. Sepsis and meningitis are rare. In some disorders the frequency of infection is variable, and patients can go for months or even years without major infection. Aggressive management of these congenital diseases has extended the life span of patients well beyond 30 years.

Neutropenia The consequences of absent neutrophils are dramatic. Susceptibility to infectious diseases increases sharply when neutrophil counts fall below 1000 cells/μL. When the absolute neutrophil count (ANC; band forms and mature neutrophils combined) falls to <500 cells/μL, control of endogenous microbial flora (e.g., mouth, gut) is impaired; when the ANC is <200/μL, the inflammatory process is absent. Neutropenia can be due to depressed production, increased peripheral destruction, or excessive peripheral pooling. A falling

neutrophil count or a significant decrease in the number of neutrophils below steady-state levels, together with a failure to increase neutrophil counts in the setting of infection or other challenge, requires investigation. Acute neutropenia, such as that caused by cancer chemotherapy, is more likely to be associated with increased risk of infection than neutropenia of long duration (months to years) that reverses in response to infection or carefully controlled administration of endotoxin (see "Laboratory Diagnosis," below).

Some causes of inherited and acquired neutropenia are listed in Table 61-1. The most common neutropenias are iatrogenic, resulting from the use of cytotoxic or immunosuppressive therapies for malignancy or control of autoimmune disorders. These drugs cause neutropenia because they result in decreased production of rapidly growing progenitor (stem) cells of the marrow. Certain antibiotics such as chloramphenicol, trimethoprim-sulfamethoxazole, flucytosine, vidarabine, and the antiretroviral drug zidovudine may cause neutropenia by inhibiting proliferation of myeloid precursors. The marrow suppression is generally dose-related and dependent on continued administration of the drug. Recombinant human G-CSF usually reverses this form of neutropenia.

Another important mechanism for iatrogenic neutropenia is the effect of drugs that serve as immune haptens and sensitize neutrophils or neutrophil precursors to immune-mediated peripheral destruction. This form of drug-induced neutropenia can be seen within 7 days of exposure to the drug; with previous drug exposure, resulting in preexisting antibodies, neutropenia may occur a few hours after administration of the drug. Although any drug can cause this form of neutropenia, the most frequent causes are commonly used antibiotics, such as sulfa-containing compounds, penicillins, and cephalosporins. Fever and eosinophilia may also be associated with drug reactions, but often these signs are not present. Drug-induced neutropenia can be severe, but discontinuation of the sensitizing drug is sufficient for recovery, which is usually seen within 5–7 days and is complete by 10 days. Readministration of the sensitizing drug should be avoided, since abrupt neutropenia will often result. For this reason, diagnostic challenge should be avoided.

Autoimmune neutropenias caused by circulating antineutrophil antibodies are another form of acquired neutropenia that results in increased destruction of neutrophils. Acquired neutropenia may also be seen with viral infections, including infection with HIV. Acquired neutropenia may be cyclic in nature, occurring at intervals of several weeks. Acquired cyclic or stable neutropenia may be associated with an expansion of large granular lymphocytes (LGLs), which may be T cells, NK cells, or NK-like cells. Patients with LGL lymphocytosis may have moderate blood and bone marrow lymphocytosis, neutropenia, polyclonal hypergammaglobulinemia, splenomegaly, rheumatoid arthritis, and absence of lymphadenopathy. Such patients may have a chronic and relatively stable course. Recurrent bacterial infections are frequent. Benign and malignant forms of this syndrome occur. In some patients, a spontaneous regression has occurred even after 11 years, suggesting an immunoregulatory defect as the basis for at least one form of the disorder. Glucocorticoids, cyclosporine, IFN-α, and nucleosides such as 2-chlorodeoxyadenosine each have induced remission.

Hereditary Neutropenias Hereditary neutropenias are rare and may manifest in early childhood as a profound constant neutropenia or agranulocytosis. Congenital forms of neutropenia include Kostmann's syndrome (neutrophil count <100/μL), which is often fatal due to mutations in the anti-apoptosis gene HAX-1; severe chronic neutropenia (neutrophil count of 300–1500/μL) due to mutations in neutrophil elastase; hereditary cyclic neutropenia, or, more appropriately, cyclic hematopoiesis, also due to mutations in neutrophil elastase; the cartilage-hair hypoplasia syndrome due to mutations in the mitochondrial RNA-processing endoribonuclease RMRP; Shwachman-Diamond syndrome associated with pancreatic insufficiency due to mutations in the Shwachman-Bodian-Diamond syndrome gene *SBDS*; the WHIM [*w*arts, *hy*pogammaglobulinemia, *i*nfections, *m*yelokathexis (retention of WBCs in the marrow)] syndrome, characterized by neutrophil hypersegmentation and bone marrow myeloid arrest due to mutations in the chemokine receptor CXCR4; and neutropenias associated with other immune defects, such as X-linked agammaglobulinemia, Wiskott-Aldrich syndrome, and CD40 ligand deficiency. Mutations in the G-CSF receptor can develop in severe congenital neutropenia and are linked to leukemia.

Maternal factors can be associated with neutropenia in the newborn. Transplacental transfer of IgG directed against antigens on fetal neutrophils can result in peripheral destruction. Drugs (e.g., thiazides) ingested during pregnancy can cause neutropenia in the newborn by either depressed production or peripheral destruction.

In Felty's syndrome—the triad of rheumatoid arthritis, splenomegaly, and neutropenia (Chap. 314)—spleen-produced antibodies can shorten neutrophil life span, while LGLs can attack marrow neutrophil precursors. Splenectomy may increase neutrophil count in Felty's syndrome and lower serum neutrophil-binding IgG. Some Felty's syndrome patients also have neutropenia associated with an increased number of LGLs. Splenomegaly with peripheral trapping and destruction of neutrophils is also seen in lysosomal storage diseases and in portal hypertension.

Neutrophilia Neutrophilia results from increased neutrophil production, increased marrow release, or defective margination (Table 61-2). The most important acute cause of neutrophilia is infection.

TABLE 61-1 CAUSES OF NEUTROPENIA

Decreased Production
- Drug-induced—alkylating agents (nitrogen mustard, busulfan, chlorambucil, cyclophosphamide); antimetabolites (methotrexate, 6-mercaptopurine, 5-flucytosine); noncytotoxic agents [antibiotics (chloramphenicol, penicillins, sulfonamides), phenothiazines, tranquilizers (meprobamate), anticonvulsants (carbamazepine), antipsychotics (clozapine), certain diuretics, anti-inflammatory agents, antithyroid drugs, many others]
- Hematologic diseases—idiopathic, cyclic neutropenia, Chédiak-Higashi syndrome, aplastic anemia, infantile genetic disorders (see text)
- Tumor invasion, myelofibrosis
- Nutritional deficiency—vitamin B_{12}, folate (especially alcoholics)
- Infection—tuberculosis, typhoid fever, brucellosis, tularemia, measles, infectious mononucleosis, malaria, viral hepatitis, leishmaniasis, AIDS

Peripheral Destruction
- Antineutrophil antibodies and/or splenic or lung trapping
- Autoimmune disorders—Felty's syndrome, rheumatoid arthritis, lupus erythematosus
- Drugs as haptens—aminopyrine, α-methyldopa, phenylbutazone, mercurial diuretics, some phenothiazines
- Wegener's granulomatosis

Peripheral Pooling (Transient Neutropenia)
- Overwhelming bacterial infection (acute endotoxemia)
- Hemodialysis
- Cardiopulmonary bypass

TABLE 61-2 CAUSES OF NEUTROPHILIA

Increased Production
- Idiopathic
- Drug-induced—glucocorticoids, G-CSF
- Infection—bacterial, fungal, sometimes viral
  - Inflammation—thermal injury, tissue necrosis, myocardial and pulmonary infarction, hypersensitivity states, collagen vascular diseases
  - Myeloproliferative diseases—myelocytic leukemia, myeloid metaplasia, polycythemia vera

Increased Marrow Release
- Glucocorticoids
- Acute infection (endotoxin)
- Inflammation—thermal injury

Decreased or Defective Margination
- Drugs—epinephrine, glucocorticoids, nonsteroidal anti-inflammatory agents
- Stress, excitement, vigorous exercise
- Leukocyte adhesion deficiency type 1 (integrin β chain, CD18); leukocyte adhesion deficiency type 2 (selectin ligand, CD15s, sialyl-Lewis^x)

Miscellaneous
- Metabolic disorders—ketoacidosis, acute renal failure, eclampsia, acute poisoning
- Drugs—lithium
- Other—metastatic carcinoma, acute hemorrhage or hemolysis

TABLE 61-3 TYPES OF GRANULOCYTE AND MONOCYTE DISORDERS

Function	Cause of Indicated Dysfunction		
	Drug-Induced	Acquired	Inherited
Adherence-aggregation	Aspirin, colchicine, alcohol, glucocorticoids, ibuprofen, piroxicam	Neonatal state, hemodialysis	Leukocyte adhesion deficiency types 1 and 2
Deformability		Leukemia, neonatal state, diabetes mellitus, immature neutrophils	
Chemokinesis-chemotaxis	Glucocorticoids (high dose), aurano-fin, colchicine (weak effect), phenylbutazone, naproxen, indomethacin, interleukin 2	Thermal injury, malignancy, malnutrition, periodontal disease, neonatal state, systemic lupus erythematosus, rheumatoid arthritis, diabetes mellitus, sepsis, influenza virus infection, herpes simplex virus infection, acrodermatitis enteropathica, AIDS	Chédiak-Higashi syndrome, neutrophil-specific granule deficiency, hyper IgE–recurrent infection (Job's) syndrome (in some patients), Down syndrome, α-mannosidase deficiency, severe combined immunodeficiency, Wiskott-Aldrich syndrome
Microbicidal activity	Colchicine, cyclophosphamide, glucocorticoids (high dose), TNF-α blocking antibodies	Leukemia, aplastic anemia, certain neutropenias, tuftsin deficiency, thermal injury, sepsis, neonatal state, diabetes mellitus, malnutrition, AIDS	Chédiak-Higashi syndrome, neutrophil-specific granule deficiency, chronic granulomatous disease, defects in IFN-γ/IL-12 axis

Neutrophilia from acute infection represents both increased production and increased marrow release. Increased production is also associated with chronic inflammation and certain myeloproliferative diseases. Increased marrow release and mobilization of the marginated leukocyte pool are induced by glucocorticoids. Release of epinephrine, as with vigorous exercise, excitement, or stress, will demarginate neutrophils in the spleen and lungs and double the neutrophil count in minutes. Cigarette smoking can increase neutrophil counts into the abnormal range. Leukocytosis with cell counts of 10,000–25,000/μL occurs in response to infection and other forms of acute inflammation and results from both release of the marginated pool and mobilization of marrow reserves. Persistent neutrophilia with cell counts of ≥30,000–50,000/μL is called a *leukemoid reaction*, a term often used to distinguish this degree of neutrophilia from leukemia. In a leukemoid reaction, the circulating neutrophils are usually mature and not clonally derived.

Abnormal Neutrophil Function Inherited and acquired abnormalities of phagocyte function are listed in Table 61-3. The resulting diseases are best considered in terms of the functional defects of adherence, chemotaxis, and microbicidal activity. The distinguishing features of the important inherited disorders of phagocyte function are shown in Table 61-4.

DISORDERS OF ADHESION Two main types of leukocyte adhesion deficiency (LAD) have been described, LAD 1 and LAD 2. Both are autosomal recessive traits and result in the inability of neutrophils to exit the circulation to sites of infection, leading to leukocytosis and increased susceptibility to infection (Fig. 61-8). Patients with LAD 1 have mutations in CD18, the common component of the integrins LFA-1, Mac-1, and p150,95, leading to a defect in tight adhesion between neutrophils and the endothelium. The heterodimer formed by CD18/CD11b (Mac-1) is also the receptor for the complement-derived opsonin C3bi (CR3). The *CD18* gene is located on distal chromosome 21q. The severity of the defect determines the severity of clinical disease. Complete lack of expression of the leukocyte integrins results in a severe phenotype in which inflammatory stimuli do not increase the expression of leukocyte integrins on neutrophils or activated T and B cells. Neutrophils (and monocytes) from patients with LAD 1 adhere poorly to endothelial cells and protein-coated surfaces and exhibit defective spreading, aggregation, and chemotaxis. Patients with LAD 1 have recurrent bacterial infections involving the skin, oral and genital mucosa, and respiratory and intestinal tracts; persistent leukocytosis (neutrophil counts of 15,000–20,000/μL) because cells do not marginate; and, in severe cases, a history of delayed separation of the umbilical stump. Infections, especially of the skin, may become necrotic with progressively enlarging borders, slow healing, and development of dysplastic scars. The most common bacteria are *Staphylococcus aureus* and enteric gram-negative bacteria. LAD 2 is caused by an abnormality of fucosylation of SLe^x (CD15s), the ligand on neutrophils that interacts with selectins on endothelial cells and is responsible for neutrophil rolling along the endothelium. Infection susceptibility in LAD 2 appears to be less severe than in LAD 1. LAD 2 is also known as *congenital disorder of glycosylation IIc* (CDGIIc).

DISORDERS OF NEUTROPHIL GRANULES The most common neutrophil defect is myeloperoxidase deficiency, a primary granule defect inherited as an autosomal recessive trait; the incidence is ~1 in 2000 persons. Isolated myeloperoxidase deficiency is not associated with clinically compromised defenses, presumably because other defense systems such as hydrogen peroxide generation are amplified. Microbicidal activity of neutrophils is delayed but not absent. Myeloperoxidase deficiency may make other acquired host defense defects more serious. An acquired form of myeloperoxidase deficiency occurs in myelomonocytic leukemia and acute myeloid leukemia.

Chédiak-Higashi syndrome (CHS) is a rare disease with autosomal recessive inheritance due to defects in the lysosomal transport protein LYST, encoded by the gene *CHS1* at 1q42. This protein is required for normal packaging and disbursement of granules. Neutrophils (and all cells containing lysosomes) from patients with CHS characteristically have large granules (Fig. 61-9) making it a systemic disease. Patients with CHS have nystagmus, partial oculocutaneous albinism, and an increased number of infections resulting from many bacterial agents. Some CHS patients develop an "accelerated phase" in childhood with a hemophagocytic syndrome and an aggressive lymphoma requiring bone marrow transplantation. CHS neutrophils and monocytes have impaired chemotaxis and abnormal rates of microbial killing due to slow rates of fusion of the lysosomal granules with phagosomes. NK cell function is also impaired. CHS patients may develop a severe disabling peripheral neuropathy in adulthood that can lead to bed confinement.

Specific granule deficiency is a rare autosomal recessive disease in which the production of secondary granules and their contents, as well as the primary granule component defensins, is defective. The defect in bacterial killing leads to severe bacterial infections. One type of specific granule deficiency is due to a mutation in the CCAAT/enhancer binding protein-ε, a regulator of expression of granule components.

CHRONIC GRANULOMATOUS DISEASE Chronic granulomatous disease (CGD) is a group of disorders of granulocyte and monocyte oxidative metabolism. Although CGD is rare, with an incidence of 1 in 200,000 individuals, it is an important model of defective neutrophil oxidative metabolism. Most often CGD is inherited as an X-linked recessive trait; 30% of patients inherit the disease in an autosomal recessive pattern.

TABLE 61-4 INHERITED DISORDERS OF PHAGOCYTE FUNCTION: DIFFERENTIAL FEATURES

Clinical Manifestations	Cellular or Molecular Defects	Diagnosis
Chronic Granulomatous Diseases (70% X-linked, 30% Autosomal Recessive)		
Severe infections of skin, ears, lungs, liver, and bone with catalase-positive microorganisms such as *S. aureus*, *Burkholderia cepacia*, *Aspergillus* spp., *Chromobacterium violaceum*; often hard to culture organism; excessive inflammation with granulomas, frequent lymph node suppuration; granulomas can obstruct GI or GU tracts; gingivitis, aphthous ulcers, seborrheic dermatitis	No respiratory burst due to the lack of one of four NADPH oxidase subunits in neutrophils, monocytes, and eosinophils	NBT or DHR test; no superoxide and H_2O_2 production by neutrophils; immunoblot for NADPH oxidase components; genetic detection
Chédiak-Higashi Syndrome (Autosomal Recessive)		
Recurrent pyogenic infections, especially with *S. aureus*; many patients get lymphoma-like illness during adolescence; periodontal disease; partial oculocutaneous albinism, nystagmus, progressive peripheral neuropathy, mental retardation in some patients	Reduced chemotaxis and phagolysosome fusion, increased respiratory burst activity, defective egress from marrow, abnormal skin window; defect in LYST	Giant primary granules in neutrophils and other granule-bearing cells (Wright's stain); genetic detection
Specific Granule Deficiency (Autosomal Recessive)		
Recurrent infections of skin, ears, and sinopulmonary tract; delayed wound healing; decreased inflammation; bleeding diathesis	Abnormal chemotaxis, impaired respiratory burst and bacterial killing, failure to upregulate chemotactic and adhesion receptors with stimulation, defect in transcription of granule proteins; defect in C/EBPε	Lack of secondary (specific) granules in neutrophils (Wright's stain), no neutrophil-specific granule contents (i.e., lactoferrin), no defensins, platelet α granule abnormality; genetic detection
Myeloperoxidase Deficiency (Autosomal Recessive)		
Clinically normal except in patients with underlying disease such as diabetes mellitus; then candidiasis or other fungal infections	No myeloperoxidase due to pre- and post-translational defects	No peroxidase in neutrophils; genetic detection
Leukocyte Adhesion Deficiency		
Type 1: Delayed separation of umbilical cord, sustained neutrophilia, recurrent infections of skin and mucosa, gingivitis, periodontal disease	Impaired phagocyte adherence, aggregation, spreading, chemotaxis, phagocytosis of C3bi-coated particles; defective production of CD18 subunit common to leukocyte integrins	Reduced phagocyte surface expression of the CD18-containing integrins with monoclonal antibodies against LFA-1 (CD18/CD11a), Mac-1 or CR3 (CD18/CD11b), p150,95 (CD18/CD11c); genetic detection
Type 2: Mental retardation, short stature, Bombay (hh) blood phenotype, recurrent infections, neutrophilia	Impaired phagocyte rolling along endothelium	Reduced phagocyte surface expression of Sialyl-Lewis^x, with monoclonal antibodies against CD15s; genetic detection
Phagocyte Activation Defects (X-linked and Autosomal Recessive)		
NEMO deficiency: mild hypohidrotic ectodermal dysplasia; broad based immune defect: pyogenic and encapsulated bacteria, viruses, *Pneumocystis*, mycobacteria; X-linked	Impaired phagocyte activiation by IL-1, IL-18, TLR, CD40, TNF-α leading to problems with inflammation and antibody production	Poor in vitro response to endotoxin; lack of NF-κB activation; genetic detection
IRAK4 deficiency: susceptibility to pyogenic bacteria such as staphylococci, streptococci, clostridia; resistant to mycobacteria; autosomal recessive	Impaired phagocyte activation by endotoxin through TLR and other pathways; TNF-α signaling preserved	Poor in vitro response to endotoxin; lack of NF-κB activation by endotoxin; genetic detection
Hyper IgE–Recurrent Infection Syndrome (Autosomal Dominant) (Job's Syndrome)		
Eczematoid or pruritic dermatitis, "cold" skin abscesses, recurrent pneumonias with *S. aureus* with bronchopleural fistulae and cyst formation, mild eosinophilia, mucocutaneous candidiasis, characteristic facies, restrictive lung disease, scoliosis, delayed primary dental deciduation	Reduced chemotaxis in some patients, reduced suppressor T cell activity	Clinical features, involving lungs, skeleton, and immune system; serum IgE > 2000 IU/mL
Mycobacteria Susceptibility (Autosomal Dominant and Recessive Forms)		
Severe local or disseminated infections with bacille Calmette-Guérin (BCG), nontuberculous mycobacteria, salmonella, histoplasmosis, poor granuloma formation	Inability to kill intracellular organisms due to low IFN-γ production; mutations in IFN-γ receptors, IL-12 receptor, IL-12 p40, STAT-1, NEMO	Low or very high levels of IFN-γ receptor 1; functional assays of cytokine production and response; genetic detection

Abbreviations: GI, gastrointestinal; GU, genitourinary; NADPH, nicotinamide-adenine dinucleotide phosphate, NBT, nitroblue tetrazolium (dye test), DHR, dihydrorhodamine (oxidation test); LYST, lysosomal transport protein; C/EBPε, CCAAT/enhancer binding protein-ε; NEMO, NF-κB essential modulator; TLR, Toll-like receptor; IL, interleukin; TNF, tumor necrosis factor; IRAK4, IL-1 receptor–associated kinase protein-ε, NEMO 4; IFN, interferon.

Mutations in the genes for the four proteins that assemble at the plasma membrane account for all patients with CGD. Two proteins (a 91-kDa protein, abnormal in X-linked CGD, and a 22-kDa protein, absent in one form of autosomal recessive CGD) form the heterodimer cytochrome b-558 in the plasma membrane. Two other proteins (47 and 67 kDa, abnormal in the other autosomal recessive forms of CGD) are cytoplasmic in origin and interact with the cytochrome after cell activation to form NADPH oxidase, required for hydrogen peroxide production. Leukocytes from patients with CGD have severely diminished hydrogen peroxide production. The genes involved in each of the defects have been

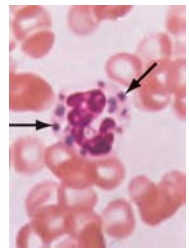

FIGURE 61-9 Chédiak-Higashi syndrome. The granulocytes contain huge cytoplasmic granules formed from aggregation and fusion of azurophilic and specific granules. Large abnormal granules are found in other granule-containing cells throughout the body.

cloned and sequenced and the chromosome locations identified. Patients with CGD characteristically have increased numbers of infections due to catalase-positive microorganisms (organisms that destroy their own hydrogen peroxide). When patients with CGD become infected, they often have extensive inflammatory reactions, and lymph node suppuration is common despite the administration of appropriate antibiotics. Aphthous ulcers and chronic inflammation of the nares are often present. Granulomas are frequent and can obstruct the gastrointestinal or genitourinary tracts. The excessive inflammation probably reflects failure to inhibit the synthesis or degradation of chemoattractants and antigens, leading to persistent neutrophil accumulation. Impaired killing of intracellular microorganisms by macrophages may lead to persistent cell-mediated immune activation and granuloma formation. Autoimmune complications such as immune thrombocytopenic purpura and juvenile rheumatoid arthritis are also increased in CGD. In addition, discoid lupus is more common in X-linked carriers.

DISORDERS OF PHAGOCYTE ACTIVATION Phagocytes depend on cell-surface stimulation to induce signals that evoke multiple levels of the inflammatory response, including cytokine synthesis, chemotaxis, and antigen presentation. Mutations affecting the major pathway that signals through NF-κB have been noted in patients with a variety of infection susceptibility syndromes. If the defects are at a very late stage of signal transduction, in the protein critical for NF-κB activation known as the NF-κB essential modulator (NEMO), then affected males develop ectodermal dysplasia and severe immune deficiency with susceptibility to bacteria, fungi, mycobacteria, and viruses. If the defect in NF-κB activation is closer to the signaling source, in the IL-1 receptor–associated kinase 4 (IRAK4), then children have a marked susceptibility to pyogenic infections early in life but develop resistance to infection later.

MONONUCLEAR PHAGOCYTES

The mononuclear phagocyte system is composed of monoblasts, promonocytes, and monocytes, in addition to the structurally diverse tissue macrophages that make up what was previously referred to as the reticuloendothelial system. Macrophages are long-lived phagocytic cells capable of many of the functions of neutrophils. They are also secretory cells that participate in many immunologic and inflammatory processes distinct from neutrophils. Monocytes leave the circulation by diapedesis more slowly than neutrophils and have a half-life in the blood of 12–24 h.

After blood monocytes arrive in the tissues, they differentiate into macrophages ("big eaters") with specialized functions suited for specific anatomic locations. Macrophages are particularly abundant in capillary walls of the lung, spleen, liver, and bone marrow, where they function to remove microorganisms and other noxious elements from the blood. Alveolar macrophages, liver Kupffer cells, splenic macrophages, peritoneal macrophages, bone marrow macrophages, lymphatic macrophages, brain microglial cells, and dendritic macrophages all have specialized functions. Macrophage-secreted products include lysozyme, neutral proteases, acid hydrolases, arginase, complement components, enzyme inhibitors (plasmin, α_2-macroglobulin), binding proteins (transferrin, fibronectin, transcobalamin II), nucleosides, and cytokines (TNF-α; IL-1, -8, -12, -18). IL-1 (Chaps. 17 and 308) has many functions, including initiating fever in the hypothalamus, mobilizing leukocytes from the bone marrow, and activating lymphocytes and neutrophils. TNF-α is a pyrogen that duplicates many of the actions of IL-1 and plays an important role in the pathogenesis of gram-negative shock (Chap. 265). TNF-α stimulates production of hydrogen peroxide and related toxic oxygen species by macrophages and neutrophils. In addition, TNF-α induces catabolic changes that contribute to the profound wasting (cachexia) associated with many chronic diseases.

Other macrophage-secreted products include reactive oxygen and nitrogen metabolites, bioactive lipids (arachidonic acid metabolites and platelet-activating factors), chemokines, CSFs, and factors stimulating fibroblast and vessel proliferation. Macrophages help regulate the replication of lymphocytes and participate in the killing of tumors, viruses, and certain bacteria (*Mycobacterium tuberculosis* and *Listeria monocytogenes*). Macrophages are key effector cells in the elimination of intracellular microorganisms. Their ability to fuse to form giant cells that coalesce into granulomas in response to some inflammatory stimuli is important in the elimination of intracellular microbes and is under the control of IFN-γ. Nitric oxide induced by IFN-γ is an important effector against intracellular parasites, including tuberculosis and *Leishmania*.

Macrophages play an important role in the immune response (Chap. 308). They process and present antigen to lymphocytes and secrete cytokines that modulate and direct lymphocyte development and function. Macrophages participate in autoimmune phenomena by removing immune complexes and other substances from the circulation. Polymorphisms in macrophage receptors for immunoglobulin (FcγRII) determine susceptibility to some infections and autoimmune diseases. In wound healing, they dispose of senescent cells, and they contribute to atheroma development. Macrophage elastase mediates development of emphysema from cigarette smoking.

DISORDERS OF THE MONONUCLEAR PHAGOCYTE SYSTEM

Many disorders of neutrophils extend to mononuclear phagocytes. Thus, drugs that suppress neutrophil production in the bone marrow can cause monocytopenia. Transient monocytopenia occurs after stress or glucocorticoid administration. Monocytosis is associated with tuberculosis, brucellosis, subacute bacterial endocarditis, Rocky Mountain spotted fever, malaria, and visceral leishmaniasis (kala azar). Monocytosis also occurs with malignancies, leukemias, myeloproliferative syndromes, hemolytic anemias, chronic idiopathic neutropenias, and granulomatous diseases such as sarcoidosis, regional enteritis, and some collagen vascular diseases. Patients with LAD, hyperimmunoglobulin E–recurrent infection (Job's) syndrome, CHS, and CGD all have defects in the mononuclear phagocyte system.

Monocyte cytokine production or response is impaired in some patients with disseminated nontuberculous mycobacterial infection who are not infected with HIV. Genetic defects in the pathways regulated by IFN-γ and IL-12 lead to impaired killing of intracellular bacteria, mycobacteria, salmonellae, and certain viruses (Fig. 61-10).

Certain viral infections impair mononuclear phagocyte function. For example, influenza virus infection causes abnormal monocyte chemotaxis. Mononuclear phagocytes can be infected by HIV using CCR5, the chemokine receptor that acts as a co-receptor with CD4 for HIV. T lymphocytes produce IFN-γ, which induces FcR expression and phagocytosis and stimulates hydrogen peroxide production by mononuclear phagocytes and neutrophils. In certain diseases, such as AIDS, IFN-γ production may be deficient, while in other diseases, such as T cell lymphomas, excessive release of IFN-γ may be associated with erythrophagocytosis by splenic macrophages.

Autoinflammatory diseases are characterized by abnormal cytokine regulation leading to excess inflammation in the absence of infection. These diseases can mimic infectious or immunodeficient syndromes. Gain-of-function mutations in the TNF-α receptor cause TNF-α receptor–associated periodic syndrome (TRAPS), which is characterized by recurrent fever in the absence of infection, due to persistent stimulation of the TNF-α receptor (Chap. 323). Diseases with abnormal IL-1 regulation leading to fever include familial Mediterranean fever due to mutations in *pyrin*. Mutations in *cold-induced autoinflammatory syndrome 1* lead to neonatal onset multisystem autoinflammatory disease, familial

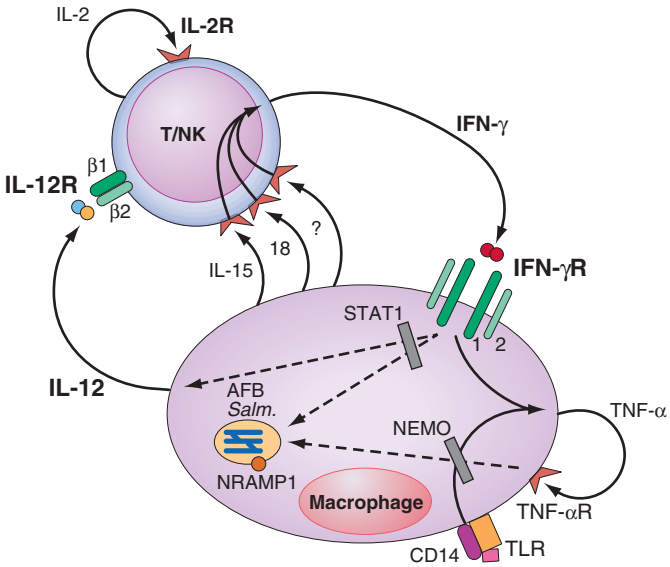

FIGURE 61-10 Lymphocyte-macrophage interactions underlying resistance to mycobacteria and other intracellular parasites such as *Salmonella*. Mycobacteria infect macrophages, leading to the production of IL-12, which activates T or NK cells through its receptor, leading to production of IL-2 and IFN-γ. IFN-γ acts through its receptor on macrophages to upregulate TNF-α and IL-12 and kill intracellular parasites. Mutant forms of the cytokines and receptors shown in large type have been found in severe cases of nontuberculous mycobacterial infection and salmonellosis.

cold urticaria, and Muckle-Wells syndrome. Pyoderma gangrenosum, acne, and sterile pyogenic arthritis is caused by mutations in CD2BP1. In contrast to these syndromes of overexpression of proinflammatory cytokines, blockade of TNF-α by the antagonists infliximab, etanercept, and adalimumab has been associated with severe infections due to tuberculosis, nontuberculous mycobacteria, and fungi (Chap. 323).

Monocytopenia occurs with acute infections, with stress, and after treatment with glucocorticoids. Monocytopenia also occurs in aplastic anemia, hairy cell leukemia, acute myeloid leukemia, and as a direct result of myelotoxic drugs.

EOSINOPHILS

Eosinophils and neutrophils share similar morphology, many lysosomal constituents, phagocytic capacity, and oxidative metabolism. Eosinophils express a specific chemoattractant receptor and respond to a specific chemokine, eotaxin. Little is known about the role of eosinophils. Eosinophils are much longer lived than neutrophils, and unlike neutrophils, tissue eosinophils can recirculate. During most infections, eosinophils are not important. However, in invasive helminthic infections, such as hookworm, schistosomiasis, strongyloidiasis, toxocariasis, trichinosis, filariasis, echinococcosis, and cysticercosis, the eosinophil plays a central role in host defense. Eosinophils are associated with bronchial asthma, cutaneous allergic reactions, and other hypersensitivity states.

The distinctive feature of the red-staining (Wright's stain) eosinophil granule is its crystalline core consisting of an arginine-rich protein (major basic protein) with histaminase activity, important in host defense against parasites. Eosinophil granules also contain a unique eosinophil peroxidase that catalyzes the oxidation of many substances by hydrogen peroxide and may facilitate killing of microorganisms.

Eosinophil peroxidase, in the presence of hydrogen peroxide and halide, initiates mast cell secretion in vitro and thereby promotes inflammation. Eosinophils contain cationic proteins, some of which bind to heparin and reduce its anticoagulant activity. Eosinophil-derived neurotoxin and eosinophil cationic protein are ribonucleases that can kill respiratory syncytial virus. Eosinophil cytoplasm contains Charcot-Leyden crystal protein, a hexagonal bipyramidal crystal first observed in a patient with leukemia and then in sputum of patients with asthma; this protein is lysophospholipase and may function to detoxify certain lysophospholipids.

Several factors enhance the eosinophil's function in host defense. T cell–derived factors enhance the ability of eosinophils to kill parasites. Mast cell–derived eosinophil chemotactic factor of anaphylaxis (ECFa) increases the number of eosinophil complement receptors and enhances eosinophil killing of parasites. Eosinophil CSFs (e.g., IL-5) produced by macrophages increase eosinophil production in the bone marrow and activate eosinophils to kill parasites.

EOSINOPHILIA

Eosinophilia is the presence of >500 eosinophils per μL of blood and is common in many settings besides parasite infection. Significant tissue eosinophilia can occur without an elevated blood count. A common cause of eosinophilia is allergic reaction to drugs (iodides, aspirin, sulfonamides, nitrofurantoin, penicillins, and cephalosporins). Allergies such as hay fever, asthma, eczema, serum sickness, allergic vasculitis, and pemphigus are associated with eosinophilia. Eosinophilia also occurs in collagen vascular diseases (e.g., rheumatoid arthritis, eosinophilic fasciitis, allergic angiitis, and periarteritis nodosa) and malignancies (e.g., Hodgkin's disease; mycosis fungoides; chronic myeloid leukemia; and cancer of the lung, stomach, pancreas, ovary, or uterus), as well as in Job's syndrome and CGD. Eosinophilia is commonly present in the helminthic infections. IL-5 is the dominant eosinophil growth factor. Therapeutic administration of the cytokines IL-2 and GM-CSF frequently leads to transient eosinophilia. The most dramatic hypereosinophilic syndromes are Loeffler's syndrome, tropical pulmonary eosinophilia, Loeffler's endocarditis, eosinophilic leukemia, and idiopathic hypereosinophilic syndrome (50,000–100,000/μL).

The idiopathic hypereosinophilic syndrome represents a heterogeneous group of disorders with the common feature of prolonged eosinophilia of unknown cause and organ system dysfunction, including the heart, central nervous system, kidneys, lungs, gastrointestinal tract, and skin. The bone marrow is involved in all affected individuals, but the most severe complications involve the heart and central nervous system. Clinical manifestations and organ dysfunction are highly variable. Eosinophils are found in the involved tissues and likely cause tissue damage by local deposition of toxic eosinophil proteins such as eosinophil cationic protein and major basic protein. In the heart, the pathologic changes lead to thrombosis, endocardial fibrosis, and restrictive endomyocardiopathy. The damage to tissues in other organ systems is similar. Some cases are due to mutations involving the platelet-derived growth factor receptor, and these are extremely sensitive to the tyrosine kinase inhibitor imatinib. Glucocorticoids, hydroxyurea, and IFN-α each have been used successfully, as have therapeutic antibodies against IL-5. Cardiovascular complications are managed aggressively.

The *eosinophilia-myalgia syndrome* is a multisystem disease, with prominent cutaneous, hematologic, and visceral manifestations, that frequently evolves into a chronic course and can occasionally be fatal. The syndrome is characterized by eosinophilia (eosinophil count >1000/μL) and generalized disabling myalgias without other recognized causes. Eosinophilic fasciitis, pneumonitis, and myocarditis; neuropathy culminating in respiratory failure; and encephalopathy may occur. The disease is caused by ingesting contaminants in L-tryptophan–containing products. Eosinophils, lymphocytes, macrophages, and fibroblasts accumulate in the affected tissues, but their role in pathogenesis is unclear. Activation of eosinophils and fibroblasts and the deposition of eosinophil-derived toxic proteins in affected tissues may contribute. IL-5 and transforming growth factor β have been implicated as potential mediators. Treatment is withdrawal of products containing L-tryptophan and the administration of glucocorticoids. Most patients recover fully, remain stable, or show slow recovery, but the disease can be fatal in up to 5% of patients.

EOSINOPENIA

Eosinopenia occurs with stress, such as acute bacterial infection, and after treatment with glucocorticoids. The mechanism of eosinopenia

of acute bacterial infection is unknown but is independent of endogenous glucocorticoids, since it occurs in animals after total adrenalectomy. There is no known adverse effect of eosinopenia.

HYPERIMMUNOGLOBULIN E–RECURRENT INFECTION SYNDROME

The hyperimmunoglobulin E–recurrent infection syndrome, or Job's syndrome, is a rare multisystem disease in which the immune system, bone, teeth, lung, and skin are affected. Abnormal chemotaxis is a variable feature. The molecular basis for this syndrome is still not known, but some cases show clear autosomal dominant transmission with linkage to 4q. Patients with this syndrome have characteristic facies with broad nose, kyphoscoliosis and osteoporosis, and eczema. The primary teeth erupt normally but do not deciduate, often requiring extraction. Patients develop recurrent sinopulmonary and cutaneous infections that tend to be much less inflamed than appropriate for the degree of infection and have been referred to as "cold abscesses." A high degree of suspicion is required to diagnose infections in these patients, who may appear well despite extensive disease. The cold abscesses have been considered a reflection of too few phagocytes arriving too late, perhaps due to a lymphocyte factor inhibiting chemotaxis. However, the chemotactic defect in these patients is variable, and the fundamental basis for the impaired defenses is complex and poorly defined.

LABORATORY DIAGNOSIS AND MANAGEMENT

Initial studies of WBC and differential and often a bone marrow examination may be followed by assessment of bone marrow reserves (steroid challenge test), marginated circulating pool of cells (epinephrine challenge test), and marginating ability (endotoxin challenge test) (Fig. 61-7). In vivo assessment of inflammation is possible with a Rebuck skin window test or an in vivo skin blister assay, which measures the ability of leukocytes and inflammatory mediators to accumulate locally in the skin. In vitro tests of phagocyte aggregation, adherence, chemotaxis, phagocytosis, degranulation, and microbicidal activity (for *S. aureus*) may help pinpoint cellular or humoral lesions. Deficiencies of oxidative metabolism are detected with either the nitroblue tetrazolium (NBT) dye test or the dihydrorhodamine (DHR) oxidation test. These tests are based on the ability of products of oxidative metabolism to alter the oxidation states of reporter molecules so that they can be detected microscopically (NBT) or by flow cytometry (DHR). Qualitative studies of superoxide and hydrogen peroxide production may further define neutrophil oxidative function.

Patients with leukopenias or leukocyte dysfunction often have delayed inflammatory responses. Therefore, clinical manifestations may be minimal despite overwhelming infection, and unusual infections must always be suspected. Early signs of infection demand prompt, aggressive culturing for microorganisms, use of antibiotics, and surgical drainage of abscesses. Prolonged courses of antibiotics are often required. In patients with CGD, prophylactic antibiotics (trimethoprim-sulfamethoxazole) and antifungals (itraconazole) markedly diminish the frequency of life-threatening infections. Short courses of glucocorticoids may relieve gastrointestinal or genitourinary tract obstruction by granulomas in patients with CGD. Recombinant human IFN-γ, which nonspecifically stimulates phagocytic cell function, reduces the frequency of infections in patients with CGD by 70% and reduces the severity of infection. This effect of IFN-γ in CGD is additive to the effect of prophylactic antibiotics. The recommended dose is 50 $\mu g/m^2$ subcutaneously three times weekly. IFN-γ has also been used successfully in the treatment of leprosy, nontuberculous mycobacteria, and visceral leishmaniasis.

Rigorous oral hygiene reduces but does not eliminate the discomfort of gingivitis, periodontal disease, and aphthous ulcers; chlorhexidine mouthwash and tooth brushing with a hydrogen peroxide–sodium bicarbonate paste helps many patients. Oral antifungal agents (fluconazole or itraconazole) have reduced mucocutaneous candidiasis in patients with Job's syndrome. Androgens, glucocorticoids, lithium, and immunosuppressive therapy have been used to restore myelopoiesis in patients with neutropenia due to impaired production. Recombinant G-CSF is useful in the management of certain forms of neutropenia due to depressed neutrophil production, especially those related to cancer chemotherapy. Patients with chronic neutropenia with evidence of a good bone marrow reserve need not receive prophylactic antibiotics. Patients with chronic or cyclic neutrophil counts < 500/μL may benefit from prophylactic antibiotics and G-CSF during periods of neutropenia. Oral trimethoprim-sulfamethoxazole (160/800 mg) twice daily can prevent infection. Increased numbers of fungal infections are not seen in patients with CGD on this regimen. Oral quinolones such as levofloxacin and ciprofloxacin are alternatives.

In the setting of cytotoxic chemotherapy with severe, persistent neutropenia, trimethoprim-sulfamethoxazole prevents *Pneumocystis jiroveci* pneumonia. These patients, and patients with phagocytic cell dysfunction, should avoid heavy exposure to airborne soil, dust, or decaying matter (mulch, manure), which are often rich in *Nocardia* and the spores of *Aspergillus* and other fungi. Restriction of activities or social contact has no proven role in reducing risk of infection.

Cure of some congenital phagocyte defects is possible by bone marrow transplantation (Chap. 108). However, complications of bone marrow transplantation are still serious, and with rigorous medical care many patients with phagocytic disorders can go for years without a life-threatening infection. The identification of specific gene defects in patients with LAD 1, CGD, and other immunodeficiencies has led to gene therapy trials in a number of genetic white cell disorders.

e11 Atlas of Hematology and Analysis of Peripheral Blood Smears

Dan L. Longo

Some of the relevant findings in peripheral blood, enlarged lymph nodes, and bone marrow are illustrated here. Systematic histologic examination of the bone marrow and lymph node are beyond the scope of a general medicine textbook. However, every internist should know how to examine a peripheral blood smear.

The examination of the peripheral blood smear is one of the most informative exercises a physician can perform. While advances in automated technology have made the examination of the peripheral blood smear by the physician seem less important, the technology is not a completely satisfactory replacement for blood smear interpretation by a trained medical professional who also knows the patient's clinical history, family history, social history, and physical findings. It is useful to ask the laboratory to generate a Wright's-stained peripheral blood smear and to examine it.

The best place to examine blood cell morphology is the feathered edge of the blood smear where red cells lie in a single layer, side by side, just barely touching each other but not overlapping. My own approach is to look at the smallest cellular elements first, the platelets, and work my way up in size to red cells and then white cells.

Using an oil immersion lens that magnifies the cells 100-fold, one first counts the platelets in five to six fields, averages the number per field, and multiplies by 20,000 to get a rough estimate of the platelet count. The platelets are usually 1–2 μm in diameter and have a blue granulated appearance. There is usually 1 platelet for every 20 or so red cells. Of course, the automated counter is much more accurate, but gross disparities between the automated and manual counts should be assessed. Large platelets may be a sign of rapid platelet turnover, as young platelets are often larger than old platelets; alternatively, certain rare inherited syndromes can produce large platelets. Platelet clumping visible on the smear can be associated with falsely low automated platelet counts. Similarly, neutrophil fragmentation can be a source of falsely elevated automated platelet counts.

Next one examines the red blood cells. One can gauge their size by comparing the red cell to the nucleus of a small lymphocyte. Both are normally about 8 μm wide. Red cells that are smaller than the small lymphocyte nucleus may be microcytic; those larger than the small lymphocyte nucleus may be macrocytic. The automated mean corpuscular volume (MCV) can assist in making a classification. However, some patients may have both iron and vitamin B_{12} deficiency, which will produce an MCV in the normal range but wide variation in red cell size. When the red cells vary greatly in size, *anisocytosis* is said to be present. When the red cells vary greatly in shape, *poikilocytosis* is said to be present.

After red cell size is assessed, one examines the hemoglobin content of the cells. They are either normal in color (*normochromic*) or they are pale in color (*hypochromic*). They are never "hyperchromic." If more than the normal amount of hemoglobin is made, the cells get larger—they do not become darker. In addition to hemoglobin content, the red cells are examined for inclusions. Red cell inclusions are the following:

1. *Basophilic stippling*—diffuse fine or coarse blue dots in the red cell representing usually RNA residue—especially common in lead poisoning
2. *Howell-Jolly bodies*—dense blue circular inclusions that represent nuclear remnants—their presence implies defective splenic function
3. *Nuclei*—red cells may be released or pushed out of the marrow prematurely before nuclear extrusion—often implies a myelophthisic process
4. *Parasites*—red cell parasites include malaria and babesia (**Chap. e18**)
5. *Polychromatophilia*—the red cell cytoplasm has a bluish hue, reflecting the persistence of ribosomes still actively making hemoglobin in a young red cell

Vital stains are necessary to see precipitated hemoglobin called *Heinz bodies*.

Red cells can take on a variety of different shapes. All abnormally shaped red cells are *poikilocytes*. Small red cells without the central pallor are *spherocytes*; they can be seen in hereditary spherocytosis, hemolytic anemias of other causes, and clostridial sepsis. *Dacrocytes* are teardrop-shaped cells that can be seen in hemolytic anemias, severe iron deficiency, thalassemias, myelofibrosis, and myelodysplastic syndromes. *Schistocytes* are helmet-shaped cells that reflect microangiopathic hemolytic anemia or fragmentation on an artificial heart valve. *Echinocytes* are spiculated red cells with the spikes evenly spaced; they can represent an artifact of abnormal drying of the blood smear or reflect changes in stored blood. They can also be seen in renal failure and malnutrition and are often reversible. *Acanthocytes* are spiculated red cells with the spikes irregularly distributed. This process tends to be irreversible and reflects underlying renal disease, abetalipoproteinemia, or splenectomy. *Elliptocytes* are elliptical-shaped red cells that can reflect an inherited defect in the red cell membrane, but they are also seen in iron deficiency, myelodysplastic syndrome, megaloblastic anemia, and thalassemias. *Stomatocytes* are red cells in which the area of central pallor takes on the morphology of a slit instead of the usual round shape. Stomatocytes can indicate an inherited red cell membrane defect and can also be seen in alcoholism. *Target cells* have an area of central pallor that contains a dense center, or bull's eye. These cells are seen classically in thalassemia, but they are also present in iron deficiency, cholestatic liver disease, and some hemoglobinopathies. They can also be generated artifactually by improper slide making.

One last feature of the red cells to assess before moving to the white blood cells is the distribution of the red cells on the smear. In most individuals, the cells lie side by side in a single layer. Some patients have red cell clumping (called *agglutination*) in which the red cells pile upon one another; it is seen in certain paraproteinemias and autoimmune hemolytic anemias. Another abnormal distribution involves red cells lying in single cell rows on top of one another like stacks of coins. This is called *rouleaux formation* and reflects abnormal serum protein levels.

Finally, one examines the white blood cells. Three types of granulocytes are usually present; neutrophils, eosinophils, and basophils, in decreasing frequency. Neutrophils are generally the most abundant white cell. They are round, 10–14 μm wide, and contain a lobulated nucleus with two to five lobes connected by a thin chromatin thread. Bands are immature neutrophils that have not yet completed nuclear condensation and have a U-shaped nucleus. Bands reflect a left shift in neutrophil maturation in an effort to make more cells more rapidly. Neutrophils can provide clues to a variety of conditions. Vacuolated neutrophils may be a sign of bacterial sepsis. The presence of 1- to 2-μm blue cytoplasmic inclusions, called *Dohle bodies*, can reflect infections, burns, or other inflammatory states. If the neutrophil granules are larger than normal and stain a darker blue, "toxic granulations" are said to be present, and they also suggest a systemic inflammation. The presence of neutrophils with more than five nuclear lobes suggests megaloblastic anemia. Large misshapen granules may reflect the inherited Chédiak-Higashi syndrome.

Eosinophils are slightly larger than neutrophils, have bilobed nuclei, and contain large red granules. Diseases of eosinophils are associated with too many of them rather than any morphologic or qualitative change. They normally total less than one-thirtieth the number of neutrophils. Basophils are even more rare than eosinophils in the blood. They have large dark-blue granules and may be increased as part of chronic myeloid leukemia,

Lymphocytes can be present in several morphologic forms. Most common in healthy individuals are the small lymphocytes with a small dark nucleus and scarce cytoplasm. In the presence of viral infections, more of the lymphocytes are larger, about the size of neutrophils, with abundant cytoplasm and a less condensed nuclear chromatin. These

Copyright © 2008 The McGraw-Hill Companies. All rights reserved.

are called *reactive lymphocytes*. About 1% of the lymphocytes are larger and contain blue granules in a light blue cytoplasm; these are called *large granular lymphocytes*. In chronic lymphoid leukemia, the small lymphocytes are increased in number, and many of them are ruptured in making the blood smear, leaving a smudge of nuclear material without a surrounding cytoplasm or cell membrane; these are called *smudge cells* and are rare in the absence of chronic lymphoid leukemia.

Monocytes are the largest white blood cells, ranging from 15–22 μm in diameter. The nucleus can take on a variety of shapes but usually appears to be folded; the cytoplasm is gray.

Abnormal cells may appear in the blood. Most often the abnormal cells originate from neoplasms of bone marrow–derived cells including lymphoid cells, myeloid cells, and occasionally red cells. More rarely, other types of tumors can get access to the blood stream, and rare epithelial malignant cells may be identified. The chances of seeing such abnormal cells is increased by examining blood smears made from buffy coats, the layer of cells that is visible on top of sedimenting red cells when blood is left in the test tube for an hour. Smears made from finger sticks may include rare endothelial cells.

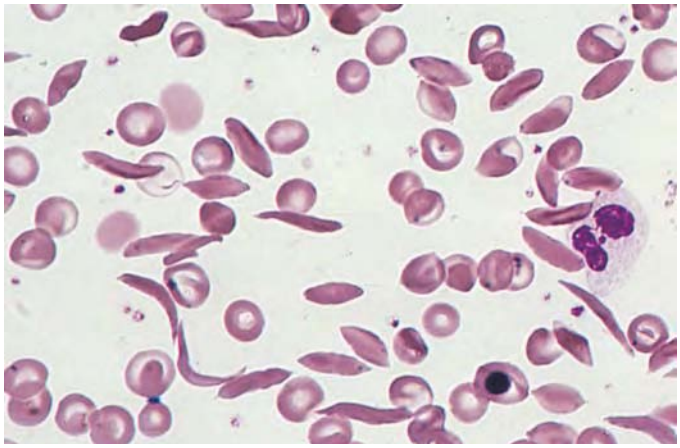

FIGURE e11-12 Sickle cells. Homozygous sickle cell disease. A nucleated red cell and neutrophil are also in the field.

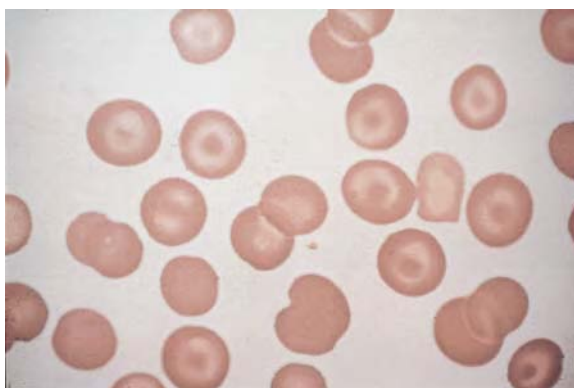

FIGURE e11-13 Target cells. Target cells are recognized by the bull's-eye appearance of the cell. Small numbers of target cells are seen with liver disease and thalassemia. Larger numbers are typical of hemoglobin C disease.

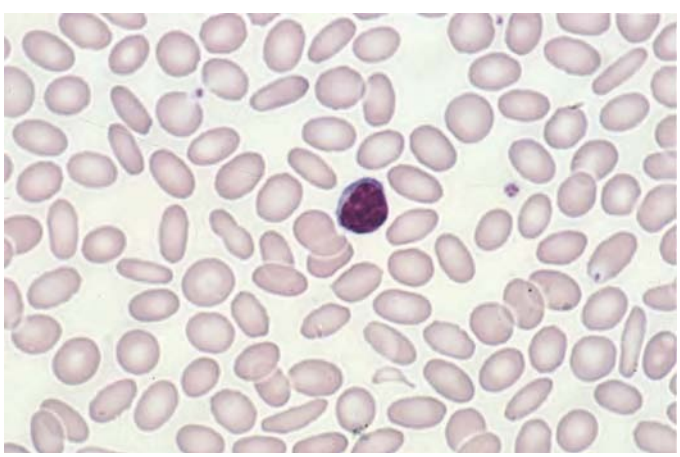

FIGURE e11-14 Elliptocytosis. Small lymphocyte in center of field. Elliptical shape of red cells related to weakened membrane structure, usually due to mutations in spectrin.

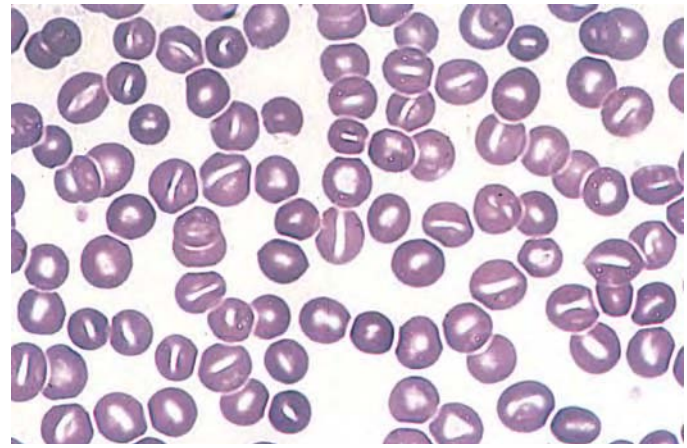

FIGURE e11-15 Stomatocytosis. Red cells characterized by a wide transverse slit or stoma. This is often seen as an artifact in a dehydrated blood smear. These cells can be seen in hemolytic anemias and in conditions in which the red cell is overhydrated or dehydrated.

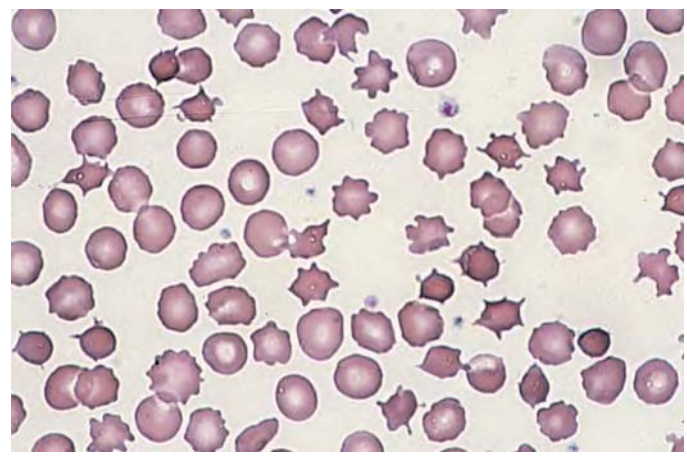

FIGURE e11-16 Acanthocytosis. Spiculated red cells are of two types: *acanthocytes* are contracted dense cells with irregular membrane projections that vary in length and width; *echinocytes* have small, uniform, and evenly spaced membrane projections. Acanthocytes are present in severe liver disease, in patients with abetalipoproteinemia, and in rare patients with McLeod blood group. Echinocytes are found in patients with severe uremia, in glycolytic red cell enzyme defects, and in microangiopathic hemolytic anemia.

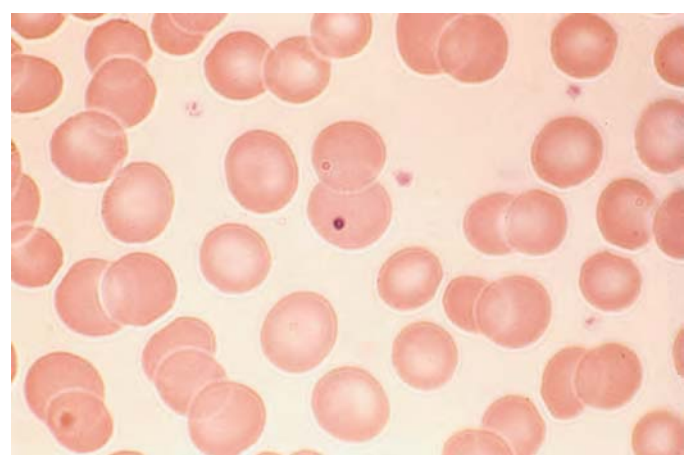

FIGURE e11-17 Howell-Jolly bodies. Howell-Jolly bodies are tiny nuclear remnants that are normally removed by the spleen. They appear in the blood after splenectomy (defect in removal) and with maturation/dysplastic disorders (excess production).

62 Principles of Human Genetics

J. Larry Jameson, Peter Kopp

IMPACT OF GENETICS ON MEDICAL PRACTICE

The beginning of the new millennium was marked by the announcement that the vast majority of the human genome had been sequenced. This milestone in the exploration of the human genome was preceded by numerous conceptual and technological advances. They include, among others, the elucidation of the DNA double-helix structure, the discovery of restriction enzymes and the polymerase chain reaction (PCR), the development and automatization of DNA sequencing, and the generation of genetic and physical maps by the Human Genome Project (HGP). The consequences of this wealth of knowledge for the practice of medicine are profound. To date, the most significant impact of genetics has been to enhance our understanding of disease etiology and pathogenesis. However, genetics is rapidly playing a more prominent role in the diagnosis, prevention, and treatment of disease (Chap. 64). Genetic approaches have proven invaluable for the detection of infectious pathogens and are used clinically to identify agents that are difficult to culture such as mycobacteria, viruses, and parasites. In many cases, molecular genetics has improved the feasibility and accuracy of diagnostic testing and is beginning to open new avenues for therapy, including gene and cellular therapy (Chaps. 65 and 67). Molecular genetics has already significantly changed the treatment of human disease. Peptide hormones, growth factors, cytokines, and vaccines can now be produced in large amounts using recombinant DNA technology. Targeted modification of these peptides provides the practitioner with improved therapeutic tools, as illustrated by genetically modified insulin analogues with more favorable kinetics. There is hope that a better understanding of the genetic basis of human disease will also have an increasing impact on disease prevention.

Genetics has traditionally been viewed through the window of relatively rare single-gene diseases. Taken together, these disorders account for ~10% of pediatric admissions and childhood mortality. It is, however, increasingly apparent that virtually every medical condition, maybe with the exception of simple trauma, has a genetic component. As is often evident from a patient's family history, many common disorders such as hypertension, heart disease, asthma, diabetes mellitus, and mental illnesses are significantly influenced by the genetic background. These polygenic or multifactorial (complex) disorders involve the contributions of many different genes, as well as environmental factors, that can modify disease risk (Chap. 64). A major current challenge is to elucidate the genetic components that contribute to the pathogenesis of complex disorders. The recent publication of a comprehensive catalogue of human single-nucleotide polymorphism (SNP) haplotypes, the HapMap Project, provides an essential resource for genome-wide association studies (see below).

Cancer has a genetic basis since it results from acquired somatic mutations in genes controlling growth, apoptosis, and cellular differentiation (Chap. 79). In addition, the development of many cancers is associated with a hereditary predisposition. The prevalence of genetic diseases, combined with their severity and chronic nature, imposes a great financial, social, and emotional burden on society.

Genetics has historically focused on chromosomal and metabolic disorders, reflecting the long-standing availability of techniques to diagnose these conditions. For example, conditions such as trisomy 21 (Down syndrome) or monosomy X (Turner syndrome) can be diagnosed using cytogenetics (Chap. 63). Likewise, many metabolic disorders (e.g., phenylketonuria, familial hypercholesterolemia) are diagnosed using biochemical analyses. Recent advances in DNA diagnostics have extended the field of genetics to include virtually all medical specialties. In cardiology, for example, the molecular basis of inherited cardiomyopathies and ion channel defects that predispose to arrhythmias is being defined (Chaps. 226 and 231). In neurology, genetics has unmasked the pathophysiology of a startling number of neurodegenerative disorders (Chap. 360). Hematology has evolved dramatically, from its incipient genetic descriptions of hemoglobinopathies to the current understanding of the molecular basis of red cell membrane defects, clotting disorders, and thrombotic disorders (Chaps. 99 and 110).

New concepts derived from genetic studies can sometimes clarify the pathogenesis of disorders that were previously opaque. For example, although many different genetic defects can cause peripheral neuropathies, disruption of the normal folding of the myelin sheaths is frequently a common final pathway (Chap. 379). Several genetic causes of obesity appear to converge on a physiologic pathway that involves products of the proopiomelanocortin polypeptide and the MC4R receptor, thus identifying a key mechanism for appetite control (Chap. 74). A similar phenomenon is emerging for genetically distinct forms of Alzheimer's disease, several of which lead to the formation of neurofibrillary tangles (Chap. 365). The identification of defective genes often leads to the detection of cellular pathways involved in key physiologic processes. Examples include identification of the cystic fibrosis conductance regulator (*CFTR*) gene; the Duchenne muscular dystrophy (*DMD*) gene, which encodes dystrophin; and the fibroblast growth factor receptor-3 (*FGFR3*) gene, which is responsible for achondroplastic dwarfism. Similarly, transgenic (over)expression, and targeted gene "knock-out" and "knock-in" models help to unravel the physiologic function of genes.

The astounding rate at which new genetic information is being generated creates a major challenge for physicians, health care providers, and basic investigators. The terminology and techniques used for discovery evolve continuously. Much genetic information presently resides in computer databases or is being published in basic science journals. Databases provide easy access to the expanding information about the human genome, genetic disease, and genetic testing (Table 62-1). For example, several thousand monogenic disorders are summarized in a large, continuously evolving compendium, referred to as the *Online Mendelian Inheritance in Man* (OMIM) catalogue (Table 62-1). The ongoing refinement of bioinformatics is simplifying the access to this seemingly daunting onslaught of new information.

CHROMOSOMES AND DNA REPLICATION

Organization of DNA into Chromosomes • *SIZE OF THE HUMAN GENOME*

The human genome is divided into 23 different chromosomes, including 22 autosomes (numbered 1–22) and the X and Y sex chromosomes. Adult cells are *diploid*, meaning they contain two homologous sets of 22 autosomes and a pair of sex chromosomes. Females have two X chromosomes (XX), whereas males have one X and one Y chromosome (XY). As a consequence of meiosis, germ cells (sperm or oocytes) are haploid and contain one set of 22 autosomes and one of the sex chromosomes. At the time of fertilization, the diploid genome is reconstituted by pairing of the homologous chromosomes from the mother and father. With each cell division (mitosis), chromosomes are replicated, paired, segregated, and divided into two daughter cells (Chap. 63).

The human genome is estimated to contain ~30,000–40,000 genes, a smaller number than initially predicted, that are divided among the 23 chromosomes. A *gene* is a functional unit that is regulated by transcription (see below) and encodes a RNA product, which is most commonly, but not always, translated into a protein that exerts activity within or outside the cell. Historically, genes were identified because they conferred specific traits that are transmitted from one generation to the next. Increasingly, they are characterized based on expression in

Note: Databases are evolving constantly. Pertinent information may be found by using links listed in the few selected databases. Instructions for the use of genome-related databases have been published [Nat Genet 32(Suppl):1–79, 2002].

various tissues. The number of genes greatly underestimates the complexity of genetic expression, as single genes can generate multiple spliced mRNA products, which are translated into proteins that are subject to complex posttranslational modification, such as phosphorylation. *Proteomics*, the study of the proteome using technologies of large-scale protein separation and identification, is an emerging field focused on protein variation and function. Similarly, the field of *metabolomics* aims at determining the composition and modifications of the *metabolome*, the complement of low-molecular-weight molecules, many of which participate in various metabolic functions. These analyses, which are heavily dependent on bioinformatics, reveal that physiologic or pathologic alterations have myriad effects on the proteome and the metabolome and emphasize that these processes involve *modular networks* rather than *linear pathways*.

Human DNA consists of ~3 billion base pairs (bp) of DNA per haploid genome. DNA length is normally measured in units of 1000 bp (kilobases, kb) or 1,000,000 bp (megabases, Mb). Not all DNA encodes genes. In fact, genes account for only ~10–15% of DNA. Much of the remaining DNA consists of highly repetitive sequences, the function of which is poorly understood. These repetitive DNA regions, along with nonrepetitive sequences that do not encode genes, may serve a structural role in the packaging of DNA into chromatin, i.e., DNA bound to histone proteins, and chromosomes (Fig. 62-1). If only 10% of DNA is expressed and there are 30,000 genes, the average gene would be ~10 kb in length. Although many genes are about this size, the range is quite broad. For example, some genes are only a few hundred bp, whereas others, such as the *DMD* gene, are extraordinarily large (2 Mb).

STRUCTURE OF DNA Each gene is composed of a linear polymer of DNA. DNA is a double-stranded helix composed of four different bases: adenine (A), thymidine (T), guanine (G), and cytosine (C). Adenine is paired to thymidine, and guanine is paired to cytosine, by hydrogen bond interactions that span the double helix. DNA has several remarkable features that make it ideal for the transmission of genetic information. It is relatively stable, at least in comparison to RNA or proteins. The double-stranded nature of DNA and its feature of strict base-pair complementarity permit faithful replication during cell division. As described below, complementarity also allows the transmission of genetic information from DNA → RNA → protein (Fig. 62-2). Messenger RNA (mRNA) is encoded by the so-called sense or coding strand of the DNA double helix and is translated into proteins by ribosomes.

The presence of four different bases provides surprising genetic diversity. In the protein-coding regions of genes, the DNA bases are arranged into codons, a triplet of bases that specifies a particular amino acid. It is possible to arrange the four bases into 64 different triplet codons (4^3). Each codon specifies 1 of the 20 different amino acids, or a regulatory signal, such as initiation and stop of translation. Because there are more codons than amino acids, the genetic code is degenerate; that is, most amino acids can be specified by several different codons. By arranging the codons in different combinations and in various lengths, it is possible to generate the tremendous diversity of primary protein structure.

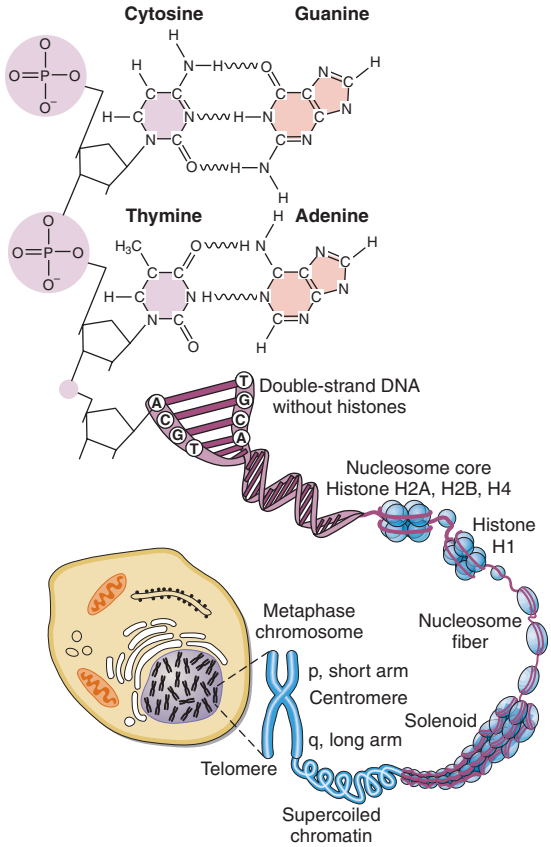

FIGURE 62-1 Structure of chromatin and chromosomes. Chromatin is composed of double-strand DNA that is wrapped around histone and nonhistone proteins forming nucleosomes. The nucleosomes are further organized into solenoid structures. Chromosomes assume their characteristic structure, with short (p) and long (q) arms at the metaphase stage of the cell cycle.

Replication of DNA and Mitosis Genetic information in DNA is transmitted to daughter cells under two different circumstances: (1) somatic cells divide by mitosis, allowing the diploid ($2n$) genome to replicate itself completely in conjunction with cell division; and (2) germ cells (sperm and ova) undergo meiosis, a process that enables the reduction of the diploid ($2n$) set of chromosomes to the haploid state ($1n$) (Chap. 63).

Prior to mitosis, cells exit the resting, or G_0 state, and enter the cell cycle (Chap. 80). After traversing a critical checkpoint in G_1, cells undergo DNA synthesis (S phase), during which the DNA in each chromosome is replicated, yielding two pairs of sister chromatids ($2n \rightarrow 4n$). The process of DNA synthesis requires stringent fidelity in order to avoid transmitting errors to subsequent generations of cells. Genetic abnormalities of DNA mismatch/repair include xeroderma pigmentosum, Bloom syndrome, ataxia telangiectasia, and hereditary nonpolyposis colon cancer (HNPCC), among others. Many of these disorders strongly predispose to neoplasia because of the rapid acquisition of additional mutations (Chap. 79). After completion of DNA synthesis, cells enter G_2 and progress through a second checkpoint before entering mitosis. At this stage, the chromosomes condense and are aligned along the equatorial plate at metaphase. The two identical sister chromatids, held together at the centromere, divide and migrate to opposite poles of the cell (see Fig. 63-3). After formation of a nuclear membrane around the two separated sets of chromatids, the cell divides and two daughter cells are formed, thus restoring the diploid ($2n$) state.

Assortment and Segregation of Genes during Meiosis Meiosis occurs only in germ cells of the gonads. It shares certain features with mitosis but involves two distinct steps of cell division that reduce the chromosome number to the haploid state. In addition, there is active recombination that generates genetic diversity. During the first cell division, two sister chromatids ($2n \rightarrow 4n$) are formed for each chromosome pair and there is an exchange of DNA between homologous paternal and maternal chromosomes. This process involves the formation of *chiasmata*, structures that correspond to the DNA segments that cross over between the maternal and paternal homologues (Fig. 62-3). Usually there is at least one crossover on each chromosomal arm; recombination occurs more frequently in female meiosis than in male meiosis. Subsequently, the chromosomes segregate randomly. Because there are 23 chromosomes, there exist 2^{23} (>8 million) possible combinations of chromosomes. Together with the genetic exchanges that occur during recombination, chromosomal segregation generates tremendous diversity, and each gamete is genetically unique. The process of recom-

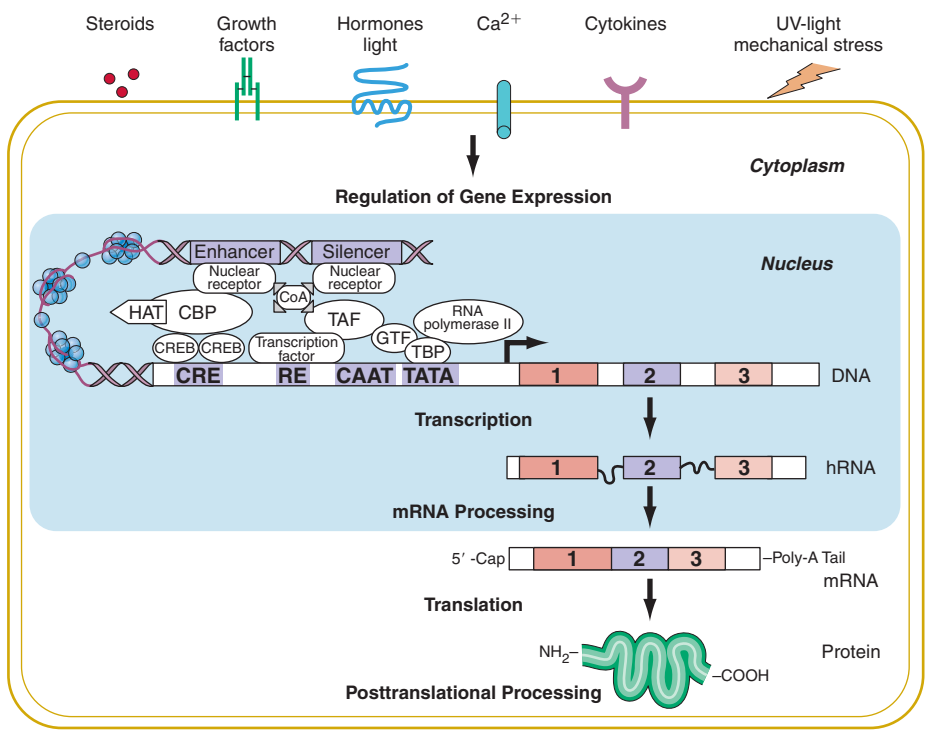

FIGURE 62-2 Flow of genetic information. Multiple extracellular signals activate intracellular signal cascades that result in altered regulation of gene expression through the interaction of transcription factors with regulatory regions of genes. RNA polymerase transcribes DNA into RNA that is processed to mRNA by excision of intronic sequences. The mRNA is translated into a polypeptide chain to form the mature protein after undergoing posttranslational processing. HAT, histone acetyl transferase; CBP, CREB-binding protein; CREB, cyclic AMP response element–binding protein; CRE, cyclic AMP responsive element; CoA, Co activator; TAF, TBP-associated factors; GTF, general transcription factors; TBP, TATA-binding protein; TATA, TATA box; RE, response element; NH_2, aminoterminus; COOH, carboxyterminus.

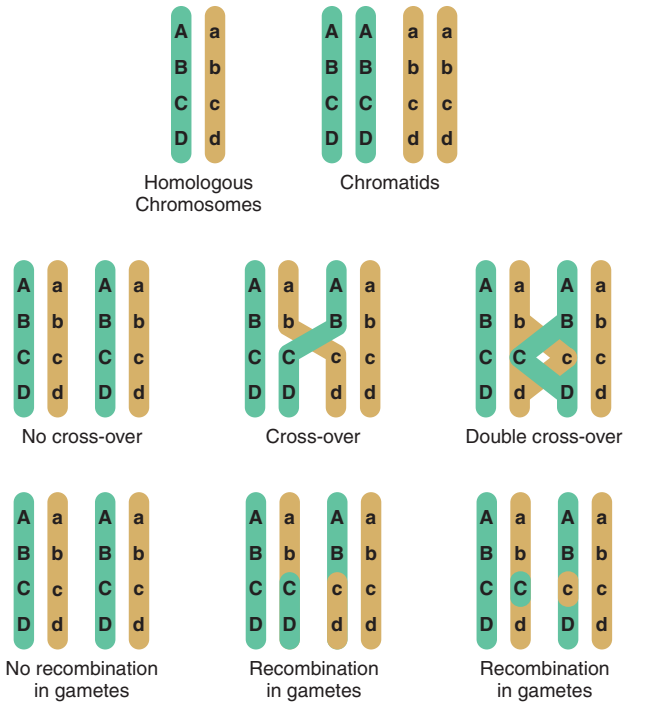

FIGURE 62-3 Crossing-over and genetic recombination. During chiasma formation, either of the two sister chromatids on one chromosome pairs with one of the chromatids of the homologous chromosome. Genetic recombination occurs through crossing-over and results in recombinant and nonrecombinant chromosome segments in the gametes. Together with the random segregation of the maternal and paternal chromosomes, recombination contributes to genetic diversity and forms the basis of the concept of linkage.

bination, and the independent segregation of chromosomes, provide the foundation for performing linkage analyses, whereby one attempts to correlate the inheritance of certain chromosomal regions (or linked genes) with the presence of a disease or genetic trait (see below).

After the first meiotic division, which results in two daughter cells ($2n$), the two chromatids of each chromosome separate during a second meiotic division to yield four gametes with a haploid state ($1n$). When the egg is fertilized by sperm, the two haploid sets are combined, thereby restoring the diploid state ($2n$) in the zygote.

REGULATION OF GENE EXPRESSION

Mechanisms that regulate gene expression play a critical role in the function of genes. The transcription of genes is controlled primarily by *transcription factors* that bind to DNA sequences in the regulatory regions of genes. As described below, mutations in transcription factors cause a significant number of genetic disorders. Gene expression is also influenced by *epigenetic events*, such as X-inactivation and imprinting, processes in which DNA methylation or histone modifications are associated with gene silencing. Several genetic disorders, such as Prader-Willi syndrome (neonatal hypotonia, developmental delay, obesity, short stature, and hypogonadism) and Albright hereditary osteodystrophy (resistance to parathyroid hormone, short stature, brachydactyly, resistance to other hormones in certain subtypes), exhibit the consequences of genomic imprinting. Most studies of gene expression have focused on the regulatory DNA elements of genes that control transcription. However, it should be emphasized that gene expression requires a series of steps, including mRNA processing, protein translation, and posttranslational modifications, all of which are actively regulated (Fig. 62-2).

The new field of *functional genomics* is based on the concept that understanding alterations of gene expression under various physiologic and pathologic conditions provides insight into the underlying processes, and by revealing certain gene expression profiles, this knowledge may be of diagnostic and therapeutic relevance. The large-scale study of expression profiles, which takes advantage of microarray technologies, is also referred to as *transcriptomics* because the complement of mRNAs transcribed by the cellular genome is called the *transcriptome*.

Structure of Genes A gene product is usually a protein but can occasionally consist of RNA that is not translated (e.g., microRNAs). *Exons* refer to the portion of genes that are eventually spliced together to form mRNA. *Introns* refer to the spacing regions between the exons that are spliced out of precursor RNAs during RNA processing (Fig. 62-2).

The gene locus also includes regions that are necessary to control its expression. The regulatory regions most commonly involve sequences upstream (5′) of the transcription start site, although there are also examples of control elements within introns or downstream of the coding regions of a gene. The upstream regulatory regions are also referred to as the *promoter*. The minimal promoter usually consists of a TATA box (which binds TATA-binding protein, TBP) and initiator sequences that enhance the formation of an active transcription complex. A gene may generate various transcripts through the use of alternative promoters and/or alternative splicing of exons, mechanisms that contribute to the enormous diversity of proteins and their functions. Transcriptional termination signals reside downstream, or 3′, of a gene. Specific sequences, such as the AAUAAA sequence at the 3′ end of the mRNA, designate the site for polyadenylation (poly-A tail), a process that influences mRNA transport to the cytoplasm, stability, and translation efficiency. A rigorous test of the regulatory region boundaries involves expressing a gene in a transgenic animal to determine whether the isolated DNA flanking sequences are sufficient to recapitulate the normal developmental, tissue-specific, and signal-responsive features of the endogenous gene. This has been accomplished for only a few genes; there are many examples in which large genomic fragments only partially reconstitute normal gene regulation in vivo, implying the presence of distant regulatory sequences. Genome-wide analyses of selected transcription factor binding sites, such as for the estrogen receptor, reveal that the majority of regulatory sites are very distant from the transcription start sites of genes. A detailed understanding of mechanisms that regulate genes is also relevant for gene therapy strategies that require normal gene regulation (Chap. 65).

The number of DNA sequences and transcription factors that regulate transcription is much greater than originally anticipated. Most genes contain at least 15–20 discrete regulatory elements within 300 bp of the transcription start site. This densely packed promoter region often contains binding sites for ubiquitous transcription factors such as CAAT box/enhancer binding protein (C/EBP), cyclic AMP response element–binding (CREB) protein, selective promoter factor 1 (Sp-1), or activator protein 1 (AP-1). However, factors involved in cell-specific expression may also bind to these sequences. For example, basic helix-loop-helix (bHLH) proteins bind to E-boxes in the promoters of myogenic genes, and steroidogenic factor 1 (SF-1) binds to a specific recognition site in the regulatory region of multiple steroidogenic enzyme genes. Key regulatory elements may also reside at a large distance from the proximal promoter. The globin and the immunoglobulin genes, for example, contain *locus control regions* that are several kilobases away from the structural sequences of the gene. Specific groups of transcription factors that bind to these promoter and enhancer sequences provide a combinatorial code for regulating transcription. In this manner, relatively ubiquitous factors interact with more restricted factors to allow each gene to be expressed and regulated in a unique manner that is dependent on developmental state, cell type, and numerous extracellular stimuli. As described below, the transcription factors that bind to DNA actually represent only the first level of regulatory control. Other proteins—*coactivators* and *co-repressors*—interact with the DNA-binding transcription factors to generate large regulatory complexes. These complexes are subject to control by numerous cell-signaling pathways, including phosphorylation, acetylation, sumoylation, and ubiquitinylation. Ultimately, the recruited transcription factors interact with, and stabilize, components of the basal transcription complex that assembles at the site of the TATA box

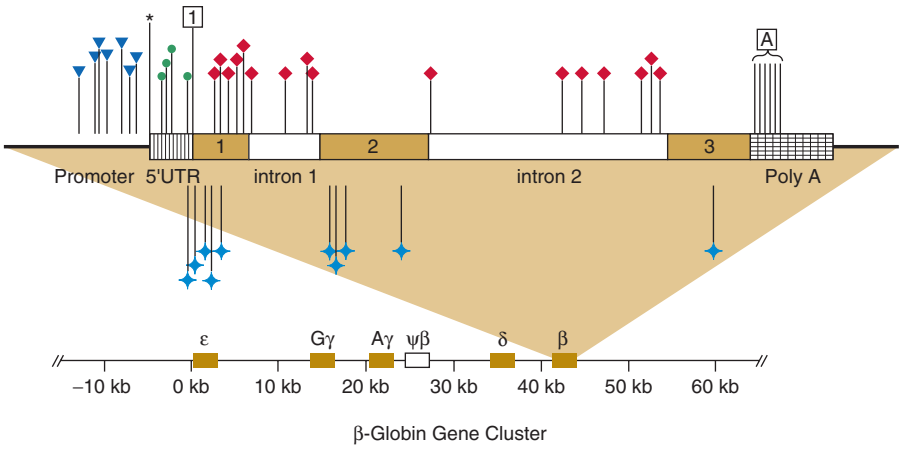

FIGURE 62-4 Point mutations causing β-thalassemia as example of allelic heterogeneity. The β-globin gene is located in the globin gene cluster. Point mutations can be located in the promoter, the CAP site, the 5′-untranslated region, the initiation codon, each of the three exons, the introns, or the polyadenylation signal. Many mutations introduce missense or nonsense mutations, whereas others cause defective RNA splicing. Not shown here are deletion mutations of the β-globin gene or larger deletions of the globin locus that can also result in thalassemia. ▼, Promoter mutations; *, CAP site; ●, 5′UTR; 1, Initiation codon; ♦, Defective RNA processing; ✦, Missense and nonsense mutations; A, Poly A signal.

and initiator region. This basal transcription factor complex consists of >30 different proteins. Gene transcription occurs when RNA polymerase begins to synthesize RNA from the DNA template.

Mutations can occur in all domains of a gene (Fig. 62-4). A point mutation occurring within the coding region leads to an amino acid substitution if the codon is altered. Point mutations that introduce a premature stop codon result in a truncated protein. Large deletions may affect a portion of a gene or an entire gene, whereas small deletions and insertions alter the reading frame if they do not represent a multiple of three bases. These "frameshift" mutations lead to an entirely altered carboxy terminus. Mutations occurring in regulatory or intronic regions may result in altered expression or splicing of genes. Examples are shown in Fig. 62-5.

Transcriptional Activation and Repression Every gene is controlled uniquely, whether in its spatial or temporal pattern of expression or in its response to extracellular signals. It is estimated that transcription factors account for ~30% of expressed genes. A growing number of identified genetic diseases involve transcription factors (Table 62-2). The MODY (maturity-onset diabetes of the young) disorders are representative of this group of diseases; mutations in several different islet cell–specific transcription factors cause various forms of MODY (Chap. 338).

Transcriptional activation can be divided into three main mechanisms:

1. Events that alter chromatin structure can enhance the access of transcription factors to DNA. For example, histone acetylation generally opens chromatin structure and is correlated with transcriptional activation.
2. Posttranslational modifications of transcription factors, such as phosphorylation, can induce the assembly of active transcription complexes. As an example, phosphorylation of CREB protein on serine 133 induces a conformational change that allows the recruitment of CREB-binding protein (CBP), a factor that integrates the actions of many transcription factors, including proteins, with histone acetyltransferase activity.
3. Transcriptional activators can displace a repressor protein. This mechanism is particularly common during development when the pattern of transcription factor expression changes dynamically.

Of course, these mechanisms are not mutually exclusive, and most genes are activated by some combination of these events.

Suppression of gene expression is as important as gene activation in the control of cell differentiation and function. Some mechanisms of repression are the corollary of activation. For example, repression is often associated with histone deacetylation or protein dephosphorylation. For nuclear hormone receptors, transcriptional silencing involves the recruitment of repression complexes that contain histone deacetylase activity. Aberrant expression of repressor proteins is sometimes associated with neoplasia. The t(15;17) chromosomal translocation that occurs in promyelocytic leukemia fuses the *PML* gene to a portion of the retinoic acid receptor α (*RAR* α) gene (Table 62-2). This event causes unregulated transcriptional repression in a manner that precludes normal cellular differentiation. The addition of the RAR ligand, retinoic acid, activates the receptor, thereby relieving repression and allowing cells to differentiate and ultimately undergo apoptosis. This mechanism has therapeutic importance as the addition of retinoic acid to treatment regimens induces a higher remission rate in patients with promyelocytic leukemia (Chap. 104). Methylation of promoter regions is frequently found in neoplasms and silences gene expression.

CLONING AND SEQUENCING DNA

A description of recombinant DNA techniques, the methodology used for the manipulation, analysis, and characterization of DNA segments, is beyond the scope of this chapter. As these methods are wide-

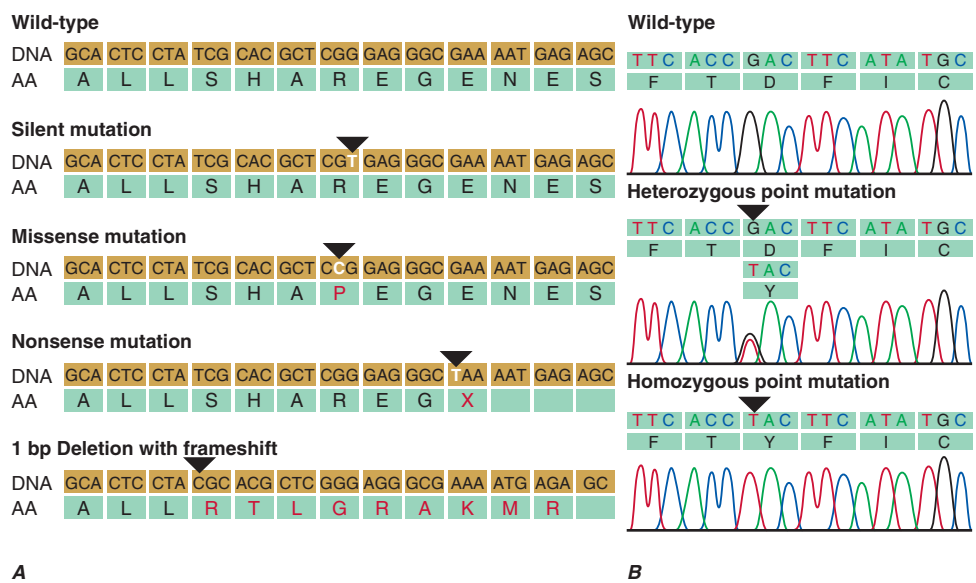

FIGURE 62-5 ***A.*** Examples of mutations. The coding strand is shown with the encoded amino acid sequence. ***B.*** Chromatograms of sequence analyses after amplification of genomic DNA by polymerase chain reaction.

TABLE 62-2 SELECTED EXAMPLES OF DISEASES CAUSED BY MUTATIONS AND REARRANGEMENTS IN TRANSCRIPTION FACTOR CLASSES

Transcription Factor Class	Example	Associated Disorder
Nuclear receptors	Androgen receptor	Complete or partial androgen insensitivity (recessive missense mutations) Spinobulbar muscular atrophy (CAG repeat expansion)
Zinc finger proteins	WT1	WAGR syndrome: Wilm's tumor, aniridia, genitourinary malformations, mental retardation
Basic helix-loop-helix	MITF	Waardenburg syndrome type 2A
Homeobox	IPF1	Maturity onset of diabetes mellitus type 4 (heterozygous mutation/haploinsufficiency) Pancreatic agenesis (homozygous mutation)
Leucine zipper	Retina leucine zipper (NRL)	Autosomal dominant retinitis pigmentosa
High mobility group (HMG) proteins	SRY	Sex-reversal
Forkhead	HNF4α, HNF1α, HNF1β	Maturity-onset of diabetes mellitus types 1, 3, 5
Paired box	PAX3	Waardenburg syndrome types 1 and 3
T-box	TBX5	Holt-Oram syndrome (thumb anomalies, atrial or ventricular septum defects, phocomelia)
Cell cycle control proteins	P53	Li-Fraumeni syndrome, other cancers
Coactivators	CREB binding protein (CBP)	Rubinstein-Taybi syndrome
General transcription factors	TATA-binding protein (TBP)	Spinocerebellar ataxia 17 (CAG expansion)
Transcription elongation factor	VHL	Von Hippel–Lindau syndrome (renal cell carcinoma, pheochromocytoma, pancreatic tumors, hemangioblastomas) Autosomal dominant inheritance, somatic inactivation of second allele (Knudson two-hit model)
Runt	CBFA2	Familial thrombocytopenia with propensity to acute myelogenous leukemia
Chimeric proteins due to translocations	PML—RAR	Acute promyelocytic leukemia t(15;17)(q22;q11.2-q12) translocation

Note: Selected abbreviations include: SRY, sex determining region Y; HNF, hepatocyte nuclear factor; CREB (cAMP responsive element binding) binding protein; VHL, Von Hippel–Lindau; PML, promyelocytic leukemia; RAR, retinoic acid receptor.

ly used in genetics and molecular diagnostics, however, it is useful to review briefly some of the fundamental principles of cloning and DNA sequencing.

Cloning of Genes *Cloning* refers to the creation of a recombinant DNA molecule that can be propagated indefinitely. The ability to clone genes and cDNAs therefore provides a permanent and renewable source of these reagents. Cloning is essential for DNA sequencing, nucleic acid hybridization studies, expression of recombinant proteins, and other recombinant DNA procedures.

The cloning of DNA involves the insertion of a DNA fragment into a cloning vector, followed by the propagation of the recombinant DNA in a host cell. The most straightforward cloning strategy involves inserting a DNA fragment into bacterial plasmids. Plasmids are small, autonomously replicating, circular DNA molecules that propagate separately from the chromosome in bacterial cells. The process of DNA insertion relies heavily on the use of restriction enzymes, which cleave DNA at highly specific sequences (usually 4–6 bp in length). Restriction enzymes generate complementary, cohesive sequences at the ends of the DNA fragment, which allow them to be efficiently ligated to the plasmid vector. Because plasmids contain genes that confer resistance to antibiotics, their presence in the host cell can be used for selection and DNA amplification.

A variety of vectors (e.g., plasmids, phage, bacterial, or yeast artificial chromosomes) are used for cloning. Many of these are used for creating *libraries*, a term that refers to a collection of DNA clones. A genomic library represents an array of clones derived from genomic DNA. These overlapping DNA fragments represent the entire genome and can ultimately be arranged according to their linear order. cDNA libraries reflect clones derived from mRNA, typically from a particular tissue source. Thus, a cDNA library from the heart contains copies of mRNA expressed specifically in cardiac myocytes, in addition to those that are expressed ubiquitously. For this reason, a heart cDNA library will be enriched with cardiac-specific gene products and will differ from cDNA libraries generated from liver or pituitary mRNAs. As an example of the complexity of a genomic library, consider that the human genome contains 3×10^9 bp and the average genomic insert in a λ phage library is ~10^4 bp. Therefore, it requires at least 3×10^5 clones to represent all genomic DNA. Specific clones are isolated from the several hundred thousand clones by using DNA hybridization.

With completion of the HGP, all human genes have been cloned and sequenced. As a result, many of these cloning procedures are now unnecessary or greatly facilitated by the extensive information concerning DNA markers and the sequence of DNA (see below).

Nucleic Acid Hybridization Nucleic acid *hybridization* is a fundamental principle in molecular biology that takes advantage of the fact that the two complementary strands of nucleic acids bind, or *hybridize*, to one another with very high specificity. The goal of hybridization is to detect specific nucleic acid (DNA or RNA) sequences in a complex background of other sequences. This technique is used for Southern blotting, Northern blotting, and for screening libraries (see above). Further adaptation of hybridization techniques has led to the development of microarray DNA chips.

SOUTHERN BLOT Southern blotting is used to analyze whether genes have been deleted or rearranged. It is also used to detect restriction fragment length polymorphisms (RFLPs). Genomic DNA is digested with restriction endonucleases and separated by gel electrophoresis. Individual fragments can then be transferred to a membrane and detected after hybridization with specific radioactive DNA probes. Because single base-pair mismatches can disrupt the hybridization of short DNA probes (oligonucleotides), a variation of the Southern blot, termed *oligonucleotide-specific hybridization* (OSH), uses short oligonucleotides to distinguish normal from mutant genes.

NORTHERN BLOT Northern blots are used to analyze patterns and levels of gene expression in different tissues. In a Northern blot, mRNA is separated on a gel and transferred to a membrane, and specific transcripts are detected using radiolabeled DNA as a probe. This technique has been largely supplanted by more sensitive and comprehensive methods such as reverse transcriptase (RT)–PCR and gene expression arrays on DNA chips (see below).

MICROARRAY TECHNOLOGY A comprehensive approach to genome-scale studies consists of *microarrays*, or *DNA chips*. These microarrays consist of thousands of synthetic nucleic acid sequences aligned on thin glass or silicon surfaces. Fluorescently labeled test sample DNA or RNA is hybridized to the chip, and a computerized scanner detects sequence matches. Microarrays allow the detection of variations in DNA sequence and are used for mutational analysis and genotyping. Alternatively, the expression pattern of large numbers of mRNA transcripts can be determined by hybridization of RNA samples to cDNA or genomic microar-

rays. This method has tremendous potential in the era of functional genomics and permits comprehensive analyses of gene expression profiles. As one example, microarrays can be used to develop genetic fingerprints of different types of malignancies, providing information useful for classification, pathophysiology, prognosis, and treatment.

The Polymerase Chain Reaction The PCR, introduced in 1985, has revolutionized the way DNA analyses are performed and has become a cornerstone of molecular biology and genetic analysis. In essence, PCR provides a rapid way of amplifying specific DNA fragments in vitro. Exquisite specificity is conferred by the use of PCR primers, which are designed for a given DNA sequence. The geometric amplification of the DNA after multiple cycles yields remarkable sensitivity. As a result, PCR can be used to amplify DNA from very small samples, including single cells. These properties also allow DNA amplification from a variety of tissue sources including blood samples, biopsies, surgical or autopsy specimens, or cells from hair or saliva. PCR can also be used to study mRNA. In this case, the enzyme RT is first used to convert the RNA to DNA, which can then be amplified by PCR. This procedure, commonly known as *RT-PCR*, is useful as a quantitative measure of gene expression.

PCR provides a key component of molecular diagnostics. It provides a strategy for the rapid amplification of DNA (or mRNA) to search for mutations by a wide array of techniques, including DNA sequencing. PCR is also used for the amplification of highly polymorphic di- or trinucleotide repeat sequences or the genotyping of SNPs, which allow various polymorphic alleles to be traced in genetic linkage or association studies. PCR is increasingly used to diagnose various microbial pathogens.

DNA Sequencing DNA sequencing is now an automated procedure. Although many protocols exist, the most commonly used strategy currently uses the capillary electrophoresis-based Sanger method in which dideoxynucleotides are used to randomly terminate DNA polymerization at each of the four bases (A,G,T,C). After separating the array of terminated DNA fragments using high-resolution gel or capillary electrophoresis, it is possible to deduce the DNA sequence by examining the progression of fragment lengths generated in each of the four nucleotide reactions. The use of fluorescently labeled dideoxynucleotides allows automated detection of the different bases and direct computer analysis of the DNA sequence (Fig. 62-5). Significant efforts are underway to develop faster, more cost-effective DNA sequencing technologies. These include the use of pyrosequencing chemistries; whole-genome sequencing using solid-phase sequencing; mass spectrometry; detection of fluorescently labeled bases in flow cytometry; direct reading of the DNA sequence by scanning, tunneling, or atomic force microscopy; and sequence analysis using DNA chips.

TRANSGENIC MICE AS MODELS OF GENETIC DISEASE

Several organisms have been studied extensively as genetic models, including *Mus musculus* (mouse), *Drosophila melanogaster* (fruit fly), *Caenorhabditis elegans* (nematode), *Saccharomyces cerevisiae* (baker's yeast), and *Escherichia coli* (colonic bacterium). The ability to use these evolutionarily distant organisms as genetic models that are relevant to human physiology reflects a surprising conservation of genetic pathways and gene function. Transgenic mouse models have been particularly valuable, because many human and mouse genes exhibit similar structure and function, and because manipulation of the mouse genome is relatively straightforward compared to those of other mammalian species.

Transgenic strategies in mice can be divided into two main approaches: (1) expression of a gene by random insertion into the genome, and (2) deletion or targeted mutagenesis of a gene by homologous recombination with the native endogenous gene (knock-out, knock-in) (Fig. 62-6; Table 62-3). Transgenic mice are generated by pronuclear injection of foreign DNA into fertilized mouse oocytes and subsequent transfer into the oviduct of pseudopregnant foster mothers.

Transgenic expression of genes can be useful for studying disorders that are sensitive to gene dosage. Overexpression of *PMP22*, for example, mimics a common duplication of this gene in type IA Charcot-Marie-Tooth disease (Chap. 379). Duplication of the *PMP22* gene results in high levels of expression of peripheral myelin protein 22, and this dosage effect is responsible for the demyelinating neuropathy. Expression of the Y chromosome–specific gene, *SRY*, in XX females demonstrates that *SRY* is sufficient to induce the formation of testes. This finding confirms the pathogenic role of *SRY* translocations to the X chromosome in sex-reversed XX females. Huntington disease is an autosomal dominant disorder caused by expansion of a CAG trinucleotide repeat that encodes a polyglutamine tract. Targeted deletion of the Huntington disease (*HD*) gene does not induce the neurologic disorder. On the other hand, transgenic expression of the entire gene or of the first exon containing the sequence encoding the expanded polyglutamine repeat is sufficient to cause many features of the neurologic disorder, indicating a gain-of-function property for the expanded polyglutamine-containing protein. Transgenic strategies can also be used as a precursor to gene therapy. Expression of dystrophin, the pro-

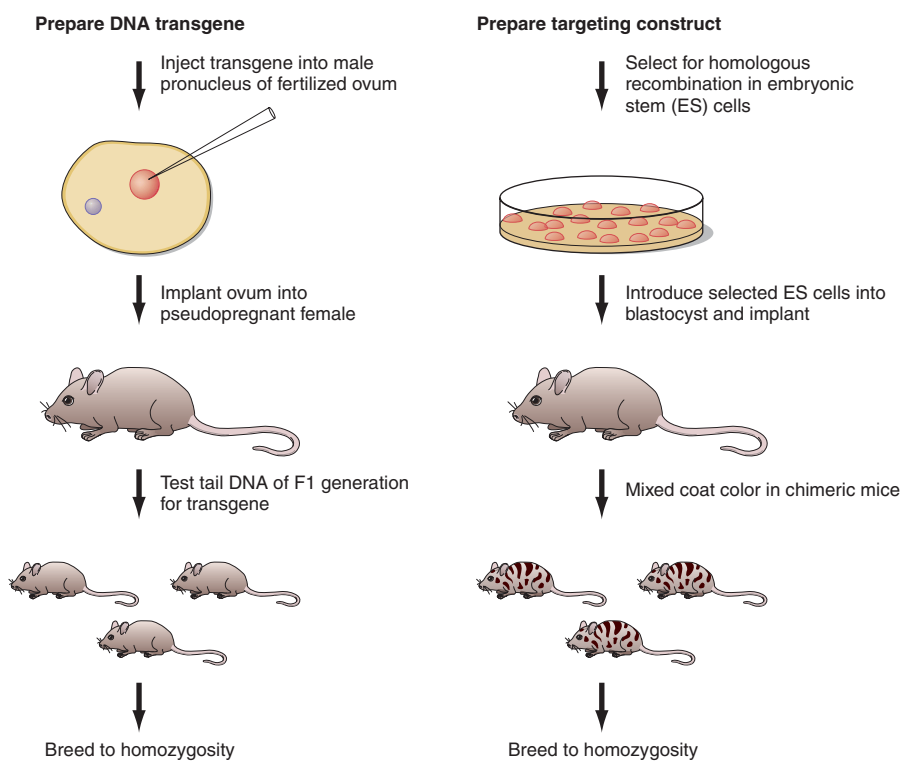

FIGURE 62-6 Transgenic mouse models. ***Left.*** Transgenic mice are generated by pronuclear injection of foreign DNA into fertilized mouse oocytes and subsequent transfer into the oviduct of pseudopregnant foster mothers. ***Right.*** For targeted mutagenesis (gene knock-out/knock-in), embryonic stem (ES) cells are transfected with the targeted (mutagenized) transgene. The transgene undergoes homologous recombination with the wild-type gene. After selection, positive ES cells are introduced into blastocysts and implanted into foster mothers. Chimeric mice can be identified based on the mixed coat color of the offspring. Heterozygous mice are bred to obtain mice homozygous for the mutant allele.

TABLE 62-3 GENETICALLY MODIFIED ANIMALS

Commonly Used Description	Technical Principle	Remarks
Transgenic	Pronuclear injection of transgene	Commonly used Genomic DNA or cDNA constructs Random integration of transgene Variable copy numbers of transgene Variable expression in each individual founder Gain-of-function models due to overexpression using tissue-specific promoters Loss-of-function models using anti-sense and dominant negative transgenes Inducible expression possible (Tetracycline, ecdysone) Applicable to several species
(Targeted) Knock-out	Substitution of functional gene with inactive gene by homologous recombination in embryonic stem cells	Predominantly used in mice Tissue-specific knock-out possible (Cre/lox) Absence of phenotype possible due to redundancy
(Targeted) Knock-in	Introduction of subtle mutation(s) into gene by substitution of endogenous gene with gene carrying a specific mutation. Homologous recombination in embryonic stem cells	Predominantly used in mice Can accurately model human disease
Forward genetics	Mutations created randomly by ENU (*N*-ethyl-*N*-nitrourea)	Selection of phenotype followed by genetic characterization Useful for identifying novel genes
Congenic strains	Mating of an inbred *donor* strain with a disease phenotype with an inbred *recipient* strain in order to define the genomic region responsible for the disorder	Useful for mapping disease-causing genes
Cloning	Introduction of nucleus into enucleated eggs (nuclear transfer)	Successful in several mammalian species including sheep (Dolly), mice, cows, monkeys Cloning of genetically identical individuals May affect life-span Ethical concerns

tein that is deleted in Duchenne muscular dystrophy, partially corrects the disorder in a mouse model of Duchenne's. Targeted expression of oncogenes has been valuable to study mechanisms of neoplasia and to generate immortalized cell lines. For example, expression of the simian virus 40 (SV40) large T antigen under the direction of the insulin promoter induces the formation of islet cell tumors.

The creation of gene knock-out and knock-in models takes advantage of the fact that a segment of DNA can be substituted by another that is identical (homologous), or nearly identical, by recombination. This permits integration of deletions that disrupt the gene (knock-out) or selected mutations (knock-in) into the target gene of choice. The transgene is introduced into embryonic stem (ES) cells by transfection and, after selection of cells with an integrated transgene, the positive ES cells are introduced into blastocysts and implanted into foster mothers. Chimeric mice can be identified based on the mixed coat color of the offspring. Heterozygous mice are bred to obtain mice homozygous for the mutant allele. This is particularly useful for genes that would be lethal if deleted universally or during early development. The list of genes that have been modified by this approach is very large.

Many of these knock-outs do not have an apparent phenotype, either because of redundant functions of the other genes or because the phenotype is subtle. For example, deletion of the hypoxanthine phosphoribosyltransferase (HPRT) gene (*Hprt*) does not cause characteristic features of Lesch-Nyhan syndrome in mice because of their reliance on adenine phosphoribosyltransferase (APRT) in the purine salvage pathway. Deletion of the retinoblastoma (*Rb*) gene encoding p105 does not lead to retinoblastoma or other tumors that characterize the human syndrome. However, mice with combinatorial deletion of several Rb-related proteins exhibit features similar to the human disorder. These examples underscore the fact that the functions of genes, and their interactions with genetic background and the environment, are not necessarily identical in mice and humans. On the other hand, the deletion of many genes provides a remarkably faithful model of human disorders. In addition to clarifying pathophysiology, these models facilitate the development of therapies, both genetic and pharmaceutical.

Many variations of these basic approaches now exist that allow genes to be expressed or deleted in specific cell types, at different times during development, or at varying levels. Consequently, transgenic technology has emerged as a powerful strategy for defining the physiologic effects of deleting or overexpressing a gene, as well as providing unique genetic models for dissecting pathophysiology or testing therapies. In addition to transgenic animal models, naturally occurring mutations in mice and other species continue to provide fundamental insights into human disease. A compendium of natural and transgenic animal models is provided in continuously evolving databases (Table 62-1).

IMPLICATIONS OF THE HUMAN GENOME PROJECT

The HGP was initiated in the mid-1980s as an ambitious effort to characterize the human genome, culminating in a complete DNA sequence. The initial main goals were (1) creation of genetic maps, (2) development of physical maps, and (3) determination of the complete human DNA sequence. Some analogies help in appreciating the scope of the HGP. The 23 pairs of human chromosomes encode ~30,000–40,000 genes. The total length of DNA is ~3 billion bp, which is nearly 1000-fold greater than that of the *E. coli* genome. If the human DNA sequence were printed out, it would correspond to about 120 volumes of *Harrison's Principles of Internal Medicine.*

The Genetic Map Given the size and complexity of the human genome, initial efforts aimed at developing genetic maps to provide orientation and to delimit where a gene of interest may be located. A *genetic map* describes the order of genes and defines the position of a gene relative to other loci on the same chromosome. It is constructed by assessing how frequently two markers are inherited together (i.e., *linked*) by association studies. Distances of the genetic map are expressed in recombination units, or centiMorgans (cM). One cM corresponds to a recombination frequency of 1% between two polymorphic markers; 1 cM corresponds to ~1 Mb of DNA (Fig. 62-3). Any polymorphic sequence variation can be useful for mapping purposes. Examples of polymorphic markers include variable number of tandem repeats (VNTRs), RFLPs, microsatellite repeats, and SNPs; the latter two methods are now used predominantly because of the high density of markers and because they are amenable to automated procedures.

The Physical Map Cytogenetics and chromosomal banding techniques provide a relatively low-resolution microscopic view of genetic loci. Physical maps indicate the position of a locus or gene in absolute values. Sequence-tagged sites (STSs) are used as a standard unit for physical mapping and serve as sequence-specific landmarks for arranging overlapping cloned fragments in the same order as they occur in the genome. These overlapping clones allow the characterization of contiguous DNA sequences, commonly referred to as *contigs*. This approach led to high-resolution physical maps by cloning the whole genome into overlapping fragments and has been essential for the identification of disease-causing genes by positional cloning.

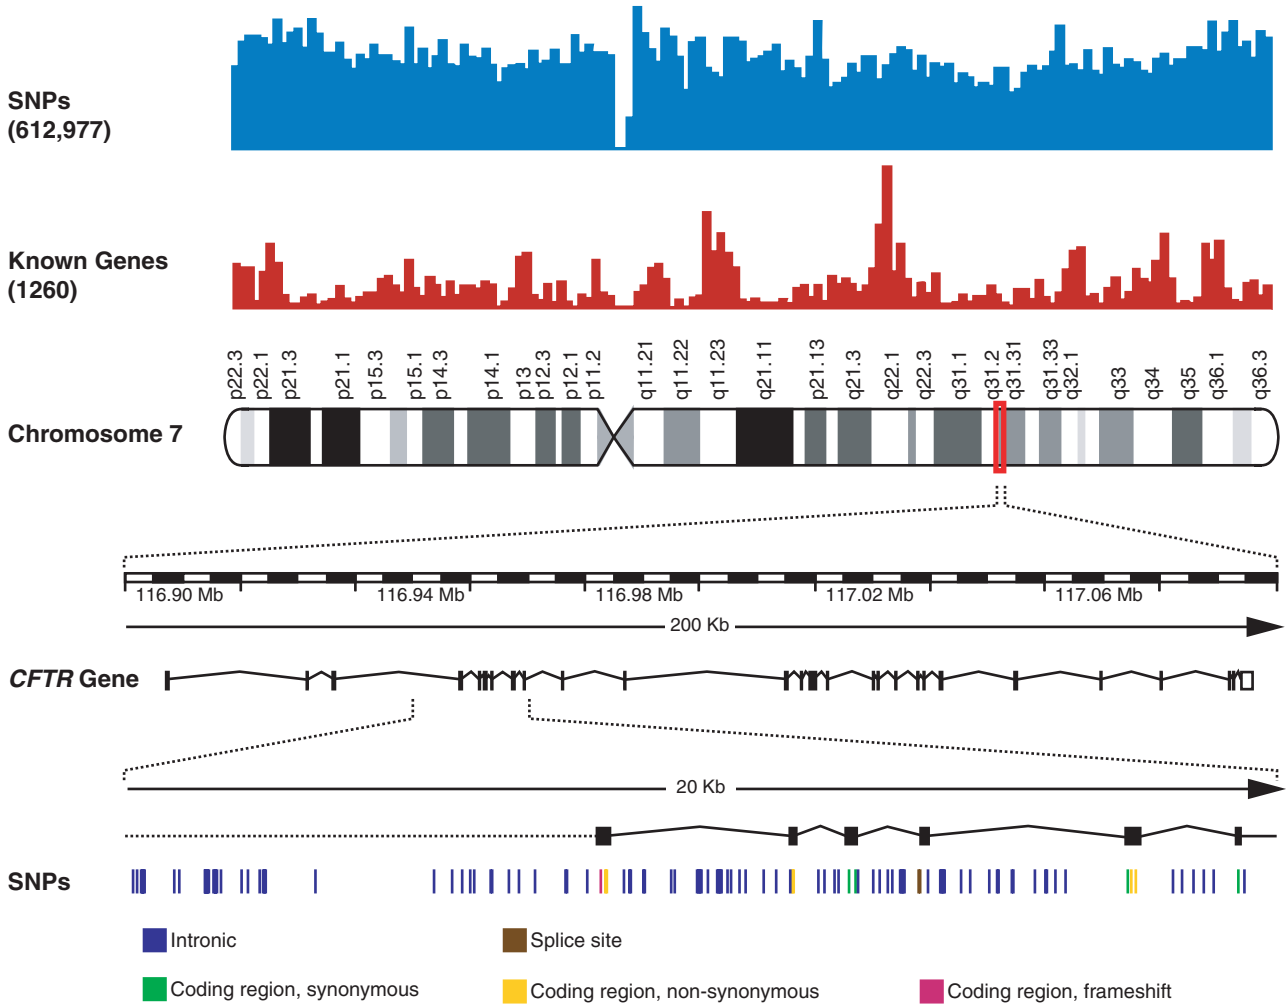

FIGURE 62-7 Chromosome 7 is shown with the density of single nucleotide polymorphisms (SNPs) and genes above. A 200-kb region in 7q31.2 containing the *CFTR* gene is shown below. The *CFTR* gene contains 27 exons. More than 1420 mutations in this gene have been found in patients with cystic fibrosis. A 20-kb region encompassing exons 4–9 is shown in further amplified in order to illustrate the SNPs in this region.

Recent insights into the structure of the normal human genome show that certain blocks of DNA sequences, often containing numerous genes, can be duplicated one or several times. This *copy number variation* (CNV), which tends to vary in a specific manner among different populations, is associated with hot spots of chromosomal rearrangements and is thought to play an important role in normal human variation and in genetic disease.

The identification of the ~10 million SNPs estimated to occur in the human genome has generated a catalogue of common genetic variants that occur in human beings from distinct ethnic backgrounds (Fig. 62-7). SNPs that are in close proximity are inherited together, i.e., they are linked, and are referred to as *haplotypes*, hence the name HapMap (Fig. 62-8). The HapMap describes the nature and location of these SNP haplotypes and how they are distributed among individuals within and among populations. The HapMap information is greatly facilitating genome-wide association studies designed to elucidate the complex interactions among multiple genes and lifestyle factors in multifactorial disorders (see below). Moreover, haplotype analyses may become useful to assess variations in responses to medications (*pharmacogenomics*) and environmental factors, as well as the prediction of disease predisposition.

The Human DNA Sequence The complete DNA sequence of each chromosome provides the highest resolution physical map. The primary focus of the HGP was to obtain DNA sequence for the entire human genome as well as model organisms. Although the prospect of

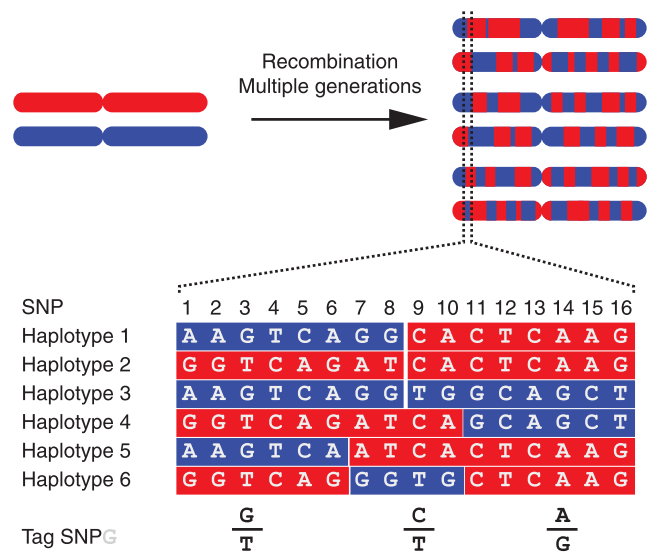

FIGURE 62-8 The origin of haplotypes is due to repeated recombination events occurring in multiple generations. Over time, this leads to distinct haplotypes. These haplotype blocks can often be characterized by genotyping selected Tag single nucleotide polymorphisms, an approach that now facilitates performing genome-wide association studies.

determining the complete sequence of the human genome seemed daunting several years ago, technical advances in DNA sequencing and bioinformatics led to the completion of a draft human sequence in June 2000, well in advance of the original goal year of 2003. High-quality reference sequences, completed in 2003, further closed gaps and reduced remaining ambiguities, and the HGP announced the completion of the DNA sequence for the last of the human chromosomes in May 2006. In addition to the human genome, the whole genomes of >2000 organisms have been sequenced partially or completely [Genomes Online Database (GOLD); Table 62-1]. They include, among others, eukaryotes such as man and mouse; *S. cerevisiae*, *C. elegans*, and *D. melanogaster*; bacteria (e.g., *E. coli*); and archeae, viruses, organelles (mitochondriae, chloroplasts), and plants (e.g., *Arabidopsis thaliana*). This information, together with technological advances and refinement of computational bioinformatics, has led to a fast-paced transition from the study of single genes to whole genomes. The current directions arising from the HGP include, among others, (1) the comparison of entire genomes (*comparative genomics*), (2) the study of large-scale expression of RNAs (*functional genomics)* and proteins *(proteomics*) in order to detect differences between various tissues in health and disease, (3) the characterization of the variation among individuals by establishing catalogues of sequence variations and SNPs (HapMap project), and (4) the identification of genes that play critical roles in the development of polygenic and multifactorial disorders.

Ethical Issues Implicit in the HGP is the idea and hope that identifying disease-causing genes can lead to improvements in diagnosis, treatment, and prevention. It is estimated that most individuals harbor several serious recessive genes. However, completion of the human genome sequence, determination of the association of genetic defects with disease, and studies of genetic variation raise many new issues with implications for the individual and mankind. The controversies concerning the cloning of mammals and the establishment of human ES cells underscore the relevance of these questions. Moreover, the information gleaned from genotypic results can have quite different impacts, depending on the availability of strategies to modify the course of disease. For example, the identification of mutations that cause multiple endocrine neoplasia (MEN) type 2 or hemochromatosis allows specific interventions for affected family members. On the other hand, at present, the identification of an Alzheimer or Huntington disease gene does not alter therapy and outcomes. In addition, the progress in this area is unpredictable, as underscored by the finding that angiotensin II receptor blockers may slow disease progression in Marfan syndrome.

Genetic test results can generate anxiety in affected individuals and family members, and there is the possibility of discrimination on the basis of the test results. Most genetic disorders are likely to fall into an intermediate category where the opportunity for prevention or treatment is significant but limited (Chap. 64). For these reasons, the scientific components of the HGP have been paralleled by efforts to examine ethical and legal implications as new issues arise. About 5% of the HGP budget has been allocated to studies addressing the ethical, legal, and social implications associated with the increasing knowledge about the human genome and the genetic basis of disease.

Many issues raised by the genome project are familiar, in principle, to medical practitioners. For example, an asymptomatic patient with increased low-density lipoprotein (LDL) cholesterol, high blood pressure, or a strong family history of early myocardial infarction is known to be at increased risk of coronary heart disease. In such cases, it is clear that the identification of risk factors and an appropriate intervention are beneficial. Likewise, patients with phenylketonuria, cystic fibrosis, or sickle cell anemia are often identified as having a genetic disease early in life. These precedents can be helpful for adapting policies that relate to genetic information. We can anticipate similar efforts, whether based on genotypes or other markers of genetic predisposition, to be applied to many disorders. One confounding aspect of the rapid expansion of information is that our ability to make clinical decisions often lags behind initial insights into genetic mechanisms of disease. For example, when genes that predispose to breast cancer, such as *BRCA1*, are described, they generate tremendous public interest in the potential to predict disease, but many years of clinical research are still required to rigorously establish genotype and phenotype correlations.

Whether related to informed consent, participation in research, or the management of a genetic disorder that affects an individual or their families, there is a great need for more information about fundamental principles of genetics. The pervasive nature of the role of genetics in medicine makes it imperative for physicians and other health care professionals to become more informed about genetics and to provide advice and counseling in conjunction with trained genetic counselors (Chap. 64). The application of screening and prevention strategies will therefore require intensive patient and physician education, changes in health care financing, and legislation to protect patient's rights.

TRANSMISSION OF GENETIC DISEASE

Origins and Types of Mutations A *mutation* can be defined as any change in the primary nucleotide sequence of DNA regardless of its functional consequences. Some mutations may be lethal, others are less deleterious, and some may confer an evolutionary advantage. Mutations can occur in the germline (sperm or oocytes); these can be transmitted to progeny. Alternatively, mutations can occur during embryogenesis or in somatic tissues. Mutations that occur during development lead to *mosaicism*, a situation in which tissues are composed of cells with different genetic constitutions. If the germline is mosaic, a mutation can be transmitted to some progeny but not others, which sometimes leads to confusion in assessing the pattern of inheritance. Somatic mutations that do not affect cell survival can sometimes be detected because of variable phenotypic effects in tissues (e.g., pigmented lesions in McCune-Albright syndrome). Other somatic mutations are associated with neoplasia because they confer a growth advantage to cells. Epigenetic events, heritable changes that do not involve changes in gene sequence (e.g., altered DNA methylation), may influence gene expression or facilitate genetic damage. With the exception of triplet nucleotide repeats, which can expand (see below), mutations are usually stable.

Mutations are structurally diverse—they can involve the entire genome, as in triploidy (one extra set of chromosomes), or gross numerical or structural alterations in chromosomes or individual genes (Chap. 63). Large deletions may affect a portion of a gene or an entire gene, or, if several genes are involved, they may lead to a *contiguous gene syndrome*. Unequal crossing-over between homologous genes can result in fusion gene mutations, as illustrated by color blindness (Chap. 29). Mutations involving single nucleotides are referred to as *point mutations* (Fig. 62-5). Substitutions are called *transitions* if a purine is replaced by another purine base (A ↔ G) or if a pyrimidine is replaced by another pyrimidine (C ↔ T). Changes from a purine to a pyrimidine, or vice versa, are referred to as *transversions*. If the DNA sequence change occurs in a coding region and alters an amino acid, it is called a *missense mutation*. Depending on the functional consequences of such a missense mutation, amino acid substitutions in different regions of the protein can lead to distinct phenotypes. *Polymorphisms* are sequence variations that have a frequency of at least 1%. Usually, they do not result in a perceptible phenotype. Often they consist of single base-pair substitutions that do not alter the protein coding sequence because of the degenerate nature of the genetic code (synonymous polymorphism), although it is possible that some might alter mRNA stability, translation, or the amino acid sequence (nonsynonymous polymorphism) (Fig. 62-7). These types of base substitutions are encountered frequently during genetic testing and must be distinguished from true mutations that alter protein expression or function. Small nucleotide deletions or insertions cause a shift of the codon reading frame (*frameshift)*. Most commonly, reading frame alterations result in an abnormal protein segment of variable length before termination of translation occurs at a stop codon (*nonsense mutation*) (Fig. 62-5). Mutations in intronic sequences or in exon

junctions may destroy or create splice donor or splice acceptor sites. Mutations may also be found in the regulatory sequences of genes, resulting in reduced gene transcription.

MUTATION RATES As noted before, mutations represent an important cause of genetic diversity as well as disease. Mutation rates are difficult to determine in humans because many mutations are silent and because testing is often not adequate to detect the phenotypic consequences. Mutation rates vary in different genes but are estimated to occur at a rate of ~10^{-10}/bp per cell division. Germline mutation rates (as opposed to somatic mutations) are relevant in the transmission of genetic disease. Because the population of oocytes is established very early in development, only ~20 cell divisions are required for completed oogenesis, whereas spermatogenesis involves ~30 divisions by the time of puberty and 20 cell divisions each year thereafter. Consequently, the probability of acquiring new point mutations is much greater in the male germline than the female germline, in which rates of aneuploidy are increased (Chap. 63). Thus, the incidence of new point mutations in spermatogonia increases with paternal age (e.g., achondrodysplasia, Marfan syndrome, neurofibromatosis). It is estimated that about 1 in 10 sperm carries a new deleterious mutation. The rates for new mutations are calculated most readily for autosomal dominant and X-linked disorders and are ~10^{-5}–10^{-6}/locus per generation. Because most monogenic diseases are relatively rare, new mutations account for a significant fraction of cases. This is important in the context of genetic counseling, as a new mutation can be transmitted to the affected individual but does not necessarily imply that the parents are at risk to transmit the disease to other children. An exception to this is when the new mutation occurs early in germline development, leading to *gonadal mosaicism*.

UNEQUAL CROSSING-OVER Normally, DNA recombination in germ cells occurs with remarkable fidelity to maintain the precise junction sites for the exchanged DNA sequences (Fig. 62-3). However, mispairing of homologous sequences leads to unequal crossover, with gene duplication on one of the chromosomes and gene deletion on the other chromosome. A significant fraction of growth hormone (*GH*) gene deletions, for example, involve unequal crossing-over (Chap. 333). The *GH* gene is a member of a large gene cluster that includes a growth hormone variant gene as well as several structurally related chorionic somatomammotropin genes and pseudogenes (highly homologous but functionally inactive relatives of a normal gene). Because such gene clusters contain multiple homologous DNA sequences arranged in tandem, they are particularly prone to undergo recombination and, consequently, gene duplication or deletion. On the other hand, duplication of the *PMP22* gene because of unequal crossing-over results in increased gene dosage and type IA Charcot-Marie-Tooth disease. Unequal crossing-over resulting in deletion of *PMP22* causes a distinct neuropathy called *hereditary liability to pressure palsy* (Chap. 379).

Glucocorticoid-remediable aldosteronism (GRA) is caused by a rearrangement involving the genes that encode aldosterone synthase (*CYP11B2*) and steroid 11β-hydroxylase (*CYP11B1*), normally arranged in tandem on chromosome 8q. These two genes are 95% identical, predisposing to gene duplication and deletion by unequal crossing-over. The rearranged gene product contains the regulatory regions of 11β-hydroxylase fused to the coding sequence of aldosterone synthetase. Consequently, the latter enzyme is expressed in the adrenocorticotropic hormone (ACTH)-dependent zona fasciculata of the adrenal gland, resulting in overproduction of mineralocorticoids and hypertension (Chap. 336).

Gene conversion refers to a nonreciprocal exchange of homologous genetic information; it is probably more common than generally recognized. In human genetics, gene conversion has been used to explain how an internal portion of a gene is replaced by a homologous segment copied from another allele or locus; these genetic alterations may range from a few nucleotides to a few thousand nucleotides. As a result of gene conversion, it is possible for short DNA segments of two chromosomes to be identical, even though these sequences are distinct in the parents. A practical consequence of this phenomenon is that nucleotide substitutions can occur during gene conversion between related genes, often altering the function of the gene. In disease states, gene conversion often involves intergenic exchange of DNA between a gene and a related pseudogene. For example, the 21-hydroxylase gene (*CYP21A2*) is adjacent to a nonfunctional pseudogene (*CYP21A1P)*. Many of the nucleotide substitutions that are found in the *CYP21A2* gene in patients with congenital adrenal hyperplasia correspond to sequences that are present in the *CYP21A1P* pseudogene, suggesting gene conversion as a mechanism of mutagenesis. In addition, mitotic gene conversion has been suggested as a mechanism to explain revertant mosaicism in which an inherited mutation is "corrected" in certain cells. For example, patients with autosomal recessive generalized atrophic benign epidermolysis bullosa have acquired reverse mutations in one of the two mutated *COL17A1* alleles, leading to clinically unaffected patches of skin.

INSERTIONS AND DELETIONS Though many instances of insertions and deletions occur as a consequence of unequal crossing-over, there is also evidence for internal duplication, inversion, or deletion of DNA sequences. The fact that certain deletions or insertions appear to occur repeatedly as independent events suggests that specific regions within the DNA sequence predispose to these errors. For example, certain regions of the *DMD* gene appear to be hot spots for deletions. Some regions within the human genome are rearrangement hot spots and lead to CNVs (see above).

ERRORS IN DNA REPAIR Because mutations caused by defects in DNA repair accumulate as somatic cells divide, these types of mutations are particularly important in the context of neoplastic disorders (Chap. 80). Several genetic disorders involving DNA repair enzymes underscore their importance. Patients with xeroderma pigmentosum have defects in DNA damage recognition or in the nucleotide excision and repair pathway (Chap. 83). Exposed skin is dry and pigmented and is extraordinarily sensitive to the mutagenic effects of ultraviolet irradiation. More than 10 different genes have been shown to cause the different forms of xeroderma pigmentosum. This finding is consistent with the earlier classification of this disease into different complementation groups in which normal function is rescued by the fusion of cells derived from two different forms of xeroderma pigmentosum.

Ataxia telangiectasia causes large telangiectatic lesions of the face, cerebellar ataxia, immunologic defects, and hypersensitivity to ionizing radiation (Chap. 368). The discovery of the ataxia telangiectasia mutated (*ATM*) gene reveals that it is homologous to genes involved in DNA repair and control of cell cycle checkpoints. Mutations in the *ATM* gene give rise to defects in meiosis as well as increasing susceptibility to damage from ionizing radiation. Fanconi's anemia is also associated with an increased risk of multiple acquired genetic abnormalities. It is characterized by diverse congenital anomalies and a strong predisposition to develop aplastic anemia and acute myelogenous leukemia (Chap. 104). Cells from these patients are susceptible to chromosomal breaks caused by a defect in genetic recombination. At least eight different complementation groups have been identified, and several loci and genes associated with Fanconi's anemia have been mapped or cloned. HNPCC (Lynch syndrome) is characterized by autosomal dominant transmission of colon cancer, young age (<50 years) of presentation, predisposition to lesions in the proximal large bowel, and associated malignancies such as uterine cancer and ovarian cancer. HNPCC is caused by mutations in one of several different mismatch repair (MMR) genes including MutS homologue 2 (*MSH2*), MutL homologue 1 (*MLH1*), and *MSH6* (Chap. 87). These enzymes are involved in the detection of nucleotide mismatches and in the recognition of slipped-strand trinucleotide repeats. Germline mutations in these genes lead to microsatellite instability and a high mutation rate in colon cancer. Genetic screening tests for this disorder are now being used for families considered to be at risk (Chap. 64). Recognition of HNPCC allows early screening with colonoscopy and the implementation of prevention strategies using nonsteroidal anti-inflammatory drugs.

DIPYRIMIDINE AND CPG SEQUENCES Certain DNA sequences are particularly susceptible to mutagenesis. Successive pyrimidine residues (e.g., T-T or C-C) are subject to the formation of ultraviolet light–induced photoadducts. If these pyrimidine dimers are not repaired by the nucleotide excision repair pathway, mutations will be introduced after DNA synthesis. The dinucleotide C-G, or CpG, is also a hot spot for a specific type of mutation. In this case, methylation of the cytosine is associated with an enhanced rate of deamination to uracil, which is then replaced with thymine. This C → T transition (or G → A on the opposite strand) accounts for at least one-third of point mutations associated with polymorphisms and mutations. Many of the *MSH2* mutations in HNPCC, for example, involve CpG sequences. In addition to the fact that certain types of mutations (C → T or G → A) are relatively common, the nature of the genetic code also results in overrepresentation of certain amino acid substitutions.

UNSTABLE DNA SEQUENCES *Trinucleotide repeats* may be unstable and expand beyond a critical number. Mechanistically, the expansion is thought to be caused by unequal recombination and slipped mispairing. A premutation represents a small increase in trinucleotide copy number. In subsequent generations, the expanded repeat may increase further in length and result in an increasingly severe phenotype, a process called *dynamic mutation* (see below for discussion of anticipation). Trinucleotide expansion was first recognized as a cause of the fragile X syndrome, one of the most common causes of mental retardation. Other disorders arising from a similar mechanism include Huntington disease (Chap. 365), X-linked spinobulbar muscular atrophy (Chap. 369), and myotonic dystrophy (Chap. 382). Malignant cells are also characterized by genetic instability, indicating a breakdown in mechanisms that regulate DNA repair and the cell cycle.

Functional Consequences of Mutations Functionally, mutations can be broadly classified as gain-of-function and loss-of-function mutations. Gain-of-function mutations are typically dominant, i.e., they result in phenotypic alterations when a single allele is affected. Inactivating mutations are usually recessive, and an affected individual is homozygous or compound heterozygous (e.g., carrying two different mutant alleles of the same gene) for the disease-causing mutations. Alternatively, mutation in a single allele can result in *haploinsufficiency*, a situation in which one normal allele is not sufficient to maintain a normal phenotype. Haploinsufficiency is a commonly observed mechanism in diseases associated with mutations in transcription factors (Table 62-2). Remarkably, the clinical features among patients with an identical mutation in a transcription factor often vary significantly. One mechanism underlying this variability consists in the influence of modifying genes. Haploinsufficiency can also affect the expression of rate-limiting enzymes. For example, haploinsufficiency in enzymes involved in heme synthesis can cause porphyrias (Chap. 352).

An increase in dosage of a gene product may also result in disease, as illustrated by the duplication of the *DAX1* gene in dosage-sensitive sex-reversal (Chap. 343). Mutation in a single allele can also result in loss of function due to a dominant-negative effect. In this case, the mutated allele interferes with the function of the normal gene product by one of several different mechanisms: (1) a mutant protein may interfere with the function of a multimeric protein complex, as illustrated by mutations in type 1 collagen (*COL1A1*, *COL1A2*) genes in osteogenesis imperfecta (Chap. 357); (2) a mutant protein may occupy binding sites on proteins or promoter response elements, as illustrated by thyroid hormone resistance, a disorder in which inactivated thyroid hormone receptor binds to target genes and functions as an antagonist of normal receptors (Chap. 335); or (3) a mutant protein can be cytotoxic as in α_1 antitrypsin deficiency (Chap. 254) or autosomal dominant neurohypophyseal diabetes insipidus (Chap. 334), in which the abnormally folded proteins are trapped within the endoplasmic reticulum and ultimately cause cellular damage.

Genotype and Phenotype • ***ALLELES, GENOTYPES, AND HAPLOTYPES*** An observed trait is referred to as a *phenotype*; the genetic information defining the phenotype is called the *genotype*. Alternative forms of a gene or a genetic marker are referred to as *alleles*. Alleles may be polymorphic variants of nucleic acids that have no apparent effect on gene expression or function. In other instances, these variants may have subtle effects on gene expression, thereby conferring the adaptive advantages associated with genetic diversity. On the other hand, allelic variants may reflect mutations in a gene that clearly alter its function. The common Glu6Val (E6V) sickle cell mutation in the β-*globin* gene and the ΔF508 deletion of phenylalanine (F) in the *CFTR* gene are examples of allelic variants of these genes that result in disease. Because each individual has two copies of each chromosome (one inherited from the mother and one inherited from the father), he or she can have only two alleles at a given locus. However, there can be many different alleles in the population. The normal or common allele is usually referred to as *wild type*. When alleles at a given locus are identical, the individual is *homozygous*. Inheriting identical copies of a mutant allele occurs in many autosomal recessive disorders, particularly in circumstances of consanguinity. If the alleles are different on the maternal and the paternal copy of the gene, the individual is *heterozygous* at this locus (Fig. 62-5). If two different mutant alleles are inherited at a given locus, the individual is said to be a *compound heterozygote*. *Hemizygous* is used to describe males with a mutation in an X chromosomal gene or a female with a loss of one X chromosomal locus.

Genotypes describe the specific alleles at a particular locus. For example, there are three common alleles (E2, E3, E4) of the apolipoprotein E (*APOE*) gene. The genotype of an individual can therefore be described as *APOE3/4* or *APOE4/4* or any other variant. These designations indicate which alleles are present on the two chromosomes in the *APOE* gene at locus 19q13.2. In other cases, the genotype might be assigned arbitrary numbers (e.g., 1/2) or letters (e.g., B/b) to distinguish different alleles.

A *haplotype* refers to a group of alleles that are closely linked together at a genomic locus (Fig. 62-8). Haplotypes are useful for tracking the transmission of genomic segments within families and for detecting evidence of genetic recombination, if the crossover event occurs between the alleles (Fig. 62-3). As an example, various alleles at the histocompatibility locus antigen (HLA) on chromosome 6p are used to establish haplotypes associated with certain disease states. For example, 21-hydroxylase deficiency, complement deficiency, and hemochromatosis are each associated with specific HLA haplotypes. It is now recognized that these genes lie in close vicinity to the HLA locus, which explains why HLA associations were identified even before the disease genes were cloned and localized. In other cases, specific HLA associations with diseases such as ankylosing spondylitis (HLA-B27) or type 1 diabetes mellitus (HLA-DR4) reflect the role of specific HLA allelic variants in susceptibility to these autoimmune diseases. The recent characterization of common SNP haplotypes in four populations from different parts of the world through the HapMap project is providing a novel tool for association studies designed to detect genes involved in the pathogenesis of complex disorders (Table 62-1). The presence or absence of certain haplotypes may also become relevant for the customized choice of medical therapies (pharmacogenomics) or for preventative strategies.

ALLELIC HETEROGENEITY *Allelic heterogeneity* refers to the fact that different mutations in the same genetic locus can cause an identical or similar phenotype. For example, many different mutations of the β-globin locus can cause β-thalassemia **(Table 62-4)** (Fig. 62-4). In essence, allelic heterogeneity reflects the fact that many different mutations are capable of altering protein structure and function. For this reason, maps of inactivating mutations in genes usually show a near-random distribution. Exceptions include: (1) a founder effect, in which a particular mutation that does not affect reproductive capacity can be traced to a single individual; (2) "hot spots" for mutations, in which the nature of the DNA sequence predisposes to a recurring mutation; and (3) localization of mutations to certain domains that are particularly critical for protein function. Allelic heterogeneity creates a practical problem for genetic testing because one must often examine the entire genetic locus for mutations, as these can differ in each pa-

TABLE 62-4 SELECTED EXAMPLES OF LOCUS HETEROGENEITY AND PHENOTYPIC HETEROGENEITY

Phenotypic Heterogeneity

Gene, Protein	Phenotype	Inheritance	OMIM
LMNA, Lamin A/C	Emery–Dreifuss muscular dystrophy (AD)	AD	181350
	Familial partial lipodystrophy Dunnigan	AD	151660
	Hutchinson-Gilford progeria	AD	176670
	Atypical Werner syndrome	AD	150330
	Dilated cardiomyopathy	AD	115200
	Early-onset atrial fibrillation	AD	607554
	Emery–Dreifuss muscular dystrophy (AR)	AR	604929
	Limb-girdle muscular dystrophy type 1B	AR	159001
	Charcot-Marie-Tooth type 2B1	AR	605588
KRAS	Noonan syndrome	AD	163950
	Cardio-facio-cutaneous syndrome	AD	115150

Locus Heterogeneity

Phenotype	Gene	Chromosomal Location	Protein
Familial hypertrophic cardiomyopathy			
Genes encoding sarcomeric proteins	*MYH7*	14q12	Myosin heavy chain beta
	TNNT2	1q2	Troponin-T2
	TPM1	15q22.1	Tropomyosin alpha
	MYBPC3	11p11q	Myosin binding protein C
	TNNI3	19q13.4	Troponin 1
	MYL2	12q23-24.3	Myosin light chain 2
	MYL3	3p	Myosin light chain 3
	TTN	2q24.3	Cardiac titin
	ACTC	15q11	Cardiac alpha actin
	MYH6	14q1	Myosin heavy chain alpha
	MYLK2	20q13.3	Myosin light-peptide kinase
	CAV3	3p25	Caveolin 3
Genes encoding nonsarcomeric proteins	*MTT1*	Mitochondrial	tRNA isoleucine
	MTTG	Mitochondrial	tRNA glycine
	PRKAG2	7q35-q36	AMP-activated protein kinase γ2 subunit
	DMPK	19q13.2-13.3	Myotonin protein kinase (myotonic dystrophy)
	FRDA	9q13	Frataxin (Friedreich ataxia)
Polycystic kidney disease	*PKD1*	16p13.3-13.12	Polycystin 1 (AD)
	PKD2	4q21.-23	Polycystin 2 (AD)
	PKHD1	6p21.1-p12	Fibrocystin (AR)
Noonan syndrome	PTPN11	12q24.1	Protein-tyrosine phosphatase 2c
	KRAS	12p12.1	KRAS

Note: AD, autosomal dominant; AR, autosomal recessive.

tient. For example, there are >1400 reported mutations in the *CFTR* gene (Fig. 62-7). The mutational analysis initially focuses on a panel of mutations that are particularly frequent (often taking the ethnic background of the patient into account), but a negative result does not exclude the presence of a mutation elsewhere in the gene. One should also be aware that mutational analyses generally focus on the coding region of a gene without considering regulatory and intronic regions. Because disease-causing mutations may be located outside the coding regions, negative results should be interpreted with caution.

PHENOTYPIC HETEROGENEITY *Phenotypic heterogeneity* occurs when more than one phenotype is caused by allelic mutations (e.g., different mutations in the same gene) (Table 62-4). For example, laminopathies are monogenic multisystem disorders that result from mutations in the *LMNA* gene, which encodes the nuclear lamins A and C. Twelve autosomal dominant and four autosomal recessive disorders are caused by mutations in the *LMNA* gene. They include several forms of lipodystrophies, Emery-Dreifuss muscular dystrophy, progeria syndromes, a form of neuronal Charcot-Marie-Tooth disease (type 2B1), and a group of overlapping syndromes. Remarkably, hierarchical cluster analysis has revealed that the phenotypes vary depending on the position of the mutation. Similarly, identical mutations in the *FGFR2* gene can result in very distinct phenotypes: Crouzon syndrome (craniofacial synostosis), or Pfeiffer syndrome (acrocephalopolysyndactyly).

LOCUS OR NONALLELIC HETEROGENEITY AND PHENOCOPIES *Nonallelic or locus heterogeneity* refers to the situation in which a similar disease phenotype results from mutations at different genetic loci. This often occurs when more than one gene product produces different subunits of an interacting complex or when different genes are involved in the same genetic cascade or physiologic pathway. For example, osteogenesis imperfecta can arise from mutations in two different procollagen genes (*COL1A1* or *COL1A2*) that are located on different chromosomes (Chap. 357). The effects of inactivating mutations in these two genes are similar because the protein products comprise different subunits of the helical collagen fiber. Similarly, muscular dystrophy syndromes can be caused by mutations in various genes, consistent with the fact that it can be transmitted in an X-linked (Duchenne or Becker), autosomal dominant (limb-girdle muscular dystrophy type 1), or autosomal recessive (limb-girdle muscular dystrophy type 2) manner (Chap. 382). Mutations in the X-linked *DMD* gene, which encodes dystrophin, are the most common cause of muscular dystrophy. This feature reflects the large size of the gene as well as the fact that the phenotype is expressed in hemizygous males because they have only a single copy of the X chromosome. Dystrophin is associated with a large protein complex linked to the membrane-associated cytoskeleton in muscle. Mutations in several different components of this protein complex can also cause muscular dystrophy syndromes. Although the phenotypic features of some of these disorders are distinct, the phenotypic spectrum caused by mutations in different genes overlaps, thereby leading to nonallelic heterogeneity. It should be noted that mutations in dystrophin also cause allelic heterogeneity. For example, mutations in the *DMD* gene can cause either Duchenne or the less severe Becker muscular dystrophy, depending on the severity of the protein defect.

Recognition of nonallelic heterogeneity is important for several reasons: (1) the ability to identify disease loci in linkage studies is reduced by including patients with similar phenotypes but different genetic disorders; (2) genetic testing is more complex because several different genes need to be considered along with the possibility of different mutations in each of the candidate genes; and (3) novel information is gained about how genes or proteins interact, providing unique insights into molecular physiology.

Phenocopies refer to circumstances in which nongenetic conditions mimic a genetic disorder. For example, features of toxin- or drug-induced neurologic syndromes can resemble those seen in Huntington disease, and vascular causes of dementia share phenotypic features with familial forms of Alzheimer dementia (Chap. 365). Children born with activating mutations of the thyroid-stimulating hormone receptor (TSH-R) exhibit goiter and thyrotoxicosis similar to that seen in neonatal Graves' disease, which is caused by the transfer of maternal autoantibodies to the fetus (Chap. 335). As in nonallelic heterogeneity, the presence of phenocopies has the potential to confound linkage studies and genetic testing. Patient history and subtle differences in phenotype can often provide clues that distinguish these disorders from related genetic conditions.

VARIABLE EXPRESSIVITY AND INCOMPLETE PENETRANCE The same genetic mutation may be associated with a phenotypic spectrum in different

affected individuals, thereby illustrating the phenomenon of *variable expressivity*. This may include different manifestations of a disorder variably involving different organs (e.g., MEN), the severity of the disorder (e.g., cystic fibrosis), or the age of disease onset (e.g., Alzheimer dementia). MEN-1 illustrates several of these features. Families with this autosomal dominant disorder develop tumors of the parathyroid gland, endocrine pancreas, and the pituitary gland (Chap. 345). However, the pattern of tumors in the different glands, the age at which tumors develop, and the types of hormones produced vary among affected individuals, even within a given family. In this example, the phenotypic variability arises, in part, because of the requirement for a second mutation in the normal copy of the *MEN1* gene, as well as the large array of different cell types that are susceptible to the effects of *MEN1* gene mutations. In part, variable expression reflects the influence of modifier genes, or genetic background, on the effects of a particular mutation. Even in identical twins, in whom the genetic constitution is essentially the same, one can occasionally see variable expression of a genetic disease.

Interactions with the environment can also influence the course of a disease. For example, the manifestations and severity of hemochromatosis can be influenced by iron intake (Chap. 351), and the course of phenylketonuria is affected by exposure to phenylalanine in the diet (Chap. 358). Other metabolic disorders, such as hyperlipidemias and porphyria, also fall into this category. Many mechanisms, including genetic effects and environmental influences, can therefore lead to variable expressivity. In genetic counseling, it is particularly important to recognize this variability, as one cannot always predict the course of disease, even when the mutation is known.

Penetrance refers to the proportion of individuals with a mutant genotype that express the phenotype. If all carriers of a mutant express the phenotype, penetrance is complete, whereas it is said to be *incomplete* or *reduced* if some individuals do not have any features of the phenotype. Dominant conditions with incomplete penetrance are characterized by skipping of generations with unaffected carriers transmitting the mutant gene. For example, hypertrophic obstructive cardiomyopathy (HCM) caused by mutations in the *myosin-binding protein C* gene is a dominant disorder with clinical features in only a subset of patients who carry the mutation (Chap. 231). Patients who have the mutation but no evidence of the disease can still transmit the disorder to subsequent generations. In many conditions with postnatal onset, the proportion of gene carriers who are affected varies with age. Thus, when describing penetrance, one has to specify age. For example, for disorders such as Huntington disease or familial amyotrophic lateral sclerosis, which present late in life, the rate of penetrance is influenced by the age at which the clinical assessment is performed. *Imprinting* can also modify the penetrance of a disease (see below). For example, in patients with Albright hereditary osteodystrophy, mutations in the Gsα subunit (*GNAS1* gene) are expressed clinically only in individuals who inherit the mutation from their mother (Chap. 347).

SEX-INFLUENCED PHENOTYPES Certain mutations affect males and females quite differently. In some instances, this is because the gene resides on the X or Y sex chromosomes (X-linked disorders and Y-linked disorders). As a result, the phenotype of mutated X-linked genes will be expressed fully in males but variably in heterozygous females, depending on the degree of X-inactivation and the function of the gene. For example, most heterozygous female carriers of factor VIII deficiency (hemophilia A) are asymptomatic because sufficient factor VIII is produced to prevent a defect in coagulation (Chap. 110). On the other hand, some females heterozygous for the X-linked lipid storage defect caused by α-galactosidase A deficiency (Fabry disease) experience mild manifestations of painful neuropathy, as well as other features of the disease (Chap. 355). Because only males have a Y chromosome, mutations in genes such as *SRY*, which causes male-to-female sex-reversal, or *DAZ* (deleted in azoospermia), which causes abnormalities of spermatogenesis, are unique to males (Chap. 343).

Other diseases are expressed in a sex-limited manner because of the differential function of the gene product in males and females. Activating mutations in the luteinizing hormone receptor cause dominant male-limited precocious puberty in boys (Chap. 340). The phenotype is unique to males because activation of the receptor induces testosterone production in the testis, whereas it is functionally silent in the immature ovary. Biallelic inactivating mutations of the follicle-stimulating hormone (FSH) receptor cause primary ovarian failure in females because the follicles do not develop in the absence of FSH action. In contrast, affected males have a more subtle phenotype, because testosterone production is preserved (allowing sexual maturation) and spermatogenesis is only partially impaired (Chap. 340). In congenital adrenal hyperplasia, most commonly caused by 21-hydroxylase deficiency, cortisol production is impaired and ACTH stimulation of the adrenal gland leads to increased production of androgenic precursors (Chap. 336). In females, the increased androgen level causes ambiguous genitalia, which can be recognized at the time of birth. In males, the diagnosis may be made on the basis of adrenal insufficiency at birth, because the increased adrenal androgen level does not alter sexual differentiation, or later in childhood, because of the development of precocious puberty. Hemochromatosis is more common in males than in females, presumably because of differences in dietary iron intake and losses associated with menstruation and pregnancy in females (Chap. 351).

Chromosomal Disorders Chromosomal or cytogenetic disorders are caused by numerical or structural aberrations in chromosomes. Deviations in chromosome number are common causes of abortions, developmental disorders, and malformations. *Contiguous gene syndromes*, i.e., large deletions affecting several genes, have been useful for identifying the location of new disease-causing genes. Because of the variable size of gene deletions in different patients, a systematic comparison of phenotypes and locations of deletion breakpoints allows positions of particular genes to be mapped within the critical genomic region. **For discussion of disorders of chromosome number and structure, see Chap. 63.**

Monogenic Mendelian Disorders Monogenic human diseases are frequently referred to as *Mendelian disorders* because they obey the principles of genetic transmission originally set forth in Gregor Mendel's classic work. The continuously updated OMIM catalogue lists several thousand of these disorders and provides information about the clinical phenotype, molecular basis, allelic variants, and pertinent animal models (Table 62-1). The mode of inheritance for a given phenotypic trait or disease is determined by pedigree analysis. All affected and unaffected individuals in the family are recorded in a pedigree using standard symbols (Fig. 62-9). The principles of allelic segregation, and the transmission of alleles from parents to children, are illustrated in Fig. 62-10. One dominant (A) allele and one recessive (a) allele can display three Mendelian modes of inheritance: autosomal dominant, autosomal recessive, and X-chromosomal. About 65% of human monogenic disorders are autosomal dominant, 25% are autosomal recessive, and 5% are X-linked. Genetic testing is now available for many of these disorders and plays an increasingly important role in clinical medicine (Chap. 64).

AUTOSOMAL DOMINANT DISORDERS Autosomal dominant disorders assume particular relevance because mutations in a single allele are sufficient to cause the disease. In contrast to recessive disorders, in which disease pathogenesis is relatively straightforward because there is loss of gene function, dominant disorders can be caused by various disease mechanisms, many of which are unique to the function of the genetic pathway involved.

In autosomal dominant disorders, individuals are affected in successive generations; the disease does not occur in the offspring of unaffected individuals. Males and females are affected with equal frequency because the defective gene resides on one of the 22 autosomes (Fig. 62-11*A*). Autosomal dominant mutations alter one of the two alleles at a given locus. Because the alleles segregate randomly at meiosis, the probability that an offspring will be affected is 50%. Unless there is a new germline mutation, an affected individual has an af-

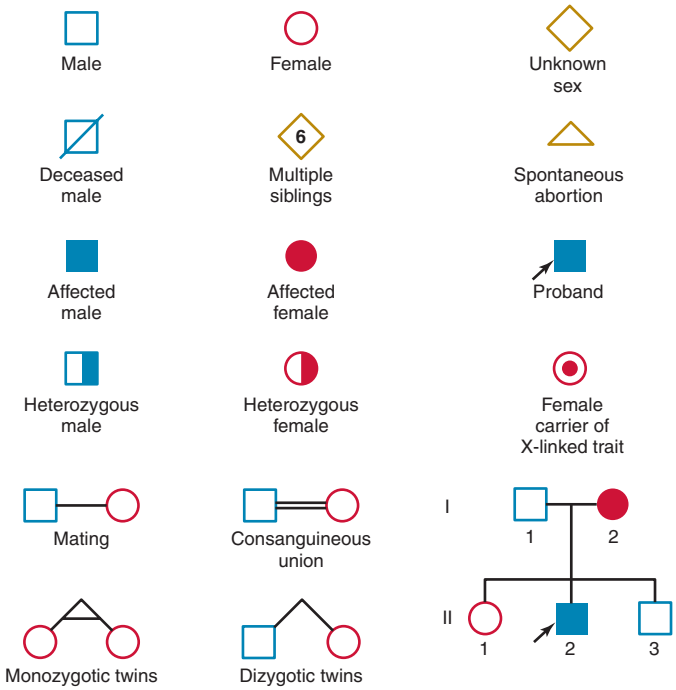

FIGURE 62-9 Standard pedigree symbols.

fected parent. Children with a normal genotype do not transmit the disorder. Due to differences in penetrance or expressivity (see above), the clinical manifestations of autosomal dominant disorders may be variable. Because of these variations, it is sometimes challenging to determine the pattern of inheritance.

It should be recognized, however, that some individuals acquire a mutated gene from an unaffected parent. De novo germline mutations occur more frequently during later cell divisions in gametogenesis, which explains why siblings are rarely affected. As noted before, new germline mutations occur more frequently in fathers of advanced age. For example, the average age of fathers with new germline mutations that cause Marfan's syndrome is ~37 years, whereas fathers who transmit the disease by inheritance have an average age of ~30 years.

AUTOSOMAL RECESSIVE DISORDERS In recessive disorders, the mutated alleles result in a complete or partial loss of function. They frequently involve enzymes in metabolic pathways, receptors, or proteins in signaling cascades. In an autosomal recessive disease, the affected individual, who can be of either sex, is a homozygote or compound heterozygote for a single-gene defect. With a few important exceptions, autosomal recessive diseases are rare and often occur in the context of parental consanguinity. The relatively high frequency of certain recessive disorders, such as sickle cell anemia, cystic fibrosis, and thalassemia, is partially explained by a selective biologic advantage for the heterozygous state (see below). Though heterozygous carriers of a defective allele are usually clinically normal, they may display subtle differences in phenotype that only become apparent with more precise

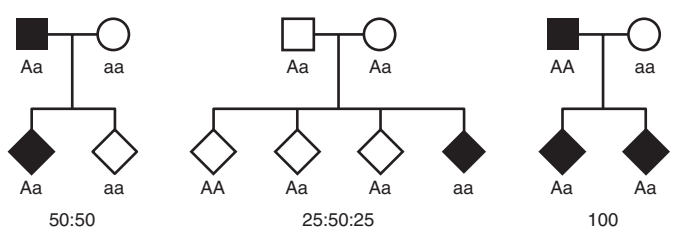

FIGURE 62-10 Segregation of alleles. Segregation of genotypes in the offspring of parents with one dominant (A) and one recessive (a) allele. The distribution of the parental alleles to their offspring depends on the combination present in the parents. Filled symbols = affected individuals.

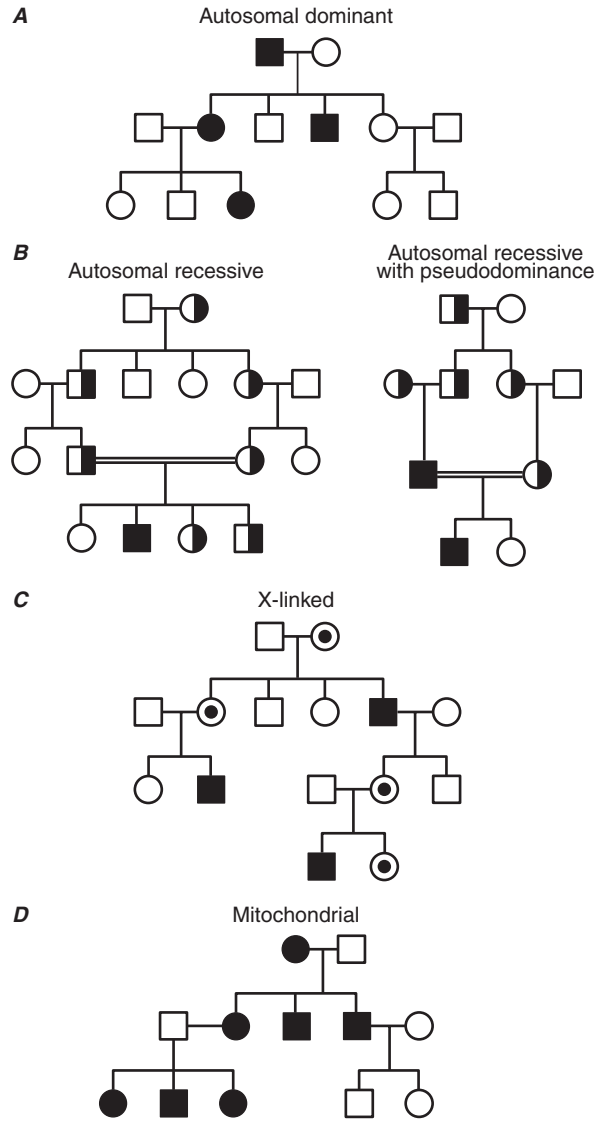

FIGURE 62-11 Dominant, recessive, X-linked, and mitochondrial (matrilinear) inheritance.

testing or in the context of certain environmental influences. In sickle cell anemia, for example, heterozygotes are normally asymptomatic. However, in situations of dehydration or diminished oxygen pressure, sickle cell crises can also occur in heterozygotes (Chap. 99).

In most instances, an affected individual is the offspring of heterozygous parents. In this situation, there is a 25% chance that the offspring will have a normal genotype, a 50% probability of a heterozygous state, and a 25% risk of homozygosity for the recessive alleles (Figs. 62-10, 62-11*B*). In the case of one unaffected heterozygous and one affected homozygous parent, the probability of disease increases to 50% for each child. In this instance, the pedigree analysis mimics an autosomal dominant mode of inheritance (*pseudodominance*). In contrast to autosomal dominant disorders, new mutations in recessive alleles are rarely manifest because they usually result in an asymptomatic carrier state.

X-LINKED DISORDERS Males have only one X chromosome; consequently, a daughter always inherits her father's X chromosome in addition to one of her mother's two X chromosomes. A son inherits the Y chromosome from his father and one maternal X chromosome. Thus, the characteristic features of X-linked inheritance are (1) the absence of father-to-son transmission, and (2) the fact that all daughters of an affected male are obligate carriers of the mutant allele (Fig. 62-11*C*). The risk of developing disease due to a mutant X-chromosomal gene

differs in the two sexes. Because males have only one X chromosome, they are hemizygous for the mutant allele; thus, they are more likely to develop the mutant phenotype, regardless of whether the mutation is dominant or recessive. A female may be either heterozygous or homozygous for the mutant allele, which may be dominant or recessive. The terms *X-linked dominant* or *X-linked recessive* are therefore only applicable to expression of the mutant phenotype in women. In addition, the expression of X-chromosomal genes is influenced by X chromosome inactivation (see below).

Y-LINKED DISORDERS The Y chromosome has a relatively small number of genes. One such gene, the sex-region determining Y factor (*SRY*), which encodes the testis-determining factor (*TDF*), is crucial for normal male development. Normally there is infrequent exchange of sequences on the Y chromosome with the X chromosome. The *SRY* region is adjacent to the pseudoautosomal region, a chromosomal segment on the X and Y chromosomes with a high degree of homology. A crossing-over occasionally involves the *SRY* region with the distal tip of the X chromosome during meiosis in the male. Translocations can result in XY females with the Y chromosome lacking the *SRY* gene or XX males harboring the *SRY* gene on one of the X chromosomes (Chap. 343). Point mutations in the *SRY* gene may also result in individuals with an XY genotype and an incomplete female phenotype. Most of these mutations occur de novo. Men with oligospermia/azoospermia frequently have microdeletions on the long arm of the Y chromosome that involve one or more of the azoospermia factor (*AZF*) genes.

Exceptions to Simple Mendelian Inheritance Patterns • ***MITOCHONDRIAL DISORDERS*** Mendelian inheritance refers to the transmission of genes encoded by DNA contained in the nuclear chromosomes. In addition, each mitochondrion contains several copies of a small circular chromosome. The mitochondrial DNA (mtDNA) is ~16.5 kb and encodes transfer and ribosomal RNAs and 13 proteins that are components of the respiratory chain involved in oxidative phosphorylation and ATP generation. The mitochondrial genome does not recombine and is inherited through the maternal line because sperm does not contribute significant cytoplasmic components to the zygote. A noncoding region of the mitochondrial chromosome, referred to as D-loop, is highly polymorphic. This property, together with the absence of mtDNA recombination, makes it a valuable tool for studies tracing human migration and evolution, and it is also used for specific forensic applications.

Inherited mitochondrial disorders are transmitted in a matrilineal fashion; all children from an affected mother will inherit the disease, but it will not be transmitted from an affected father to his children (Fig. 62-11*D*). Alterations in the mtDNA affecting enzymes required for oxidative phosphorylation lead to reduction of ATP supply, generation of free radicals, and induction of apoptosis. Several syndromic disorders arising from mutations in the mitochondrial genome are known in humans and they affect both protein-coding and tRNA genes (Table 62-1 and Table 62-5). The broad clinical spectrum often involves (cardio)myopathies and encephalopathies because of the high dependence of these tissues on oxidative phosphorylation. The age of onset and the clinical course are highly variable because of the unusual mechanisms of mtDNA transmission, which replicates independently from nuclear DNA. During cell replication, the proportion of wild-type and mutant mitochondria can drift among different cells and tissues. The resulting heterogeneity in the proportion of mitochondria with and without a mutation is referred to as *heteroplasmia* and underlies the phenotypic variability that is characteristic of mitochondrial diseases.

Acquired somatic mutations in mitochondria are thought to be involved in several age-dependent degenerative disorders affecting predominantly muscle and the peripheral and central nervous system (e.g., Alzheimer's and Parkinson's disease). Establishing that a mtDNA alteration is causal for a clinical phenotype is challenging because of the high degree of polymorphism in mtDNA and the phenotypic variability characteristic of these disorders. Certain pharmacologic treatments may have an impact on mitochondria and/or their function.

TABLE 62-5 SELECTED MITOCHONDRIAL DISEASES

Disease/Syndrome	OMIM #
MELAS syndrome: mitochondrial myopathy with encephalopathy, lactacidosis, and stroke	540000
Leber's optic atrophy: hereditary optical neuropathy	535000
Kearns-Sayre syndrome (KSS): ophthalmoplegia, pigmental degeneration of the retina, cardiomyopathy	530000
MERRF syndrome: myoclonic epilepsy and ragged-red fibers	545000
Neurogenic muscular weakness with ataxia and retinitis pigmentosa (NARP)	551500
Progressive external ophthalmoplegia (CEOP)	258470
Pearson syndrome (PEAR): bone marrow and pancreatic failure	557000
Autosomal dominant inherited mitochondrial myopathy with mitochondrial deletion (ADMIMY)	157640
Somatic mutations in cytochrome *b* gene: exercise intolerance, lactic acidosis, complex III deficiency, muscle pain, ragged-red fibers	516020

For example, treatment with the antiretroviral compound azidothymidine (AZT) causes an acquired mitochondrial myopathy through depletion of muscular mtDNA.

MOSAICISM Mosaicism refers to the presence of two or more genetically distinct cell lines in the tissues of an individual. It results from a mutation that occurs during embryonic, fetal, or extrauterine development. The developmental stage at which the mutation arises will determine whether germ cells and/or somatic cells are involved. Chromosomal mosaicism results from non-disjunction at an early embryonic mitotic division, leading to the persistence of more than one cell line, as exemplified by some patients with Turner syndrome (Chap. 343). Somatic mosaicism is characterized by a patchy distribution of genetically altered somatic cells. The McCune-Albright syndrome, for example, is caused by activating mutations in the stimulatory G protein α ($G_s\alpha$) that occur early in development (Chap. 347). The clinical phenotype varies depending on the tissue distribution of the mutation; manifestations include ovarian cysts that secrete sex steroids and cause precocious puberty, polyostotic fibrous dysplasia, café-au-lait skin pigmentation, growth hormone–secreting pituitary adenomas, and hypersecreting autonomous thyroid nodules (Chap. 341).

X-INACTIVATION, IMPRINTING, AND UNIPARENTAL DISOMY According to traditional Mendelian principles, the parental origin of a mutant gene is irrelevant for the expression of the phenotype. There are, however, important exceptions to this rule. *X-inactivation* prevents the expression of most genes on one of the two X-chromosomes in every cell of a female. Gene inactivation also occurs on selected chromosomal regions of autosomes. This phenomenon, referred to as *genomic imprinting*, leads to inheritable preferential expression of one of the parental alleles. It is of pathophysiologic importance in disorders where the transmission of disease is dependent on the sex of the transmitting parent and, thus, plays an important role in the expression of certain genetic disorders. Two classic examples are the Prader-Willi syndrome and Angelman syndrome (Chap. 63). Prader-Willi syndrome is characterized by diminished fetal activity, obesity, hypotonia, mental retardation, short stature, and hypogonadotropic hypogonadism. Deletions of the paternal copy of the Prader-Willi locus located on the short arm of chromosome 15 result in a contiguous gene syndrome involving missing paternal copies of the *necdin* and *SNRPN* genes, among others. In contrast, patients with Angelman syndrome, characterized by mental retardation, seizures, ataxia, and hypotonia, have deletions involving the maternal copy of this region on chromosome 15. These two syndromes may also result from *uniparental disomy*. In this case, the syndromes are not caused by deletions on chromosome 15 but by the inheritance of either two maternal chromosomes (Prader-Willi syndrome) or two paternal chromosomes (Angelman syndrome).

Imprinting and the related phenomenon of allelic exclusion may be more common than currently documented, as it is difficult to examine

TABLE 62-6 SELECTED TRINUCLEOTIDE REPEAT DISORDERS

Disease	Locus	Repeat	Triplet Length (Normal/Disease)	Inheritance	Gene Product
X-chromosomal spinobulbar muscular atrophy (SBMA)	Xq11-q12	CAG	11–34/40–62	XR	Androgen receptor
Fragile X-syndrome (FRAXA)	Xq27.3	CGG	6–50/200–300	XR	FMR-1 protein
Fragile X-syndrome (FRAXE)	Xq28	GCC	6–25/>200	XR	FMR-2 protein
Dystrophia myotonica (DM)	19q13.2-q13.3	CTG	5–30/200–1000	AD, variable penetrance	Myotonin protein kinase
Huntington disease (HD)	4p16.3	CAG	6–34/37–180	AD	Huntingtin
Spinocerebellar ataxia type 1 (SCA1)	6p21.3-21.2	CAG	6–39/40–88	AD	Ataxin 1
Spinocerebellar ataxia type 2 (SCA2)	12q24.1	CAG	15–31/34–400	AD	Ataxin 2
Spinocerebellar ataxia type 3 (SCA3); Machado Joseph disease (MD)	14q21	CAG	13–36/55–86	AD	Ataxin 3
Spinocerebellar ataxia type 6 (SCA6, CACNAIA)	19p13.1-13.2	CAG	4–16/20–33	AD	Alpha 1A voltage-dependent L-type calcium channel
Spinocerebellar ataxia type 7 (SCA7)	3p21.1-p12	CAG	4–19/37 to >300	AD	Ataxin 7
Spinocerebellar ataxia type 12 (SCA12)	5q31	CAG	6–26/66–78	AD	Protein phosphatase 2A
Dentorubral pallidoluysiane atrophy (DRPLA)	12p	CAG	7–23/49–75	AD	Atrophin 1
Friedreich ataxia (FRDA1)	9q13-21	GAA	7–22/200–900	AR	Frataxin

Note: AD, autosomal dominant; AR, autosomal recessive; XR, X-linked recessive.

levels of mRNA expression from the maternal and paternal alleles in specific tissues or in individual cells. Genomic imprinting, or uniparental disomy, is involved in the pathogenesis of several other disorders and malignancies (Chap. 63). For example, hydatidiform moles contain a normal number of diploid chromosomes, but they are all of paternal origin. The opposite situation occurs in ovarian teratomata, with 46 chromosomes of maternal origin. Expression of the imprinted gene for insulin-like growth factor II (IGF-II) is involved in the pathogenesis of the cancer-predisposing Beckwith-Wiedemann syndrome (BWS) (Chap. 79). These children show somatic overgrowth with organomegalies and hemihypertrophy, and they have an increased risk of embryonal malignancies such as Wilm's tumor. Normally, only the paternally derived copy of the *IGF-II* gene is active and the maternal copy is inactive. Imprinting of the *IGF-II* gene is regulated by *H19*, which encodes an RNA transcript that is not translated into protein. Disruption or lack of *H19* methylation leads to a relaxation of *IGF-II* imprinting and expression of both alleles.

Meiotically and mitotically heritable changes in gene expression not associated with DNA sequence alterations are referred to as *epigenetic effects*. These changes involve DNA methylation, histone modifications, and RNA-mediated silencing, resulting in gene repression without a change in the coding sequence. Epigenetic alterations are increasingly recognized to play a role in human diseases such as cancer, mental retardation, hematologic disorders, and possibly in aging. For example, de novo methylation of CpG islands, regions of >500 bp in size with a GC content >55% in promoter regions that are normally unmethylated, is a hallmark of human cancers. Inhibitors of enzymes controlling epigenetic modifications such as histone deacetylases and DNA methyltransferases reverse gene silencing and represent a promising new group of antineoplastic agents.

SOMATIC MUTATIONS Cancer can be defined as a genetic disease at the cellular level (Chap. 79). Cancers are monoclonal in origin, indicating that they have arisen from a single precursor cell with one or several mutations in genes controlling growth (proliferation or apoptosis) and/or differentiation. These acquired somatic mutations are restricted to the tumor and its metastases and are not found in the surrounding normal tissue. The molecular alterations include dominant gain-of-function mutations in oncogenes, recessive loss-of-function mutations in tumor-suppressor genes and DNA repair genes, gene amplification, and chromosome rearrangements. Rarely, a single mutation in certain genes may be sufficient to transform a normal cell into a malignant cell. In most cancers, however, the development of a malignant phenotype requires several genetic alterations for the gradual progression from a normal cell to a cancerous cell, a phenomenon termed *multistep carcinogenesis* (Chaps. 79, 80). Most human tumors express telomerase, an enzyme formed of a protein and an RNA component, which adds telomere repeats at the ends of chromosomes during replication. This mechanism impedes shortening of the telomers, which is associated with senescence in normal cells, and is associated with enhanced replicative capacity in cancer cells. Telomerase inhibitors may provide a novel strategy for treating advanced human cancers.

In many cancer syndromes, there is an inherited *predisposition* to tumor formation. In these instances, a germline mutation is inherited in an autosomal dominant fashion inactivating one allele of an autosomal tumor-suppressor gene. If the second allele is inactivated by a somatic mutation or by epigenetic silencing in a given cell, this will lead to neoplastic growth (Knudson two-hit model). Thus, the defective allele in the germline is transmitted in a dominant mode, though tumorigenesis results from a biallelic loss of the tumor-suppressor gene in an affected tissue. The classic example to illustrate this phenomenon is retinoblastoma, which can occur as a sporadic or hereditary tumor. In sporadic retinoblastoma, both copies of the retinoblastoma (*RB*) gene are inactivated through two somatic events. In hereditary retinoblastoma, one mutated or deleted *RB* allele is inherited in an autosomal dominant manner and the second allele is inactivated by a subsequent somatic mutation. This two-hit model applies to other inherited cancer syndromes such as MEN-1 (Chap. 345) and neurofibromatosis type 2 (Chap. 374).

NUCLEOTIDE REPEAT EXPANSION DISORDERS Several diseases are associated with an increase in the number of nucleotide repeats above a certain threshold (Table 62-6). The repeats are sometimes located within the coding region of the genes, as in Huntington disease or the X-linked form of spinal and bulbar muscular atrophy (SBMA, Kennedy syndrome). In other instances, the repeats probably alter gene regulatory sequences. If an expansion is present, the DNA fragment is unstable and tends to expand further during cell division. The length of the nucleotide repeat often correlates with the severity of the disease. When repeat length increases from one generation to the next, disease manifestations may worsen or be observed at an earlier age; this phenomenon is referred to as *anticipation*. In Huntington disease, for example, there is a correlation between age of onset and length of the triplet codon expansion (Chap. 360). Anticipation has also been documented in other diseases caused by dynamic mutations in trinucleotide repeats (Table 62-6). The repeat number may also vary in a tissue-specific manner. In myotonic dystrophy, the CTG repeat may be tenfold greater in muscle tissue than in lymphocytes (Chap. 382).

Complex Genetic Disorders The expression of many common diseases such as cardiovascular disease, hypertension, diabetes, asthma, psychiatric disorders, and certain cancers is determined by a combination of ge-

TABLE 62-7 GENES AND LOCI INVOLVED IN MONO- AND POLYGENIC FORMS OF DIABETES

Disorder	Genes or Susceptibility Locus	Chromosomal Location	Other Factors
Monogenic forms of diabetes			
MODY 1	HNF4α (hepatocyte nuclear factor 4α)	20q12-q13.1	AD inheritance
MODY 1	GCK (glucokinase)	7p15-p13	
MODY 1	HNF1α (hepatocyte nuclear factor 1α)	12q24.2	
MODY 1	IPF1 (insulin receptor substrate)	13q12.1	
MODY 5 (renal cysts, diabetes)	HNF1β (hepatocyte nuclear factor 1β)	17cen-q21.3	
MODY 6	NeuroD1 (neurogenic differention factor 1)	2q32	
Diabetes mellitus type 2; loci and genes linked and/or associated with susceptibility for diabetes mellitus type 2	Genes and loci identified by linkage/association studies		
	CPN10 (Calpain-10)	2q37.3	Diet

netic background, environmental factors, and lifestyle. A trait is called *polygenic* if multiple genes contribute to the phenotype or *multifactorial* if multiple genes are assumed to interact with environmental factors. Genetic models for these complex traits need to account for genetic heterogeneity and interactions with other genes and the environment. Complex genetic traits may be influenced by modifying genes that are not linked to the main gene involved in the pathogenesis of the trait. This type of gene-gene interaction, or *epistasis*, plays an important role in polygenic traits that require the simultaneous presence of variations in multiple genes to result in a pathologic phenotype.

Type 2 diabetes mellitus provides a paradigm for considering a multifactorial disorder, as genetic, nutritional, and lifestyle factors are intimately interrelated in disease pathogenesis (Table 62-7) (Chap. 338). The identification of genetic variations and environmental factors that either predispose to or protect against disease is essential for predicting disease risk, designing preventive strategies, and developing novel therapeutic approaches. The study of rare monogenic diseases may provide insight into some of genetic and molecular mechanisms important in the pathogenesis of complex diseases. For example, the identification of the hepatocyte nuclear factor α (HNFα) in maturity-onset of diabetes type 4 defined it as a *candidate gene* in the pathogenesis of diabetes mellitus type 2 (Tables 62-2 and 62-8). Genome scans have identified various loci that may be associated with susceptibility to development of diabetes mellitus in certain populations. Efforts to identify susceptibility genes require very large sample sizes, and positive results may depend on ethnicity, ascertainment criteria, and statistical analysis. Association studies analyzing the potential influence of (biologically functional) SNPs and SNP haplotypes on a particular phenotype are a promising approach for the detection of involved genes.

Linkage and Association Studies There are two primary strategies for mapping genes that cause or increase susceptibility to human disease: (1) classic linkage can be performed based on a known genetic model or, when the model is unknown, by studying pairs of affected relatives; or (2) disease genes can be mapped using allelic association studies (Table 62-8).

GENETIC LINKAGE *Genetic linkage* refers to the fact that genes are physically connected, or linked, to one another along the chromosomes. Two fundamental principles are essential for understanding the concept of linkage: (1) when two genes are close together on a chromosome, they are usually transmitted together, unless a recombination event separates them (Figs. 62-3, 62-8); and (2) the odds of a crossover, or recombination event, between two linked genes is proportional to the distance that separates them. Thus, genes that are further apart are more likely to undergo a recombination event than genes that are very close together. The detection of chromosomal loci that segregate with a disease by linkage can be used to identify the gene responsible for the disease (*positional cloning*) and to predict the odds of disease gene transmission in genetic counseling.

Polymorphisms are essential for linkage studies because they provide a means to distinguish the maternal and paternal chromosomes in an individual. On average, 1 out of every 1000 bp varies from one person to the next. Although this degree of variation seems low (99.9% identical), it means that >3 million sequence differences exist between any two unrelated individuals and the probability that the sequence at such loci will differ on the two homologous chromosomes is high (often >70–90%). These sequence variations include VNTRs, short tandem repeats (STRs), and SNPs. Most STRs, also called *polymorphic microsatellite markers*, consist of di-, tri-, or tetranucleotide repeats that can be measured readily using PCR (Fig. 62-12). Characterization of SNPs, using DNA chips, provides an important new tool for comprehensive analyses of genetic variation, linkage, and association studies. Although these sequence variations usually have no apparent functional consequences, they provide much of the basis for variation in genetic traits.

TABLE 62-8 GENETIC APPROACHES FOR IDENTIFYING DISEASE GENES

Method	Indications and Advantages	Limitations
Linkage Studies		
Classical linkage analysis (parametric methods)	Analysis of monogenic traits Suitable for genome scan Control population not required Useful for multifactorial disorders in isolated populations	Difficult to collect large informative pedigrees Difficult to obtain sufficient statistical power for complex traits
Allele-sharing methods (nonparametric methods) Affected sib and relative pair analyses Sib pair analysis	Suitable for identification of susceptibility genes in polygenic and multifactorial disorders Suitable for genome scan Control population not required if allele frequencies are known Statistical power can be increased by including parents and relatives	Difficult to collect sufficient number of subjects Difficult to obtain sufficient statistical power for complex traits Reduced power compared to classical linkage, but not sensitive to specification of genetic mode
Association Studies		
Case-control studies Linkage disequilibrium Transmission disequilibrium test (TDT) Whole-genome association studies	Suitable for identification of susceptibility genes in polygenic and multifactorial disorders Suitable for testing specific allelic variants of known candidate loci Facilitated by HapMap data, making whole-genome studies more feasible Does not necessarily need relatives	Requires large sample size and matched control population False-positive results in the absence of suitable control population Candidate gene approach does not permit to detect novel genes and pathways Whole-genome association studies very expensive

In order to identify a chromosomal locus that segregates with a disease, it is necessary to characterize polymorphic DNA markers from affected and unaffected individuals of one or several pedigrees. One can then assess whether certain marker alleles cosegregate with the disease. Markers that are closest to the disease gene are less likely to undergo recombination events and therefore receive a higher linkage score. Linkage is expressed as a lod (logarithm of odds) score—the ratio of the probability that the disease and marker loci are linked rather than unlinked. Lod scores of +3 (1000:1) are generally accepted as supporting linkage, whereas a score of –2 is consistent with the absence of linkage.

An example of the use of linkage analysis is shown in Fig. 62-12. In this case, the gene for the autosomal dominant disorder MEN-1 is known to be located on chromosome 11q13. Using positional cloning, the *MEN1* gene was identified and shown to encode menin, a tumor suppressor. Affected individuals inherit a mutant form of the *MEN1* gene, predisposing them to certain types of tumors (parathyroid, pituitary, pancreatic islet) (Chap. 345). In the tissues that develop a tumor, a "second hit" occurs in the normal copy of the *MEN1* gene. This somatic mutation may be a point mutation, a microdeletion, or loss of a chromosomal fragment (detected as loss of heterozygosity, LOH). Within a given family, linkage to the *MEN1* gene locus can be assessed without necessarily knowing

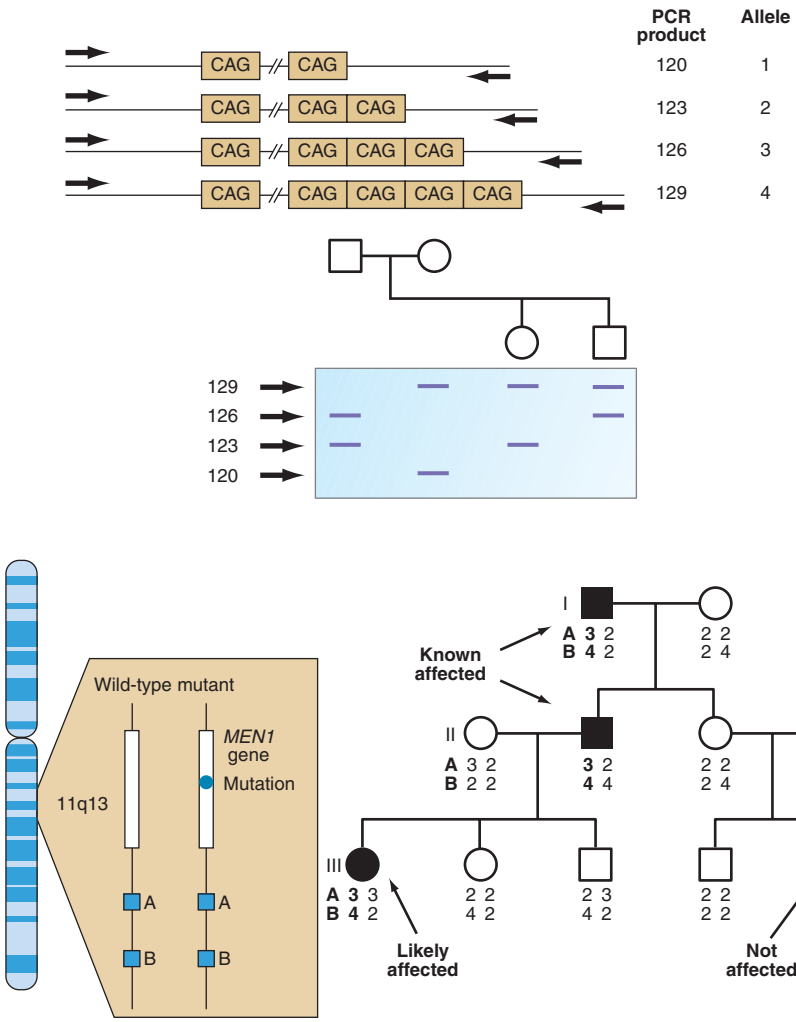

FIGURE 62-12 CAG repeat length and linkage analysis in multiple endocrine neoplasia (MEN) type 1. ***Upper panel.*** Detection of different alleles using polymorphic microsatellite markers. The example depicts a CAG trinucleotide repeat. PCR with primers flanking the polymorphic region results in products of variable length, depending on the number of CAG repeats. After characterization of the alleles in the parents, transmission of the paternal and maternal alleles can be determined. ***Lower panel.*** Genotype analysis using microsatellite markers in a family with MEN-1. Two microsatellite markers, A and B, are located in close proximity to the *MEN1* gene on chromosome 11q13. For each individual, the A and B alleles have been determined. Based on this analysis, the genotype A3,B4 is linked to the disease because it occurs in the two affected individuals I-1 and II-1 but not in unaffected siblings. Because the disease allele is linked to A3,B4 within the affected family, it is likely that the individual III-1 is a carrier of the mutated *MEN1* gene. Although III-5 also has the A3,B4 genotype, she has inherited the allele from her unaffected father (II-4), who is not related to the original family. The A3,B4 genotype is only associated with MEN-1 in the original family, but not in the general population. Therefore, individual III-5 is not at risk for developing the disease.

the specific mutation in the *MEN1* gene. Using polymorphic STRs that are close to the *MEN1* gene, one can assess transmission of the different *MEN1* alleles and compare this pattern to development of the disorder to determine which allele is associated with risk of MEN-1. In the pedigree shown, the affected grandfather in generation I carries alleles 3 and 4 on the chromosome with the mutated *MEN1* gene and alleles 2 and 2 on his other chromosome 11. Consistent with linkage of the 3/4 genotype to the *MEN1* locus, his son in generation II is affected, whereas his daughter (who inherits the 2/2 genotype from her father) is unaffected. In the third generation, transmission of the 3/4 genotype indicates risk of developing MEN-1, assuming that no genetic recombination between the 3/4 alleles and the *MEN1* gene has occurred. After a specific mutation in the *MEN1* gene is identified within a family, it is possible to track transmission of the mutation itself, thereby eliminating uncertainty caused by recombination.

ALLELIC ASSOCIATION, LINKAGE DISEQUILIBRIUM, AND HAPLOTYPES *Allelic association* refers to a situation in which the frequency of an allele is significantly increased or decreased in individuals affected by a particular disease in comparison to controls. Linkage and association differ in several aspects. Genetic linkage is demonstrable in families or sibships. Association studies, on the other hand, compare a population of affected individuals with a control population. Association studies can be performed as case-control studies that include unrelated affected individuals and matched controls, or as family-based studies that compare the frequencies of alleles transmitted or not transmitted to affected children.

Allelic association studies are particularly useful for identifying susceptibility genes in complex diseases. When alleles at two loci occur more frequently in combination than would be predicted (based on known allele frequencies and recombination fractions), they are said to be in *linkage disequilibrium*. In Fig. 62-13, a mutation, Z, has occurred at a susceptibility locus where the normal allele is Y. The mutation is in close proximity to a genetic polymorphism with allele A or B. With time, the chromosomes carrying the A and Z alleles accumulate and represent 10% of the chromosomes in the population. The fact that the disease susceptibility gene, Z, is found preferentially, or exclusively, in association with the A allele illustrates linkage disequilibrium. Though not all chromosomes carrying the A allele carry the disease gene, the A allele is associated with an increased risk because of its possible association with the Z allele. This model implies that it may be possible in the future to identify Z directly to provide a more accurate prediction of disease susceptibility. Evidence for linkage disequilibrium can be helpful in mapping disease genes because it suggests that the two loci, in this case A and Z, are tightly linked.

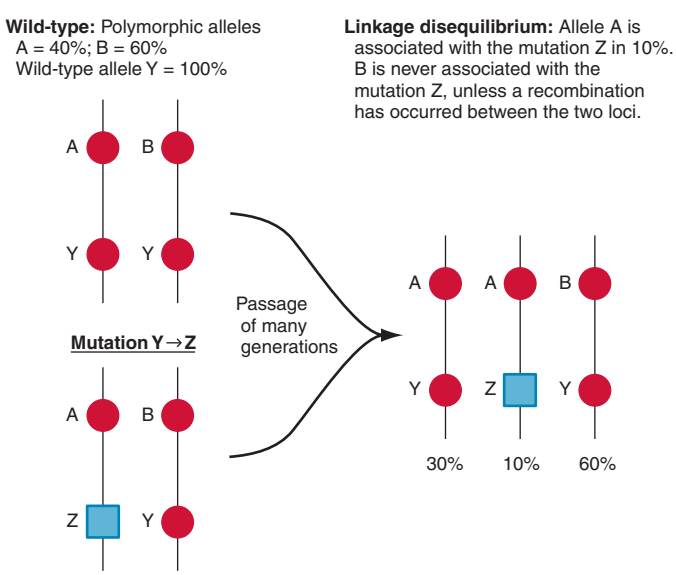

FIGURE 62-13 **Linkage disequilibrium.**

Detecting the genetic factors contributing to the pathogenesis of common complex disorders remains a great challenge. In many instances, these are low-penetrance alleles, i.e., variations that individually only have a subtle effect on disease development, and they can only be identified by unbiased genome-wide association studies. Most variants are in noncoding or regulatory sequences but do not alter protein structure. The analysis of complex disorders is further complicated by ethnic differences in disease prevalence, differences in allele frequencies in known susceptibility genes among different populations, locus and allelic heterogeneity, gene-gene and gene-environment interactions, and the possibility of phenocopies. The HapMap Project is now making genome-wide association studies for the characterization of complex disorders more realistic. Adjacent SNPs are inherited together as blocks, and these blocks can be identified by genotyping selected marker SNPs, so-called *Tag SNPs*, thereby reducing cost and workload (Fig. 62-8). The availability of this information permits the characterization of a limited number of SNPs to identify the set of haplotypes present in an individual, e.g., in cases and controls. This, in turn, permits genome-wide association studies by searching for associations of certain haplotypes with a disease phenotype of interest, an essential step for unraveling the genetic factors contributing to complex disorders.

POPULATION GENETICS In population genetics, the focus changes from alterations in an individual's genome to the distribution pattern of different genotypes in the population. In a case where there are only two alleles, A and a, the frequency of the genotypes will be $p^2 + 2pq + q^2 = 1$, with p^2 corresponding to the frequency of AA, $2pq$ to the frequency of Aa, and q^2 to aa. When the frequency of an allele is known, the frequency of the genotype can be calculated. Alternatively, one can determine an allele frequency, if the genotype frequency has been determined.

Allele frequencies vary among ethnic groups and geographical regions. For example, heterozygous mutations in the *CFTR* gene are relatively common in populations of European origin but are rare in the African population. Allele frequencies may vary because certain allelic variants confer a selective advantage. For example, heterozygotes for the sickle cell mutation, which is particularly common in West Africa, are more resistant to malarial infection because the erythrocytes of heterozygotes provide a less favorable environment for *Plasmodium* parasites. Though homozygosity for the sickle cell gene is associated with severe anemia and sickle crises (Chap. 99), heterozygotes have a higher probability of survival because of the reduced morbidity and mortality from malaria; this phenomenon has led to an increased frequency of the mutant allele. Recessive conditions are more prevalent in geographically isolated populations because of the more restricted gene pool.

APPROACH TO THE PATIENT: Inherited Disorders

For the practicing clinician, the family history remains an essential step in recognizing the possibility of a hereditary component. When taking the history, it is useful to draw a detailed pedigree of the first-degree relatives (e.g., parents, siblings, and children), since they share 50% of genes with the patient. Standard symbols for pedigrees are depicted in Fig. 62-9. The family history should include information about ethnic background, age, health status, and (infant) deaths. Next, the physician should explore whether there is a family history of the same or related illnesses to the current problem. An inquiry focused on commonly occurring disorders such as cancers, heart disease, and diabetes mellitus should follow. Because of the possibility of age-dependent expressivity and penetrance, the family history will need intermittent updating. If the findings suggest a genetic disorder, the clinician will have to assess whether some of the patient's relatives may be at risk of carrying or transmitting the disease. In this circumstance, it is useful to confirm and extend the pedigree based on input from several family members. This information may form the basis for carrier detection, genetic

counseling, early intervention, and prevention of a disease in relatives of the index patient (Chap. 64).

In instances where a diagnosis at the molecular level may be relevant, the physician will have to identify an appropriate laboratory that can perform the test. Genetic testing is becoming more readily available through commercial laboratories. For uncommon disorders, the test may only be performed in a specialized research laboratory. Approved laboratories offering testing for inherited disorders can be identified in continuously updated on-line resources (GeneTests; Table 62-1). If genetic testing is considered, the patient and the family should be informed about the potential implications of positive results, including psychological distress and the possibility of discrimination. The patient or caretakers should be informed about the meaning of a negative result, technical limitations, and the possibility of false-negative and inconclusive results. For these reasons, genetic testing should only be performed after obtaining *informed consent*. Published ethical guidelines address the specific aspects that should be considered when testing children and adolescents. Genetic testing should usually be limited to situations in which the results may have an impact on the medical management.

IDENTIFYING THE DISEASE-CAUSING GENE *Genomic medicine* aims to enhance the quality of medical care through the use of genotypic analysis (DNA testing) to identify genetic predisposition to disease, to select more specific pharmacotherapy, and to design individualized medical care based on genotype. Genotype can be deduced by analysis of protein (e.g., hemoglobin, apoprotein E), mRNA, or DNA. However, technological advances have made DNA analysis particularly useful because it can be readily applied to all but the largest genes (Fig. 62-14).

DNA testing is performed by mutational analysis or linkage studies in individuals at risk for a genetic disorder known to be present in a family. Mass screening programs require tests of high sensitivity and specificity to be cost-effective. Prerequisites for the success of genetic screening programs include the following: that the disorder is potentially serious; that it can be influenced at a presymptomatic stage by changes in behavior, diet, and/or pharmaceutical manipulations; and that the screening does not result in any harm or discrimination. Screening in Jewish populations for the autosomal recessive neurodegenerative storage disease Tay-Sachs has reduced the number of affected individuals. In contrast, screening for sickle cell trait/disease in African Americans has led to unanticipated problems of discrimination by health insurers and employers. Mass screening programs harbor additional potential problems. For example, screening for the most common genetic alteration in cystic fibrosis, the ΔF508 mutation with a frequency of ~70% in northern Europe, is feasible and seems to be effective. One has to keep in mind, however, that there is pronounced allelic heterogeneity and that the disease can be caused by >1400 other mutations. The search for these less common mutations would substantially increase costs but not the effectiveness of the screening program as a whole. Occupational screening programs aim to detect individuals with increased risk for certain professional activities (e.g., α_1 antitrypsin deficiency and smoke or dust exposure).

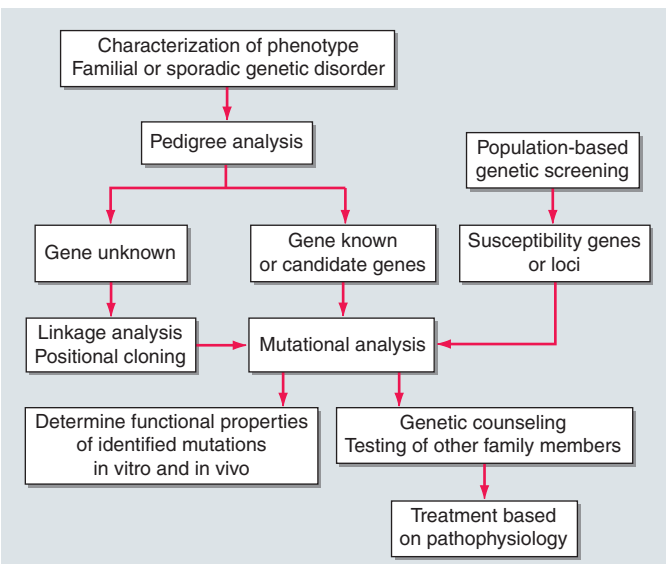

FIGURE 62-14 Approach to genetic disease.

Mutational Analyses DNA sequence analysis is increasingly used as a diagnostic tool and has significantly enhanced diagnostic accuracy. It is used for determining carrier status and for prenatal testing in monogenic disorders (Chap. 64). Numerous techniques are available for the detection of mutations (Table 62-9). In a very broad sense, one can distinguish between techniques that allow for screening the absence or presence of known mutations (screening mode) or techniques that definitively characterize mutations. Analyses of large alterations in the genome are possible using classic methods such as cytogenetics, fluorescent in situ hybridization (FISH), and Southern blotting (Chap. 63), as well as more sensitive novel techniques that search for multiple single exon deletions or duplications.

More discrete sequence alterations rely heavily on the use of the PCR, which allows rapid gene amplification and analysis. Moreover, PCR makes it possible to perform genetic testing and mutational analysis with small amounts of DNA extracted from leukocytes or even from single cells, buccal cells, or hair roots. Screening for point mutations can be performed by numerous methods (Table 62-9); most are based on the recognition of mismatches between nucleic acid duplexes, electrophoretic separation of single- or double-stranded DNA, or sequencing of DNA fragments amplified by PCR. DNA sequencing can be performed directly on PCR products or on fragments cloned into plasmid vectors amplified in bacterial host cells.

RT-PCR may be useful to detect absent or reduced levels of mRNA expression due to a mutated allele. Protein truncation tests (PTT) can be used to detect the broad array of mutations that result in premature termination of a polypeptide during its synthesis. The isolated cDNA is transcribed and translated in vitro, and the proteins are analyzed by gel electrophoresis. Comparison of electrophoretic mobility with the wild-type protein allows detection of truncated mutants.

The majority of traditional diagnostic methods are gel-based. Novel technologies for the analysis of mutations, genotyping, large-scale sequencing, and mRNA expression profiles are in rapid development. DNA chip technologies allow hybridization of DNA or RNA to hundreds of thousands of probes simultaneously. Microarrays are being used clinically for mutational analysis of several human disease genes, as well as for the identification of viral sequence variations. Together with the knowledge gained from the HGP, these technologies provide the foundation to expand from a focus on single genes to analyses at the scale of the genome. Faster and cheaper sequencing technologies are under development, and it has been anticipated that sequencing the whole genome of an individual for a cost of ≤$1000 will become a reality within this decade. The availability of comprehensive individual sequence information is expected to have a significant impact on medical care and preventative strategies, but it also raises ethical and legal concerns how such information may be used by insurers and employers.

A general algorithm for the approach to mutational analysis is outlined in Fig. 62-14. The importance of a detailed clinical phenotype cannot be overemphasized. This is the step where one should also consider the possibility of genetic heterogeneity and phenocopies. If obvious candidate genes are suggested by the phenotype, they can be analyzed directly. After identification of a mutation, it is essential to demonstrate that it segregates with the phenotype. The functional characterization of novel mutations is labor inten-

TABLE 62-9 METHODS USED FOR THE DETECTION OF MUTATIONS

Method	Principle	Type of Mutation Detected
Commonly Used Techniques		
Cytogenetic analysis	Unique visual appearance of various chromosomes	Numerical or structural abnormalities in chromosomes
Fluorescent in situ hybridization (FISH)	Hybridization to chromosomes with fluorescently labeled probes	Numerical or structural abnormalities in chromosomes
Southern blot	Hybridization with genomic probe or cDNA probe after digestion of high molecular DNA	Large deletion, insertion, rearrangement, expansions of triplet repeat, amplification
Polymerase chain reaction (PCR)	Amplification of DNA segment	Expansion of triplet repeats, variable number of tandem repeats (VNTR), gene rearrangements, translocations; prepare DNA for other mutation methods
Reverse transcriptase PCR (RT-PCR)	Reverse transcription, amplification of DNA segment → absence or reduction of mRNA transcription	Analyze expressed mRNA (cDNA) sequence; detect loss of expression
DNA sequencing	Direct sequencing of PCR products Sequencing of DNA segments cloned into plasmid vectors	Point mutations, small deletions and insertions
Restriction fragment polymorphism (RFLP)	Detection of altered restriction pattern of genomic DNA (Southern blot) or PCR products	Point mutations, small deletions and insertions
Other Techniques		
Single-strand conformational polymorphism (SSCP)	PCR of DNA segment: Mutations result in conformational change and altered mobility	Point mutations, small deletions and insertions
Denaturing gradient gel electrophoresis (DGGE)	PCR of DNA segment: Mutations result in conformational change and altered mobility	Point mutations, small deletions and insertions
RNAse cleavage	Cleavage of mismatch between mutated and wild-type sequence	Point mutations, small deletions and insertions
Oligonucleotide specific hybridization (OSH)	Hybridization of PCR products to wild-type or mutated oligonucleotides immobilized on chips or slides	Point mutations, small deletions and insertions
Microarrays	Hybridization of PCR products to wild-type or mutated oligonucleotides	Point mutations, small deletions and insertions Genotyping of SNPs
Protein truncation test (PTT)	Transcription/translation of cDNA isolated from tissue sample	Mutations leading to premature truncations
Pyrosequencing	Clonal amplification of single DNA fragments on microparticles followed by massive parallel sequencing	Sequencing of whole genomes of microorganisms, resequencing of amplicons
Multiplex ligation-dependent probe amplification (MLPA)	Quantification of PCR-generated amplicons reflecting the number of copies of a specific DNA sequence	Copy number variations

sive and may require analyses in vitro or in transgenic models in order to document the relevance of the genetic alteration.

Prenatal diagnosis of numerous genetic diseases in instances with a high risk for certain disorders is now possible by direct DNA analysis. *Amniocentesis* involves the removal of a small amount of amniotic fluid, usually at 16 weeks of gestation. Cells can be collected and submitted for karyotype analyses, FISH, and mutational analysis of selected genes. The main indications for amniocentesis include advanced maternal age above age 35, abnormal serum triple marker test (α-fetoprotein, β human chorionic gonadotropin, pregnancy-associated plasma protein A, or unconjugated estriol), a family history of chromosomal abnormalities, or a Mendelian disorder amenable to genetic testing. Prenatal diagnosis can also be performed by *chorionic villus sampling* (CVS), in which a small amount of the chorion is removed by a transcervical or transabdominal biopsy. Chromosomes and DNA obtained from these cells can be submitted for cytogenetic and mutational analyses. CVS can be performed earlier in gestation (weeks 9–12) than amniocentesis, an aspect that may be of relevance when termination of pregnancy is a consideration. Later in pregnancy, beginning at about 18 weeks of gestation, percutaneous umbilical blood sampling (PUBS) permits collection of fetal blood for lymphocyte culture and analysis. In combination with in vitro fertilization (IVF) techniques, it is even possible to perform genetic diagnoses in a single cell removed from the four- to eight-cell embryo or to analyze the first polar body from an oocyte. Preconceptual diagnosis thereby avoids therapeutic abortions but is extremely costly and labor intensive. Lastly, it has to be emphasized that excluding a specific disorder by any of these approaches is never equivalent to the assurance of having a normal child.

Mutations in certain cancer susceptibility genes, such as *BRCA1* and *BRCA2*, may identify individuals with an increased risk for the development of malignancies and result in risk-reducing interventions. The detection of mutations is an important diagnostic and prognostic tool in leukemias and lymphomas. The demonstration of the presence or absence of mutations and polymorphisms is also relevant for the rapidly evolving field of pharmacogenomics, including the identification of differences in drug treatment response or metabolism as a function of genetic background. For example, the thiopurine drugs 6-mercaptopurine and azathioprine are commonly used cytotoxic and immunosuppressive agents. They are metabolized by thiopurine methyltransferase (TPMT), an enzyme with variable activity associated with genetic polymorphisms in 10% of Caucasians and complete deficiency in about 1/300 individuals. Patients with intermediate or deficient TPMT activity are at risk for excessive toxicity, including fatal myelosuppression. Characterization of these polymorphisms allows mercaptopurine doses to be modified based on TPMT genotype. Pharmacogenomics may increasingly permit individualized drug therapy, improve drug effectiveness, reduce adverse side effects, and provide cost-effective pharmaceutical care.

63 Chromosome Disorders

Terry Hassold, Stuart Schwartz

In humans, the normal diploid number of chromosomes is 46, consisting of 22 pairs of autosomal chromosomes (numbered 1–22 in decreasing size) and one pair of sex chromosomes (XX in females and XY in males). The genome is estimated to contain between 30,000 and 40,000 genes. Even the smallest autosome contains between 200 and 300 genes. Not surprisingly, duplications or deletions of chromosomes, or even small chromosome segments, have profound consequences on normal gene expression, leading to severe developmental and physiologic abnormalities.

Deviations in number or structure of the 46 human chromosomes are astonishingly common, despite severe deleterious consequences. Chromosomal disorders occur in an estimated 10–25% of all pregnancies. They are the leading cause of fetal loss and, among pregnancies surviving to term, the leading known cause of birth defects and mental retardation.

In recent years, the practice of cytogenetics has shifted from conventional cytogenetic methodology to a union of cytogenetic and molecular techniques. Formerly the province of research laboratories, fluorescence in situ hybridization (FISH) and related molecular cytogenetic technologies have been incorporated into everyday practice in clinical laboratories. As a result, there is an increased appreciation of the importance of "subtle" constitutional cytogenetic abnormalities, such as microdeletions and imprinting disorders, as well as previously recognized translocations and disorders of chromosome number.

VISUALIZING CHROMOSOMES

CONVENTIONAL CYTOGENETIC ANALYSIS

In theory, chromosome preparations can be obtained from any actively dividing tissue by causing the cells to arrest in metaphase, the stage of the cell cycle when chromosomes are maximally condensed. In practice, only a small number of tissues are used for routine chromosome analysis: amniocytes or chorionic villi for prenatal testing and blood, bone marrow, or skin fibroblasts for postnatal studies. Samples of blood, bone marrow, and chorionic villi can be processed using short-term culture techniques that yield results in 1–3 days. Analysis of other tissue types typically involves long-term cell culture, requiring 1–3 weeks of processing before cytogenetic analysis is possible.

Cells are isolated at metaphase or prometaphase and treated chemically or enzymatically to reveal chromosome "bands" (Fig. 63-1). Analysis of the number of chromosomes in the cell and the distribution of bands on individual chromosomes allow the identification of numerical or structural abnormalities. This strategy is useful for characterizing the normal chromosome complement and determining the incidence and types of major chromosome abnormalities.

Each human chromosome contains two specialized structures: a centromere and two telomeres. The centromere, or primary constriction, divides the chromosome into short (p) and long (q) arms and is responsible for the segregation of chromosomes during cell division. The telomeres, or chromosome ends, "cap" the p and q arms and are important for allowing DNA replication at the ends of the chromosomes. Prior to DNA replication, each chromosome consists of a single chromatid copy of the DNA double helix. After DNA replication and continuing until the time of cell division (including metaphase, when chromosomes are typically visualized), each chromosome consists of two identical sister chromatids (Fig. 63-1).

MOLECULAR CYTOGENETICS

The introduction of FISH methodologies in the late 1980s revolutionized the field of cytogenetics. In principle, FISH is similar to other DNA-DNA hybridization methodologies. The probe is labeled with a hapten, such as biotin or digoxigenin, to allow detection with a fluorophore (e.g., FITC or rhodamine). After the hybridization step, the specimen is counter-stained and the preparations are visualized with a fluorescence microscope.

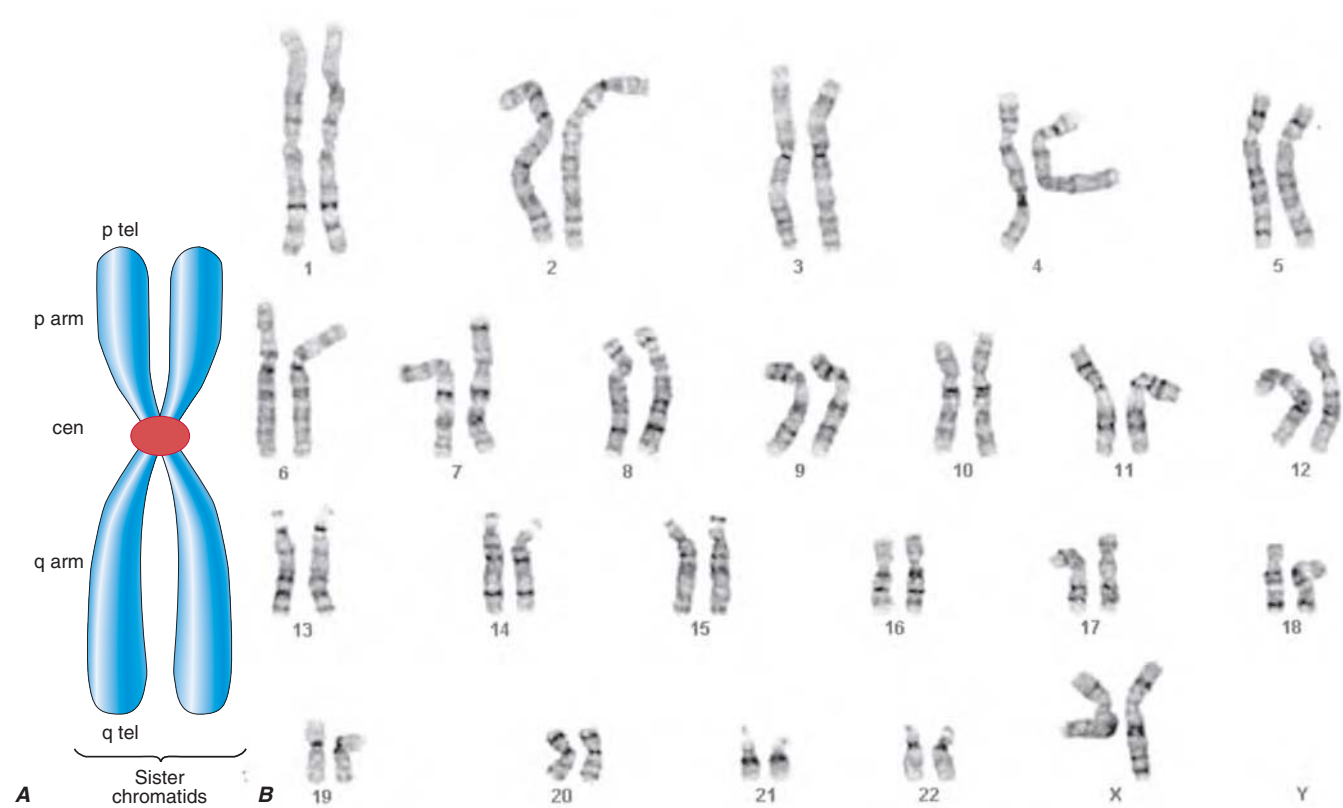

FIGURE 63-1 ***A.*** An idealized human chromosome, showing the centromere (cen), long (q) and short (p) arms, and telomeres (tel). ***B.*** A G-banded human karyotype from a normal (46,XX) female.

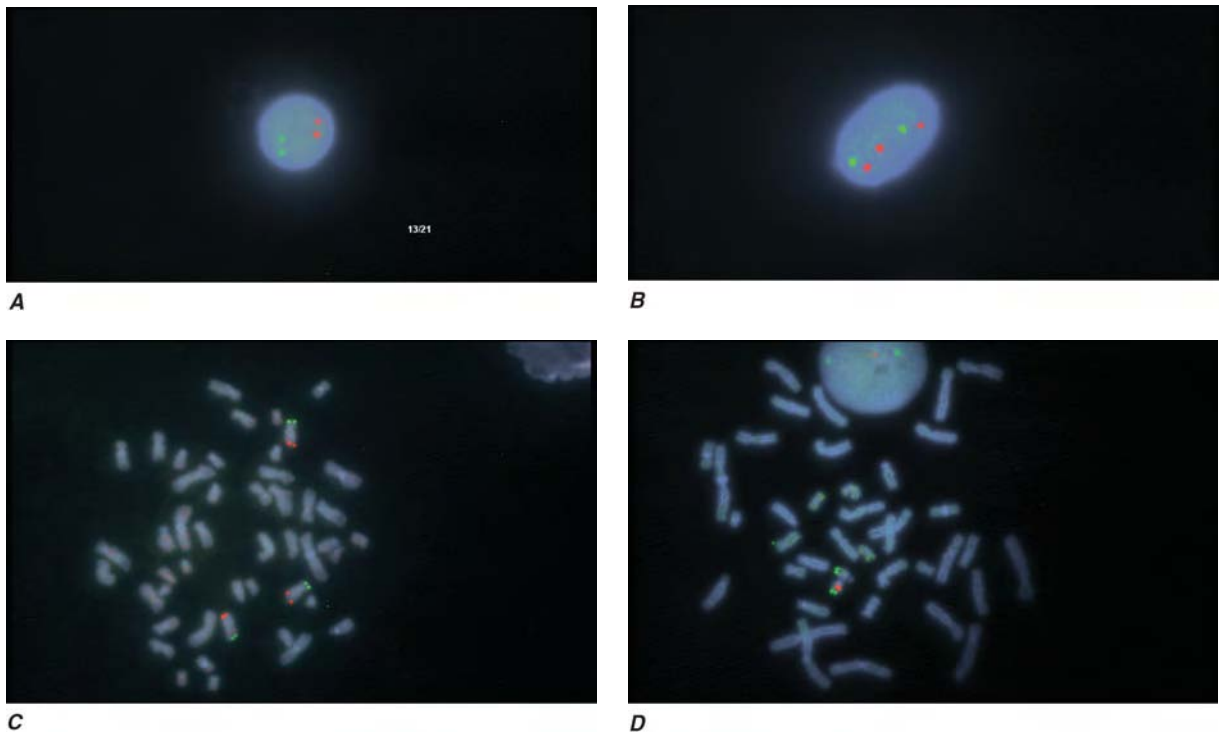

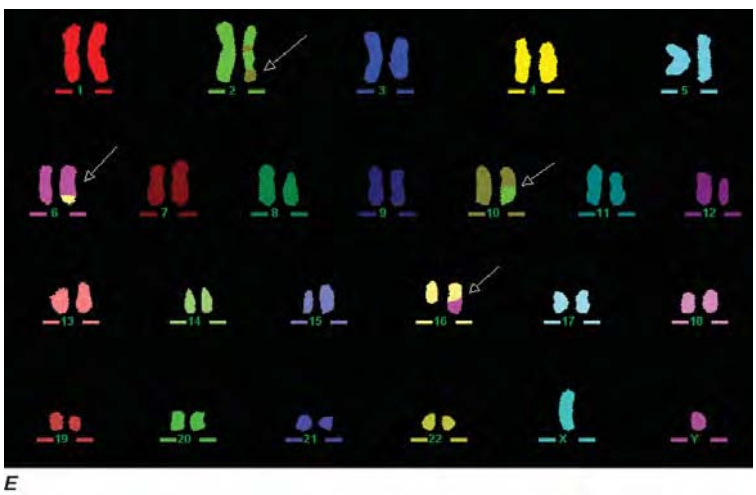

FIGURE 63-2 Examples of different applications of fluorescence in situ hybridization (FISH) to human metaphase and interphase preparations. ***A, B.*** Aneuploidy detection: Interphase FISH using chromosome 13 (green) and chromosome 21 (red) unique sequence probes on interphase cells from direct amniotic fluid preparations. In "A" (a normal cell), two signals for both chromosomes 13 and 21 are seen; in "B," three signals for chromosome 21 are seen, indicating trisomy 21 in the fetus. ***C.*** Aneuploidy detection: Two-color FISH with telomere probes from the short arm (green) and the long arm (red) of chromosome 8. Hybridization with these probes shows fluorescence of both probes to three separate chromosomes, indicating the presence of trisomy 8 in this individual. ***D.*** Microdeletion detection: Two-color FISH is used to detect a microdeletion of chromosome 22 associated with velocardiofacial (VCF) syndrome. A probe for ARSA (a locus on the distal portion of chromosome 22, visualized as a green signal) is observed on both chromosomes 22. However, a probe for TUPLE1 (a locus within the VCF region of chromosome 22, visualized in red) hybridizes to only the normal chromosome. ***E.*** Characterization of structural rearrangements: M-FISH (multicolor FISH) is used to detect a complex chromosome rearrangement involving a translocation between chromosome 6 and 16, as well as a translocation and inversion involving chromosomes 2 and 10.

Types of FISH Probes A variety of probes are available for use with FISH, including chromosome-specific paints (chromosome libraries), repetitive probes, and single-copy probes (Fig. 63-2). Chromosome libraries hybridize to sequences that span the entirety of the chromosome from which they are derived and, as a result, they can be used to "paint" individual chromosomes.

Repetitive probes recognize amplified DNA sequences present in chromosomes. The most common are α-satellite DNA probes that are complementary to DNA sequences found at the centromeric regions of all human chromosomes. A vast number of *single-copy probes* are now available as a result of the human genome project. These probes can be as small as 1 kb, though normally they are much larger and are packaged into cosmids (40 kb), bacterial artificial chromosomes (BACs) or P1 clones (100–200 kb), or yeast artificial chromosomes (YACs) (1–2 Mb). Many are available commercially, including probes for a variety of microdeletion syndromes and for subtelomeric regions of individual chromosomes.

Applications of FISH The majority of FISH applications involve hybridization of one or two probes of interest as an adjunctive procedure to conventional chromosomal banding techniques. In this regard, FISH can be utilized to identify specific chromosomes, characterize de novo duplications or deletions, and clarify subtle chromosomal rearrangements. Its greatest utilization, however, is in the detection of microdeletions (see below). Though conventional cytogenetic studies can detect some microdeletions, initial detection and/or confirmation with FISH is essential. In fact, since appropriate FISH probes have become available, detection of microdeletion syndromes has increased significantly.

In addition to metaphase FISH, cells can be analyzed at a variety of stages. Interphase analysis, for example, can be used to make a rapid diagnosis in instances when metaphase chromosome preparations are not yet available (e.g., amniotic fluid interphase analysis). Interphase analysis also increases the number of cells available for examination, allows for investigation of nuclear organization, and provides results when cells do not progress to metaphase. One specialized type of in-

terphase analysis involves the application of FISH to paraffin-embedded sections, thereby preserving the architecture of the tissue.

The use of interphase FISH has increased recently, especially for analyses of amniocentesis samples. These studies are performed on uncultured amniotic fluid, typically using DNA probes specific for the chromosomes most commonly identified in trisomies (chromosomes 13, 18, 21, and the X and Y). These studies can be performed rapidly (24–72 h) and will ascertain about 60% of the abnormalities detected prenatally. Another area in which interphase analysis is routinely utilized is cancer cytogenetics (Chap. 79). Many site-specific translocations are associated with specific types of malignancies. For example, there are probes available for both the Abelson (Abl) oncogene and breakpoint cluster region (bcr) involved in chronic myelogenous leukemia (CML); these probes are labeled in red and green, respectively; the fusion of these genes in CML combines the fluorescent colors and appears as a yellow hybridization signal.

In addition to standard metaphase and interphase FISH analyses, a number of enhanced techniques have been developed for specific types of analysis, including multicolor FISH techniques, reverse painting, comparative genomic hybridization, and fiber FISH. *Spectral karyotyping* (SKY) and multicolor FISH (m-FISH) techniques use combinatorially labeled probes that create a unique color for individual chromosomes. This technology is useful in the identification of unknown chromosome material (such as markers of duplications) but is most commonly used with the complex rearrangements seen in cancer specimens.

Fiber FISH is a technique in which chromosomes are mechanically stretched, using a variety of different methods. It provides a higher resolution of analysis than conventional FISH.

Comparative genomic hybridization (CGH) is a method that can be used only when DNA is available from a specimen of interest. The entire DNA specimen from the sample of interest is labeled in one color (e.g., green), and the normal control DNA specimen is indicated by another color (e.g., red). These are mixed in equal amounts and hybridized to normal metaphase chromosomes. The red-to-green ratio is analyzed by a computer program, which determines where the DNA of interest may have gains or losses of material. This technique is useful in the analysis of tumors, particularly in those cases where cytogenetic analysis is not possible.

An extension of CGH promises to yield another major advance for examining human chromosomes. Specifically, the development of CGH "arrays" uses protocols that are similar to standard CGH, except that test DNA is hybridized to DNAs that are spread on arrays, rather than hybridized to normal chromosomes. Depending on the type of array (most are constructed utilizing either BACs or oligonucleotides), the resolution can be up to 150 kb, far greater than for standard chromosome analysis. This technology has been used to study cryptic chromosomal imbalances in patients with mental retardation and multiple congenital anomalies, as well as in prenatal diagnosis. It has also been used to detect microdeletions and microduplications in cancer and in previously unidentified genomic disorders. Although this technology is still in development, its use is anticipated to increase in the near term.

INDICATIONS FOR CYTOGENETIC ANALYSIS

Primary indications for karyotypic analysis vary according to the developmental stage/age of the conceptus/individual under investigation. One especially important application is in prenatal diagnosis (particularly for pregnancies involving older women), assaying for chromosomal abnormalities in either chorionic villi of first-trimester fetuses or amniotic fluid of second-trimester fetuses. Tissue specimens from spontaneously aborted fetuses or stillbirths can also be examined for chromosome abnormalities. Interphase cytogenetics (using FISH) is increasingly being used to study individual blastomeres of preimplantation embryos (with in vitro fertilization–derived pregnancies). This makes it possible to detect aneuploid or structurally unbalanced embryos or, in the case of sex-linked disorders, to identify male conceptuses; such embryos would not be used to initiate pregnancies.

Among infants and children, peripheral blood is examined, most often in individuals with specific phenotypic abnormalities. For example, karyotypic analysis can be used for the confirmation or exclusion of a specific chromosomal syndrome (e.g., trisomy 21); in patients with unexplained psychomotor retardation with or without dysmorphic features; in cases of monogenic disorders associated with mental retardation and/or dysmorphic features; and with abnormalities of sexual differentiation and development.

In adults, peripheral blood can be examined in patients with infertility or recurrent miscarriages, since chromosome abnormalities can lead to meiotic arrest or to genetically unbalanced gametes. An important branch of cytogenetics is concerned with analyses of bone marrow, unstimulated peripheral blood, and lymph nodes of tumors, as chromosomal abnormalities are a common correlate of leukemia, lymphoma, and solid tumors (Chap. 79).

CYTOGENETIC TESTING IN PRENATAL DIAGNOSIS

The vast majority of prenatal diagnostic studies are performed to rule out a chromosomal abnormality, but cells may also be propagated for biochemical studies or molecular analyses of DNA. Three procedures are used to obtain samples for prenatal diagnosis: amniocentesis, chorionic villus sampling (CVS), and fetal blood sampling. Amniocentesis is the most common procedure and is routinely performed at 15–17 weeks of gestation. On some occasions, early amniocentesis at 12–14 weeks is performed to expedite results, although less fluid is obtained at this time. Early amniocentesis carries a greater risk of spontaneous abortion or fetal injury but provides results at an earlier stage of pregnancy.

The vast majority of amniocenteses are performed in the context of advanced maternal age, the best-known correlate of trisomy (see below). Additional reasons for amniocentesis referral include an abnormal "triple- or quad-marker assay" and/or detection of ultrasound abnormalities. In this assay, levels of human chorionic gonadotropin, α-fetoprotein, and unconjugated estriol (and, in the quad assay, inhibin) in the maternal serum are quantified and used to adjust the maternal age-predicted risk of a trisomy 21 or trisomy 18 fetus. Specific ultrasound abnormalities, when detected at midtrimester, can also be associated with chromosomal defects. When a nonspecific ultrasound abnormality is present, the estimated risk of a chromosomal defect is ~16%. Associations of chromosomal abnormalities and specific types of abnormal ultrasound findings are listed in Table 63-1.

CVS is the second most common procedure for genetic prenatal diagnosis. Because this procedure is routinely performed at about 10–12 weeks of gestation, it allows for an earlier detection of abnormalities and a safer pregnancy termination, if desired. CVS is a relatively safe procedure (spontaneous abortions, <0.5–1%). Because there is an increased association of limb defects when the procedure is performed earlier (<10 weeks of gestation), CVS is applicable during a narrow time frame of gestation. CVS involves the use of a catheter inserted transvaginally; ~25 mg of villi are aspirated from the chorion frondosum (the fetal portion of the placenta). By adding colchicine directly to the rapidly dividing cytotrophoblasts, results can be obtained within 24–48 h. Findings from these procedures should be confirmed

TABLE 63-1 FREQUENCY OF CHROMOSOME ABNORMALITIES, IDENTIFIED ON THE BASIS OF ABNORMAL ULTRASOUND FINDINGS

	Chromosomal Abnormalities (Frequency)	
Ultrasound Finding	Average, %	Range in Different Studies, %
Abnormal ultrasound (nonspecific)	16	13–35
Omphalocele	39	26–54
Cystic hygroma	68	46–78
Congenital heart disease	30	8–40
Choroid plexus cyst	5	4–10

by analyses of cultured mesenchymal cells, as they are more reliably derived from the fetus.

Percutaneous umbilical blood sampling (PUBS) is a method for obtaining fetal blood during the second and third trimesters of pregnancy. PUBS is usually performed when ultrasound abnormalities are detected late in the second trimester. PUBS is also used when cytogenetic results from amniocentesis need clarification, such as in the detection of mosaicism.

CHROMOSOME ABNORMALITIES

CHROMOSOMES IN CELL DIVISION

To understand the etiology of chromosome abnormalities, it is important to review the movement of chromosomes during cell division. In somatic tissues, chromosomes are replicated during the S-phase of the cell cycle, so that each replicated chromosome consists of two identical sister chromatids. When the cell enters mitosis, each of the 46 chromosomes align on the metaphase plate, with the centromeres co-oriented toward opposite spindle poles (Fig. 63-3). At anaphase the sister chromatids separate, with each of the daughter cells receiving one sister chromatid from each of the 46 chromosomes.

Chromosome segregation is more complicated in germ cell division, since the number of chromosomes must be reduced from 46 to 23 in the mature sperm and eggs. This is accomplished by two rounds of division—meiosis I and meiosis II (Fig. 63-3). In meiosis I, homologous chromosomes pair and exchange genetic material, then align on the metaphase plate, and finally separate from one another. Thus, by the end of meiosis I, only 23 of the original 46 chromosomes are represented in each of the two daughter cells. Meiosis II quickly follows meiosis I and is essentially a "haploid mitosis," involving separation of the sister chromatids in each of the 23 chromosomes.

Although the fundamentals of meiosis are the same in males and females, there are important distinctions, particularly in the timing of meiotic divisions. In males, meiosis begins with puberty and continues throughout the individual's lifetime. In females, meiosis begins prenatally, with oocytes proceeding through the first stages of meiosis I but arresting at mid-prophase. At the time of birth, the first meiotic division is suspended in oocytes. Only after ovulation many years later do oocytes complete meiosis I and proceed to the metaphase stage of meiosis II; if fertilized, the oocyte then completes the second meiotic division. Thus, in females, the first meiotic division takes at least 10–15 years and as many as 40–45 years to complete. Maternal age–related increases in the incidence of trisomy are likely the consequence of this protracted process of cell division.

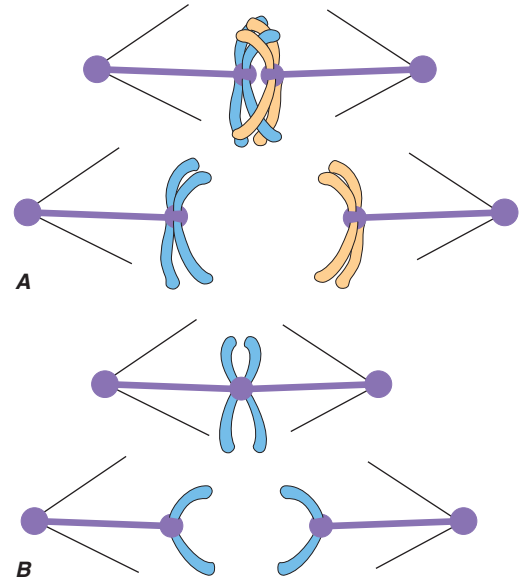

FIGURE 63-3 Chromosome segregation in meiosis. *A.* In meiosis I, each of the 23 pairs of chromosomes finds its "partner," or homologue, and exchanges genetic material (recombines) with it. At metaphase, each homologous pair aligns on the equatorial plate; at anaphase, each member of the homologous pair segregates from its partner. Thus, at the end of meiosis I, each daughter cell contains 23 chromosomes, with each chromosome consisting of two sister chromatids. ***B.*** In meiosis II, each chromosome aligns on the metaphase plate, and at anaphase, each of the two sister chromatids divides from the other. Thus, at the end of meiosis II, each daughter cell (e.g., the oocyte or spermatocyte) contains 23 chromosomes, with each chromosome consisting of one sister chromatid. In mitosis, the chromosomes behave exactly as they do in meiosis II, except that somatically dividing cells contain 46 chromosomes, not the 23 that are present in the meiosis II cell.

INCIDENCE AND TYPES OF CHROMOSOME ABNORMALITIES

Errors in meiosis, or in early cleavage divisions, occur with extraordinary frequency. At least 10–25% of all pregnancies, for example, involve chromosomally abnormal conceptions. A large proportion of these terminate in the earliest stages of pregnancy, many of which go unrecognized. Nevertheless, even among clinically recognized pregnancies, nearly 10% of fetuses are chromosomally unbalanced. For the three types of clinically recognized pregnancies—spontaneous abortions, stillbirths, and livebirths—the frequencies of different chromosomal abnormalities are summarized in Table 63-2. The most common abnormalities are numerical, involving fetuses with additional (trisomy) or missing (monosomy) chromosomes, or those with one (triploidy) or two (tetraploidy) additional sets of chromosomes. Structural chromosome abnormalities are much less common, although several of the most important clinical chromosomal disorders involve structural rearrangements (see below).

By far the most common abnormality is trisomy, which is identified in ~25% of spontaneous abortions and 0.3% of newborns. Trisomies for all chromosomes have now been identified in embryos or fetuses, but there is considerable variation in frequency for various chromosomes. For example, trisomy 16 is extraordinarily common, accounting for about one-third of all trisomies in spontaneous abortions, whereas trisomies 1, 5, 11, and 19 have been identified less often. Available evidence suggests two reasons for this variation: (1) some chromosomes (e.g., chromosome 16) are more likely to segregate abnormally or undergo nondisjunction during meiosis than are others; and (2) the potential for development varies widely among different trisomic conditions, with some being eliminated very early in gestation, others surviving to the time of clinical pregnancy recognition, and some (e.g., trisomies 13, 18, and 21 and sex chromosome trisomies) being compatible with survival to term.

TABLE 63-2 FREQUENCY AND DISTRIBUTION OF CHROMOSOME ABNORMALITIES IN DIFFERENT TYPES OF CLINICALLY RECOGNIZABLE PREGNANCIES

Chromosome Abnormality	Frequency of Abnormality			Probability of Surviving to Term, %
	Spontaneous Abortion	Stillbirth	Livebirth	
Trisomy, all	25.1	4.0	0.3	5
+13, 18, 21	4.5	2.7	0.14	15
+16	7.5	—	—	0
Sex chromosome monosomy (45,X)	8.7	0.1	0.01	1
Triploidy	6.4	0.2	—	0
Tetraploidy	2.4	—	—	0
Structural abnormality	2.0	0.8	0.3	45
Total abnormalities	50.0	5.1	0.6	5

CHROMOSOMAL SYNDROMES

While most chromosomally abnormal conceptions perish in utero, several conditions are compatible with survival to term. The best-characterized of these are numerical abnormalities, involving loss or gain of individual chromosomes, and abnormalities resulting from unbalanced translocations. FISH and other molecular studies have led to the identification of two "new" types of chromosome abnormalities, commonly referred to as *microdeletion syndromes* and *imprinting syndromes*.

NUMERICAL ABNORMALITIES

Virtually all types of numerical abnormalities are eliminated prenatally, so that only those involving small, gene-poor autosomes or the sex chromosomes are identified with any frequency among live-borns. Clinically, the most important of these is trisomy 21, the most frequent cause of Down syndrome. Depending on the maternal age structure of the population and the utilization of prenatal testing, the incidence of trisomy 21 ranges from 1/600 to 1/1000 live births, making it the most common chromosome abnormality in live-born individuals. Like most trisomies, the incidence of trisomy 21 is highly correlated with maternal age, increasing from about 1/1500 live births for women 20 years of age to 1/30 for women ≥45 years.

In addition to trisomy 21, only two other autosomal trisomies, 13 and 18, occur with any frequency in livebirths. Incidence rates for trisomies 13 and 18 in livebirths are 1/20,000 and 1/10,000, respectively. Unlike trisomy 21, which is associated with near-normal life expectancy, both trisomies 13 and 18 are associated with death in infancy, typically occurring during the first year of life.

Three sex chromosome trisomies—the 47,XXX, 47,XXY (Klinefelter syndrome), and 47,XYY conditions—are quite common, with each occurring in about 1/2000 newborns. Of all the trisomic conditions, these three have the fewest phenotypic complications. In fact, with the exception of infertility in Klinefelter syndrome (Chap. 343), it is likely that most individuals with such trisomic conditions would go undetected. The additional Y chromosome in the 47,XYY condition is small and contains only a few genes. Most Y-linked genes are involved in testicular development or spermatogenesis. Thus, dosage imbalance of Y-linked genes has relatively little effect on other developmental processes. The 47,XYY genotype is associated with increased height. Its role in antisocial behavior, postulated initially because of an increased prevalence among some penalized populations, is unclear.

For the 47,XXX and 47,XXY conditions, the situation is different—the X chromosome contains >1000 genes, many of them essential for normal development. How, then, are 47,XXX and 47,XXY individuals spared from the catastrophic consequences of dosage imbalance? The answer lies in the biology of X chromosome gene expression. In normal females, one of the chromosomes undergoes *X inactivation* in somatic cells. The inactivation of the paternal or maternal X chromosome occurs randomly in each somatic cell and thereby serves as a mechanism of dosage compensation, ensuring that males and females have equal expression of most X-linked genes. The inactivation process occurs at the blastocyst stage of development; prior to this, both X chromosomes are active. In addition, not all X-linked genes are inactivated. Some genes on the X chromosome "escape" the inactivating mechanism and are expressed from both X chromosomes. In disorders such as Klinefelter syndrome, some genes may be expressed from both X chromosomes, resulting in its phenotypic features.

As a rule, monosomic conditions are incompatible with fetal development and, consequently, autosomal monosomies are only rarely identified in spontaneous abortions and are not found among live-born individuals. In fact, the only monosomy compatible with live birth is the 45,X condition, which causes Turner syndrome. The 45,X chromosome constitution occurs with surprisingly high frequency, present in at least 1–2% of all pregnancies. More than 99% of all 45,X conceptions are spontaneously aborted. Thus, live-born individuals with a 45,X chromosome constitution represent a rare group of survivors. The 45,X phenotype is mild, presumably because the second copy of many X chromosomal genes is normally inactivated. Nonetheless, Turner syndrome causes gonadal dysgenesis, resulting in infertility and failure to undergo secondary sexual development, along with a number of other phenotypic features (Chap. 343). Several other structural abnormalities of the X chromosome such as deletions, isochromosome X, or ring chromosomes can cause Turner syndrome. Mosaicism, including 45,X/45,XX, 45X/45,XXX, 45,X/45,XY, and others, also occurs (see below) and contributes to the phenotypic spectrum in Turner syndrome.

TABLE 63-3 STUDIES OF THE PARENT AND MEIOTIC/MITOTIC STAGE OF ORIGIN OF HUMAN TRISOMIES AND SEX CHROMOSOME MONOSOMY

	Origin, %				
	Paternal		Maternal

Monosomy					
X[a]	80		20		

[a]Results pertain to nonmosaic 45,X individuals.

Because numerical abnormalities originate in meiosis (Table 63-3), affected individuals have missing or extra chromosomes in all cells. In a small proportion of cases, a mitotic nondisjunctional event occurs at an early stage in an individual with an initially normal chromosome constitution. Alternatively, a "normalizing" mitotic nondisjunctional event may result in a normal chromosome complement in some cells of an embryo. In either case, the embryo is a mosaic, with some cells bearing a normal chromosome constitution and others an aneuploid number of chromosomes. The phenotypic consequences are difficult to predict because they depend on the timing of nondisjunction and the distribution of normal and abnormal cells in different tissues. Nevertheless, mosaicism may lead to clinical abnormalities indistinguishable from those of nonmosaic individuals; for example, nearly 5% of all cases of Down syndrome involve individuals with mosaic trisomy 21, and about 15% of individuals with Turner syndrome are mosaic for various sex chromosomal constitutions as described above.

The Origin and Etiology of Numerical Abnormalities Over the past decade, a number of studies have used DNA polymorphisms to investigate the origin of different types of chromosome abnormalities (Fig. 63-4). The most thoroughly investigated types have been numerical abnormalities (Table 63-3). Sex chromosome monosomy usually results from loss of the paternal sex chromosome, regardless of whether the conception is live-born or spontaneously aborted.

Trisomies show remarkable variation in parental origin. For example, paternal nondisjunction is responsible for nearly 50% of 47,XXY but only 5–10% of cases of trisomies 13, 14, 15, 21, and 22; it is rarely, if ever, the source of the additional chromosome in trisomy 16. Similarly, there is considerable variability in the meiotic stage of origin. For example, all cases of trisomy 16 may be due to meiosis I errors, whereas for trisomy 21, one-third of cases are associated with meiosis II errors, and for trisomy 18, the majority of cases are apparently due to meiosis II nondisjunction. In spite of this variation in parental and meiotic origin, nondisjunction at maternal meiosis I appears to be the most common source of trisomy.

Maternal Age and Trisomy The association between increasing maternal age and trisomy is the most important etiologic factor in con-

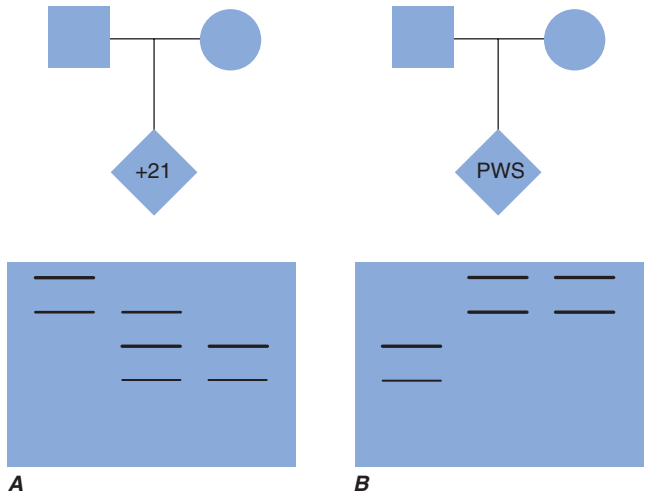

FIGURE 63-4 Use of DNA technology to determine the origin of chromosome abnormalities. *A.* Analysis of a chromosome 21–specific DNA polymorphism demonstrates that the trisomic individual received two chromosomes 21 from his mother and one from his father; thus, the extra chromosome 21 resulted from an error in oogenesis. ***B.*** Inheritance of a chromosome 15–specific DNA polymorphism in an individual with Prader-Willi syndrome (PWS). The affected individual has received two maternal, but no paternal, chromosomes 15; thus, the individual is said to have maternal uniparental disomy 15, a common cause of PWS.

genital chromosomal disorders. Among women under the age of 25, ~2% of all clinically recognized pregnancies are trisomic; by the age of 36, however, this figure increases to 10% and by the age of 42, to >33% (Fig. 63-5). This association between maternal age and trisomy is exerted without respect to race, geography, or socioeconomic factors and likely affects segregation of all chromosomes.

Despite the importance of increasing age, little is known about the mechanism by which aging leads to abnormal chromosomal segregation. As noted above, it is thought to originate in maternal meiosis I owing to the protracted time to completion (often ≥40 years) in females, and recent studies suggest that it may be associated with alterations in meiotic crossing-over. In trisomy 21, for example, crossover patterns appear to be similarly abnormal in younger and older mothers of trisomic conceptions. Thus, it has been suggested that two distinct steps, or "hits," may be involved in maternal age–related nondisjunction. The first hit, which is age independent, involves the establishment of a "vulnerable" crossover configuration in the fetal oocyte; the second hit, which is age dependent, involves abnormal processing of the vulnerable bivalent structure at metaphase I. If this model is correct, it suggests that the nondisjunctional process is the same in younger and older women, but it occurs more frequently with aging, possibly because of age-dependent degradation of meiotic proteins.

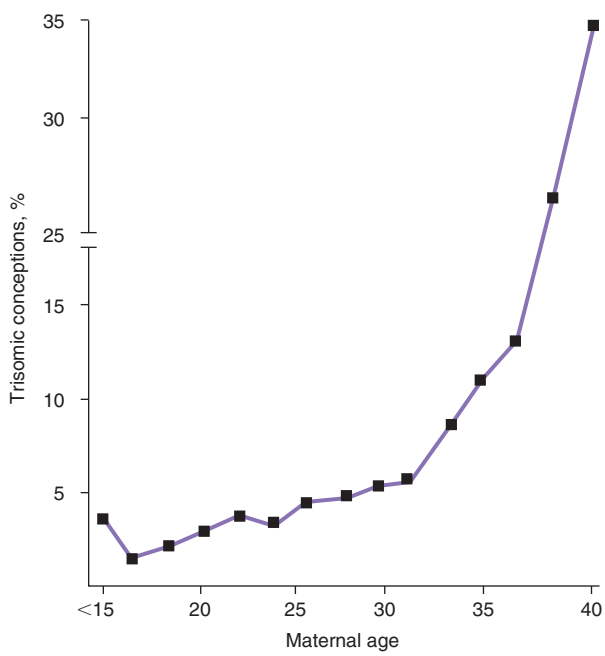

FIGURE 63-5 Estimated maternal age–adjusted rates of trisomy among all clinically recognized pregnancies (e.g., spontaneous abortions, stillbirths, and livebirths). Among women in their forties, over 25% of all pregnancies are estimated to involve a trisomic conception; the vast majority of these spontaneously abort, with only trisomies 13, 18, and 21 and sex chromosome trisomies surviving to term with any appreciable frequency.

STRUCTURAL CHROMOSOME ABNORMALITIES

Structural rearrangements involve breakage and reunion of chromosomes. Although less common than numerical abnormalities, they present additional challenges from a genetic counseling standpoint. This is because structural abnormalities, unlike numerical abnormalities, can be present in "balanced" form in clinically normal individuals but transmitted in "unbalanced" form to progeny, thereby resulting in a hereditary form of chromosome abnormality.

Rearrangements may involve exchanges of material between different chromosomes (translocations) or loss, gain, or rearrangements of individual chromosomes (e.g., deletions, duplications, inversions, rings, or isochromosomes). Of particular clinical importance are *translocations*, which involve two basic types: Robertsonian and reciprocal. Robertsonian rearrangements are a special class of translocation, in which the long arms of two acrocentric chromosomes (chromosomes 13, 14, 15, 21, and 22) join together, generating a fusion chromosome that contains virtually all of the genetic material of the original two chromosomes. If the Robertsonian translocation is present in unbalanced form, a monosomic or trisomic conception ensues. For example, ~3% of Down syndrome cases are attributable to unbalanced Robertsonian translocations, most often involving chromosomes 14 and 21. In this instance, the affected individual has 46 chromosomes, including one structurally normal chromosome 14, two structurally normal chromosomes 21, and one fusion 14/21 chromosome. This effect leads to a normal diploid dosage for chromosome 14 and to a triplication of chromosome 21, thus resulting in Down syndrome. Similarly, a small proportion of individuals with trisomy 13 syndrome are clinically affected because of an unbalanced Robertsonian translocation.

Reciprocal translocations involve mutual exchanges between any two chromosomes. In this circumstance, the phenotypic consequences associated with unbalanced translocations depend on the location of the breakpoints, which dictate the amount of material that has been "exchanged" between the two chromosomes. Because most reciprocal translocations involve unique sets of breakpoints, it is difficult to predict the phenotypic consequences in any one situation. In general, severity is determined by the amount of excess or missing chromosome material in individuals with unbalanced translocations.

In addition to rearrangements between chromosomes, there are several examples of intrachromosome structural abnormalities. The most common and deleterious of these involve loss of chromosome material due to deletions. The two best-characterized deletion syndromes, Wolf-Hirschhorn syndrome and cri-du-chat syndrome, result from loss of relatively small chromosomal segments on chromosomes 4p and 5p, respectively. Nonetheless, each is associated with multiple congenital anomalies, developmental delays, profound retardation, and reduced lifespan.

Microdeletion Syndromes The term *contiguous gene syndrome* refers to genetic disorders that mimic a combination of single-gene disorders. They result from the deletion of a small number of tightly clustered genes. Because some are too small to be detected cytogenetically, they are termed *microdeletions*. The application of molecular tech-

TABLE 63-4 SOME COMMONLY IDENTIFIED MICRODELETION AND MICRODUPLICATION SYNDROMES

Syndrome	Cytogenetic Location	Principal Features	Imprinting Effects
Langer-Giedion syndrome	8q24.1 (del)	Sparse hair, bulbous nose, variable mental retardation	No
WAGR complex	11p13 (del)	Wilms' tumor, aniridia, genitourinary disorders, mental retardation	No
Beckwith-Wiedemann syndrome	11p15 (dup)	Macrosomia, macroglossia, omphalocoele	Yes, occasionally associated with "paternal uniparental disomy" (see text)
Retinoblastoma	13q14.11 (del)	Retinoblastoma due to homozygous loss of functional RB allele	No obvious effect, although abnormal RB allele more likely to be paternal
Prader-Willi syndrome	15q11-13 (del)	Obesity, hypogonadism, mental retardation	Yes, prototypic imprinting disorder (see text)
Angelman syndrome	15q11-13 (del)	Ataxic gait	With Prader-Willi syndrome, prototypic imprinting disorder (see text)
α-Thalassemia and mental retardation	16p13.3 (del)	α-Thalassemia and mental retardation, due to deletion of distal 16p, including α-globin locus	No
Smith-Magenis syndrome	17p11.2 (del)	Brachycephaly, midface hypoplasia, mental retardation	No
Miller-Dieker syndrome	17p13 (del)	Dysmorphic facies, lissencephaly	No
Charcot-Marie-Tooth syndrome type 1A	17p11.2 (dup)	Progressive neuropathy due to microduplication	No
DiGeorge syndrome/ velocardiofacial syndrome	22q11 (del)	Abnormalities of third and fourth branchial arches	No

niques has led to the identification of at least 18 of these microdeletion syndromes (Table 63-4). Some of the more common ones include the Wilms' tumor–aniridia complex (WAGR), Miller Dieker syndrome (MDS), and velocardiofacial (VCF) syndrome. WAGR is characterized by mental retardation and involvement of multiple organs, including kidney (Wilm's tumor), eye (aniridia), and the genitourinary system. The cytogenetic abnormality involves a deletion of a part of the short arm of chromosome 11 (11p13), which typically is detectable on well-banded chromosome preparations. In MDS, a disorder characterized by mental retardation, dysmorphic faces, and lissencephaly, the deletion involves chromosome 17 (17p13). Using FISH, 17p deletions have been detected in >90% of patients with MDS as well as in 20% of cases of isolated lissencephaly.

Deletions involving the long arm of chromosome 22 (22q11) are the most common microdeletions identified to date, present in ~1/3000 newborns. VCF syndrome, the most commonly associated syndrome, consists of learning disabilities or mild mental retardation, palatal defects, a hypoplastic aloe nasi and long nose, and congenital heart defects (conotruncal defect). Some individuals with 22q11 deletion are more severely affected and present with DiGeorge syndrome, which involves abnormalities in the development of the third and fourth branchial arches leading to thymic hypoplasia, parathyroid hypoplasia, and conotruncal heart defects. In ~30% of these cases, a deletion at 22q11 can be detected with high-resolution banding; by combing conventional cytogenetics, FISH, and molecular detection techniques (i.e., Southern blotting or polymerase chain reaction analyses), these rates improve to >90%. Additional studies have demonstrated a surprisingly high frequency of 22q11 deletions in individuals with nonsyndromic conotruncal defects. Approximately 10% of individuals with a 22q11 deletion inherited it from a parent with a similar deletion.

Smith-Magenis syndrome involves a microdeletion localized to the proximal region of the short arm of chromosome 17 (17p11.2). Affected individuals have mental retardation, dysmorphic facial features, delayed speech, peripheral neuropathy, and behavior abnormalities. Most of these deletions can be detected with cytogenetic analysis, although FISH is available to confirm these findings. In contrast, William syndrome, a chromosome 7 (7q11.23) microdeletion, cannot be diagnosed with standard or high-resolution analysis; it is only detectable utilizing FISH or other molecular methods. William syndrome involves a deletion of the elastin gene and is characterized by mental retardation, dysmorphic features, a gregarious personality, premature aging, and congenital heart disease (usually supravalvular aortic stenosis).

In addition to microdeletion syndromes, there is now at least one well-described microduplication syndrome, Charcot-Marie-Tooth type 1A (CMT1A). This is a nerve conduction disease previously thought to be transmitted as a simple autosomal dominant disorder. Recent molecular studies have demonstrated that affected individuals are heterozygous for duplication of a small region of chromosome 17 (17p11.2–12). Although it is not yet clear why increased gene dosage would result in CMT1A, the inheritance pattern is explained by the fact that one-half of the offspring of affected individuals inherit the duplication-carrying chromosome.

IMPRINTING DISORDERS

Two other microdeletion syndromes, Prader-Willi syndrome (PWS) and Angelman syndrome (AS), exhibit parent-of-origin, or "imprinting," effects. For many years, it has been known that cytogenetically detectable deletions of chromosome 15 occur in a proportion of patients with PWS, as well as in those with AS. This seemed curious, as the clinical manifestations of the two syndromes are very dissimilar. PWS is characterized by obesity, hypogonadism, and mild to moderate mental retardation, whereas AS is associated with microcephaly, ataxic gait, seizures, inappropriate laughter, and severe mental retardation. New insight into the pathogenesis of these disorders has been provided by the recognition that parental origin of the deletion determines which phenotype ensues: if the deletion is paternal, the result is PWS, whereas if the deletion is maternal, the result is AS (Fig. 63-2).

This scenario is complicated further by the recognition that not all individuals with PWS or AS carry the chromosome 15 deletion. For such individuals, the parental origin of the chromosome 15 region is again the important determinant. In PWS, for example, nondeletion patients invariably have two maternal and no paternal chromosomes 15 [maternal uniparental disomy (UPD)], whereas for some nondeletion AS patients the reverse is true (paternal UPD). This indicates that at least some genes on chromosome 15 are differently expressed, depending on which parent contributed the chromosome. Additionally, this means that normal fetal development requires the presence of one maternal and one paternal copy of chromosome 15.

Approximately 70% of PWS cases are due to paternal deletions of 15q11-q13, whereas 25% are due to maternal UPD, and about 5% are caused by mutations in a chromosome 15 imprinting center. In AS, 75% of cases are due to maternal deletions, and only 2% are due to paternal UPD. The remaining cases are presumably caused by imprinting mutations (5%), or mutations in the *UBE3A* gene, which is associated with AS. The UPD cases are mostly caused by meiotic nondisjunction resulting in trisomy 15, subsequently followed by a normalizing mitotic nondisjunction event ("trisomy rescue") resulting in two normal chromosomes 15, both from the same parent. *UBE3A* is the only maternally imprinted gene known in the critical region of chromosome 15. However, several paternally imprinted genes, or expressed-sequence tags (ESTs), have been identified, including *ZNF127*, *IPW*, *SNRPN*, *SNURF*, *PAR1*, and *PAR5*.

Chromosomal regions that behave in the manner observed in PWS and AS are said to be *imprinted*. This phenomenon is involved in differential expression of certain genes on different chromosomes. Chromosome 11 is one of these with an imprinted region, since it is known that a small proportion of individuals with the Beckwith-Wiedemann overgrowth syndrome have two paternal but no maternal copies of this chromosome.

ACQUIRED CHROMOSOME ABNORMALITIES IN CANCER

In addition to the constitutional cytogenetic chromosomal abnormalities that are present at birth, somatic chromosomal changes can be acquired later in life and are often associated with malignant conditions. As with constitutional abnormalities, somatic changes can include the net loss of chromosomal material (due to a deletion or loss of a chromosome), net gain of material (duplication or gain of a chromosome), and relocation of DNA sequences (translocation). Cytogenetic changes have been particularly well studied in (1) leukemias, e.g., Philadelphia chromosome translocation in CML [t(9;22)(q34.1;q11.2)]; and (2) lymphomas, e.g., translocations of *MYC* in Burkitt's [t(8;14)(q24;q32)]. These and other translocations are useful for diagnosis, classification, and prognosis. Analyses of cytogenetic changes are also useful in certain solid tumors. For example, a complex karyotype with Wilms' tumor, diploidy in medulloblastoma, and Her-2/neu amplification in breast cancer are poor prognostic signs. **For detailed discussion of cancer genetics, see Chap. 79.**

64 The Practice of Genetics in Clinical Medicine

Susan Miesfeldt, J. Larry Jameson

IMPLICATIONS OF MOLECULAR GENETICS FOR INTERNAL MEDICINE

The field of medical genetics has traditionally focused on chromosomal abnormalities (Chap. 63) and Mendelian disorders (Chap. 62). However, there is genetic susceptibility to many common adult-onset diseases, including atherosclerosis, cardiac disorders, asthma, hypertension, autoimmune diseases, diabetes mellitus, macular degeneration, Alzheimer's disease, psychiatric disorders, and many forms of cancer. Genetic contributions to these common disorders involve more than the ultimate expression of an illness; these genes can also influence the severity of infirmity, effect of treatment, and progression of disease.

The primary care clinician is now faced with the role of recognizing and counseling patients at risk for a number of genetically influenced illnesses. Among the greater than 20,000 genes in the human genome, it is estimated that each of us harbors several potentially deleterious mutations. Fortunately, many of these alterations are recessive and clinically silent. An even greater number, however, represent genetic variants that alter disease susceptibility, severity, or response to therapy.

Genetic medicine is changing the way diseases are classified, enhancing our understanding of pathophysiology, providing practical information concerning drug metabolism and therapeutic responses, and allowing for individualized screening and health care management programs. In view of these changes, the physician must integrate personal medical history, family history, and diagnostic molecular testing into the overall care of individual patients and their families. Surveys indicate that patients still turn to their primary care internist for guidance about genetic disorders, even though they may be seeing other specialists. The internist has an important role in educating patients about the indications, benefits, risks, and limitations of genetic testing in the management of a number of diverse diseases. This is a difficult task, as scientific advances in genetic medicine have outpaced the translation of these discoveries into standards of clinical care.

COMMON ADULT-ONSET GENETIC DISORDERS

MULTIFACTORIAL INHERITANCE

The risk for many adult-onset disorders reflects the combined effects of genetic factors at multiple loci that may function independently or in combination with other genes or environmental factors. Our understanding of the genetic basis of these disorders is incomplete, despite the clear recognition of genetic susceptibility. In type 2 diabetes mellitus, for example, the concordance rate in monozygotic twins ranges between 50 and 90%. Diabetes or impaired glucose tolerance occurs in 40% of siblings and in 30% of the offspring of an affected individual. Despite the fact that diabetes affects 5% of the population and exhibits a high degree of heritability, only a few genetic mutations (most of which are rare) that might account for the familial nature of the disease have been identified. They include certain mitochondrial DNA disorders (Chap. 62), mutations in a cascade of genes that control pancreatic islet cell development and function (*HNF4α*, *HNF1α*, *IPF1*, *TCF7L2, glucokinase*), insulin receptor mutations, and others (Chap. 338). Superimposed on this genetic background are environmental influences such as diet, exercise, pregnancy, and medications.

Identifying susceptibility genes associated with multifactorial adult-onset disorders is a formidable task. Nonetheless, a reasonable goal for these types of diseases is to identify genes that increase (or decrease) disease risk by a factor of two or more. For common diseases such as diabetes or heart disease, this level of risk has important implications for health. In much the same way that cholesterol is currently used as a biochemical marker of cardiovascular risk, we can anticipate the development of genetic panels with similar predictive power. The advent of DNA-sequencing chips represents an important technical advance that promises to make large-scale testing more feasible (Chap. 62). Whether to perform a genetic test for a particular inherited adult-onset disorder, such as hemochromatosis, multiple endocrine neoplasia (MEN) type 1, prolonged QT syndrome, or Huntington disease, is a complex decision; it depends on the clinical features of the disorder, the desires of the patient and family, and whether the results of genetic testing will alter medical decision-making or treatment (see below).

Population Screening Mass genetic screening programs require tests of high enough sensitivity and specificity to be cost-effective. An effective screening program should fulfill the following criteria: that the tested disorder is prevalent and serious; that it can be influenced presymptomatically through lifestyle changes, screening, or medications;

and that identification of risk does not result in undue discrimination or harm. Screening individuals of Jewish descent for the autosomal recessive neurodegenerative disorder Tay-Sachs disease has resulted in a dramatic decline in the incidence of this syndrome in the United States. On the other hand, screening for sickle cell disease or trait in the African-American population has sometimes resulted in insurance and employment discrimination.

Mass screening for complex genetic disorders can result in potential problems. For example, cystic fibrosis is most commonly associated with alterations in ΔF508. This variant accounts for 30–80% of mutant alleles depending on the ethnic group. Nevertheless, cystic fibrosis is associated with pronounced genetic heterogeneity with more than 1000 disease-related mutations. The American College of Medical Genetics recommends a panel of 23 alleles, including the ΔF508 allele, for routine diagnostic and carrier testing. Analysis for the less common cystic fibrosis–associated mutations would greatly impact the cost of testing without significantly influencing the effectiveness of mass screening. Nevertheless, the individual who carries one of the less common cystic fibrosis–associated alterations will not benefit if testing is limited to a routine panel.

Occupational health screening programs hold promise but also raise concerns about employment discrimination. These concerns were brought to light in 2001 when it was discovered that a railroad company was testing its employees, without consent, for a rare genetic condition that results in susceptibility to carpal tunnel syndrome. The Equal Employment Opportunity Commission argued that the tests were unlawful under the Americans with Disabilities Act.

THE FAMILY HISTORY

When two or more first-degree relatives are affected with asthma, cardiovascular disease, type 2 diabetes, breast cancer, colon cancer, or melanoma, the relative risk ranges from two- to fivefold, underscoring the importance of family history for these prevalent disorders. Pending further advances in genetic testing, the key to assessing the inherited risk for common adult-onset diseases rests in the collection and interpretation of a detailed personal and family medical history in conjunction with a directed physical examination. For example, a history of multiple family members with early-onset coronary artery disease, glucose intolerance, and hypertension should suggest increased risk for genetic, and perhaps environmental, predisposition to metabolic syndrome (Chap. 236). Individual patients with this family history should be monitored for the possible development of hypertension, diabetes, and hyperlipidemia. They should be counseled about the importance of avoiding additional risk factors such as obesity and cigarette smoking.

Family history should be recorded in the form of a pedigree. At a minimum, pedigrees should convey health-related data on all first-degree relatives and selected second-degree relatives, including grandparents. When pedigrees appear to suggest an inherited disease, they should be extended to include additional family members. The determination of risk for an asymptomatic individual will vary depending on the size of the pedigree, the number of unaffected relatives, and the types of diagnoses, as well as the ages of disease onset within the family. For example, a woman with two first-degree relatives with breast cancer is at greater risk for a Mendelian disorder if she has a total of three female first-degree relatives than if she has a total of ten female first-degree relatives. Additional variables that should be documented in the pedigree include the presence or absence of nonhereditary risk factors among those affected with diseases, and the finding of multiple diseases in an individual patient. For instance, a woman with a history of both colon cancer and endometrial cancer is at risk for hereditary nonpolyposis colon cancer (HNPCC) regardless of her family history.

When assessing the personal and family history, the physician should be alert to a younger age of disease onset than is usually seen in the general population. A 30-year-old with acute myocardial infarction should be considered at risk for a hereditary trait, even if there is no family history of premature coronary artery disease (Chap. 235). The absence of the nonhereditary risk factors typically associated with a disease also raises the prospect of genetic causation. A personal or family history of deep-vein thrombosis, in the absence of known environmental or medical risk factors, suggests a hereditary thrombotic disorder (Chap. 111). The physical examination also may provide important clues about the risk for a specific inherited disorder. A patient presenting with xanthomas at a young age should prompt consideration of familial hypercholesterolemia. Some adult-onset disease-causing mutations are more prevalent in certain ethnic groups. For instance, >2% of the Ashkenazi population carry one of three specific mutations in the *BRCA1* or *BRCA2* genes. The prevalence of the factor V Leiden allele ranges from 3 to 7% in Caucasians but is much lower in Africans or Asians.

Recall of family history is often inaccurate. This is especially so when the history is remote and families become more dispersed geographically. It can be helpful to ask patients to fill out family history forms before or after their visits, as this provides them with an opportunity to contact relatives. Attempts should be made to confirm the illnesses reported in the family history before making important and, in certain circumstances, irreversible management decisions. This process is often labor intensive and ideally involves interviews of additional family members or reviewing medical records, autopsy reports, and death certificates.

Although many inherited disorders will be suggested by the clustering of relatives with the same or related conditions, it is important to note that *disease penetrance* is incomplete for most multifactorial genetic disorders. As a result, the pedigree obtained in such families may not exhibit a clear Mendelian inheritance pattern, as not all family members carrying the disease-associated alleles will manifest a clinical disorder. Furthermore, genes associated with some of these disorders often exhibit *variable expression* of disease. For example, the breast cancer–associated gene *BRCA1* can predispose to several different malignancies in the same family, including cancers of the breast, ovary, and prostate (Chap. 79). For common diseases such as breast cancer, some family members without the disease-causing mutation may also develop breast cancer, representing another confounding variable in the pedigree analysis.

Some of the aforementioned features of the family history are illustrated in Fig. 64-1. In this example, the proband, a 36-year-old woman (IV-1), has a strong history of breast and ovarian cancer on the paternal side of her family. The early age of onset, as well as the co-occurrence of breast and ovarian cancer in this family, suggests the

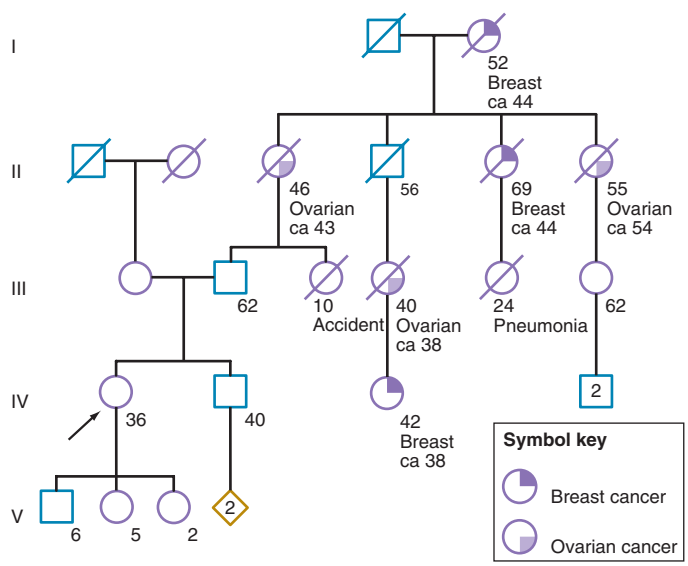

FIGURE 64-1 A 36-year-old woman (*arrow*) seeks consultation because of her family history of cancer. The patient expresses concern that the multiple cancers in her relatives imply an inherited predisposition to develop cancer. The family history is recorded and records of the patient's relatives confirm the reported diagnoses.

possibility of an inherited mutation in *BRCA1* or *BRCA2*. It is unclear though—without genetic testing—whether her father inherited such a mutation and transmitted it to her. After appropriate genetic counseling of the proband and her family, one approach to DNA analysis in this family is to test the cancer-affected 42-year-old living cousin for the presence of a *BRCA1* or *BRCA2* mutation. If a mutation is found, then it is possible to test for this particular alteration in the proband and other family members, if they so desire. In the example shown, if the proband's father has the *BRCA1* mutation, there is a 50:50 probability that the mutation was transmitted to her, and genetic testing can be used to establish the absence or presence of this alteration.

GENETIC TESTING FOR ADULT-ONSET DISORDERS

A critical first step before initiating genetic testing is to ensure that the correct clinical diagnosis has been made, whether based on family history, characteristic physical findings, or biochemical testing. Careful clinical assessment can define the *phenotype*, thereby preventing unnecessary testing and directing testing toward the most probable candidate genes (Fig. 64-2). For patients identified by population-based screening (e.g., diabetes, hypercholesterolemia), testing might involve known candidate genes, or genome-wide linkage studies (HapMap) of the population could be used as part of a research study to identify susceptibility alleles. For patients with a strong family history (e.g., breast cancer, hemochromatosis), testing often includes known candidate genes, or traditional linkage analyses within pedigrees can identify disease-causing genes. Once candidate genes are known, mutational analyses can be performed after pretest genetic counseling (see below).

Many disorders exhibit the feature of *locus heterogeneity*, which refers to the fact that mutations in different genes can cause phenotypically similar disorders. For example, osteogenesis imperfecta (Chap. 357), long QT syndrome (Chap. 226), muscular dystrophy (Chap. 382), homocystinuria (Chap. 358), retinitis pigmentosa (Chap. 29), and hereditary predisposition to colon cancer (Chap. 87) or breast cancer (Chap. 86) can each be caused by mutations in distinct genes. The pattern of disease transmission, clinical course, and treatment may differ significantly, depending on the specific gene affected. In these cases, the choice of which genes to test is often determined by unique clinical and family history features, the relative prevalence of mutations in various genes, or test availability.

METHODOLOGIC APPROACHES TO GENETIC TESTING

Genetic testing is performed in much the same way as other specialized laboratory tests. In the United States, genetic testing laboratories are CLIA (Clinical Laboratory Improvement Act) approved to ensure that they meet quality and proficiency standards. A useful source for various genetic tests is *www.genetests.org*.

DNA testing is most commonly performed by DNA sequence analysis for mutations, although genotype can also be deduced through the study of RNA or protein (e.g., apoprotein E, hemoglobin, immunohistochemistry). The determination of DNA sequence alterations relies heavily on the use of polymerase chain reaction (PCR), which allows rapid amplification and analysis of the gene of interest. In addition, PCR enables genetic testing on minimal amounts of DNA extracted from a wide range of tissue sources including leukocytes, fibroblasts, epithelial cells in saliva or hair, and archival tissues. Amplified DNA can be analyzed directly by DNA sequencing or it can be hybridized to DNA chips or blots to detect the presence of normal and mutant DNA sequences. Direct DNA sequencing is increasingly used for prenatal diagnosis as well as for determination of hereditary disease susceptibility. Analyses of large alterations in the genome are possible using cytogenetics, fluorescent in situ hybridization (FISH), or Southern blotting (Chap. 63).

Protein truncation tests (PTTs) are used to detect mutations that result in the premature termination of a polypeptide occurring during protein synthesis. In this assay, the isolated complementary DNA (cDNA) is transcribed and translated in vitro, and the protein is analyzed by gel electrophoresis. The truncated (mutant) gene product is readily identified as its electrophoretic mobility differs from that of the normal protein. This test is used most commonly for analyses of large genes with significant genetic heterogeneity such as *DMD*, *APC*, and the *BRCA* genes.

Like all laboratory tests, there are limitations to the accuracy and interpretation of genetic tests. In addition to technical errors, genetic tests are sometimes designed to detect only the most common mutations. In this case, a negative result must be qualified by the possibility that the individual may have a mutation that is not included in the test. In addition, a negative result does not mean that there is not a mutation in some other gene that causes a similar inherited disorder.

In addition to molecular testing for established disease, genetic testing for susceptibility to chronic disease is being increasingly integrated into the practice of medicine. In most cases, however, the discovery of disease-associated genes has greatly outpaced studies that assess clinical outcomes and the impact of interventions. Until such evidence-based studies are available, predictive molecular testing must be approached with caution and should be offered only to patients who have been adequately counseled and have provided informed consent. In the majority of cases, genetic testing should be offered only to individuals with a suggestive personal or family medical history or in the context of a clinical trial.

Predictive genetic testing falls into two distinct categories. *Presymptomatic testing* applies to diseases where a specific genetic alteration is associated with a near 100% likelihood of developing disease. In contrast, *predisposition testing* predicts a risk for disease that is less than 100%. For example, presymptomatic testing is available for those at risk for Huntington's disease, whereas predisposition testing is considered for those at risk for hereditary breast cancer. It is important to note that, for the majority of adult-onset, multifactorial genetic disorders, testing is purely predictive. Test results cannot reveal with confidence whether, when, or how the disease will manifest itself. For example, not everyone with the apolipoprotein E allele (ε4) will develop Alzheimer's disease, and individuals without this genetic marker can still develop the disorder (Chap. 365).

Molecular analysis is generally more informative if testing is initiated in a symptomatic family member, since the identification of a mutation can direct the testing of other at-risk family members (whether they are symptomatic or not). In the absence of additional familial or environmental risk factors, individuals who test negative for the mutation found in the affected family member can be informed that they are at general population risk for that particular disease. Furthermore, they can be reassured that they are not at risk for passing on the mutation to their children. On the other hand, asymptomatic family members who test positive for the known mutation must be informed that they are at increased risk for disease development and for transmitting the alteration to their children.

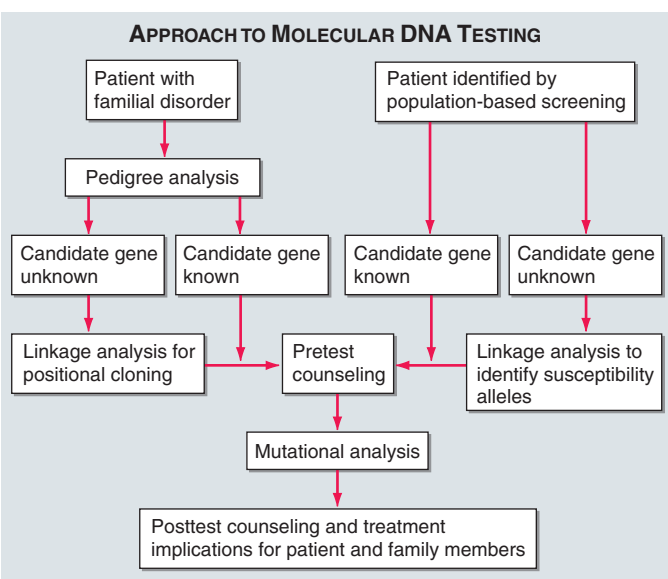

FIGURE 64-2 Approach to identifying a disease-causing gene.

Clinicians providing pretest counseling and education should assess the patient's ability to cope with test results. Individuals who demonstrate signs and symptoms of emotional distress should have their psychosocial needs addressed before proceeding with molecular testing. Generally, genetic testing should not be offered at a time of personal crisis or acute illness within the family. Patients will derive more benefit from test results if they are emotionally able to comprehend and absorb the information. It is important to assess patients' preconceived notions of their personal likelihood of disease in preparing pretest educational strategies. Often, patients harbor unwarranted fear or denial of their likelihood of genetic risk.

Genetic testing has the potential of affecting the way individual family members relate to one another, both negatively and positively. As a result, patients addressing the option of molecular testing must consider how test results might impact their relationships with relatives, partners, spouses, and friends. In families with a known genetic mutation, those who test positive must consider the impact of their carrier status on their present and future lifestyles; those who test negative may manifest *survivor guilt*. Family members are likely to differ in their emotional and social responses to the same information. Counseling should also address the potential consequences of test results on relationships with a spouse or child. Parents who are found to have a disease-associated mutation often express considerable anxiety and despair as they address the issue of risk to their children.

When a condition does not manifest until adulthood, clinicians will be faced with the question of whether at-risk children should be offered molecular testing and, if so, at what age. Although the matter is debated, several professional organizations have cautioned that genetic testing for adult-onset disorders should not be offered to children. Many of these conditions are not preventable; consequently, such information can pose significant psychosocial risk to the child. In addition, there is concern that testing during childhood violates a child's right to make an informed decision regarding testing upon reaching adulthood. On the other hand, testing should be offered in childhood for disorders that may manifest early in life, especially when management options are available. For example, children at risk for familial adenomatous polyposis (FAP), associated with alterations in the *APC* gene, may develop polyps as early as their teens, and progression to an invasive cancer can occur by their twenties. Likewise, children at risk for MEN type 2, which is caused by mutations in the *RET* proto-oncogene, may develop medullary thyroid cancer early in childhood, and the issue of prophylactic thyroidectomy should be addressed with the parents of children with documented mutations (Chap. 345).

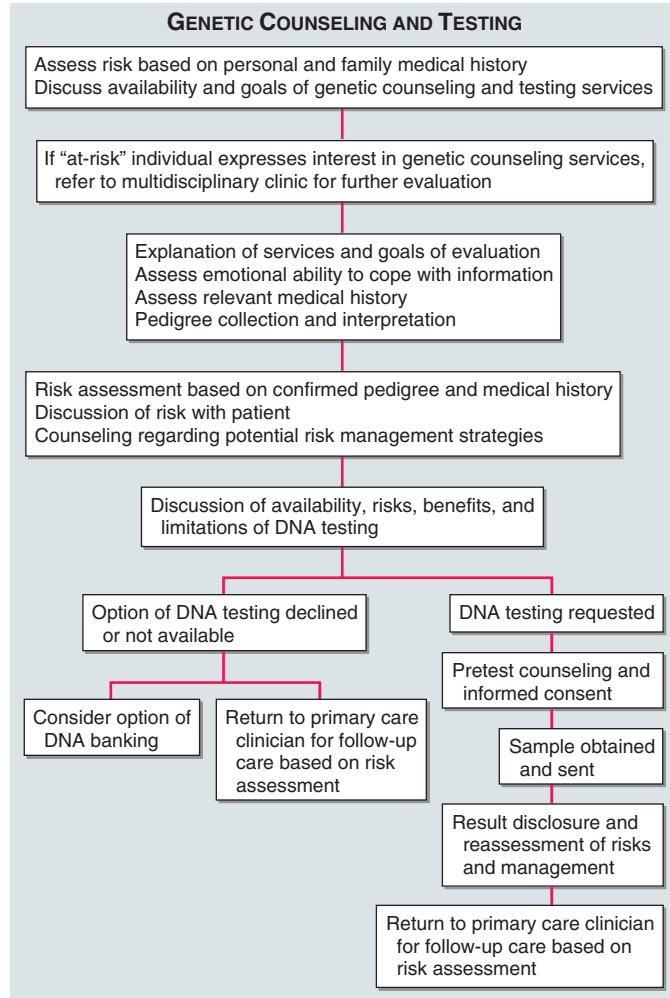

FIGURE 64-3 Algorithm for genetic counseling in association with genetic testing.

INFORMED CONSENT

When the issue of testing is addressed, patients should be strongly encouraged to involve other relatives in the decision-making process, as molecular diagnostics will likely have an impact on the entire family. Informed consent for molecular testing begins with detailed education and counseling (Fig. 64-3). The patient must fully understand the risks, benefits, and limitations of undergoing the analysis. Informed consent should include a written document, drafted clearly and concisely in a language and format that is comprehensible to the patient, who should be made aware of the disposition of test results. Informed consent should also include a discussion of the mechanics of testing. Most molecular testing for hereditary disease involves DNA-based analysis of peripheral blood. In the majority of circumstances, test results should be given only to the individual, in person, and with a support person in the room.

Because molecular testing of an asymptomatic individual often allows prediction of future risk, the patient should understand any potential long-term medical, psychological, and social implications of this decision. In the United States, legislation affecting this area is still evolving, and it is important to explore with the patient the potential impact that test results may have on employment and future health, as well as disability and life insurance coverage.

Patients should understand that alternatives to molecular analysis remain available if they decide not to proceed with this option. They should also be notified that testing is available in the future if they are not currently prepared to undergo analysis. The option of DNA banking should be presented so that samples are readily available for future use by family members, if needed.

FOLLOW-UP CARE AFTER TESTING

Depending on the nature of the genetic disorder, posttest interventions may include (1) cautious surveillance and appropriate health care screening, (2) specific medical interventions, (3) chemoprevention, (4) risk avoidance, and (5) referral to support services. For example, patients with known pathologic mutations in *BRCA1* or *BRCA2* are offered intensive screening as well as the option of prophylactic mastectomy and oophorectomy. In addition, such women may be eligible for preventive treatment with tamoxifen, or enrollment in a chemoprevention clinical trial. In contrast, those at known risk for Huntington's disease are offered continued follow-up and supportive services, including physical and occupational therapy, and social services or support groups, as indicated. Specific interventions will change as translational research continues to enhance our understanding of these genetic diseases and as more is learned about the functions of the gene products involved.

Individuals who test negative for a mutation in a disease-associated gene identified in an affected family member must be reminded that they may still be at risk for the disease. This is of particular importance for common diseases such as diabetes mellitus, cancer, and coronary artery disease. For example, a woman who finds that she does not carry the disease-associated mutation in *BRCA2* previously discovered in her family must be reminded that she still requires the same breast cancer screening recommended for the general population.

TABLE 64-1 INDICATIONS FOR GENETIC COUNSELING

Advanced maternal (>35) or paternal (>50) age
Consanguinity
Previous history of a child with birth defects or a genetic disorder
Personal or family history suggestive of a genetic disorder
High-risk ethnic groups; known carriers of genetic alterations
Documented genetic alteration in a family member
Ultrasound or prenatal testing suggesting a genetic disorder

GENETIC COUNSELING AND EDUCATION

Genetic counseling should be distinguished from genetic testing and screening, even though genetic counselors are often involved in issues related to testing. Genetic counseling refers to *a communication process that deals with human problems associated with the occurrence or risk of a genetic disorder in a family*. Genetic risk assessment is complex and often involves elements of uncertainty. Counseling therefore includes genetic education as well as psychosocial counseling. Genetic counselors may be called upon by other health care professionals (or by individual patients and families) to address a broad range of issues directly and indirectly related to genetic disease (Table 64-1). The role of the genetic counselor includes the following:

- Gather and document a detailed family history;
- Educate patients about general genetic principles related to disease risk, both for themselves and for others in their family;
- Assess and enhance the patient's ability to cope with the genetic information offered;
- Discuss how nongenetic factors may relate to the ultimate expression of disease;
- Address medical management issues;
- Assist in determining the role of genetic testing for the individual and family;
- Ensure that the patient is aware of the indications, process, risks, benefits, and limitations of the various genetic testing options;
- Assist the patient, family, and referring physician in the interpretation of the test results; and
- Refer the patient and other at-risk family members for additional medical and support services, if necessary.

The complexity of genetic counseling and the broad scope of genetic diseases have led to the development of specialized, multidisciplinary clinics designed to provide broad-based support and medical care for those at risk and their family members. Such specialty clinics are well established in the areas of cancer and neurodegenerative disorders. The multidisciplinary teams are often composed of medical geneticists, specialist physicians, genetic counselors, nurses, psychologists, social workers, and biomedical ethicists who work together to consider difficult diagnostic, treatment, and testing decisions. Such a format also provides primary care physicians with invaluable support and assistance as they follow and treat at-risk patients.

The approach to genetic counseling has important ethical, social, and financial implications. Philosophies related to genetic counseling vary widely by country and center. In North American centers, for example, counseling is generally offered in a nondirective manner, wherein patients learn to understand how their values factor into a particular medical decision. Nondirective counseling is particularly appropriate when there are no data demonstrating a clear benefit associated with a particular intervention or when an intervention is considered experimental. For example, nondirective genetic counseling is employed when a person is deciding whether to undergo genetic testing for Huntington's disease (Chap. 365). At this time, there is no clear benefit (in terms of medical outcome) to an at-risk individual undergoing genetic testing for this disease, as its course cannot be altered by therapeutic interventions. However, testing can have an important impact on this individual's perception of the future and his or her interpersonal relationships and plans for reproduction. Therefore, the decision to pursue testing rests on the individual's belief system and values. On the other hand, a more directive approach is appropriate when a condition can be treated. In a family with FAP, colon cancer screening and prophylactic colectomy should be recommended for known *APC* mutation carriers. The counselor and clinician following this family must ensure that the at-risk family members have access to the resources necessary to adhere to these recommendations.

Genetic education is central to an individual's ability to make an informed decision regarding testing options and treatment. Although genetic counselors represent one source of genetic education, other health care providers also need to contribute to patient education. Patients at risk for genetic disease should understand fundamental medical genetic principles and terminology relevant to their situation. This includes the concept of genes, how they are transmitted, and how they confer hereditary disease risk. An adequate knowledge of patterns of inheritance will allow patients to understand the probability of disease risk for themselves and other family members. It is also important to impart the concepts of disease penetrance and expression. For most complex adult-onset genetic disorders, asymptomatic patients should be advised that a positive test result does not always translate into future disease development. In addition, the role of nongenetic factors, such as environmental exposures, must be discussed in the context of multifactorial disease risk and disease prevention. Finally, patients should understand the natural history of the disease as well as the potential options for intervention, including screening, prevention, and—in certain circumstances—pharmacologic treatment or prophylactic surgery.

THERAPEUTIC INTERVENTIONS BASED ON GENETIC RISK FOR DISEASE

Specific treatments are now available for an increasing number of genetic disorders, whether identified through population-based screening or directed testing (Table 64-2). Although the strategies for therapeutic interventions are best developed for childhood hereditary metabolic diseases, these principles are making their way into the diagnosis and

TABLE 64-2 EXAMPLES OF GENETIC TESTING AND POSSIBLE INTERVENTIONS

Genetic Disorder	Inheritance	Genes	Interventions
Oncologic			
Hereditary nonpolyposis colon cancer	AD	*MSH2, MLH1, MSH6, PMS1, PMS2, TGFBR2*	Early endoscopic screening
Familial adenomatous polyposis	AD	*APC*	Early endoscopic screening Nonsteroidal anti-inflammatory drugs Colectomy
Familial breast and ovarian cancer	AD	*BRCA1, BRCA2*	Estrogen receptor antagonists Early screening by exams and mammography Consideration of prophylactic surgery
Familial melanoma	AD	*CDKN2A*	Avoidance of UV light Screening and biopsies
Basal cell nevus syndrome	AD	*PTCH*	Avoidance of UV light Screening and biopsies

TABLE 64-2 EXAMPLES OF GENETIC TESTING AND POSSIBLE INTERVENTIONS (CONTINUED)

Genetic Disorder	Inheritance	Genes	Interventions
Hematologic			
Factor V Leiden	AD	*F5*	Avoidance of thrombogenic risk factors and oral contraceptives
Hemophilia A	XL	*F8C*	Factor VIII replacement
Hemophilia B	XL	*F9*	Factor IX replacement Possible gene therapy
Glucose 6-PO4 dehydrogenase deficiency	XL	*G6PD*	Avoidance of oxidant drugs
Cardiovascular			
Hypertrophic cardiomyopathy	AD	*MYH7, MYBPC3, TMSA, TNNT2, TPM1*	Echocardiographic screening Early pharmacologic intervention Myomectomy
Long QT syndrome	AD	*KCNQ1, SCN5A, HERG, MiRP1, KCNE1, KCNE2*	Electrocardiographic screening Early pharmacologic intervention Implantable cardioverter defibrillator devices
Marfan syndrome	AD	*FBN1*	Echocardiographic screening Prophylactic beta blockers
Gastrointestinal			
Familial Mediterranean fever	AR	*MEFV*	Colchicine treatment
Hemochromatosis	AR	*HFE*	Phlebotomy
Pulmonary			
α_1 Antitrypsin deficiency	AR	*PI*	Avoidance of smoking Avoidance of occupational and environmental toxins
Primary pulmonary hypertension	AD	*BMPR2*	Treatment with pulmonary vasodilators
Renal			
Polycystic kidney disease	AD	*PKHD1, PKHD2*	Prevention of hypertension Prevention of urinary tract infections Kidney transplantation
Nephrogenic diabetes insipidus	XL, AR	*AVPR2, AQP2*	Fluid replacement Thiazides, amiloride
Endocrine			
Neurohypophyseal diabetes insipidus	AD	*AVP*	Replace vasopressin
Maturity-onset diabetes of the young	AD	Multiple genes	Screen and treat for diabetes
Familial hypocalciuric hypercalcemia	AD	*CASR*	Avoidance of parathyroidectomy
Kallmann syndrome	XL	*KAL*	Induction of puberty with hormone replacement
Multiple endocrine neoplasia type 2	AD	*RET*	Prophylactic thyroidectomy Screening for pheochromocytoma and hyperparathyroidism
21-hydroxylase deficiency	AR	*CYP21*	Glucocorticoid and mineralocorticoid treatment
Neurologic			
Malignant hyperthermia	AD	*RYR1*	Avoidance of precipitating anesthetics
Hyperkalemic periodic paralysis	AD	*SCN4A*	Acetazolamide
Adrenoleukodystrophy	XL	*ABCD1*	Possible bone marrow transplant for severe childhood CNS form
Duchenne and Becker muscular dystrophy	XL	*DMD*	Corticosteroids Possible future myoblast transfer
Familial Parkinson disease	AD	*SNCA, PARK2*	Amantadine, anticholinergics, levodopa, monoamine oxidase B inhibitors
Wilson disease	AR	*ATP7B*	Zinc, trientene

Abbreviations: AD, autosomal dominant; AR, autosomal recessive; CNS, central nervous system; XL, X-linked.

management of adult-onset disorders. Hereditary hemochromatosis illustrates many of the issues raised by the availability of genetic screening in the adult population. For instance, it is relatively common (approximately 1 in 200 individuals of northern European descent are homozygous), and its complications are potentially preventable through phlebotomy (Chap. 351). The identification of the *HFE* gene, mutations of which are associated with this syndrome, has sparked interest in the use of DNA-based testing for presymptomatic diagnosis of the disorder. However, up to one-third of individuals who are homozygous for the *HFE* mutation do not have evidence of iron overload. Consequently, in the absence of a positive family history, current recommendations include phenotypic screening for evidence of iron overload followed by genetic testing. Whether genetic screening for hemochromatosis will someday be coupled to assessment of phenotypic expression awaits further studies. In contrast to the issue of population screening, it is important to test and counsel other family members when the diagnosis of hemochromatosis has been made in a proband. Testing allows the physician to exclude family members who are not at risk. It also permits presymptomatic detection of iron overload and the institution of treatment (phlebotomy) before the development of organ damage.

Preventive measures and therapeutic interventions are not restricted to metabolic disorders. Identification of familial forms of long QT syn-

drome, associated with ventricular arrhythmias, allows early electrocardiographic testing and the use of prophylactic antiarrhythmic therapy, overdrive pacemakers, or defibrillators (Chap. 226). Individuals with familial hypertrophic cardiomyopathy can be screened by ultrasound, treated with beta blockers or other drugs, and counseled about the importance of avoiding strenuous exercise and dehydration (Chap. 231). Likewise, individuals with Marfan syndrome can be treated with beta blockers and monitored for the development of aortic aneurysms (Chap. 242). Individuals with α_1 antitrypsin deficiency can be strongly counseled to avoid cigarette smoking and exposure to environmental pulmonary and hepatotoxins. Various host genes influence the pathogenesis of certain infectious diseases in humans, including HIV (Chap. 182). The factor V Leiden allele increases risk of thrombosis (Chap. 59). Approximately 3% of the worldwide population is heterozygous for this mutation. Moreover, it is found in up to 25% of patients with recurrent deep-vein thrombosis or pulmonary embolism. Women who are heterozygous or homozygous for this allele should therefore avoid the use of oral contraceptives and receive heparin prophylaxis after surgery or trauma.

The field of pharmacogenomics seeks to identify genes that alter drug metabolism or confer susceptibility to toxic drug reactions. Pharmacogenomics permits individualized drug therapy, resulting in improved treatment outcomes, reduced toxicities, and more cost-effective pharmaceutical care. Examples include succinylcholine sensitivity, thiopurine methyltransferase (TPMT) deficiency, malignant hyperthermia, dihydropyrimidine dehydrogenase deficiency, the porphyrias, and glucose-6-phosphase dehydrogenase (G6PD) deficiency.

As noted above, the identification of genes that increase the risk of specific types of neoplasia is rapidly changing the management of many cancers. Identifying family members with mutations that predispose to FAP or hereditary nonpolyposis colon cancer (HNPCC) can lead to recommendations of early cancer screening or prophylactic surgery (Chap. 87). Similar principles apply to familial forms of melanoma, basal cell carcinoma, and cancers of the breast, ovary, and thyroid gland. It should be recognized, however, that most cancers harbor several distinct genetic abnormalities by the time they acquire invasive or metastatic potential (Chaps. 79 and 80). Consequently, the major impact of genetic testing in these cases is to allow more intensive clinical screening, as it remains very challenging to predict disease penetrance, expression, or clinical course.

Although genetic diagnosis of these and other disorders is only beginning to be used in the clinical setting, predictive testing holds the promise of allowing earlier and more targeted interventions that can reduce morbidity and mortality. We can expect the availability of genetic tests to expand. A critical challenge for physicians and other health care providers is to keep pace with these advances in genetic medicine and to implement testing judiciously.

65 Gene Therapy in Clinical Medicine

Katherine A. High

Gene transfer is a novel area of therapeutics in which the active agent is a nucleic acid sequence rather than a protein or small molecule. Because delivery of naked DNA or RNA to a cell is an inefficient process, most gene transfer is carried out using a vector, or gene delivery vehicle. These vehicles have generally been engineered from viruses by deleting some or all of the viral genome and replacing it with the therapeutic gene of interest under the control of a suitable promoter (Table 65-1). Gene transfer strategies can be described in terms of three essential elements: (1) a vector, (2) a gene to be delivered, and

TABLE 65-1 CHARACTERISTICS OF GENE DELIVERY VEHICLES

	Viral Vectors							
Features	**Retroviral**	**Lentiviral**	**Adenoviral**	**AAV**	**Human Foamy Virus**	**HSV-1**	**SV-40**	**Alpha-Viruses**
Viral genome	RNA	RNA	DNA	DNA	RNA	DNA	DNA	RNA
Cell division requirement	Yes	G1 phase	No	No	No	No	No	No
Packaging limitation	8 kb	8 kb	8–30 kb	5 kb	8.5 kb	40–150 kb	5 kb	5 kb
Immune responses to vector	Few	Few	Extensive	Few	Few	Few in recombinant virus	Few	Few
Genome integration	Yes	Yes	Poor	Poor	Yes	No	Poor	No
Long-term expression	Yes	Yes	No	Yes	Yes	No	No	No
Main advantages	Persistent gene transfer in dividing cells	Persistent gene transfer in transduced tissues	Highly effective in transducing various tissues	Elicits few inflammatory responses, nonpathogenic	Persistent gene expression in both dividing and nondividing cells	Large packaging capacity with persistent gene transfer	Wide host cell range; lack of immunogenicity	Limited immune responses against the vector
Main disadvantages	Theoretical risk of insertional mutagenesis (occurred in 3 cases)	Might induce oncogenesis in some cases	Viral capsid elicits strong immune responses	Limited packaging capacity	In need of a stable packaging system	Residual cytotoxicity with neuron specificity	Limited packaging capacity	Transduced gene expression is transient

Note: AAV, adeno-associated virus; HSV, herpes simplex virus; SV, sarcoma virus.

(3) a relevant target cell to which the DNA or RNA is delivered. The series of steps in which the donated DNA enters the target cell and begins expression is referred to as *transduction*. Gene delivery can take place in vivo, in which the vector is directly injected into the patient or, in the case of hematopoietic and some other target cells, ex vivo, with removal of the target cells from the patient, followed by return of the modified autologous cells after gene transfer in the laboratory. The latter approach offers opportunities to integrate gene transfer techniques with cellular therapies (Chap. 67).

Gene transfer technology is still under development and protocols are experimental. Gene therapy is one of the most complex therapeutic modalities yet attempted, and each new disease represents a therapeutic problem for which dosing, safety, and efficacy must be defined. Nonetheless, gene transfer remains one of the most powerful concepts in modern molecular medicine and has the potential to address a host of diseases for which there are currently no cures or, in some cases, no available treatment. Over 5000 subjects have been enrolled in gene transfer studies, and serious adverse events have been rare. Gene therapies are being developed for a wide variety of disease entities (Fig. 65-1).

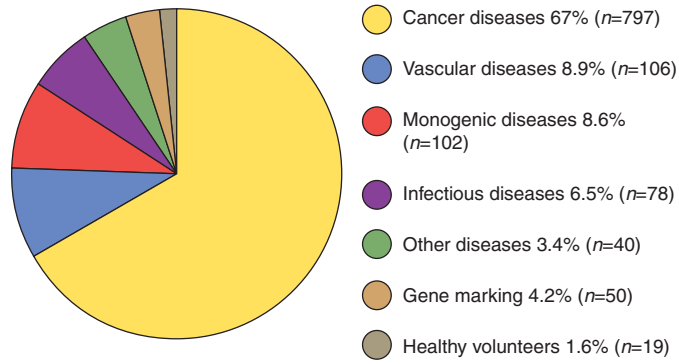

FIGURE 65-1 Indications in gene therapy clinical trials. The chart divides clinical gene transfer studies by disease classification. A majority of trials have addressed cancer, with monogenic disorders and cardiovascular diseases the next largest categories. *(Reproduced with permission from J Gene Med. New Jersey, Wiley, 2006.)*

GENE TRANSFER FOR GENETIC DISEASE

Gene transfer strategies for genetic disease generally involve gene addition therapy. This approach most commonly involves transfer of the missing gene to a physiologically relevant target cell. However, other strategies are possible, including supplying a gene that achieves a similar biologic effect through an alternative pathway (e.g., factor VIIa for hemophilia A); supplying an antisense oligonucleotide to splice out a mutant exon if the sequence is not critical to the function of the protein (as has been done with the dystrophin gene in Duchenne muscular dystrophy); or downregulating a harmful response through an siRNA. Two distinct strategies are used to achieve long-term gene expression: one is to transduce stem cells with an integrating vector, so that all progeny cells will carry the donated gene; the other is to transduce long-lived cells, such as skeletal muscle or neural cells. In the case of long-lived cells, integration into the target cell genome is unnecessary, provided the donated DNA can be stabilized in an episomal form.

Immunodeficiency Disorders: Proof of Principle Early attempts to provide gene replacement into hematopoietic stem cells (HSCs) were stymied by the relatively low transduction efficiency of retroviral vectors, which require dividing target cells for integration. Because HSCs are normally quiescent, they are a formidable transduction target. However, identification of cytokines that induced cell division without promoting differentiation of stem cells, along with technical improvements in the isolation and transduction of HSCs, led to modest but real gains in transduction efficiency.

The first convincing therapeutic effect from gene transfer occurred with X-linked severe combined immunodeficiency disease (SCID), which results from mutations in the gene (*IL2RG*) encoding the γc subunit of a cytokine receptor required for normal development of T and NK cells (Chap. 310). Affected infants present in the first few months of life with overwhelming infections and/or failure to thrive. In this disorder, it was recognized that the transduced cells, even if few in number, would have a proliferative advantage compared to the nontransduced cells, which lack receptors for the cytokines required for lymphocyte development and maturation. Complete reconstitution of the immune system, including documented responses to standard childhood vaccinations, clearing of infections, and remarkable gains in growth occurred in most of the treated children. However, two developed a syndrome similar to T cell acute lymphocytic leukemia, with splenomegaly, rising white counts, and the emergence of a single clone of T cells. In these children, the retroviral vector had integrated within a gene, *LMO-2* (LIM only-2), which encodes a component of a transcription factor complex involved in hematopoietic development. Insertion of the retroviral long terminal repeat is thought to increase the expression of *LMO-2*.

The X-linked SCID studies were a watershed event in the evolution of gene therapy. They demonstrated conclusively that gene therapy could cure disease; of the 16 infants eventually treated in these trials, 15 achieved correction of the immunodeficiency disorder. Unfortunately, 3 later developed a leukemia-like disorder, but 12 are alive and free of complications at time periods ranging up to 7 years after initial treatment. These studies also demonstrated that insertional mutagenesis leading to cancer was more than a hypothetical possibility. As a result of the experience in these trials, all protocols using integrating vectors in hematopoietic cells must include a plan for monitoring sites of insertion and clonal proliferation. Strategies to overcome this complication have included employing a "suicide" gene cassette in the vector, so that errant clones can be quickly

	Non-Viral Vectors			
Features	**Transposon/ Transposase System**	**Liposomes**	**Naked DNA**	**Site-Specific Integrase**
Viral genome	N/A	N/A	N/A	N/A
Cell division requirement	No	No	No	No
Packaging limitation	Undetermined, probably large	Undetermined, probably large	Undetermined, probably large	Undetermined, probably large
Immune responses to vector	No	No	No	No
Genome integration	Yes	No	No	Yes
Long-term expression	Yes	No	No	Undetermined
Main advantages	Transfects many cell types with long-term gene expression	Transfects many cell types. Large holding capacity to enable a high number of base pairs	Efficient in gene transfer; limited immunogenicity	Specific integration site
Main disadvantages	Early stage in development	Expensive to produce	Transient and low-level expression	Early stage in development

ablated; or using "insulator" elements in the cassette, which can limit the activation of genes surrounding the insertion site.

More clear-cut success has been achieved in a gene therapy trial for another form of SCID, adenosine deaminase (ADA) deficiency (Chap. 310). ADA-SCID is clinically similar to X-linked SCID, although it can be treated by enzyme replacement therapy with a pegylated form of the enzyme (PEG-ADA), which leads to immune reconstitution but not always to normal T cell counts. Enzyme replacement therapy is expensive (annual costs: $200,000–$300,000 in U.S. dollars). Gene therapy protocols have evolved to include the use of HSCs rather than T cells as the target for transduction; discontinuation of PEG-ADA at the time of vector infusion, so that the transduced cells have a proliferative advantage over the non-transduced; and the use of a mild conditioning regimen to facilitate engraftment of the transduced cells. There have been no complications in the six children treated on this protocol, with a median follow-up of >4 years. Based on current data, the efficacy of gene transfer for ADA-SCID is convincing, but longer term follow-up will be required to determine whether this approach is sufficiently safe to be routinely recommended as an alternative to PEG-ADA.

Other diseases likely to be amenable to transduction of HSCs include Wiskott-Aldrich syndrome (trials underway), chronic granulomatous disease, sickle cell disease, and thalassemia.

Long-Term Expression in Genetic Disease: In Vivo Gene Transfer with Recombinant Adeno-Associated Viral (AAV) Vectors Recombinant AAV vectors have emerged as attractive gene delivery vehicles for genetic disease. Engineered from a small replication-defective DNA virus, they are devoid of viral coding sequences and trigger very little immune response in experimental animals. They are capable of transducing nondividing target cells, and the donated DNA is stabilized primarily in an episomal form, thus minimizing risks associated with insertional mutagenesis. Because the vector has a tropism for certain long-lived cell types, such as skeletal muscle, the central nervous system (CNS), and hepatocytes, long-term expression can be achieved even in the absence of integration.

Clinical trials using recombinant AAV vectors are now ongoing for muscular dystrophies, α_1-antitrypsin deficiency, lipoprotein lipase deficiency, hemophilia B, and a form of congenital blindness called Leber's congenital amaurosis. Hemophilia is often considered a promising disease model for gene transfer, as the gene product does not require precise regulation of expression and biologically active clotting factors can be synthesized in a variety of tissue types, permitting latitude in choice of target tissue. Moreover, raising circulating factor levels from <1% (levels seen in those severely affected) into the range of 5% greatly improves the phenotype of the disease. Preclinical studies with recombinant AAV vectors infused into skeletal muscle or liver have resulted in long-term (>5 years) expression of factor VIII or factor IX in the hemophilic dog model. Administration to skeletal muscle of an AAV vector expressing factor IX in patients with hemophilia was safe and resulted in long-term expression as measured by muscle biopsy, but circulating levels never rose >1% for sustained periods, and a large number of IM injections (>80–100) was required to access a large muscle mass. Intravascular vector delivery has been employed to access large areas of skeletal muscle in animal models of hemophilia and will likely be tested in upcoming trials. Administration of an AAV vector expressing factor IX to the liver in humans with hemophilia resulted in therapeutic circulating levels at the highest dose tested, but expression at these levels (>5%) lasted for only 6–10 weeks before declining to baseline (<1%). A memory T cell response to viral capsid, present in humans but not in other animal species (which are not natural hosts for the virus), may be a contributing factor in the loss of expression. Fortunately, triggering of the memory T cell response appears tissue-specific, and it is possible that introduction of the vector into immunoprivileged sites, such as the CNS (e.g., for Parkinson's disease) or the retina, will avoid this complication.

Leber's congenital amaurosis (LCA) is a form of retinal degenerative disease, characterized by severe early-onset blindness. This disease, not currently treatable, is caused by mutations in several different genes; ~15% of cases of LCA are due to a mutation in a gene, *RPE65*, encoding a retinal pigment epithelial protein. In dogs with a null mutation in *RPE65*, sight has been restored after subretinal injection of an AAV vector expressing *RPE65*. Transgene expression appears to be stable, with the first animals treated >5 years ago continuing to manifest electrophysiologic and behavioral evidence of visual function. As is the case for X-linked SCID, gene transfer must occur relatively early in life to achieve correction of the genetic disease, although the exact limitations imposed by age await clinical studies. AAV-RPE65 trials have now been approved in both the United States and Great Britain. Other inherited retinal degenerative disorders may also be amenable to correction by gene transfer, as are certain complex acquired disorders such as age-related macular degeneration, which affects several million people worldwide. The neovascularization that occurs in age-related macular degeneration can be inhibited by expression of vascular endothelial growth factor (VEGF) inhibitors such as angiostatin, or through the use of RNAi-mediated knockdown of VEGF. Early-phase trials of siRNAs that target VEGF RNA are underway, but these require repeated intravitreal injection of the siRNAs; an AAV vector–mediated approach might allow long-term knockdown of VEGF.

GENE THERAPY FOR CANCER

The majority of clinical gene transfer experience has been in subjects with cancer (Fig. 65-1). As a general rule, a feature that distinguishes gene therapies from conventional cancer therapeutics is that the former are less toxic, in some cases because they are delivered locally (e.g., intratumoral injections), and in other cases because they are targeted specifically to elements of the tumor (immunotherapies, anti-angiogenic approaches).

Cancer gene therapies can be divided into local and systemic approaches (Table 65-2). Some of the earliest cancer gene therapy trials focused on local delivery of a prodrug or a suicide gene that would increase sensitivity of tumor cells to cytotoxic drugs. A frequently used strategy has been intratumoral injection of an adenoviral vector expressing the thymidine kinase (*TK*) gene. Cells that take up and express the *TK* gene can be killed after the administration of gancyclovir, which is phosphorylated to a toxic nucleoside by *TK*. Because cell division is required for the toxic nucleoside to affect cell viability, this strategy was initially used in aggressive brain tumors (glioblastoma multiforme) where the cycling tumor cells were affected but the nondividing normal neurons were not. More recently, this approach has been explored for locally recurrent prostate, breast, and colon tumors, among others.

Another local approach uses adenoviral-mediated expression of the tumor suppressor p53, which is mutated in a wide variety of cancers. This strategy has shown complete and partial responses in squamous cell carcinoma of the head and neck, esophageal cancer, and non-small cell lung cancer after direct intratumoral injection of the vector. Response rates (~15%) are comparable to those of other single agents. The use of oncolytic viruses that selectively replicate in tumor cells but not in normal cells has also shown promise in squamous cell carcinoma of the head and neck and in other solid tumors. This approach is based on the observation that deletion of certain viral genes abolishes their ability to replicate in normal cells but not in tumor cells. An advantage of this strategy is that the replicating vector can proliferate and spread within the tumor, facilitating eventual tumor clearance. However, physical limitations to viral spread, including fibrosis, intermixed normal cells, basement membranes, and necrotic areas within the tu-

mor, may reduce clinical efficacy. Oncolytic viruses are licensed and available in some countries, but not in the United States.

Because metastatic disease rather than uncontrolled growth of the primary tumor is the source of mortality for most cancers, there has been considerable interest in developing systemic gene therapy approaches. One strategy has been to promote more efficient recognition of tumor cells by the immune system. Approaches have included transduction of tumor cells with immune-enhancing genes encoding cytokines, chemokines, or co-stimulatory molecules. Sustained clinical responses provide evidence that the transduced cells can act as a vaccine. In a related approach, patient lymphocytes have been transduced with genes encoding a T cell receptor–like molecule, with a tumor antigen–binding domain fused to an intracellular signaling domain to allow T cell activation, thereby converting normal lymphocytes into cells capable of recognizing and destroying tumor cells. A third immunotherapy approach relies on ex vivo manipulation of dendritic cells to enhance the presentation of tumor antigens. These immunologic approaches may be of particular value in treating minimal residual disease after other anticancer modalities.

Gene transfer strategies have also been developed for inhibiting tumor angiogenesis. These have included constitutive expression of angiogenesis inhibitors such as angiostatin and endostatin; use of siRNA to reduce levels of VEGF or VEGF receptor; and combined approaches in which autologous T cells are genetically modified to recognize antigens specific to tumor vasculature. These studies are still in early-phase testing.

Another novel systemic approach is the use of gene transfer to protect normal cells from the toxicities of chemotherapy. The most extensively studied of these approaches has been transduction of hematopoietic cells with genes encoding resistance to chemotherapeutic agents, including the multidrug resistance gene *MDRI* or the gene encoding O^6-methylguanine DNA methyltransferase (*MGMT*). Ex vivo transduction of hematopoietic cells, followed by autologous transplantation, is being investigated as a strategy for allowing administration of higher doses of chemotherapy than would otherwise be tolerated.

GENE THERAPY FOR VASCULAR DISEASE

The third major category addressed by gene transfer studies is cardiovascular disease. The most extensive experience has been in trials designed to increase blood flow to either skeletal (critical limb ischemia) or cardiac muscle (angina/myocardial ischemia). Initial treatment options for both of these groups include mechanical revascularization or medical management, but a subset of patients are not candidates for, or fail, these approaches. These patients have formed the first cohorts for evaluation of gene transfer to achieve therapeutic angiogenesis. The major transgene used has been VEGF, attractive because of its specificity for endothelial cells; other transgenes have included fibroblast growth factor (FGF) and hypoxia-inducible factor 1, α subunit (HIF-1α). The design of most of the trials has included direct IM (or myocardial) injection of either a plasmid or an adenoviral vector expressing the transgene. Both of these vectors are likely to result in only short-term expression of VEGF. This strategy may be adequate, however, as there is no need for continued transgene expression once the new vessels have formed. Direct injection favors local expression, which should help to avoid systemic effects such as retinal neovascularization or new vessel formation in a nascent tumor. Initial trials of adeno-VEGF or plasmid-VEGF injection have resulted in improvement over baseline in terms of frequency of claudication/angina or amounts of nitroglycerin consumption. Study designs including placebo control groups and more objective endpoints (exercise duration at 3 or 6 months, rest and stress cardiac perfusion scans, and regional wall motion assessed by nonfluoroscopic electroanatomic mapping) continue to suggest a beneficial effect of gene transfer, although definitive conclusions will require larger studies. Continuing areas of investigation include choice of the optimal vector (adenoviral vs. plasmid), the optimal transgene (VEGF, HIF-1α, FGF, etc.), the optimal method of delivery in cardiac indications (intracoronary vs. direct myocardial), ideal objective endpoints, and whether concurrent administration of cytokines to mobilize endothelial progenitor cells will augment the therapeutic effect.

TABLE 65-3 TAKING HISTORY FROM SUBJECTS ENROLLED IN GENE TRANSFER STUDIES

Elements of History for Subjects Enrolled in Gene Transfer Trials
1. What vector was administered? Is it predominantly integrating [retroviral, lentiviral, herpesvirus (latency and reactivation)], or non-integrating (plasmid, adenoviral, AAV)?
2. What was the route of administration of the vector?
3. What was the target tissue?
4. What gene was transferred in? A disease-related gene? A marker?
5. Were there any adverse events noted after gene transfer?
Screening Questions for Long-Term Follow-Up in Gene Transfer Subjects[a]
1. Has a new malignancy been diagnosed?
2. Has a new neurologic/ophthalmologic disorder, or exacerbation of a pre-existing disorder, been diagnosed?
3. Has a new autoimmune or rheumatologic disorder been diagnosed?
4. Has a new hematologic disorder been diagnosed?

[a]Factors influencing long-term risk include: integration of the vector into the genome; vector persistence without integration; and transgene-specific effects.

OTHER DISEASES

The power and versatility of gene transfer approaches are such that there are few serious disease entities for which gene transfer therapies are *not* under development. Besides those already discussed, other areas of interest include gene therapies for HIV and for neurodegenerative disorders. The latter include studies in patients with Parkinson's disease, where AAV vectors expressing enzymes required for enhanced production of dopamine, or of the inhibitory neurotransmitter γ-aminobutyric acid, have been introduced into affected areas of the brain (striatum, subthalamic nucleus) by stereotactic neurosurgery. In Alzheimer's disease, an ex vivo approach in which autologous fibroblasts are transduced with a retroviral vector expressing nerve growth factor, then reimplanted into the basal forebrain, has slowed the rate of cognitive decline in a small Phase I study.

SUMMARY

The development of new classes of therapeutics typically takes two to three decades; monoclonal antibodies and recombinant proteins are recent examples. Gene therapeutics, which entered clinical testing in the early 1990s, are well along in the course of development, and are likely to become increasingly important as a therapeutic modality in the twenty-first century. A central question to be addressed is the long-term safety of gene transfer, and regulatory agencies have mandated a 15-year follow-up for subjects enrolled in gene therapy trials (Table 65-3). Realization of the therapeutic benefits of the Human Genome Project, and of new discoveries such as RNAi, will depend on continued progress in gene transfer technology.

ACKNOWLEDGMENT

I would like to thank Valder Arruda, MD, PhD, for his review of the manuscript.

66 Stem Cell Biology

Minoru S. H. Ko

Stem cell biology is a relatively new field that explores the characteristics and possible clinical applications of the different types of pluripotential cells that serve as the progenitors of more differentiated cell types. In addition to potential therapeutic applications (Chap. 67), patient-derived stem cells can also provide disease models and a means to test drug effectiveness.

IDENTIFICATION, ISOLATION, AND DERIVATION OF STEM CELLS

Resident Stem Cells The definition of stem cells remains elusive. Stem cells were originally postulated as *unspecified* or *undifferentiated* cells that provide a source of renewal of skin, intestine, and blood cells throughout the lifespan. These *resident stem cells* are now identified in a variety of organs, i.e., epithelia of the skin and digestive system, bone marrow, blood vessels, brain, skeletal muscle, liver, testis, and pancreas, based on their specific locations, morphology, and biochemical markers.

Isolated Stem Cells Unequivocal identification of stem cells requires the separation and purification of cells, usually based on a combination of specific cell-surface markers. These *isolated stem cells*, e.g., hematopoietic stem (HS) cells, can be studied in detail and used in clinical applications, such as bone marrow transplantation (Chap. 68). However, the lack of specific cell-surface markers for other types of stem cells has made it difficult to isolate them in large quantities. This challenge has been partially addressed in animal models by genetically marking different cell types with green fluorescence protein driven by cell-specific promoters. Alternatively, putative stem cells have been isolated from a variety of tissues as side population (SP) cells using fluorescence-activated cell sorting after staining with Hoechst 33342 dye. However, the SP phenotype should be used with caution as it may not be function for stem cells.

Cultured Stem Cells It is desirable to culture and expand stem cells in vitro to obtain a sufficient quantity for analysis and potential therapeutic use. Although the derivation of stem cells in vitro has been a major obstacle in stem cell biology, the number and types of *cultured stem cells* have increased progressively (Table 66-1). The cultured stem cells derived from resident stem cells are often called *adult stem cells* to indicate their adult origins and to distinguish them from *embryonic stem* (ES) and *embryonic germ* (EG) *cells*. However, considering the presence of embryo-derived tissue-specific stem cells, e.g., trophoblast stem (TS) cells, and the possible derivation of similar cells from embryo/fetus, e.g., neural stem (NS) cells, it is more appropriate to use the term, *tissue stem cells*.

Successful derivation of cultured stem cells (both embryonic and tissue stem cells) often requires the identification of necessary growth factors and culture conditions, mimicking the microenvironment or *niche* of the resident stem cells. For example, the derivation of mouse TS cells, once considered impossible, became possible by using FGF4, a ligand known to be expressed by cells adjacent to the developing trophoblast in vivo. Therefore, it may be possible to culture other resident stem cells (e.g., intestinal stem cells) or isolated stem cells (e.g., HS cells) by studying the factors that constitute their normal niche.

SELF-RENEWAL AND PROLIFERATION OF STEM CELLS

Symmetric and Asymmetric Cell Division The most widely accepted stem cell definition is a cell with a unique capacity to produce unaltered daughter cells (*self-renewal*) and to generate specialized cell types (*potency*). Self-renewal can be achieved in two ways. *Asymmetric cell division* produces one daughter cell that is identical to the parental cell and one daughter cell that is different from the parental cell and is a progenitor or differentiated cell. Asymmetric cell division does not increase the number of stem cells. *Symmetric cell division* produces two identical daughter cells. For stem cells to proliferate in vitro, they must divide symmetrically. Self-renewal alone cannot define stem cells, because any established cell line, e.g., HeLa cells or NIH3T3 cells, proliferate by symmetric cell division.

Unlimited Expansion In Vitro Resident stem cells are often quiescent and divide infrequently. However, once the stem cells are successfully cultured in vitro, they often acquire the capacity to divide continuously and the ability to proliferate beyond the normal limit of passages typical of primary cultured cells (sometimes called *immortality*). These features are primarily seen in ES cells, but have also been demonstrated for NS cells, MS cells, MAPCs, maGSCs (adult-derived tissue stem cells), and USSCs (newborn-derived tissue stem cells), thereby enhancing the potential of these cells for therapeutic use (Table 66-1).

Stability of Genotype and Phenotype The capacity to actively proliferate is associated with the potential accumulation of chromosomal abnormalities and mutations. Mouse ES cells have been extensively used to produce gene-targeted animals and are known to maintain their euploid karyotype and genome integrity. In contrast, human ES cells appear to be more susceptible to mutations after long-term culture. Another limitation is the possible formation of tumors after transplanting actively dividing stem cells. Mouse ES cells can form teratomas when injected into immunosuppressed animals.

POTENCY AND DIFFERENTIATION OF STEM CELLS

Developmental Potency The term *potency* is used to indicate a cell's ability to differentiate into specialized cell types. The current lack of knowledge about the molecular nature of potency requires the experimental manipulation of stem cells to demonstrate their potency. For example, in vivo testing can be done by injecting stem cells into mouse blastocysts or immunosuppressed adult mice and determining how many different cell types are formed from the injected cells. In vitro testing can be done by differentiating cells in various culture conditions to determine how many different cell types are formed from the cells. The in vivo assays are not applicable to human stem cells. The formal demonstration of self-renewal and potency is performed by demonstrating that a single cell possesses such abilities in vitro (*clonality*). Cultured stem cells are tentatively grouped according to their potency (Fig. 66-1).

From Totipotency to Unipotency *Totipotent cells* can form an entire organism autonomously. Only a fertilized egg (zygote) possesses this feature. *Pluripotent cells* (e.g., ES cells) can form almost all the body's cell lineages (endoderm, mesoderm, and ectoderm), including germ cells. *Multipotent cells* (e.g., HS cells) can form multiple cell lineages but cannot form all of the body's cell lineages. *Oligopotent cells* (e.g., NS cells) can form more than one cell lineage but are more restricted than multipotent cells. Oligopotent cells are sometimes called *progenitor cells* or *precursor cells*; however, these terms are often more strictly used to define partially differentiated or lineage-committed cells (e.g., myeloid progenitor cells) that can divide into different cell types but lack self-renewing capacity. *Unipotent cells* or *monopotent cells*, e.g., spermatogonial stem (SS) cells, can form a single differentiated cell lineage. Terminally differentiated cells, such as fibroblast cells, also have a capacity to proliferate (which may be called self-renewal) but maintain the same cell type (e.g., no potency to form another cell type) and are not, therefore, considered unipotent cells.

Nuclear Reprogramming Development naturally progresses from totipotent fertilized eggs to pluripotent epiblast cells, to multipotent cells, and finally to terminally differentiated cells. According to Wad-

TABLE 66-1 TYPES OF CULTURED STEM CELLS

Name	Source, Derivation, Maintenance, and Properties
Embryonic stem cells (ES, ESC)	ES cells can be derived by culturing blastocysts or immuno-surgically isolated inner cell mass (ICM) from blastocysts on a feeder layer of MEFs with LIF (m) or without LIF (h). ES cells are to originate from the epiblast (m, h). ES cells grow as tightly adherent multicellular colonies with a population doubling time of ~12 h (m), maintain a stable euploid karyotype even after extensive culture and manipulation, can differentiate into a variety of cell types in vitro, and can contribute to all cell types, including functional sperm and oocytes, when injected into a blastocyst (m). ES cells form relatively flat, compact colonies with the population doubling time of 35–40 h (h).
Embryonic germ cells (EG, EGC)	EG cells can be derived by culturing primordial germ cells (PGCs) from embryos at E8.5–E12.5 on a feeder layer of MEFs with FGF2 and LIF (m). EG cells can be derived by culturing gonadal tissues from 5–11 week post-fertilization embryo/fetus on a feeder layer of MEFs with FGF2, forskolin, and LIF (h). EG cells show essentially the same pluripotency as ES cells when injected into mouse blastocysts (m). The only known difference is the imprinting status of some genes (e.g., Igf2r): Imprinting is normally erased during germline development, and thus, the imprinting status of in EG cells is different from that of ES cells.
Trophoblast stem cells (TS, TSC)	TS cells can be derived by culturing trophectoderm cells of E3.5 blastocysts, extraembryonic ectoderm of E6.5 embryos, and chorionic ectoderm of E7.5 embryos on a feeder layer of MEFs with FGF4 (m). TS cells can differentiate into trophoblast giant cells in vitro (m). TS can contribute exclusively to all trophoblast subtypes when injected into blastocysts (m).
Extraembryonic endoderm cells (XEN)	XEN cells can be derived by culturing the ICM in non-ES cell culture condition (m). XEN cells can contribute only to the parietal endoderm lineage when injected into a blastocyst (m).
Embryonic carcinoma cells (EC)	EC cells can be derived from teratocarcinoma—a type of cancer that most commonly develops in the testes. EC cells rarely show pluripotency in vitro, but they can contribute to all cell types when injected into blastocysts. EC cells often have an aneuploid karyotype and other genome alterations.
Mesenchymal stem cells (MS, MSC)	MS cells can be derived from bone marrow, muscle, adipose tissue, peripheral blood, and umbilical cord blood (m, h). MS cells can differentiate into mesenchymal cell types, including adipocytes, osteocytes, chondrocytes, and myocytes (m, h).
Multipotent adult stem cells (MAPC)	MAPCs can be derived by culturing bone marrow mononuclear cells, after depleting $CD45^+$ and $GlyA^+$ cells, with FCS, EGF, and PDGF-BB (h). MAPCs are very rare cells that are present within MSC cultures from postnatal bone marrow (m, h). MAPCs can also be isolated from postnatal muscle and brain (m). MAPCs can be cultured for >120 population doublings. MAPCs can differentiate into all tissues in vivo when injected into a mouse blastocyst, and can differentiate into various cell lineages of mesodermal, ectodermal, and endodermal origin in vitro (m).
Spermatogonial stem cells (SS, SSC)	SS cells can be derived by culturing newborn testis on STS-feeder cells with GDNF (m). SS cells can reconstitute long-term spermatogenesis after transplantation into recipient testes and restore fertility.
Germline stem cells (GS, GSC)	GS cells can be derived from neonatal testis (m). GS cells can differentiate into three germlayers in vitro and contribute to a variety of tissues, including germline, when injected into blastocysts.
Multipotent adult germline stem cells (maGSC)	maGSC can be derived from adult testis (m). maGSC can differentiate into three germlayers in vitro and can contribution to a variety of tissues, including germline, when injected into blastocysts.
Neural stem cells (NS, NSC)	NS cells can be derived from fetal and adult brain (subventricular zone, ventricular zone, and hippocampus) and cultured as a heterogeneous cell population of monolayer or floating cell clusters called *neurospheres*. NS cells can differentiate into neuron and glia in vivo and in vitro. Recently, the culture of pure population of symmetrically dividing adherent NS cells became possible in the presence of FGF2 and EGF.
Unrestricted somatic stem cells (USSC)	USSCs are rare cells derived from newborn cord blood (h). USSCs can be derived by culturing the mononuclear fraction of cord blood in the presence of 30% FCS and 10^{-7} *M* dexamethasone. USSCs can differentiate into a variety of cell types in vitro and can contribute a variety of cells types in in vivo transplantation experiments in rat, mouse, and sheep (h). USSCs are $CD45^-$ adherent cells and can be expanded to 10^{15} cells without losing pluripotency (h).

Note: m, mouse; h, human; FGF, fibroblast growth factor; FCS, fetal calf serum; EGF, epidermal growth factor; PDGF, platelet-derived growth factor; GDNF, glial cell line–derived neurotrophic factor; LIF, leukemia inhibitory factor; MEF, mouse embryonic fibroblast.

dington's epigenetic landscape, this is analogous to a ball moving down a slope. The reversal of the terminally differentiated cells to totipotent or pluripotent cells (called *nuclear reprogramming*) can thus be seen as an uphill gradient that never occurs in normal conditions. However, nuclear reprogramming has been achieved using *nuclear transplantation*, or *nuclear transfer* (NT), procedures (often called "cloning"), where the nucleus of a differentiated cell is transferred into an enucleated oocyte. Although this is an error-prone procedure and the success rate is very low, live animals have been produced using adult somatic cells as donors in sheep, mouse, and other mammals. In mice, it has been demonstrated that ES cells derived from blastocysts made by somatic cell NT are indistinguishable from normal ES cells. NT can potentially be used to produce *patient-specific ES cells* carrying a genome identical to that of the patient. However, the successful implementation of this procedure has not been reported in humans. Setting aside technical and ethical issues, the limited supply of human oocytes will be a major problem for clinical applications of NT. Alternatively, successful nuclear reprogramming of somatic cells by fusing them with ES cells has been demonstrated in mouse and human. However, it is not yet clear how ES-derived DNA can be removed from hybrid cells. More direct nuclear reprogramming of somatic cells by transfecting specific genes or by exposing the cells to ES cell extracts is the subject of current research.

Stem Cell Plasticity or Transdifferentiation The prevailing paradigm in developmental biology is that once cells are differentiated, their phenotypes are stable. However, a number of reports have shown that tissue stem cells, which are thought to be lineage-committed multipotent cells, possess the capacity to differentiate into cell types outside their lineage restrictions (called *transdifferentiation*). For example, HS cells may be converted into neurons as well as germ cells. This feature may provide a means to use tissue stem cells derived directly from a patient for therapeutic purposes, thereby eliminating the need to use embryonic stem cells or elaborate procedures such as nuclear reprogramming a patient's somatic cells. However, more strict criteria and rigorous validation are required to establish tissue stem cell plasticity. For example, observations of transdifferentiation may reflect cell fusion, contamination with progenitor cells from other cell lineages, or persistence of pluripotent embryonic cells in adult organs. Therefore, the assignment of potency to each cultured stem cell in Fig. 66-1 should be taken with caution. Whether transdifferentiation exists and can be used for therapeutic purposes remains to be determined conclusively.

Directed Differentiation of Stem Cells Pluripotent stem cells (e.g., ES cells) can differentiate into multiple cell types, but in culture they normally differentiate into heterogeneous cell populations in a stochastic manner. However, for therapeutic uses, it is desirable to direct stem cells into specific cell types (e.g., insulin-secreting beta cells). This is an active area of stem cell research, and protocols are being developed to achieve this goal. In any of these directed cell differentiation systems, the cell phenotype must be evaluated critically. Interestingly, it has been reported that mouse ES cells can differentiate in vitro into oocytes as well as sperm, which are capable of fertilizing an oocyte to produce live offspring.

Potency \ Stage	Preimplantation	Embryonic, fetal	Postnatal	Adult
Totipotent	Zygote^{m,h}			
Pluripotent	ES^{m,h}	EG^{m,h}	GS^{m} USSC^{h} MAPC^{m,h}	EC^{m,h} maGSC^{m} MAPC^{m,h}
Multipotent				MS^{m,h}
Oligopotent	TS^{m}			NS^{m,h}
Unipotent	XEN^{m}			SSC^{m}
Terminally differentiated cells				

FIGURE 66-1 Potency and source developmental stage of cultured stem cells. For abbreviations of stem cells, see Table 66-1. Note that stem cells are often abbreviated with or without "cells," e.g., ES cells or ESCs for embryonic stem cells. m, mouse; h, human.

MOLECULAR CHARACTERIZATION OF STEM CELLS

Genomics and Proteomics In addition to standard molecular biological approaches, genomics and proteomics have been extensively applied to the analysis of stem cells. For example, DNA microarray analyses have revealed the expression levels of essentially all genes and identified specific markers for some stem cells. Similarly, the protein profiles of stem cells have been assessed by using mass spectrophotometry. These methodologies are beginning to provide a novel means to characterize and classify various stem cells and the molecular mechanisms that give them their unique characteristics.

Stemness This term has been used to designate the essential molecular characteristics of stem cells. It is also used to indicate common genetic programs shared among ES cells and tissue stem cells (HS and NS cells). A number of common genes, such as stress-response genes, have been identified, but the lack of commonality among different studies raises concerns about the validity of this concept.

Pivotal Genes Involved in ES Cell Regulation Recent work has begun to identify genes involved in the regulation of stem cell function. For example, three genes—*Pou5f1* (Oct3/4), *Nanog*, and *Sox2*—govern key gene regulatory pathways/networks for the maintenance of self-renewal and pluripotency of mouse and human ES cells. Similarly, it has been shown that the interaction and balance among three transcription factors—*Pou5f1*, *Cdx2*, and *Gata6*—determine the fate of mouse ES cells: upregulation of *Cdx2* differentiates ES cells into trophoblast cells, whereas upregulation of *Gata6* differentiates ES cells into primitive endoderm. These types of analyses should provide molecular clues about the function of stem cells and lead to a more effective means to manipulate stem cells for future therapeutic use.

67 Applications of Stem Cell Biology in Clinical Medicine

John A. Kessler

Organ damage and the resultant inflammatory responses initiate a series of repair processes, including stem cell proliferation, migration, and differentiation, often in combination with angiogenesis and remodeling of the extracellular matrix. Endogenous stem cells in tissues such as liver and skin have a remarkable ability to regenerate the organs, whereas heart and brain have a much more limited capability for self-repair. Under rare circumstances, circulating stem cells may contribute to regenerative responses by migrating into a tissue and differentiating into organ-specific cell types. The goal of stem cell therapies is to promote cell replacement in organs that are damaged beyond their ability for self-repair.

SOURCES OF STEM CELLS FOR TISSUE REPAIR

Different types of stem cells include embryonic stem (ES) cells, umbilical cord blood stem cells, organ-specific somatic stem cells (e.g., neural stem cells for treatment of the brain), and somatic stem cells capable of generating cell types specific for the target rather than the donor organ (e.g., bone marrow mesenchymal stem cells for cardiac repair) (Chap. 66). ES cells self-renew endlessly so that a single cell line with carefully characterized traits can generate large numbers of cells that can be immunologically matched with potential transplant recipients. However, little is currently known about the mechanisms that govern differentiation of these cells or processes that limit their unbridled proliferation. Human ES cells are difficult to culture and grow slowly. ES cells tend to develop abnormal karyotypes and have the potential to form teratomas if they are not committed to the desired cell types before transplantation. The study of human ES cells has been controversial, and their use in clinical applications would be unacceptable to some patients and physicians despite their enormous potential. Somatic cell nuclear transfer ("therapeutic cloning") represents an alternative method for creating ES cell lines that are genetically identical to the patient. It may also be possible to derive pluripotent stem cells from spermatogonia in the adult human testis, providing another strategy for obtaining genetically identical stem cells.

Umbilical cord blood stem/progenitor cells are associated with less graft-versus-host disease compared to marrow stem cells. They have less HLA restriction than adult marrow stem cells, and they are less likely to be contaminated with herpesvirus. However, it is unclear how many different cell types these cells can generate, and methods for differentiating them into nonhematopoietic phenotypes are largely lacking. The quantity of cells from any single source can also be limiting.

Organ-specific multipotent stem cells are already somewhat specialized and may be easier to induce into desired cell types. These cells could potentially be obtained from the patient and amplified in culture, thereby circumventing the problems associated with immune rejection. Multipotent stem cells are relatively easy to harvest from bone marrow (Chap. 68) but are more difficult to isolate from other tissues, such as heart and brain. Substantial efforts have therefore been devoted to obtaining more pluripotent stem cell populations, such as bone marrow mesenchymal stem cells (MSCs) or adipose stem cells, for use in regenerative strategies. Tissue culture evidence suggests that these stem cell populations are able to generate a variety of cell types, including myocytes, chondrocytes, tendon cells, osteoblasts, cardiomyocytes, adipocytes, hepatocytes, and neurons, through a process known as transdifferentiation. However, it is unclear how effectively these differentiated cells integrate into organs, survive, and function after

transplantation in vivo. Early studies of bone marrow–derived stem cells transplanted into heart, liver, and other organs suggested that the cells had differentiated into organ-specific cell types. Subsequent studies, however, revealed that the stem cells had fused with cells resident in the organs. Further studies will be necessary to determine whether transdifferentiation of MSCs or other stem cell populations occurs at a high enough frequency to be useful for stem cell replacement therapy.

Regardless of the source of the stem cells used in regenerative strategies, a number of generic problems must be overcome for the development of successful clinical applications. These include development of methods for reliably generating large numbers of specific cell types, minimizing the risk of tumor formation or proliferation of inappropriate cell types, ensuring the viability and function of the engrafted cells, overcoming immune rejection when autografts are not used, and facilitating revascularization of the regenerated tissue. Each organ system will also pose tissue-specific problems for stem cell therapies.

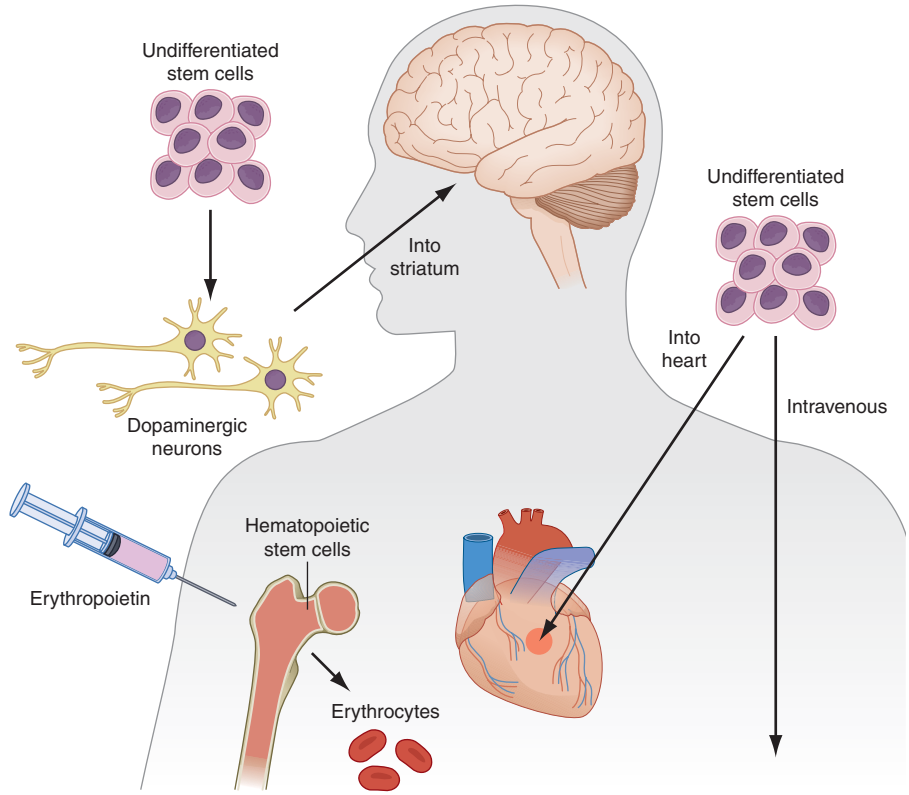

FIGURE 67-1 Strategies for transplantation of stem cells. 1. Undifferentiated or partially differentiated stem cells may be injected directly in the target organ or intravenously. 2. Stem cells may be differentiated ex vivo prior to injection into the target organ. 3. Growth factors or other drugs may be injected to stimulate endogenous stem cell populations.

STRATEGIES FOR STEM CELL REPLACEMENT

Stem cell transplantation is not a new concept and it is already part of established medical practice. Hematopoietic stem cells (HSCs) (Chap. 68) are responsible for the long-term repopulation of all blood elements in bone marrow transplant recipients. HSC transplantation is now the gold standard against which other stem cell transplantation therapies will be measured. Transplantation of differentiated cells is also a clinical reality, as donated organs (e.g., liver, kidney) and tissues (i.e., cornea, eye, skin) are often used to replace damaged tissues. However, the clinical need for transplantable tissues and organs far outweighs the available supply, and organ transplantation has limited potential for some tissues such as the brain. Stem cells offer the possibility of a renewable source of cell replacement for virtually all organs.

At least three different therapeutic concepts for cell replacement have been considered (Fig. 67-1): (1) injection of stem cells directly into the damaged organ or into the circulation, allowing them to "home" into the damaged tissue; (2) in vitro differentiation of stem cells followed by transplantation into a damaged organ—e.g., pancreatic islet cells could be generated from stem cells prior to transplantation into patients with diabetes, whereas cardiomyocytes could be generated to treat ischemic heart disease; and (3) stimulation of endogenous stem cells to facilitate repair—e.g., administration of appropriate growth factors to amplify numbers of endogenous stem/progenitor cells or direct them to differentiate into the desired cell types. In addition to these strategies for cell replacement, the ex vivo or in situ generation of tissues provides an alternative means of tissue engineering (Chap. 69). Stem cells are also excellent vehicles for cellular gene therapy (Chap. 65).

DISEASE-SPECIFIC STEM CELL APPROACHES

ISCHEMIC HEART DISEASE AND CARDIOMYOCYTE REGENERATION

Because of the high prevalence of ischemic heart disease, extensive efforts have been devoted to cell replacement of cardiomyocytes. Historically, the adult heart has been viewed as a terminally differentiated organ without the capacity for regeneration. However, the heart has the ability to achieve low levels of cardiomyocyte regeneration as well as revascularization. This regeneration is likely accomplished by cardiac stem cells resident in the heart, and possibly by cells originating in the bone marrow. If such cells could be characterized, isolated, and amplified ex vivo, they might provide an ideal source of stem cells for therapeutic use. For effective myocardial repair, cells must be delivered either systemically or locally, and the cells must survive, engraft, and differentiate into functional cardiomyocytes that couple mechanically and electrically with the recipient myocardium. The optimal method for cell delivery is not yet clear, and various experimental studies have employed intramyocardial, transendocardial, intravenous, and intracoronary injections. In experimental myocardial infarction, functional improvements have been achieved after transplantation of a variety of different cell types, including ES cells, bone marrow stem cells, endothelial stem cells, and adipose stem cells. Bone marrow stem cells in particular have been examined in clinical trials of human ischemic heart disease. These have largely been small, nonrandomized studies that typically combine cell treatment with conventional therapies. Although the fate of the cells and mechanisms by which they altered cardiac function are open questions, these studies have shown small but measurable improvement in cardiac function and, in some cases, reduction in infarct size. The preponderance of evidence suggests that the functional benefits are not derived from direct generation of cardiomyocytes but rather from indirect effects of the stem cells on resident cells. This may reflect the release of soluble growth factors, induction of angiogenesis, or some other mechanism.

DIABETES MELLITUS

The success of islet cell and pancreas transplantation provides proof of concept for a cell-based approach for type I diabetes. However, the demand for donor pancreata far exceeds the number available, and maintenance of long-term graft survival remains a problem. The search for a renewable source of stem cells capable of regenerating pancreatic islets has therefore been intensive.

Pancreatic β cell turnover occurs in the normal pancreas, although the source of the new β cells is controversial. Attempts to promote en-

dogenous regenerative processes have not yet been successful, but this remains a potentially viable approach. A number of different cell types are candidates for use in stem cell replacement, including ES cells, hepatic progenitor cells, pancreatic ductal progenitor cells, and bone marrow stem cells. Successful therapy will depend on developing a source of cells that can be amplified and have the ability to synthesize, store, and release insulin when it is required, primarily in response to changes in the glucose level. The proliferative capacity of the replacement cells must be tightly regulated to avoid excessive expansion of β cell numbers with the consequent development of hyperinsulinemia/hypoglycemia, and the cells must avoid immune rejection. Although ES cells can be differentiated into cells that produce insulin, these cells have relatively low insulin content and a high rate of apoptosis, and they generally lack the capacity to normalize blood glucose in diabetic animals. Thus, ES cells have not yet been useful for the large-scale production of differentiated islet cells.

During embryogenesis, the pancreas, liver, and gastrointestinal tract are all derived from the anterior endoderm, and transdifferentiation of the pancreas to liver and vice versa has been observed in certain pathologic conditions. Multipotential stem cells also reside within gastric glands and intestinal crypts. Thus, hepatic, pancreatic, and/or gastrointestinal precursor cells may be candidates for cell-based therapy of diabetes.

NERVOUS SYSTEM

Neural cells have been differentiated from a variety of stem cell populations. Human ES cells can be induced to generate neural stem cells, and these cells can give rise to neurons, oligodendroglia, and astrocytes. These neural stem cells have been transplanted into the rodent brain with formation of appropriate cell types and no tumor formation. Multipotent stem cells present in the adult brain can also generate all of the major neural cell types, but highly invasive procedures would be necessary to obtain autologous cells. Fetal neural stem cells derived from miscarriages or abortuses are an alternative, and a clinical trial of fetal neural stem cells in Batten disease is commencing. Transdifferentiation of bone marrow and adipose stem cells into neural stem cells, and vice versa, has been reported, and clinical trials of such cells have begun for a number of neurologic disorders. Clinical trials of a conditionally immortalized human cell line and of human umbilical cord blood cells in stroke are also planned. Neurologic disorders that have already been targeted for stem cell therapies include spinal cord injury, amyotrophic lateral sclerosis, stroke, traumatic brain injury, Batten disease, and Parkinson's disease. In Parkinson's disease, the major motor features result from the loss of a single cell population, dopaminergic neurons within the substantia nigra pars compacta. Two clinical trials of fetal nigral transplantation failed to meet their primary endpoint and were complicated by the development of dyskinesia. Transplantation of stem cell–derived dopamine-producing cells offers a number of potential advantages over fetal transplants, including the ability of stem cells to migrate and disperse within tissue, the potential for engineering regulatable release of dopamine, and the ability to engineer cells to produce factors that will enhance cell survival. Nevertheless, the experience with fetal transplants points out the difficulties that may be encountered.

At least some of the neurologic dysfunction after spinal cord injury reflects demyelination, and both ES cells and marrow-derived stem cells are able to facilitate remyelination after experimental spinal cord injury. Clinical trials of marrow-derived stem cells have already begun, and this may be the first disease targeted for the clinical use of ES cells. Marrow-derived stem cells are also being used in the treatment of stroke, traumatic brain injury, and amyotrophic lateral sclerosis (ALS), where possible benefits are more likely to be indirect trophic effects or remyelination rather than neuron replacement. At present, no population of transplanted stem cells has been shown to generate neurons that extend axons over long distances to form synaptic connections (such as would be necessary for replacement of upper motor neurons in ALS, stroke, or other disorders).

LIVER

Transplantation is currently the only successful treatment for end-stage liver diseases, but this approach is limited by the shortage of liver grafts. Clinical trials of hepatocyte transplantation demonstrate that it can potentially substitute for organ transplantation, but the paucity of available cells also limits this strategy. Potential sources of stem cells include endogenous liver stem cells (such as oval cells), ES cells, bone marrow cells, and umbilical cord blood cells. Although a series of studies in humans as well as animals suggested that transplanted bone marrow stem cells can generate hepatocytes, this phenomenon largely reflects the fusion of the transplanted cells with endogenous liver cells, giving the erroneous appearance of new hepatocytes. ES cells have been differentiated into hepatocytes and transplanted in animal models of liver failure without formation of teratomas.

OTHER ORGAN SYSTEMS AND THE FUTURE

The use of stem cells in regenerative medicine has been studied for many other organ systems and cell types, including skin, eye, cartilage, bone, kidney, lung, endometrium, vascular endothelium, smooth muscle, striated muscle, and others. In fact, the potential for stem cell regeneration of damaged organs and tissues is virtually limitless. However, numerous obstacles must be overcome before stem cell therapies can become a widespread clinical reality. Only HSCs have been adequately characterized by surface markers to allow unambiguous identification, a prerequisite for reliable clinical applications. The pathways for differentiating stem cells into specific cellular phenotypes are still unknown, the migration of transplanted cells is uncontrolled, and the response of the cells to the environment of diseased organs is unpredictable. Future strategies may employ the coadministration of scaffolding, artificial extracellular matrix, and/or growth factors to orchestrate differentiation of stem cells and their organization into appropriate constituents of the organ. Imaging techniques are needed to visualize stem cells in vivo after transplantation into humans. Fortunately, stem cells can be engineered before transplantation to contain contrast agents that may make this feasible. The potential for tumor formation and the problems associated with immune rejection are significant impediments. Many strategies for cell replacement already include vasoactive endothelial growth factor (VEGF) coadministration to foster vascularization, which is required for survival and function of the transplant. Some stem cells have been engineered to have an inducible suicide gene so that the cells can be eradicated in the event of tumor formation or some other complication. The potential for stem cell therapies to revolutionize medical care is extraordinary, and disorders such as myocardial infarction, diabetes, Parkinson's disease and many others are attractive targets. However, such stem cell–based therapies are at a very early stage of development, and perfection of techniques for clinical transplantation of predictable, well-characterized cells will be a difficult and lengthy undertaking.

ETHICAL ISSUES

Stem cell therapies raise contentious ethical issues that must be addressed in parallel with the scientific and medical opportunities. Our society has great diversity in religious beliefs, concepts of individual rights, tolerance for uncertainty and risk, and boundaries for how scientific interventions should be used to alter the outcome of disease. In the United States, the federal government has authorized research using human ES lines in existence before August 2001 but has restricted the use of federal funds for developing new human ES lines. However, these existing lines develop abnormalities with time in culture and are contaminated with mouse proteins. These findings have sparked renewed debate about the need to develop new human ES cell lines.

In considering ethical issues associated with the use of stem cells, it is helpful to draw from experience with other scientific advances, such as organ transplantation, recombinant DNA technology, implantation of mechanical devices, neuroscience and cognitive research, in vitro fertilization, and prenatal genetic testing. From these and other precedents, we learn the importance of understanding and testing fundamental biology in the laboratory setting and in animal models before

applying new techniques in carefully controlled clinical trials. When these trials occur, they must include full informed consent and have careful oversight by external review groups.

Ultimately, medical interventions will be scientifically feasible but ethically or socially unacceptable to some members of a society. Stem cell research raises questions about the definition of human life, and it has raised deep fears about our ability to balance issues of justice and safety with the needs of critically ill patients. Health care providers and experts with backgrounds in ethics, law, and sociology must help guard against the premature or inappropriate application stem cell therapies, and the inappropriate use of vulnerable population groups. On the other hand, these therapies offer important new strategies for the treatment of otherwise irreversible disorders. An open dialogue between the scientific community, physicians, patients, and their advocates, lawmakers, and the lay population is important to raise and address ethical issues and to balance the benefits and risks associated with stem cell transfer.

68 Hematopoietic Stem Cells

David T. Scadden, Dan L. Longo

All of the cell types in the peripheral blood and some cells in every tissue of the body are derived from hematopoietic (*hemo*: blood; *poiesis*: creation) stem cells. If the hematopoietic stem cell is damaged and can no longer function (e.g., due to the nuclear accident at Chernobyl), a person would survive 2–4 weeks in the absence of extraordinary support measures. With the clinical use of hematopoietic stem cells, tens of thousands of lives are saved each year (Chap. 108). Stem cells produce tens of billions of blood cells daily from a stem cell pool that is estimated to be only in the hundreds of thousands. How stem cells do this, how they persist for many decades despite the production demands, and how they may be better used in clinical care are important issues in medicine.

The study of blood cell production has become a paradigm for how other tissues may be organized and regulated. Basic research in hematopoiesis that includes defining stepwise molecular changes accompanying functional changes in maturing cells, aggregating cells into functional subgroups, and demonstrating hematopoietic stem cell regulation by a specialized microenvironment are concepts worked out in hematology, but they offer models for other tissues. Moreover, these concepts may not be restricted to normal tissue function but extend to malignancy. Stem cells are rare cells among a heterogeneous population of cell types, and their behavior is assessed mainly in experimental animal models involving reconstitution of hematopoiesis. Thus, much of what we know about stem cells is imprecise and based on inferences from genetically manipulated animals.

CARDINAL FUNCTIONS OF HEMATOPOIETIC STEM CELLS

All stem cell types have two cardinal functions: self-renewal and differentiation (Fig. 68-1). Stem cells exist to generate, maintain, and repair tissues. They function successfully if they can replace a wide variety of shorter-lived mature cells over prolonged periods. The process of self-renewal (see below) assures that a stem cell population can be sustained over time. Without self-renewal, the stem cell pool could exhaust over time and tissue maintenance would not be possible. The process of differentiation provides the effectors of tissue function: mature cells. Without proper differentiation, the integrity of tissue function would be compromised and organ failure would ensue.

In the blood, mature cells have variable average life spans, ranging from 7 h for mature neutrophils to a few months for red blood cells to many years for memory lymphocytes. However, the stem cell pool is the

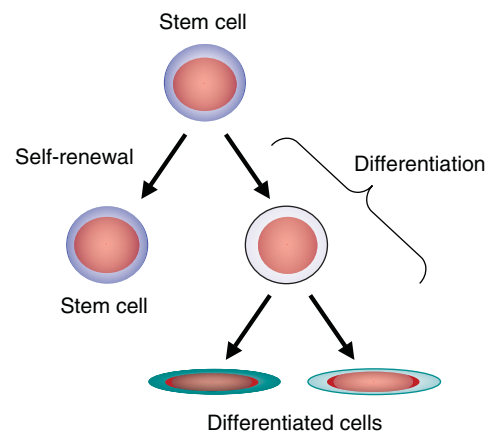

FIGURE 68-1 Signature characteristics of the stem cell. Stem cells have two essential features: the capacity to differentiate into a variety of mature cell types and the capacity for self-renewal. Intrinsic factors associated with self-renewal include expression of Bmi-1, Gfi-1, PTEN, STAT5, Tel/Atv6, p21, p18, MCL-1, Mel-18, RAE28, and HoxB4. Extrinsic signals for self-renewal include Notch, Wnt, SHH, and Tie2/Ang-1. Based mainly on murine studies, hematopoietic stem cells express the following cell surface molecules: CD34, Thy-1 (CD90), c-Kit receptor (CD117), CD133, CD164, and c-Mpl (CD110, also known as the thrombopoietin receptor).

central, durable source of all blood and immune cells, maintaining a capacity to produce a broad range of cells from a single cell source and yet keeping itself vigorous over decades of life. As an individual stem cell divides, it has the capacity to accomplish one of three division outcomes: two stem cells, two cells destined for differentiation, or one stem cell and one differentiating cell. The former two outcomes are the result of symmetric cell division, whereas the latter indicates a different outcome for the two daughter cells—an event termed *asymmetric cell division*. The relative balance for these types of outcomes may change during development and under particular kinds of demands on the stem cell pool.

DEVELOPMENTAL BIOLOGY OF HEMATOPOIETIC STEM CELLS

During development, blood cells are produced at different sites. Initially, the yolk sac provides oxygen-carrying red blood cells, and then several sites of intraembryonic blood cell production become involved. These intraembryonic sites engage in sequential order, moving from the genital ridge at a site where the aorta, gonadal tissue, and mesonephros are emerging to the fetal liver and then, in the second trimester, to the bone marrow and spleen. As the location of stem cells changes, the relative abundance of cells they produce also changes, progressively increasing

in the complexity of cell types from those simply carrying oxygen to platelets supporting a more complex vasculature to the cells of innate immunity and finally to the cells of adaptive immunity. Stem cell proliferation remains high, even in the bone marrow, until shortly after birth, when it appears to dramatically decline. The cells in the bone marrow are thought to arrive by the bloodborne transit of cells from the fetal liver after calcification of the long bones has begun. The presence of stem cells in the circulation is not unique to a time window in development. Rather, hematopoietic stem cells appear to circulate throughout life. The time that cells spend freely circulating appears to be brief (measured in minutes in the mouse), but the cells that do circulate are functional and can be used for transplantation. The number of stem cells that circulate can be increased in a number of ways to facilitate harvest and transfer to the same or a different host.

MOBILITY OF HEMATOPOIETIC STEM CELLS

Cells entering and exiting the bone marrow do so through a series of molecular interactions. Circulating stem cells (through CD162 and CD44) engage the lectins P- and E-selectin on the endothelial surface to slow the movement of the cells to a rolling phenotype. Stem cell integrins are then activated and accomplish firm adhesion between the stem cell and vessel wall, with a particularly important role for stem cell VCAM-1 engaging endothelial VLA-4. The chemokine CXCL12 (SDF1) interacting with stem cell CXCR4 receptors also appears to be important in the process of stem cells getting from the circulation to where they engraft in the bone marrow. This is particularly true in the developmental move from fetal liver to bone marrow; however, the role for this molecule in adults appears to be more related to retention of stem cells in the bone marrow rather the process of getting them there. Interrupting that retention process through either specific molecular blockers of the CXCR4/CXCL12 interaction, cleavage of CXCL12, or downregulation of the receptor can all result in the release of stem cells into the circulation. This process is an increasingly important aspect of recovering stem cells for therapeutic use as it has permitted the harvesting process to be done by leukapheresis rather than bone marrow punctures in the operating room. Refining our knowledge of how stem cells get into and out of the bone marrow may improve our ability to obtain stem cells and make them more efficient at finding their way to the specific sites for blood cell production, the so-called stem cell niche.

HEMATOPOIETIC STEM CELL MICROENVIRONMENT

The concept of a specialized microenvironment, or stem cell niche, was first proposed to explain why cells derived from the bone marrow of one animal could be used in transplantation and again be found in the bone marrow of the recipient. This niche is more than just a housing site for stem cells, however. It is an anatomic location where regulatory signals are provided that allow the stem cells to thrive, to expand if needed, and to provide varying amounts of descendant daughter cells. In addition, unregulated growth of stem cells may be problematic based on their undifferentiated state and self-renewal capacity. Thus, the niche must also regulate the number of stem cells produced. In this manner, the niche has the dual functions of serving as a site of nurture but imposing limits for stem cells: in effect, acting as both a nest and a cage.

The niche for blood stem cells changes with each of the sites of blood production during development, but for most of human life it is located in the bone marrow. Within the bone marrow, at least two niche sites have been proposed: on trabecular bone surfaces and in the perivascular space. Stem cells may be found in both places by histologic analysis, and functional regulation has been shown at the bone surface. Specifically, bone-forming mesenchymal cells, osteoblasts, participate in hematopoietic stem cell function, affecting their location, proliferation, and number. The basis for this interaction is through a number of molecules mediating location, such as the chemokine CXCL12 (SDF1) and N-cadherin, through proliferation signals mediated by angiopoietin 1, and signaling to modulate self-renewal or survival by factors such as Notch ligands, kit ligand, and Wnts. Other bone components, such as the extracellular matrix glycoprotein, osteopontin, and the high ionic calcium found at trabecular surfaces, contribute to the unique microenvironment, or stem cell niche, on trabecular bone. This physiology has practical applications. First, medications altering niche components may have an effect on stem cell function. This has now been shown for a number of compounds, and some are being clinically tested. Second, it is now possible to assess whether the niche participates in disease states and to examine whether targeting the niche with medications may alter the outcome of certain diseases.

EXCESS CAPACITY OF HEMATOPOIETIC STEM CELLS

In the absence of disease, one never runs out of hematopoietic stem cells. Indeed, serial transplantation studies in mice suggest that sufficient stem cells are present to reconstitute several animals in succession, with each animal having normal blood cell production. The fact that allogeneic stem cell transplant recipients also never run out of blood cells in their life span, which can extend for decades, argues that even the limiting numbers of stem cells provided to them are sufficient. How stem cells respond to different conditions to increase or decrease their mature cell production remains poorly understood. Clearly, negative feedback mechanisms affect the level of production of most of the cells, leading to the normal tightly regulated blood cell counts. However, many of the regulatory mechanisms that govern production of more mature progenitor cells do not apply or apply differently to stem cells. Similarly, most of the molecules shown to be able to change the size of the stem cell pool have little effect on more mature blood cells. For example, the growth factor erythropoietin, which stimulates red blood cell production from more mature precursor cells, has no effect on stem cells. Similarly, granulocyte colony-stimulating factor drives the rapid proliferation of granulocyte precursors but does not affect cell cycling of stem cells. Rather, it changes the location of stem cells by indirect means, altering molecules such as CXCL12 that tether stem cells to their niche. Molecules shown to be important for altering the proliferation of stem cells, such as the cyclin-dependent kinase inhibitor p21Cip1, have little or no effect on progenitor proliferation. Hematopoietic stem cells have governing mechanisms that are distinct from the cells they generate.

HEMATOPOIETIC STEM CELL DIFFERENTIATION

Hematopoietic stem cells sit at the base of a branching hierarchy of cells culminating in the many mature cell types that compose the blood and immune system (Fig. 68-2). The maturation steps leading to terminally differentiated and functional blood cells take place both as a consequence of intrinsic changes in gene expression and niche-directed and cytokine-directed changes in the cells. Our knowledge of the details remains incomplete (see *http://stemcell.princeton.edu/* for a comprehensive listing of gene expression in stem cells). As stem cells mature to progenitors, precursors, and, finally, mature effector cells, they undergo a series of functional changes. These include the obvious acquisition of functions defining mature blood cells, such as phagocytic capacity or hemoglobinization. They also include the progressive loss of plasticity, i.e., the ability to become other cell types. For example, the myeloid progenitor can make all cells in the myeloid series but none in the lymphoid series. As common myeloid progenitors mature, they become precursors for either monocytes and granulocytes or erythrocytes and megakaryocytes, but not both. Some amount of reversibility of this process may exist early in the differentiation cascade, but that is lost beyond a distinct stage. As cells differentiate, they may also lose proliferative capacity (Fig. 68-3). Mature granulocytes are incapable of proliferation and only increase in number by increased production from precursors. Lymphoid cells retain the capacity to proliferate but have linked their proliferation to the recognition of particular proteins or peptides by specific antigen receptors on their surface. In most tissues the proliferative cell population is a more immature progenitor population. In general, cells within the highly proliferative progenitor cell compartment are also relatively short-lived, making their way through the differentiation process in a defined molecular program involving the sequential activation of particular sets

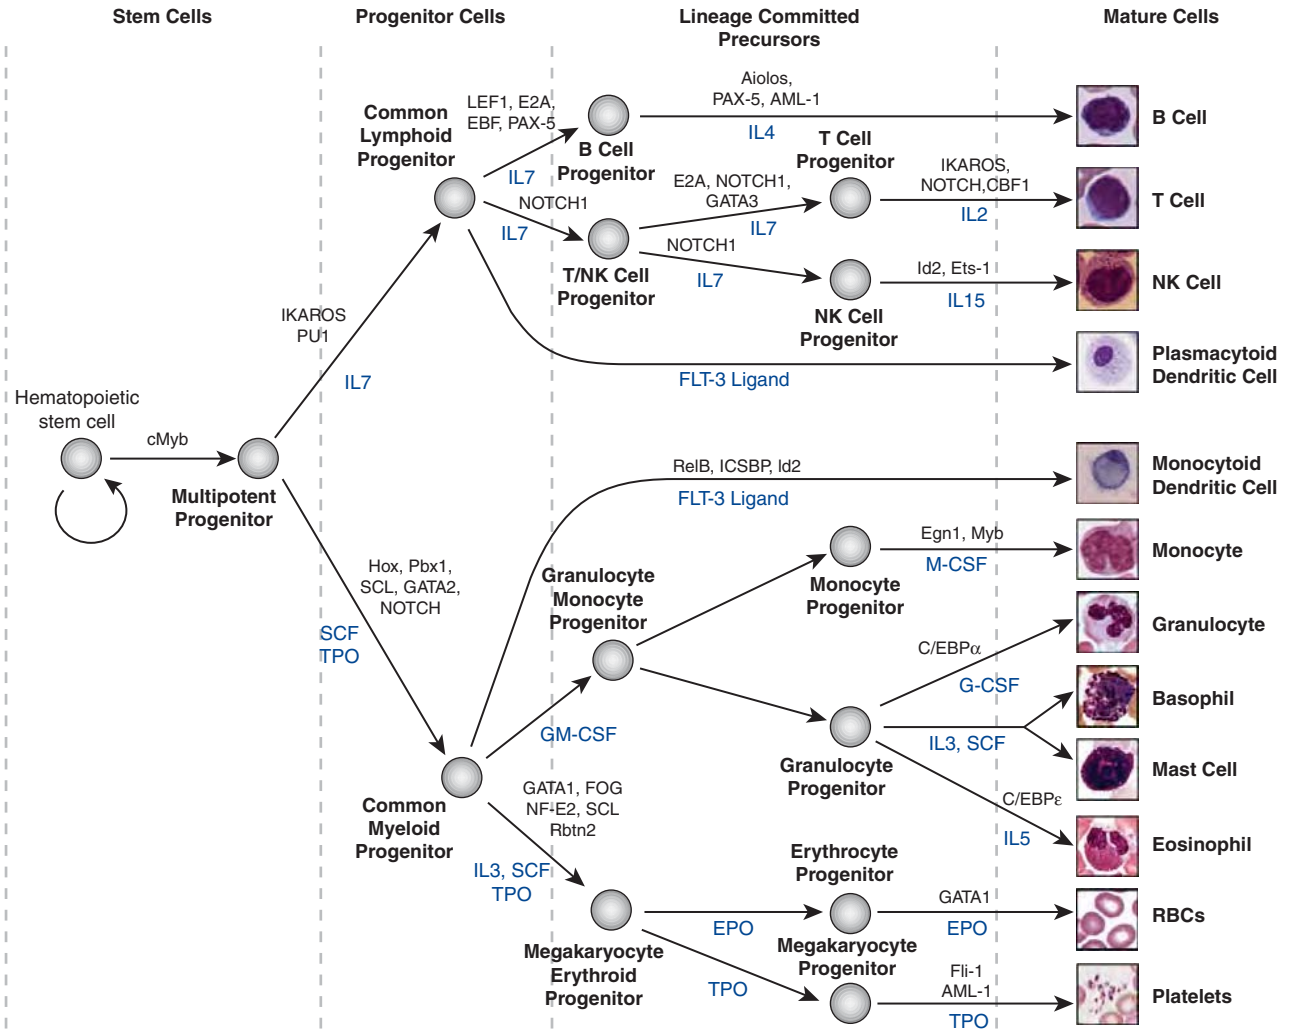

FIGURE 68-2 Hierarchy of hematopoietic differentiation. *Stem cells* are multipotent cells that are the source of all descendant cells and have the capacity to provide either long-term (measured in years) or short-term (measured in months) cell production. *Progenitor cells* have a more limited spectrum of cells they can produce and are generally a short-lived, highly proliferative population also known as transient amplifying cells. *Precursor cells* are cells committed to a single blood cell lineage but with a continued ability to proliferate; they do not have all the features of a fully mature cell. *Mature cells* are the terminally differentiated product of the differentiation process and are the effector cells of specific activities of the blood and immune system. Progress through the pathways is mediated by alterations in gene expression. The regulation of the differentiation by soluble factors and cell-cell communications within the bone marrow niche are still being defined. The transcription factors that characterize particular cell transitions are illustrated on the arrows; the soluble factors that contribute to the differentiation process are in blue. SCF, stem cell factor; EPO, erythropoietin; TPO, thrombopoietin.

of genes. For any particular cell type, the differentiation program is difficult to speed up. The time it takes for hematopoietic progenitors to become mature cells is ~10–14 days in humans, evident clinically by the interval between cytotoxic chemotherapy and blood count recovery in patients.

SELF-RENEWAL

The hematopoietic stem cell must balance its three potential fates: apoptosis, self-renewal, and differentiation. The proliferation of cells is generally not associated with the ability to undergo a self-renewing division except among memory T and B cells and among stem cells. Self-renewal capacity gives way to differentiation as the only option after cell division when cells leave the stem cell compartment, until they have the opportunity to become memory lymphocytes. In addition to this self-renewing capacity, stem cells have an additional feature characterizing their proliferation machinery. Stem cells in most mature adult tissues are deeply quiescent. In the hematopoietic system, stem cells are also highly cytokine-resistant, remaining dormant even when cytokines drive bone marrow progenitors to proliferation rates measured in hours, not days. Stem cells, in contrast, are thought to divide at intervals measured in months to years, at least as estimated in nonhuman primates. This deep quiescence is difficult to overcome in vitro, limiting the ability to effectively expand human hematopoietic stem cells. The process may be controlled by particularly high levels of expression of cyclin-dependent kinase inhibitors that restrict entry of stem cells into cell cycle, blocking the G1-S transition. Modifying the levels of molecules such as p21Cip1 and p18INK4c in the laboratory has resulted in increased stem cell proliferation and number in mice and in some limited human cell studies. Exogenous signals from the niche also appear to enforce quiescence, including the activation of the tyrosine kinase receptor Tie2 on stem cells by angiopoietin 1 on osteoblasts.

The regulation of stem cell proliferation also appears to change with age. In mice, the cyclin-dependent kinase inhibitor p16INK4a accumulates in stem cells in older animals and is associated with a change in five different stem cell functions, including cell cycling. Lowering expression of p16INK4a in older animals improves stem cell cycling and capacity to reconstitute hematopoiesis in adoptive hosts, making them similar to younger animals. Mature cell numbers are unaffected. Therefore, molecular events governing the specific functions of stem cells are being gradually made clear and offer the potential of new ap-

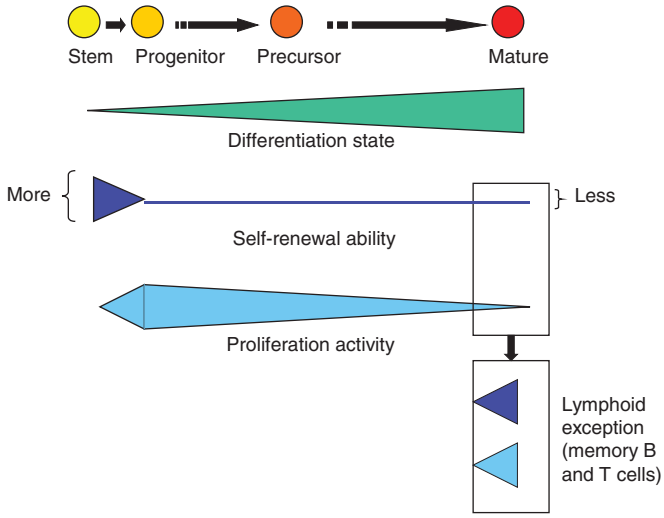

FIGURE 68-3 Relative function of cells in the hematopoietic hierarchy. The boxes represent distinct functional features of cells in the myeloid (*upper box*) versus lymphoid (*lower box*) lineages.

proaches to changing stem cell function for therapy. One critical stem cell function that remains poorly defined is the molecular regulation of self-renewal.

For medicine, self-renewal is perhaps the most important function of stem cells because it is critical in regulating the number of stem cells. Stem cell number is a key limiting parameter for both autologous and allogeneic stem cell transplantation. Were we to have the ability to use fewer stem cells or expand limited numbers of stem cells ex vivo, it might be possible to reduce the morbidity and expense of stem cell harvests and enable use of other stem cell sources. Specifically, umbilical cord blood is a rich source of stem cells. However, the volume of cord blood units is extremely small, and therefore the total number of hematopoietic stem cells that can be obtained is generally only sufficient to transplant an individual of <40 kg. This limitation restricts what would otherwise be an extremely promising source of stem cells. Two features of cord blood stem cells are particularly important. (1) They are derived from a diversity of individuals that far exceeds the adult donor pool and therefore can overcome the majority of immunologic cross-matching obstacles. (2) Cord blood stem cells have a large number of T cells associated with them, but (paradoxically) they appear to be associated with a lower incidence of graft-versus-host disease when compared with similarly mismatched stem cells from other sources. If stem cell expansion by self-renewal could be achieved, the number of cells available might be sufficient for use in larger adults. An alternative approach to this problem is to improve the efficiency of engraftment of donor stem cells. Graft engineering is exploring methods of adding cell components that may enhance engraftment. Furthermore, at least some data suggest that depletion of host NK (natural killer) cells may lower the number of stem cells necessary to reconstitute hematopoiesis.

Some limited understanding of self-renewal exists and, intriguingly, implicates gene products that are associated with the chromatin state, a high-order organization of chromosomal DNA that influences transcription. These include members of the polycomb family, a group of zinc finger–containing transcriptional regulators that interact with the chromatin structure, contributing to the accessibility of groups of genes for transcription. Certain members, including Bmi-1 and Gfi-1, are important in enabling hematopoietic stem cell self-renewal through modification of cell cycle regulators such as the cyclin-dependent kinase inhibitors. In the absence of either of these genes, hematopoietic stem cells decline in number and function. In contrast, dysregulation of *Bmi-1* has been associated with leukemia; it may promote leukemic stem cell self-renewal when it is overexpressed. Other transcription regulators have also been associated with self-renewal, particularly homeobox, or "hox," genes. These transcription factors are named for their ability to govern large numbers of genes, including those determining body patterning in invertebrates. HoxB4 is capable of inducing extensive self-renewal of stem cells through its DNA-binding motif. Other members of the hox family of genes have been noted to affect normal stem cells, but they are also associated with leukemia. External signals that may influence the relative self-renewal versus differentiation outcomes of stem cell cycling include the Notch ligands and specific Wnt ligands. Intracellular signal transducing intermediates are also implicated in regulating self-renewal but, interestingly, are not usually associated with the pathways activated by Notch or Wnt receptors. They include PTEN, an inhibitor of the AKT pathway, and STAT5, both of which are usually downstream of activated growth factor receptors and necessary for normal stem cell functions, including self-renewal, at least in mouse models. The connections between these molecules remain to be defined, and their role in physiologic regulation of stem cell self-renewal is still poorly understood.

CANCER IS SIMILAR TO AN ORGAN WITH SELF-RENEWING CAPACITY

The relationship of stem cells to cancer is an important evolving dimension of adult stem cell biology. Cancer may share principles of organization with normal tissues. Cancer might have the same hierarchical organization of cells with a base of stemlike cells capable of the signature stem-cell features, self-renewal and differentiation. These stemlike cells might be the basis for perpetuation of the tumor and represent a slowly dividing, rare population with distinct regulatory mechanisms, including a relationship with a specialized microenvironment. A subpopulation of self-renewing cells in cancer has been defined. A more sophisticated understanding of the stem-cell organization of cancers may lead to improved strategies for attacking the many common and difficult-to-treat types of malignancies that have been relatively refractory to interventions aimed at dividing cells.

Does the concept of cancer stem cells provide insight into the cellular origin of cancer? The fact that some cells within a cancer have stem cell–like properties does not necessarily mean that the cancer arose in the stem cell itself. Rather, more mature cells could have acquired the self-renewal characteristics of stem cells. Any single genetic event is unlikely to be sufficient to enable full transformation of a normal cell to a frankly malignant one. Rather, cancer is a multistep process, and for the multiple steps to accumulate, the cell of origin must be able to persist for prolonged periods. It must also be able to generate large numbers of daughter cells. The normal stem cell has these properties and, by virtue of its having intrinsic self-renewal capability, may be more readily converted to a malignant phenotype. This hypothesis has been tested experimentally in the hematopoietic system. Taking advantage of the cell-surface markers that distinguish hematopoietic cells of varying maturity, stem cells, progenitors, precursors, and mature cells can be isolated. Powerful transforming gene constructs were placed in these cells, and it was found that the cell with the greatest potential to produce a malignancy was indeed the stem cell. This does not prove that stem cells give rise to all tumors, but it does suggest that stem cells may be susceptible to malignant conversion and may be the population of greatest interest in developing strategies to protect against, monitor, or treat nascent malignancy.

WHAT ELSE CAN HEMATOPOIETIC STEM CELLS DO?

Some experimental data have suggested that hematopoietic stem cells or other cells mobilized into the circulation by the same factors that mobilize hematopoietic stem cells are capable of playing a role in healing the vascular and tissue damage associated with stroke and myocardial infarction. These data are controversial, and the applicability of a stem-cell approach to nonhematopoietic conditions remains experimental. However, the application of the evolving knowledge of hematopoietic stem cell biology may lead to wide-ranging clinical uses.

The stem cell therefore represents a true dual-edged sword. It has tremendous healing capacity and is essential for life. Uncontrolled, it can threaten the life it maintains. Understanding how stem cells function, the signals that modify their behavior, and the tissue niches that modulate stem cell responses to injury and disease are critical for more effectively developing stem cell–based medicine. That aspect of medicine will include the use of the stem cells and the use of drugs to target stem cells to enhance repair of damaged tissues. It will also include the careful balance of interventions to control stem cells where they may be dysfunctional or malignant.

69 Tissue Engineering

Jennifer Anderson, Joseph P. Vacanti

The origins of tissue engineering date to the sixteenth century when complex skin flaps were used to replace the nose. Modern tissue engineering combines the disciplines of materials sciences and life sciences to replace a diseased or damaged organ with a living, functional substitute. The most common tissue engineering approach combines cells and matrices to produce a living structure (Fig. 69-1). These strategies also include the use of scaffolding, cells, and growth factors to shape new tissues. The term *regenerative medicine* has emerged as a concept inclusive of tissue engineering and stem cell therapy (Chap. 67).

CELLULAR COMPONENTS OF TISSUE ENGINEERING

The foundation of tissue engineering is the combination of a three-dimensional scaffold with live and functional cells. Cells used in tissue engineering should be easily accessible and capable of proliferation while maintaining their differentiated function. There are three possible sources for cells: autologous, allogenic, and xenogenic. *Autologous cells* are isolated directly from the patient. They have the advantage of avoiding immune-mediated rejection. However, a potential limitation is that they may not be available or able to proliferate to the required tissue mass. *Allogenic cells* are harvested from a donor other than the patient. They have the advantage of being more readily available, but the immune system must be modulated to avoid rejection. *Xenogenic cells,* or those from a different species, may also be used but also risk immune rejection or transmission of animal pathogens.

Although cells such as fibroblasts and smooth-muscle cells proliferate rapidly, other cells proliferate slowly or lose their tissue-specific function when cultured, thereby limiting their use. In addition, cellular characteristics may depend on their location within the body. For example, the cell-to-cell interactions and function of endothelial cells in the pulmonary microvasculature are different from those in the blood-brain barrier. The microenvironment of the cell, including the presence of other cell types, soluble factors, and the presence of physical or mechanical forces may also alter the function of a transplanted cell.

Stem cells provide a promising cell source because they are capable of rapid proliferation and they can be induced to differentiate into multiple cell lineages (Chaps. 66 and 67). Human embryonic stem cells are capable of differentiating into endoderm, mesoderm, or ectoderm tissue types. Multipotent adult stem cells have been found in multiple mature tissues including the bone marrow, brain, heart, and liver. In addition to being able to differentiate into numerous lineages, adult stem cells generate a relatively muted immune response.

SCAFFOLDS

A scaffold provides a three-dimensional framework to support the tissue or organ-specific cells. The scaffold not only provides mechanical support, but it must also supply critical nutrients and transport metabolites to and from the developing tissue. Important scaffold properties vary depending on the tissue but typically include specific biomechanical properties, porosity, biocompatibility, and appropriate surface characteristics for cell adhesion and differentiation.

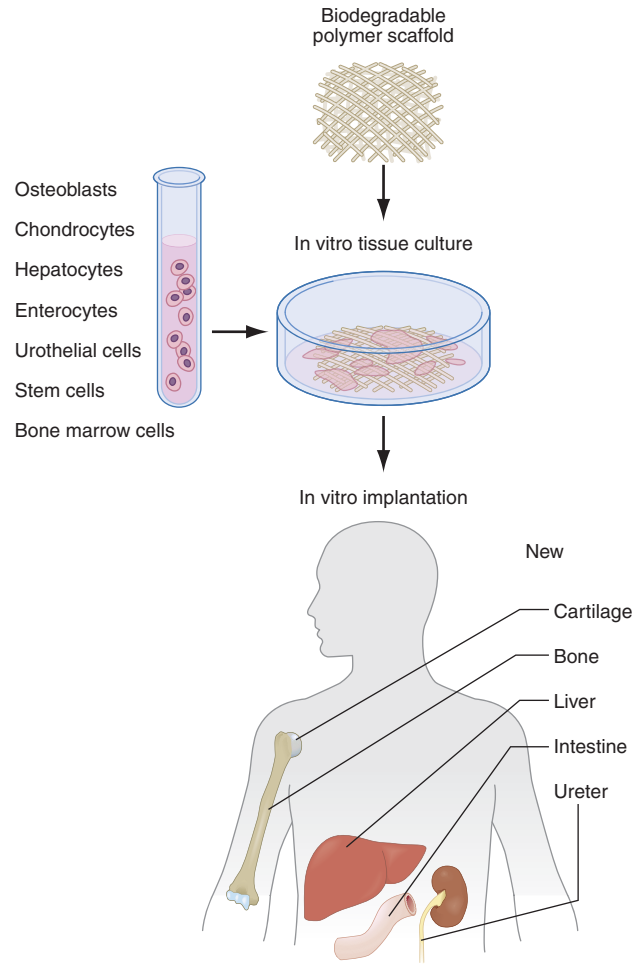

FIGURE 69-1 Schematic of basic principles of tissue engineering. *[From Langer R, Vacanti J: Tissue engineering. Science 260:1993 (Fig. 1), with permission.]*

Scaffolds can be natural materials or synthetic polymers and are typically biodegradable. Natural materials such as collagen and alginates are biocompatible. However, it is difficult to control their mechanical properties, and they may generate an immune reaction. Synthetic polymers such as polyglycolic acid and polyethylene, on the other hand, can be tailored to provide more acceptable mechanical properties but are associated with a strong inflammatory response. Nonbiodegradable synthetic polymers such as polytetrafluoroethylene and polyethylene provide well-defined mechanical and structural properties. However, their long-term presence in the body can lead to a chronic inflammatory response, which results in poor tissue quality. Polylactic acid and polyglycolic acid are examples of biodegradable polymers. Although the degradation of these materials can be partially

TABLE 69-1 FDA-APPROVED TISSUE-ENGINEERED PRODUCTS

Name of Product	Brief Description
Alloderm (LifeCell)	Acellular dermal matrix for tissue repair
Apligraf (Organogenesis)	Living skin equivalent approved for the treatment of venous leg ulcers and diabetic foot ulcers
Carticel (Genzyme Biosurgery)	Autologous chondrocytes approved for cartilage repair
Dermagraft (Smith and Nephew)	Living skin equivalent approved for full-thickness diabetic foot ulcers
Durasis (Cook Surgical Products)	Porcine small-intestine submucosa for replacement of dura mater
Epicel (Genzyme Biosurgery)	Living skin equivalent approved for burn patients
OrCel (Ortec)	Living skin equivalent approved for burn patients
Surgisis (Cook Surgical Products)	Porcine small-intestine submucosa for dermal wounds and reinforcement of weakened tissue

TABLE 69-2 TISSUE-ENGINEERING PRODUCTS IN CLINICAL TRIALS

TRC (Aastrom)	Autologous adult bone marrow cells for bone grafting
LiverX2000 (Algenix)	Extracorporeal liver assist device
Encapsulated proliferated islet (Amcyte)	Encapsulated islet cells
Myocell (Bioheart)	Encapsulated cells for myocardial infarction
BioSeed-C, BioSeed-Oral Bone (Biotissue Technologies)	Autologous tissue repair for bone and cartilage
E-matrix (Encelle)	Repair or regeneration of diseased or damaged tissue
MarkII (Excorp)	Extracorporeal liver assist device
ICX-PRO, ICX-TRC (Intercytex)	Wound repair and hair regeneration
HuCNS-SC (Stem Cell Inc)	Human central nervous system stem cells
NT-501 (Neurotech SA)	Encapsulated cell technology for long-term delivery of therapeutic factors to retina
Procord (Proneuron)	Autologous activated macrophage therapy for patients with acute complete spinal cord injury
ChondroCelect (Tigenix)	Autologous chondrocyte implantation
Spheramine (Titan Pharmaceutical)	Retinal pigment epithelial cells in microcarriers to provide continuous source of dopamine in the brain
ELAD (Vigagen)	Extracorporeal liver assist device

controlled, nonuniform degradation and varying degradation rates in different anatomic locations represent challenges.

The surface properties of the materials used for the scaffold are important for adhesion, migration, and cell differentiation. Ongoing research is focused on tethering growth factors or peptide sequences to the surface of the scaffold to improve adhesion and migration.

BIOREACTORS

Initially, cells used in tissue engineering were cultured in static conditions. Improvements in bioreactor technology more closely approximate physiologic parameters for tissue growth. By modulating rates of flow and mixing, the transfer of nutrients, gases, metabolites, and regulatory molecules can be maximized. Mechanical stimuli can also impact the newly forming tissue. For example, tissue-engineered blood vessels exposed to shear stress in a pulsatile flow bioreactor have greater burst strength and collagen content than those not exposed to shear stress.

TISSUE ENGINEERING SUCCESSES

Several tissue-engineered skin substitutes have been approved by the U.S. Food and Drug Administration (FDA) and in use for >10 years (Table 69-1). One of these products uses neonatal dermal fibroblasts isolated from human foreskins cultured on a scaffold of polylactide coglycolide. The polymer scaffold gradually degrades in the presence of water. A bilayer skin substitute has also been developed: dermal fibroblasts are cultured in a collagen solution and then coated with several layers of keratinocytes. Cartilage tissue engineering is also showing promise; autologous chondrocytes from a healthy portion of the patient's joint are expanded in culture and then implanted into the site of injury. Other scaffold-based products are based on processed animal submucosa or dura. In addition to these FDA-approved products, numerous tissue-engineered products are currently in clinical trials (Table 69-2). Engineered tissues being actively investigated include bone, mandible, teeth, cartilage, skin, cornea, bladder, urethra, small-diameter blood vessels, and the pulmonary artery.

CHALLENGES TO TISSUE ENGINEERING

The greatest success in tissue engineering to date has been in tissues such as skin and cartilage where the requirements for nutrients and oxygen are relatively low. Due to oxygen diffusion limitations, the maximal thickness of an engineered tissue is 150–200 μm if there is not an intrinsic capillary network. Strategies used to overcome this limitation include transplantation of the tissue directly into the patient's vasculature or trying to induce angiogenesis by incorporating growth factors such as vascular endothelial cell growth factor into the scaffold. A more recent approach involves the creation of an intrinsic network of vascular channels immediately adjacent to the engineered tissue. A combination of microelectro mechanical systems (MEMS) fabrication technology and computational models of fractal branching allows the construction of an intrinsic microvascular network scaffold within a biocompatible polymer. This preformed capillary-like network can be seeded with cells and ultimately sustains the growth and function of complex three-dimensional tissues.

Immune rejection of allogenic cells is another major obstacle. The use of immunosuppressive drugs is not considered an optimal solution to this problem. One potential solution is to develop "universal donor" cells by masking the histocompatibility proteins on the cell surface.

Off-the-shelf availability will need to be addressed for tissue engineering products to be used widely. Ideally, products should be reproducible and available at a wide variety of hospitals, including those without sophisticated facilities for cell culture and cell proliferation.

70 Nutritional Requirements and Dietary Assessment

Johanna Dwyer

Nutrients are substances that must be supplied by the diet because they are not synthesized in the body in sufficient amounts. Nutrient requirements for groups of healthy persons have been determined experimentally. For good health we require energy-providing nutrients (protein, fat, and carbohydrate), vitamins, minerals, and water. Specific nutrient requirements include 9 essential amino acids, several fatty acids, 4 fat-soluble vitamins, 10 water-soluble vitamins, and choline. Several inorganic substances, including 4 minerals, 7 trace minerals, 3 electrolytes, and the ultratrace elements, also must be supplied in the diet.

The required amounts of the essential nutrients differ by age and physiologic state. Conditionally essential nutrients are not required in the diet but must be supplied to individuals who do not synthesize them in adequate amounts, such as those with genetic defects, those having pathologic states with nutritional implications, and developmentally immature infants. Many organic phytochemicals and zoochemicals present in foods have health effects. For example, dietary fiber has beneficial effects on gastrointestinal function. Other bioactive food constituents or contaminants such as lead may have negative health effects.

ESSENTIAL NUTRIENT REQUIREMENTS

ENERGY

For weight to remain stable, energy intake must match energy output. The major components of energy output are resting energy expenditure (REE) and physical activity; minor sources include the energy cost of metabolizing food (thermic effect of food or specific dynamic action) and shivering thermogenesis (e.g., cold-induced thermogenesis). The average energy intake is about 2800 kcal/d for American men and about 1800 kcal/d for American women, although these estimates vary with body size and activity level. Formulas for estimating REE are useful for assessing the energy needs of an individual whose weight is stable. Thus, for males, REE = 900 + 10*w*, and for females, REE = 700 + 7*w*, where *w* is weight in kilograms. The calculated REE is then adjusted for physical activity level by multiplying by 1.2 for sedentary, 1.4 for moderately active, or 1.8 for very active individuals. The final figure provides a rough estimate of total caloric needs in a state of energy balance. Formulas to provide more precise estimates of energy requirements are provided by the Food and Nutrition Board, Institute of Medicine, National Academy of Sciences in recent reports on dietary reference intakes. **For further discussion of energy balance in health and disease, see Chap. 72.**

PROTEIN

Dietary protein consists of both essential and other amino acids that are required for protein synthesis. The nine essential amino acids are histidine, isoleucine, leucine, lysine, methionine/cystine, phenylalanine/tyrosine, threonine, tryptophan, and valine. All amino acids can be used for energy, and certain amino acids (e.g., alanine) can also be used for gluconeogenesis. When energy intake is inadequate, protein intake must be increased, since ingested amino acids are diverted into pathways of glucose synthesis and oxidation. In extreme energy deprivation, protein-calorie malnutrition may ensue (Chap. 72).

For adults, the recommended dietary allowance (RDA) for protein is about 0.6 g/kg desirable body weight per day, assuming that energy needs are met and that the protein is of relatively high biologic value. Current recommendations for a healthy diet call for at least 10–14% of calories from protein. Biologic value tends to be highest for animal proteins, followed by proteins from legumes (beans), cereals (rice, wheat, corn), and roots. Combinations of plant proteins that complement one another in biologic value or combinations of animal and plant proteins can increase biologic value and lower total protein requirements.

Protein needs increase during growth, pregnancy, lactation, and rehabilitation after malnutrition. Tolerance to normal amounts of dietary protein is decreased in renal insufficiency and liver failure, precipitating encephalopathy in patients with cirrhosis of the liver.

FAT AND CARBOHYDRATE

Fats are a concentrated source of energy and constitute on average 34% of calories in U.S. diets. For optimal health, saturated fat and trans-fat should be limited to <10% of calories, and polyunsaturated fats to <10% of calories, with monounsaturated fats constituting the remainder of fat intake. At least 55% of total calories should be derived from carbohydrates. The brain requires about 100 g/d of glucose for fuel; other tissues use about 50 g/d. Some tissues (e.g., brain and red blood cells) rely on glucose supplied either exogenously or from muscle proteolysis. Over time, some adaptations in carbohydrate needs are possible in other tissues during hypocaloric states (Chap. 339).

WATER

For adults, 1.0–1.5 mL water per kcal of energy expenditure is sufficient under usual conditions to allow for normal variations in physical activity, sweating, and solute load of the diet. Water losses include 50–100 mL/d in the feces, 500–1000 mL/d by evaporation or exhalation, and, depending on the renal solute load, ≥1000 mL/d in the urine. If external losses increase, intakes must increase accordingly to avoid underhydration. Fever increases water losses by approximately 200 mL/d per °C; diarrheal losses vary but may be as great as 5 L/d with severe diarrhea. Heavy sweating and vomiting also increase water losses. When renal function is normal and solute intakes are adequate, the kidneys can adjust to increased water intake by excreting up to 18 L/d of excess water (Chap. 334). However, obligatory urine outputs can compromise hydration status when there is inadequate intake or when losses increase in disease or kidney damage.

Infants have high requirements for water because of their large ratio of surface area to volume, the limited capacity of the immature kidney to handle high renal solute loads, and their inability to communicate their thirst. During pregnancy, 30 mL/d additional water is needed. During lactation, milk production increases water requirements by approximately 1000 mL/d, or 1 mL for each mL of milk produced. Special attention must be paid to the water needs of the elderly, who have reduced total body water and blunted thirst sensation, and may be taking diuretics.

OTHER NUTRIENTS

See Chap. 71 for a detailed description of vitamins and trace minerals.

DIETARY REFERENCE INTAKES AND RECOMMENDED DIETARY ALLOWANCES

Fortunately, human life and well-being can be maintained within a fairly wide range for most nutrients. However, the capacity for adaptation is not infinite—too much of a nutrient, as well as too little, may have adverse effects on health. Therefore, quantitative benchmark recommendations on nutrient intakes have been developed to guide clinical practice. These estimates are collectively referred to as the *dietary reference intakes* (DRIs). The DRIs supplant but include the *recommended dietary allowances* (RDAs), the single reference values used in the United States since 1989. DRIs include the *estimated average requirement* (EAR) of a nutrient, as well as three other reference values used for dietary planning for individuals: the RDA, or, if it cannot be established, the *adequate intake* (AI), and the tolerable *upper level* (UL). The current DRIs for vitamins and elements are provided in **Tables 70-1** and **70-2**, respectively.

Note: This table presents recommended dietary allowances (RDAs) in **bold type** and adequate intakes (AIs) in ordinary type. RDAs and AIs may both be used as goals for individual intake. RDAs are set to meet the needs of almost all individuals (97 to 98%) in a group. For healthy breastfed infants, the AI is the mean intake. The AI for other life stage and gender groups is believed to cover needs of all individuals in the group, but lack of data or uncertainty in the data prevent being able to specify with confidence the percentage of individuals covered by this intake.

[a]As retinol activity equivalents (RAEs). 1 RAE = 1 μg retinol, 12 μg β-carotene, 24 μg α-carotene, or 24 μg β-cryptoxanthin. To calculate RAEs from retinol equivalents (REs) of provitamin A carotenoids in foods, divide the REs by 2. For preformed vitamin A in foods or supplements and for provitamin A carotenoids in supplements, 1 RE = 1 RAE.

[b]As calciferol. 1 μg calciferol = 40 IU vitamin D.

[c]In the absence of adequate exposure to sunlight.

[d]As α-tocopherol. α-Tocopherol includes *RRR*-α-tocopherol, the only form of α-tocopherol that occurs naturally in foods, and the *2R*-stereoisomeric forms of α-tocopherol (*RRR*-, *RSR*-, *RRS*-, and *RSS*-α-tocopherol) that occur in fortified foods and supplements. It does not include the *2S*-stereoisomeric forms of α-tocopherol (*SRR*-, *SSR*-, *SRS*-, and *SSS*-α-tocopherol), also found in fortified foods and supplements.

[e]As niacin equivalents (NE). 1 mg of niacin = 60 mg of tryptophan; 0–6 months = preformed niacin (not NE).

[f]As dietary folate equivalents (DFEs). 1 DFE = 1 μg food folate = 0.6 μg of folic acid from fortified food or as a supplement consumed with food = 0.5 μg of a supplement taken on an empty stomach.

[g]Although AIs have been set for choline, there are few data to assess whether a dietary supply of choline is needed at all stages of the life cycle, and it may be that the choline requirement can be met by endogenous synthesis at some of these stages.

[h]Because 10 to 30% of older people may malabsorb food-bound B_{12}, it is advisable for those >50 years to meet their RDA mainly by consuming foods fortified with B_{12} or a supplement containing B_{12}.

[i]In view of evidence linking inadequate folate intake with neural tube defects in the fetus, it is recommended that all women capable of becoming pregnant consume 400 μg from supplements or fortified foods in addition to intake of food folate from a varied diet.

[j]It is assumed that women will continue consuming 400 μg from supplements or fortified food until their pregnancy is confirmed and they enter prenatal care, which ordinarily occurs after the end of the periconceptional period—the critical time for formation of the neural tube.

ESTIMATED AVERAGE REQUIREMENT

When florid manifestations of the classic dietary deficiency diseases such as rickets, scurvy, xerophthalmia, and protein-calorie malnutrition were common, nutrient adequacy was inferred from the absence of their clinical signs. Later, it was determined that biochemical and other changes were evident long before the clinical deficiency became apparent. Consequently, criteria of nutrient adequacy are now based on biologic markers when they are available. Priority is given to sensitive biochemical, physiologic, or behavioral tests that reflect early changes in regulatory processes or maintenance of body stores of nutrients. Current definitions focus on the amount of a nutrient that minimizes the risk of chronic degenerative diseases.

The EAR is the amount of a nutrient estimated to be adequate for half of the healthy individuals of a specific age and sex. The types of evidence and criteria used to establish nutrient requirements vary by nutrient, age, and physiologic group. The EAR is not useful clinically for estimating nutrient adequacy in individuals because it is a median requirement for a group; 50% of individuals in a group fall below the requirement and 50% fall above it. Thus, a person with a usual intake at the EAR has a 50% risk of an inadequate intake. For these reasons, other standards, described below, are more useful for clinical purposes.

RECOMMENDED DIETARY ALLOWANCES

The RDA is the nutrient-intake goal for planning diets of individuals; it is used in the MyPyramid food guide of the U.S. Department of Agriculture (USDA), therapeutic diets, and descriptions of the nutritional content of processed foods and dietary supplements. The nutrient content in a food is stated by weight or as a percentage of the daily value (DV), a variant of the RDA that, for an adult, represents the highest RDA for an adult consuming 2000 kcal/d.

The RDA is the average daily dietary intake level that meets the nutrient requirements of nearly all healthy persons of a specific sex, age, life stage, or physiologic condition (such as pregnancy or lactation).

The RDA is defined statistically as 2 standard deviations (SD) above the EAR to ensure that the needs of most individuals are met.

The risk of dietary inadequacy increases as intake falls further below the RDA. However, the RDA is an overly generous criterion for evaluating nutrient adequacy. For example, by definition the RDA exceeds the actual requirements of all but about 2 to 3% of the population. Therefore, many people whose intake falls below the RDA may still be getting enough of the nutrient.

ADEQUATE INTAKE

It is not possible to set an RDA for some nutrients that do not have an established EAR. In this circumstance, the AI is based on observed, or experimentally determined, approximations of nutrient intakes in healthy people. In the DRIs established to date, AIs rather than RDAs are proposed for infants up to age 1 year, as well as for calcium, chromium, vitamin D, fluoride, manganese, pantothenic acid, biotin, choline, sodium, chloride, potassium, and water for persons of all ages.

TOLERABLE UPPER LEVELS OF NUTRIENT INTAKE

Healthy individuals derive no established benefit from consuming nutrient levels above the RDA or AI. Excessive nutrient intake can disturb body functions and cause acute, progressive, or permanent disabilities. The tolerable UL is the highest level of chronic nutrient intake (usually daily) that is unlikely to pose a risk of adverse health effects for most of the population. Data on the adverse effects of large amounts of many nutrients are unavailable or too limited to establish a UL. Therefore, the lack of a UL does *not* mean that the risk of adverse effects from high intake is nonexistent. Individual nutrients in foods that most people eat rarely reach levels that exceed the UL. However, nutritional supplements provide more concentrated amounts of nutrients per dose and, as a result, pose a greater potential risk of toxicity. Nutrient supplements are labeled with "Supplement Facts" that express the amount of nutrient in absolute units or as the percent of the DV provided per recommended serving size. Total nutrient consumption, including both food and supplements, should not exceed RDA levels.

FACTORS ALTERING NUTRIENT NEEDS

The DRIs are affected by age, sex, rate of growth, pregnancy, lactation, physical activity, composition of diet, coexisting diseases, and drugs. When only slight differences exist between the requirements for nutrient sufficiency and excess, dietary planning becomes more difficult.

PHYSIOLOGIC FACTORS

Growth, strenuous physical activity, pregnancy, and lactation increase needs for energy and several essential nutrients, including water. Energy needs rise during pregnancy, due to the demands of fetal growth, and during lactation, because of the increased energy required for milk production. Energy needs decrease with loss of lean body mass, the major determinant of REE. Because both health and physical activity tend to decline with age, energy needs in older persons, especially those over 70, tend to be less than those of younger persons.

DIETARY COMPOSITION

Dietary composition affects the biologic availability and utilization of nutrients. For example, the absorption of iron may be impaired by high amounts of calcium or lead; non-heme iron uptake may be impaired by the lack of ascorbic acid and amino acids in the meal. Protein utilization by the body may be decreased when essential amino acids are not present in sufficient amounts. Animal foods, such as

Note: This table presents recommended dietary allowances (RDAs) in **bold type** and adequate intakes (AIs) in ordinary type. RDAs and AIs may both be used as goals for individual intake. RDAs are set to meet the needs of almost all individuals (97 to 98%) in a group. For healthy breastfed infants, the AI is the mean intake. The AI for other life stage and gender groups is believed to cover needs of all individuals in the group, but lack of data or uncertainty in the data prevent being able to specify with confidence the percentage of individuals covered by this intake.

milk, eggs, and meat, have high biologic values with most of the needed amino acids present in adequate amounts. Plant proteins in corn (maize), soy, and wheat have lower biologic values and must be combined with other plant or animal proteins to achieve optimal utilization by the body.

ROUTE OF ADMINISTRATION

The RDAs apply only to oral intakes. When nutrients are administered parenterally, similar values can sometimes be used for amino acids, carbohydrates, fats, sodium, chloride, potassium, and most of the vitamins, since their intestinal absorption is nearly 100%. However, the oral bioavailability of most mineral elements may be only half that obtained by parenteral administration. For some nutrients that are not readily stored in the body, or cannot be stored in large amounts, timing of administration may also be important. For example, amino acids cannot be used for protein synthesis if they are not supplied together; instead they will be used for energy production.

DISEASE

Specific dietary deficiency diseases include protein-calorie malnutrition; iron, iodine, and vitamin A deficiency; megaloblastic anemia due to vitamin B_{12} or folic acid deficiency; vitamin D–deficiency rickets; scurvy due to lack of ascorbic acid; beriberi due to lack of thiamine; and pellagra due to lack of niacin and protein (Chaps. 71 and 72). Each deficiency disease is characterized by imbalances at the cellular level between the supply of nutrients or energy and the body's nutritional needs for growth, maintenance, and other functions. Imbalances in nutrient intakes are recognized as risk factors for certain chronic degenerative diseases, such as saturated and trans-fat and cholesterol in coronary artery disease; sodium in hypertension; obesity in hormone-dependent endometrial and breast cancers; and ethanol in alcoholism. However, the etiology and pathogenesis of these disorders are multifactorial, and diet is only one of many risk factors. Osteoporosis, for example, is associated with calcium deficiency as well as risk factors related to environment (e.g., smoking, sedentary lifestyle), physiology (e.g., estrogen deficiency), genetic determinants (e.g., defects in collagen metabolism), and drug use (chronic steroids) (Chap. 348).

DIETARY ASSESSMENT

In clinical situations, nutritional assessment is an iterative process that involves (1) screening for malnutrition; (2) assessing food and dietary supplement intake, and establishing the absence or presence of malnutrition and its possible causes; and (3) planning for the most appropriate nutritional therapy. Some disease states affect the bioavailability, requirements, utilization, or excretion of specific nutrients. In these circumstances, specific measurements of various nutrients may be required to ensure adequate replacement (Chap. 72).

Most health care facilities have a nutrition screening process in place for identifying possible malnutrition after hospital admission. Nutritional screening is required by the Joint Commission on Accreditation of Healthcare Organizations (JCAHO), but there are no universally recognized or validated standards. The factors that are usually assessed include abnormal weight for height or body mass index (e.g., BMI <18.5 or >25); reported weight change (involuntary loss or gain of >5 kg in the past 6 months) (Chap. 41); diagnoses with known nutritional implications (metabolic disease, any disease affecting the gastrointestinal tract, alcoholism, and others); present therapeutic dietary prescription; chronic poor appetite; presence of chewing and swallowing problems or major food intolerances; need for assistance with preparing or shopping for food, eating, or other aspects of self care; and social isolation. Reassessment of nutrition status should occur periodically in hospitalized patients—at least once every week.

A more complete dietary assessment is indicated for patients who exhibit a high risk of malnutrition based on nutrition screening. The type of assessment varies with the clinical setting, severity of the patient's illness, and stability of his or her condition.

ACUTE CARE SETTINGS

Acute care settings, anorexia, various diseases, test procedures, and medications can compromise dietary intake. Under such circumstances, the goal is to identify and avoid inadequate intake and ensure appropriate alimentation. Dietary assessment focuses on what patients are currently eating, whether they are able and willing to eat, and whether they experience any problems with eating. Dietary intake assessment is based on information from observed intakes; medical record; history; clinical examination; and anthropometric, biochemical, and functional status. The objective is to gather enough information to establish the likelihood of malnutrition due to poor dietary intake or other causes and to assess whether nutritional therapy is indicated.

Simple observations may suffice to suggest inadequate oral intake. These include dietitians' and nurses' notes, the amount of food eaten on trays, frequent tests and procedures that are likely to cause meals to be skipped, nutritionally inadequate diet orders such as clear liquids or full liquids for more than a few days, fever, gastrointestinal distress, vomiting, diarrhea, a comatose state, and diseases or treatments that involve any part of the alimentary tract. Acutely ill patients with diet-related diseases such as diabetes require assessment because an inappropriate diet may exacerbate these conditions and adversely affect other therapies. Abnormal biochemical values [serum albumin levels <35 g/L (<3.5 mg/dL); serum cholesterol levels <3.9 mmol/L (<150 mg/dL)] are nonspecific but may also indicate a need for further nutritional assessment.

Most therapeutic diets offered in hospitals are calculated to meet individual nutrient requirements and the RDA. However, there are exceptions including clear liquids, some full liquid diets, and test diets, which are inadequate for several nutrients and should not be used, if possible, for more than 24 h. As much as half of the food served to hospitalized patients is not eaten, so it cannot be assumed that the intakes of hospitalized patients are adequate. Dietary assessment should compare how much and what food the patient has consumed with the diet that has been provided. Major deviations in intakes of energy, protein, fluids, or other nutrients of special concern for the patient's illness should be noted and corrected.

Nutritional monitoring is especially important for patients who are very ill and who have extended lengths of stay. Patients who are fed by special enteral and parenteral routes also require special nutritional assessment and monitoring by physicians with training in nutrition support and/or dietitians with certification in nutrition support (Chap. 73).

AMBULATORY SETTINGS

The aim of dietary assessment in the outpatient setting is to determine whether the patient's usual diet is a health risk in itself or if it contributes to existing chronic disease-related problems. Dietary assessment also provides the basis for planning a diet that fulfills therapeutic goals while ensuring patient adherence. The outpatient dietary assessment should review the adequacy of present and usual food intakes, including vitamin and mineral supplements, medications, and alcohol, as all of these may affect the patient's nutritional status. The assessment should focus on the dietary constituents that are most likely to be involved or compromised by a specific diagnosis, as well as any comorbidities that are present. More than one day's intake should be reviewed to provide a better representation of the usual diet.

There are many ways to assess the adequacy of the patient's habitual diet. These include a food guide, a food exchange list, a diet history, or a food frequency questionnaire. A commonly used food guide for healthy persons is the USDA's food pyramid, which is useful as a basis for identifying inadequate intakes of essential nutrients, as well as likely excesses in fat, saturated fat, sodium, sugar, and alcohol (Table 70-3). The guide is available online (*www.MyPyramid.gov*) and can be tailored to the needs of persons of different ages and life stages by varying the number of servings. The process of reviewing the guide with patients helps to identify food groups eaten in excess of recommendations or in insufficient quantities and helps them to transition to healthier dietary patterns. For those prescribed therapeutic diets, assessment against prescriptions stated as food exchange lists may be useful. These include, for example, the American Diabetes Association food exchange lists for diabetes, or the American Dietetic Association food exchange lists for renal disease.

TABLE 70-3 MY PYRAMID: THE USDA FOOD GUIDE PYRAMID FOR HEALTHY PERSONS

Servings and Examples of Standard Portion Sizes	Lower: 1600 kcal	Moderate: 2200 kcal	Higher: 2800 kcal
Fruits, cups	1.5	2	2.5
Vegetables, cups	2	3	3.5
Grains, oz eq (1 slice bread, 1 cup ready to eat cereal, 0.5 cup cooked rice, pasta, cooked cereal)	5	7	10
Meat and beans, oz eq (1 oz lean meat, poultry, or fish; 1 egg, 1 Tbsp. peanut butter, 0.25 cup cooked dry beans, or 0.5 oz nuts or seeds)	5	6	7

71 Vitamin and Trace Mineral Deficiency and Excess

Robert M. Russell, Paolo M. Suter

Vitamins and trace minerals are required constituents of the human diet since they are either inadequately synthesized or not synthesized in the human body. Only small amounts of these substances are needed for carrying out essential biochemical reactions (e.g., acting as coenzymes or prosthetic groups). Overt vitamin or trace mineral deficiencies are rare in Western countries due to a plentiful, varied, and inexpensive food supply; however, multiple nutrient deficiencies may appear together in persons who are chronically ill or alcoholic. Moreover, subclinical vitamin and trace mineral deficiencies, as diagnosed by laboratory testing, are quite common in the normal population—especially in the geriatric age group.

Famine, emergency-affected and displaced populations, and refugees are at increased risk for protein-energy malnutrition and classic micronutrient deficiencies (vitamin A, iron, iodine), as well as for thiamine (beriberi), riboflavin, vitamin C (scurvy), and niacin (pellagra) overt deficiencies.

Body stores of vitamins and minerals vary tremendously. For example, vitamin B_{12} and vitamin A stores are large, and an adult may not become deficient for 1 or more years after being on a depleted diet. However, folate and thiamine may become depleted within weeks when eating a deficient diet. Therapeutic modalities can deplete essential nutrients from the body; for example, hemodialysis removes water-soluble vitamins, which must be replaced by supplementation.

There are several roles for vitamins and trace minerals in diseases: (1) deficiencies of vitamins and minerals may be caused by disease states such as malabsorption; (2) both deficiency and excess of vitamins and minerals can cause disease in and of themselves (e.g., vitamin A intoxication and liver disease); and (3) vitamins and minerals in high doses may be used as drugs (e.g., niacin for hypercholesterolemia). The hematologic-related vitamins and minerals (Chaps. 98, 100) are considered only briefly in this chapter, as are the bone-related vitamins and minerals (vitamin D, calcium, phosphorus; Chap. 346), since they are covered elsewhere (Tables 71-1, 71-2, and Fig. 71-1).

NUTRITIONAL STATUS ASSESSMENT

Full nutritional status assessment is reserved for seriously ill patients and those at very high nutritional risk when the cause of malnutrition is still uncertain after initial clinical evaluation and dietary assessment. It involves multiple dimensions, including documentation of dietary intake, anthropometric measurements, biochemical measurements of blood and urine, clinical examination, health history, and functional status. For further discussion of nutritional assessment, see Chap. 72.

GLOBAL CONSIDERATIONS

New nutrient-based terminologies with dietary reference intakes have been developed not only in North America, but in the United Kingdom and Europe, and by the World Health Organization/Food and Agricultural Organization of the United Nations (WHO/FAO). These different standards have many similarities in their basic concepts, definitions, and levels of nutrients recommended, but there are some differences, owing to assumptions made, functional criteria chosen, the timeliness of the evidence reviewed, and expert judgment.

VITAMINS

THIAMINE (VITAMIN B_1)

Thiamine was the first B vitamin to be identified and is therefore also referred to as vitamin B_1. Thiamine functions in the decarboxylation of α-ketoacids, such as pyruvate α-ketoglutarate, and branched-chain amino acids and thus is a source of energy generation. In addition, thiamine pyrophosphate acts as a coenzyme for a transketolase reaction that mediates the conversion of hexose and pentose phosphates. It has also been postulated that thiamine plays a role in peripheral nerve conduction, although the exact chemical reactions underlying this function are unknown.

Food Sources The median intake of thiamine in the United States from food alone is 2 mg/d. Primary food sources for thiamine include yeast, organ meat, pork, legumes, beef, whole grains, and nuts. Milled rice or grains contain little thiamine, if any. Thiamine deficiency is therefore more common in cultures that rely heavily on a rice-based diet. Tea, coffee (regular and decaffeinated), raw fish, and shellfish contain thiaminases, which can destroy the vitamin. Thus, drinking large amounts of tea or coffee can theoretically lower thiamine body stores.

Deficiency Most dietary deficiency of thiamine worldwide is the result of poor dietary intake. In Western countries, the primary causes of thiamine deficiency are alcoholism and chronic illness, such as cancer. Alcohol interferes directly with the absorption of thiamine and with the synthesis of thiamine pyrophosphate. Thiamine should always be replenished when refeeding a patient with alcoholism, as carbohydrate repletion without adequate thiamine can precipitate acute thiamine deficiency. Other at-risk populations are women with prolonged hyperemesis gravidarum and anorexia, patients with an overall poor nutritional status on parenteral glucose, and patients on chronic diuretic therapy due to increased urinary thiamine losses. Maternal thiamine deficiency can lead to infantile beriberi in breast-fed children. Thiamine deficiency should also be considered in the setting of motor vehicle accidents associated with head injury.

Thiamine deficiency in its early stage induces anorexia and nonspecific symptoms (e.g., irritability, decrease in short-term memory). Prolonged thiamine deficiency causes beriberi, which is classically categorized as wet or dry, although there is considerable overlap. In either

TABLE 71-1 PRINCIPAL CLINICAL FINDINGS OF VITAMIN MALNUTRITION

Nutrient	Clinical Finding	Dietary Level per Day Associated with Overt Deficiency in Adults	Contributing Factors to Deficiency
Thiamine	Beriberi: neuropathy, muscle weakness and wasting, cardiomegaly, edema, ophthalmoplegia, confabulation	<0.3 mg/1000 kcal	Alcoholism, chronic diuretic use, hyperemesis
Riboflavin	Magenta tongue, angular stomatitis, seborrhea, cheilosis	<0.6 mg	—
Niacin	Pellagra: pigmented rash of sun-exposed areas, bright red tongue, diarrhea, apathy, memory loss, disorientation	<9.0 niacin equivalents	Alcoholism, vitamin B_6 deficiency, riboflavin deficiency, tryptophan deficiency
Vitamin B_6	Seborrhea, glossitis convulsions, neuropathy, depression, confusion, microcytic anemia	<0.2 mg	Alcoholism, isoniazid
Folate	Megaloblastic anemia, atrophic glossitis, depression, ↑ homocysteine	<100 μg/d	Alcoholism, sulfasalazine, pyrimethamine, triamterene
Vitamin B_{12}	Megaloblastic anemia, loss of vibratory and position sense, abnormal gait, dementia, impotence, loss of bladder and bowel control, ↑ homocysteine, ↑ methylmalonic acid	<1.0 μg/d	Gastric atrophy (pernicious anemia), terminal ileal disease, strict vegetarianism, acid reducing drugs (e.g., H_2 blockers)
Vitamin C	Scurvy: petechiae, ecchymosis, coiled hairs, inflamed and bleeding gums, joint effusion, poor wound healing, fatigue	<10 mg/d	Smoking, alcoholism
Vitamin A	Xerophthalmia, nightblindness, Bitot's spots, follicular hyperkeratosis, impaired embryonic development, immune dysfunction	<300 μg/d	Fat malabsorption, infection, measles, alcoholism, protein-energy malnutrition
Vitamin D	Rickets: skeletal deformation, rachitic rosary, bowed legs; osteomalacia	<2.0 μg/d	Aging, lack of sunlight exposure, fat malabsorption, deeply pigmented skin
Vitamin E	Peripheral neuropathy, spinocerebellar ataxia, skeletal muscle atrophy, retinopathy	Not described unless underlying contributing factor is present	Occurs only with fat malabsorption, or genetic abnormalities of vitamin E metabolism/transport
Vitamin K	Elevated prothrombin time, bleeding	<10 μg/d	Fat malabsorption, liver disease, antibiotic use

form of beriberi, patients may complain of pain and paresthesia. *Wet beriberi* presents primarily with cardiovascular symptoms, due to impaired myocardial energy metabolism and dysautonomia, and can occur after 3 months of a thiamine-deficient diet. Patients present with an enlarged heart, tachycardia, high-output congestive heart failure, peripheral edema, and peripheral neuritis. Patients with *dry beriberi* present with a symmetric peripheral neuropathy of the motor and sensory systems with diminished reflexes. The neuropathy affects the legs most markedly, and patients have difficulty rising from a squatting position.

Alcoholic patients with chronic thiamine deficiency may also have central nervous system (CNS) manifestations known as *Wernicke's encephalopathy*, consisting of horizontal nystagmus, ophthalmoplegia (due to weakness of one or more extraocular muscles), cerebellar ataxia, and mental impairment (Chap. 387). When there is an additional loss of memory and a confabulatory psychosis, the syndrome is known as *Wernicke-Korsakoff syndrome*. Despite the typical clinical picture and history, Wernicke-Korsakoff syndrome is underdiagnosed.

The laboratory diagnosis of thiamine deficiency is usually made by a functional enzymatic assay of transketolase activity measured before and after the addition of thiamine pyrophosphate. A >25% stimulation by the addition of thiamine pyrophosphate (an activity coefficient of 1.25) is taken as abnormal. Thiamine or the phosphorylated esters of thiamine in serum or blood can also be measured by high-performance liquid chromatography (HPLC) to detect deficiency.

℞ THIAMINE DEFICIENCY

In acute thiamine deficiency with either cardiovascular or neurologic signs, 100 mg/d of thiamine should be given parenterally for 7 days, followed by 10 mg/d orally until there is complete recovery. Cardiovascular improvement occurs within 24 h, and ophthalmoplegic improvement occurs within 24 h. Other manifestations gradually clear, although psychosis in Wernicke-Korsakoff syndrome may be permanent or persist for several months.

Toxicity Although anaphylaxis has been reported after high doses of thiamine, no adverse effects have been recorded from either food or supplements at high doses. Thiamine supplements may be bought over the counter in doses of up to 50 mg/d.

RIBOFLAVIN (VITAMIN B_2)

Riboflavin is important for the metabolism of fat, carbohydrate, and protein, reflecting its role as a respiratory coenzyme and an electron donor. Enzymes that contain flavin adenine dinucleotide (FAD) or flavin-mononucleotide (FMN) as prosthetic groups are known as *flavoenzymes* (e.g., succinic acid dehydrogenase, monoamine oxidase, glutathione reductase). FAD is a cofactor for methyltetrahydrofolate reductase and therefore modulates homocysteine metabolism. The vitamin also plays a role in drug and steroid metabolism, including detoxification reactions.

Although much is known about the chemical and enzymatic reactions of riboflavin, the clinical manifestations of riboflavin deficiency are nonspecific and similar to those of other B vitamin deficiencies. Riboflavin deficiency is manifested principally by lesions of the mucocutaneous surfaces of the mouth and skin (Table 71-1). In addition to the mucocutaneous lesions, corneal vascularization, anemia, and personality changes have been described with riboflavin deficiency.

Deficiency and Excess Riboflavin deficiency is almost always due to dietary deficiency. Milk, other dairy products, and enriched breads and cereals are the most important dietary sources of riboflavin in the United States, although lean meat, fish, eggs, broccoli, and legumes are also good sources. Riboflavin is extremely sensitive to light, and milk should be stored in containers that protect against photodegradation. Laboratory diagnosis of riboflavin deficiency can be made by measurement of red blood cell or urinary riboflavin concentrations or by measurement of erythrocyte glutathione reductase activity, with and without added FAD. Because the capacity of the gastrointestinal tract to absorb riboflavin is limited (~20 mg if given in one oral dose), riboflavin toxicity has not been described.

NIACIN (VITAMIN B_3)

The term *niacin* refers to nicotinic acid and nicotinamide and their biologically active derivatives. Nicotinic acid and nicotinamide serve as precursors of two coenzymes, nicotinamide adenine dinucleotide (NAD) and NAD phosphate (NADP), which are important in numer-

ous oxidation and reduction reactions in the body. In addition, NAD and NADP are active in adenine diphosphate–ribose transfer reactions involved in DNA repair and calcium mobilization.

Metabolism and Requirements Nicotinic acid and nicotinamide are absorbed well from the stomach and small intestine. Niacin bioavailability is high from beans, milk, meat, and eggs; bioavailability from cereal grains is lower. Since flour is enriched with the "free" niacin (i.e., non-coenzyme form), bioavailability is excellent. Median intakes of niacin in the United States considerably exceed the recommended dietary allowance (RDA).

The amino acid tryptophan can be converted to niacin with an efficiency of 60:1 by weight. Thus, the RDA for niacin is expressed in niacin equivalents. A lower conversion of tryptophan to niacin occurs in vitamin B_6 and/or riboflavin deficiencies, or in the presence of isoniazid. The urinary excretion products of niacin include 2-pyridone and 2-methyl nicotinamide, measurements of which are used in diagnosis of niacin deficiency.

Deficiency Niacin deficiency causes *pellagra*, which is mostly found among people eating corn-based diets in parts of China, Africa, and India. Pellagra in North America is found mainly among alcoholics; in patients with congenital defects of intestinal and kidney absorption of tryptophan (Hartnup disease; Chap. 358); and in patients with carcinoid syndrome (Chap. 344), where there is increased conversion of tryptophan to serotonin. In the setting of famine or population displacement, the occurrence of pellagra results from the absolute lack of niacin but also the deficiency of micronutrients required for the conversion of tryptophan to niacin (e.g., iron, riboflavin, and pyridoxine). The early symptoms of pellagra include loss of appetite, generalized weakness and irritability, abdominal pain, and vomiting. Bright red glossitis then ensues, followed by a characteristic skin rash that is pigmented and scaling, particularly in skin areas exposed to sunlight. This rash is known as *Casal's necklace* because it forms a ring around the neck; it is seen in advanced cases. Vaginitis and esophagitis may also occur. Diarrhea (in part due to proctitis and in part due to malabsorption), depression, seizures, and dementia are also part of the pellagra syndrome—the four *D*s: *d*ermatitis, *d*iarrhea, and *d*ementia leading to *d*eath.

℞ PELLAGRA

Treatment of pellagra consists of oral supplementation of 100–200 mg of nicotinamide or nicotinic acid three times daily for 5 days. High doses of nicotinic acid (2 g/d in a time-release form) are used for the treatment of elevated cholesterol and triglyceride levels and/or low high-density lipoprotein (HDL) cholesterol level (Chap. 350).

Toxicity Prostaglandin-mediated flushing due to binding of the vitamin to a G protein–coupled receptor has been observed at daily doses as low as 50 mg of niacin when taken as a supplement or as therapy for dyslipidemia. There is no evidence of toxicity from niacin derived from food sources. Flushing always starts in the face and may be accompanied by skin dryness, itching, paresthesia, and headache. Premedication with aspirin may alleviate these symptoms. Flushing is subject to tachyphylaxis and often improves with time. Nausea, vomiting, and abdominal pain also occur at similar doses of niacin. Hepatic toxicity is the most serious toxic reaction due to niacin and may present as jaundice with elevated aspartate aminotransferase (AST) and alanine aminotransferase (ALT) levels. A few cases of fulminant hepatitis requiring liver transplantation have been reported at doses of

TABLE 71-2 DEFICIENCIES AND TOXICITIES OF METALS

Element	Deficiency	Toxicity	Tolerable Upper (Dietary) Intake Level
Boron	No biologic function determined	Developmental defects, male sterility, testicular atrophy	20 mg/d (extrapolated from animal data)
Calcium	Reduced bone mass, osteoporosis	Renal insufficiency (milk-alkalai syndrome), nephrolithiasis, impaired iron absorption	2500 mg/d (milk-alkalai)
Copper	Anemia, growth retardation, defective keratinization and pigmentation of hair, hypothermia, degenerative changes in aortic elastin, osteopenia, mental deterioration	Nausea, vomiting, diarrhea, hepatic failure, tremor, mental deterioration, hemolytic anemia, renal dysfunction	10 mg/d (liver toxicity)
Chromium	Impaired glucose tolerance	Occupational: renal failure, dermatitis, pulmonary cancer	ND
Fluoride	↑ Dental caries	Dental and skeletal fluorosis, osteosclerosis	10 mg/d (fluorosis)
Iodine	Thyroid enlargement, ↓ T_4, cretinism	Thyroid dysfunction, acne-like eruptions	1100 μg/d (thyroid dysfunction)
Iron	Muscle abnormalities, kilonychia, pica, anemia, ↓ work performance, impaired cognitive development, premature labor, ↑ perinatal maternal mortality	Gastrointestinal effects (nausea, vomiting, diarrhea, constipation), iron overload with organ damage, acute systemic toxicity	45 mg/d of elemental iron (GI side effects)
Manganese	Impaired growth and skeletal development, reproduction, lipid and carbohydrate metabolism; upper body rash	General: Neurotoxicity, Parkinson-like symptoms Occupational: Encephalitis-like syndrome, Parkinson-like syndrome, psychosis, pneumoconiosis	11 mg/d (neurotoxicity)
Molybdenum	Severe neurologic abnormalities	Reproductive and fetal abnormalities	2 mg/d extrapolated from animal data
Selenium	Cardiomyopathy, heart failure, striated muscle degeneration	General: Alopecia, nausea, vomiting, abnormal nails, emotional lability, peripheral neuropathy, lassitude, garlic odor to breath, dermatitis Occupational: Lung and nasal carcinomas, liver necrosis, pulmonary inflammation	400 μg/d (hair, nail changes)
Phosphorous	Rickets (osteomalacia), proximal muscle weakness, rhabdomyolysis, paresthesia, ataxia, seizure, confusion, heart failure, hemolysis, acidosis	Hyperphosphatemia	4000 mg/d
Zinc	Growth retardation, ↓ taste and smell, alopecia, dermatitis, diarrhea, immune dysfunction, failure to thrive, gonadal atrophy, congenital malformations	General: Reduced copper absorption, gastritis, sweating, fever, nausea, vomiting Occupational: Respiratory distress, pulmonary fibrosis	40 mg/d (impaired copper metabolism)

Note: ND, not determined; GI, gastrointestinal.

3–9 g/d. Other toxic reactions include glucose intolerance, hyperuricemia, macular edema, and macular cysts. The upper limit for daily niacin intake has been set at 35 mg. However, this upper limit does not pertain to the therapeutic use of niacin.

PYRIDOXINE (VITAMIN B_6)

Vitamin B_6 refers to a family of compounds including pyridoxine, pyridoxal, pyridoxamine, and their 5′-phosphate derivatives. 5′-Pyridoxal phosphate (PLP) is a cofactor for more than 100 enzymes involved in amino acid metabolism. Vitamin B_6 is also involved in heme and neurotransmitter synthesis and in the metabolism of glycogen, lipids, steroids, sphingoid bases, and several vitamins, including the conversion of tryptophan to niacin.

Dietary Sources Plants contain vitamin B_6 in the form of pyridoxine, whereas animal tissues contain PLP and pyridoxamine phosphate. The vitamin B_6 contained in plants is less bioavailable than that from animal tissues. Rich food sources of vitamin B_6 include legumes, nuts, wheat bran, and meat, although it is present in all food groups.

Deficiency Symptoms of vitamin B_6 deficiency include epithelial changes, as seen frequently with other B vitamin deficiencies. In addition, severe vitamin B_6 deficiency can lead to peripheral neuropathy, abnormal electroencephalograms, and personality changes including depression and confusion. In infants, diarrhea, seizures, and anemia have been reported. Microcytic, hypochromic anemia is due to diminished hemoglobin synthesis, since the first enzyme involved in heme biosynthesis (aminolevulinate synthase) requires PLP as a cofactor (Chap. 98). In some case reports, platelet dysfunction has also been reported. Since vitamin B_6 is necessary for the conversion of homocysteine to cystathionine, it is possible that chronic low-grade vitamin B_6 deficiency may result in hyperhomocysteinemia and increased risk of cardiovascular disease (Chaps. 235, 358). Independent of homocysteine, low levels of circulating vitamin B_6 have also been associated with inflammation and elevated C-reactive protein levels.

Certain medications such as isoniazid, L-dopa, penicillamine, and cycloserine interact with PLP due to a reaction with carbonyl groups. Pyridoxine should be given concurrently with isoniazid to avoid neuropathy. The increased ratio of AST (or SGOT) to ALT (or SGPT) seen in alcoholic liver disease reflects the relative vitamin B_6 dependence of ALT. Vitamin B_6 dependency syndromes that require pharmacologic doses of vitamin B_6 are rare; they include cystathionine β-synthase deficiency, pyridoxine-responsive (primarily sideroblastic) anemias, and gyrate atrophy with chorioretinal degeneration due to decreased activity of the mitochondrial enzyme ornithine aminotransferase. In these situations, 100–200 mg/d of oral vitamin B_6 is required for treatment.

High doses of vitamin B_6 have been used to treat carpal tunnel syndrome, premenstrual syndrome, schizophrenia, autism, and diabetic neuropathy but have not been found to be effective.

Vitamin	Active derivative or cofactor form	Principal function
Thiamine (B_1) 	Thiamine pyrophosphate	Coenzyme for cleavage of carbon-carbon bonds; amino acid and carbohydrate metabolism
Riboflavin (B_2) 	Flavin mononucleotide (FMN) and flavin adenine dinucleotide (FAD)	Cofactor for oxidation, reduction reactions, and covalently attached prosthetic groups for some enzymes
Niacin 	Nicotinamide adenine dinucleotide phosphate (NADP) and nicotinamide adenine dinucleotide (NAD)	Coenzymes for oxidation and reduction reactions
Vitamin B_6 	Pyridoxal phosphate	Cofactor for enzymes of amino acid metabolism
Folate 	Polyglutamate forms of (5, 6, 7, 8) tetrahydrofolate with carbon unit attachments	Coenzyme for one carbon transfer in nucleic acid and amino acid metabolism
Vitamin B_{12} 	Methylcobalamine Adenosylcobalamin	Coenzyme for methionine synthase and L-methylmalonyl-CoA mutase

FIGURE 71-1 The structures and principal functions of vitamins associated with human disorders.

Vitamin	Active derivative or cofactor form	Principal function
Vitamin C 	Ascorbic acid and dehydrascorbic acid	Participation as a redox ion in many biological oxidation and hydrogen transfer reactions
Vitamin A 	Retinol, retinaldehyde, and retinoic acid	Formation of rhodopsin (vision) and glycoproteins (epithelial cell function); also regulates gene transcription
Vitamin D 	1, 25-Dihydroxyvitamin D	Maintenance of blood calcium and phosphorous levels; antiproliferative hormone
Vitamin E 	Tocopherols and tocotrienols	Antioxidants
Vitamin K 	Vitamin K hydroquinone	Cofactor for posttranslation carboxylation of many proteins including essential clotting factors

FIGURE 71-1 (*Continued*) The structures and principal functions of vitamins associated with human disorders.

The laboratory diagnosis of vitamin B_6 deficiency is generally made on the basis of low plasma PLP values (<20 nmol/L). Treatment of vitamin B_6 deficiency is 50 mg/d; higher doses of 100–200 mg/d are given if vitamin B_6 deficiency is related to medication use. Vitamin B_6 should not be given with L-dopa, since the vitamin interferes with the action of this drug.

Toxicity The safe upper limit for vitamin B_6 has been set at 100 mg/d, although no adverse effects have been associated with high intakes of vitamin B_6 from food sources only. When toxicity occurs, it causes a severe sensory neuropathy, leaving patients unable to walk. Some cases of photosensitivity and dermatitis have also been reported.

FOLATE, VITAMIN B_{12}

See Chap. 90.

VITAMIN C

Both ascorbic acid and its oxidized product dehydroascorbic acid are biologically active. Actions of vitamin C include antioxidant activity, promotion of nonheme iron absorption, carnitine biosynthesis, the conversion of dopamine to norepinephrine, and the synthesis of many peptide hormones. Vitamin C is also important for connective tissue metabolism and cross-linking (proline hydroxylation), and it is a component of many drug-metabolizing enzyme systems, particularly the mixed-function oxidase systems.

Absorption and Dietary Sources Almost complete absorption of vitamin C occurs if <100 mg is administered in a single dose; however, only 50% or less is absorbed at doses >1 g. Enhanced degradation and fecal and urinary excretion of vitamin C occur at higher intake levels.

Good dietary sources of vitamin C include citrus fruits, green vegetables (especially broccoli), tomatoes, and potatoes. Consumption of five servings of fruits and vegetables a day provides vitamin C in excess of the RDA, 90 mg/d for males and 75 mg/d for females. In addition, approximately 40% of the U.S. population consumes vitamin C as a dietary supplement in which "natural forms" of vitamin C are no more bioavailable than synthetic forms. Smoking, hemodialysis, pregnancy, and stress (e.g., infection, trauma) appear to increase vitamin C requirements.

Deficiency Vitamin C deficiency causes scurvy. In the United States, this is seen primarily among the poor and elderly, in alcoholics who consume <10 mg/d of vitamin C, and also in individuals consuming macrobiotic diets. In addition to generalized fatigue, symptoms of scurvy primarily reflect impaired formation of mature connective tissue and include bleeding into skin (petechiae, ecchymoses, perifollicular hemorrhages); inflamed and bleeding gums; and manifestations of bleeding into joints, the peritoneal cavity, pericardium, and the adrenal glands. In children, vitamin C deficiency may cause impaired bone growth. Laboratory diagnosis of vitamin C deficiency is made on the basis of low plasma or leukocyte levels.

Administration of vitamin C (200 mg/d) improves the symptoms of scurvy within a matter of several days. High-dose vitamin C supplementation (e.g., 1–2 g/d) might slightly decrease the symptoms and duration of upper respiratory tract infections. Vitamin C supplementation has also been reported to be useful in Chédiak-Higashi syndrome (Chap. 61) and osteogenesis imperfecta (Chap. 357). Diets high in vitamin C have been claimed to lower the incidence of certain cancers, particularly esophageal and gastric cancers. If proved, this effect may be due to the fact that vitamin C can prevent the conversion of nitrites and secondary amines to carcinogenic nitrosamines. However, one intervention study from China did not show vitamin C to be protective.

Toxicity Taking >2 g of vitamin C in a single dose may result in abdominal pain, diarrhea, and nausea. Since vitamin C may be metabolized to oxalate, it is feared that chronic, high-dose vitamin C supplementation could result in an increased prevalence of kidney stones. However, this has not been borne out in several trials, except in patients with preexisting renal disease. Thus, it is reasonable to advise patients with a past history of kidney stones to not take large doses of vitamin C. There is also an unproven but possible risk that chronic high doses of vitamin C could promote iron overload in patients taking supplemental iron. High doses of vitamin C can induce hemolysis in patients with glucose-6-phosphate dehydrogenase deficiency, and doses >1 g/d can cause false-negative guaiac reactions as well as interfere with tests for urinary glucose.

BIOTIN

Biotin is a water-soluble vitamin that plays a role in gene expression, gluconeogenesis, and fatty acid synthesis and serves as a CO_2 carrier on the surface of both cytosolic and mitochondrial carboxylase enzymes. The vitamin also functions in the catabolism of specific amino acids (e.g., leucine). Excellent food sources of biotin include organ meat such as liver or kidney, soy, beans, yeast, and egg yolks; however, egg white contains the protein avidin, which strongly binds the vitamin and reduces its bioavailability.

Biotin deficiency due to low dietary intake is rare; rather, deficiency is due to inborn errors of metabolism. Biotin deficiency has been induced by experimental feeding of egg white diets and in patients with short bowels who received biotin-free parenteral nutrition. In the adult, biotin deficiency results in mental changes (depression, hallucinations), paresthesia, anorexia, and nausea. A scaling, seborrheic, and erythematous rash may occur around the eyes, nose, and mouth as well as on the extremities. In infants, biotin deficiency presents as hypotonia, lethargy, and apathy. In addition, the infant may develop alopecia and a characteristic rash that includes the ears. The laboratory diagnosis of biotin deficiency can be established based on a decreased urinary concentration or an increased urinary excretion of 3-hydroxyisovaleric acid after a leucine challenge. Treatment requires pharmacologic doses of biotin, using up to 10 mg/d. No toxicity is known.

PANTOTHENIC ACID (VITAMIN B_5)

Pantothenic acid is a component of coenzyme A and phosphopantetheine, which are involved in fatty acid metabolism and the synthesis of cholesterol, steroid hormones, and all compounds formed from isoprenoid units. In addition, pantothenic acid is involved in the acetylation of proteins. The vitamin is excreted in the urine, and the laboratory diagnosis of deficiency is made on the basis of low urinary vitamin levels.

The vitamin is ubiquitous in the food supply. Liver, yeast, egg yolks, whole grains, and vegetables are particularly good sources. Human pantothenic acid deficiency has been demonstrated only in experimental feeding of diets low in pantothenic acid or by giving a specific pantothenic acid antagonist. The symptoms of pantothenic acid deficiency are nonspecific and include gastrointestinal disturbance, depression, muscle cramps, paresthesia, ataxia, and hypoglycemia. Pantothenic acid deficiency is believed to have caused the burning feet syndrome seen in prisoners of war during World War II. No toxicity of this vitamin has been reported.

CHOLINE

Choline is a precursor for acetylcholine, phospholipids, and betaine. Choline is necessary for the structural integrity of cell membranes, cholinergic neurotransmission, lipid and cholesterol metabolism, methyl-group metabolism, and transmembrane signaling. Recently, a recommended adequate intake was set at 550 mg/d for adult males and 425 mg/d for adult females, although certain genetic polymorphisms can increase an individual's requirement for choline. Choline is thought to be a "conditionally essential" nutrient, in that de novo synthesis occurs in the liver and is less than the vitamin's utilization only under certain stress conditions (e.g., alcoholic liver disease). The dietary requirement of choline depends on the status of other methyl-group donors (folate, vitamin B_{12}, and methionine) and thus varies widely. Choline is widely distributed in food (e.g., egg yolk, wheat germ, organ meat, milk) in the form of lecithin (phosphatidylcholine). Choline deficiency has occurred in patients receiving parenteral nutrition devoid of choline. Deficiency results in fatty liver, elevated transaminase levels, and skeletal muscle damage with high creatine phosphokinase values. The diagnosis of choline deficiency is currently made on the basis of low plasma levels, although nonspecific conditions (e.g., heavy exercise) may suppress plasma levels.

Toxicity from choline results in hypotension, cholinergic sweating, diarrhea, salivation, and a fishy body odor. The upper limit for choline has been set at 3.5 g/d. Therapeutically, choline has been suggested for patients with dementia and for patients at high risk of cardiovascular disease, due to its ability to lower cholesterol and homocysteine levels. However, such benefits have yet to be documented. Choline- and betaine-restricted diets are of therapeutic value in trimethylaminuria (fish odor syndrome).

FLAVONOIDS

Flavonoids constitute a large family of polyphenols that contribute to the aroma, taste, and color of fruits and vegetables. Major groups of dietary flavonoids include anthocyanidins in berries; catechins in green tea and chocolate; flavonols (e.g., quercitin) in broccoli, kale, leeks, onion, and the skins of grapes and apples; and isoflavones (e.g., genistein) in legumes. Isoflavones have a low bioavailability and are partially metabolized by the intestinal flora. The dietary intake of flavonoids is estimated to be between 10 and 100 mg/d, although this is almost certainly an underestimate due to the lack of knowledge of their concentrations in many foods. Several flavonoids have been shown to have antioxidant activity and to affect cell signaling. From observational epidemiologic studies and from limited clinical human and animal studies, flavonoids have been postulated to play a role in the prevention of several chronic diseases, including neurodegenerative disease, diabetes, and osteoporosis. The ultimate importance and usefulness of their compounds against human disease have yet to be demonstrated.

VITAMIN A

Vitamin A, in the strictest sense, refers to retinol. However, the oxidized metabolites, retinaldehyde and retinoic acid, are also biologically active compounds. The term *retinoids* includes all molecules (including synthetic molecules) that are chemically related to retinol. Retinaldehyde (11-*cis*) is the essential form of vitamin A that is required for normal vision, whereas retinoic acid is necessary for normal morphogenesis, growth, and cell differentiation. Retinoic acid does not function in vision and, in contrast to retinol, is not involved in reproduction. Vitamin A also plays a role in iron utilization, humoral immunity, T cell–mediated immunity, natural killer cell activity, and phagocytosis. Vitamin A is commercially available in esterified forms (e.g., acetate, palmitate) since it is more stable as an ester.

There are more than 600 carotenoids in nature, and approximately 50 of these can be metabolized to vitamin A. β-Carotene is the most prevalent carotenoid in the food supply that has provitamin A activity. In humans, significant fractions of carotenoids are absorbed intact and are stored in liver and fat. It is now estimated that 12 μg or greater of dietary β-carotene is equivalent to 1 μg of retinol, whereas 24 μg or greater of other dietary provitamin A carotenoids (e.g., cryptoxanthin, α-carotene) is equivalent to 1 μg of retinol.

Metabolism The liver contains approximately 90% of the vitamin A reserves and secretes vitamin A in the form of retinol, which is bound to retinol-binding protein. Once this has occurred, the retinol-binding protein complex interacts with a second protein, transthyretin. This trimolecular complex functions to prevent vitamin A from being filtered by the kidney glomerulus, to protect the body against the toxicity of retinol and to allow retinol to be taken up by specific cell-surface receptors that recognize retinol-binding protein. A certain amount of vitamin A enters peripheral cells even if it is not bound to retinol-binding protein. After retinol is internalized by the cell, it becomes bound to a series of cellular retinol-binding proteins, which function as sequestering and transporting agents as well as co-ligands for enzymatic reactions. Certain cells also contain retinoic acid–binding proteins, which have sequestering functions but also shuttle retinoic acid to the nucleus and enable its metabolism.

Retinoic acid is a ligand for certain nuclear receptors that act as transcription factors. Two families of receptors (RAR and RXR receptors) are active in retinoid-mediated gene transcription. Retinoid receptors regulate transcription by binding as dimeric complexes to specific DNA sites, the retinoic acid response elements, in target genes (Chap. 332). The receptors can either stimulate or repress gene expression in response to their ligands. RAR binds all-*trans* retinoic acid and 9-*cis* retinoic acid, whereas RXR binds only 9-*cis* retinoic acid.

The retinoid receptors play an important role in controlling cell proliferation and differentiation. Retinoic acid is useful in the treatment of promyelocytic leukemia (Chap. 104) and is also used in the treatment of cystic acne because it inhibits keratinization, decreases sebum secretion, and possibly alters the inflammatory reaction (Chap. 53). RXRs dimerize with other nuclear receptors to function as coregulators of genes responsive to retinoids, thyroid hormone, and calcitriol. RXR agonists induce insulin sensitivity experimentally, perhaps because RXR is a cofactor for the peroxisome-proliferator-activated receptors (PPARs), which are targets for the thiazolidinedione drugs such as rosiglitazone and troglitazone (Chap. 338).

Dietary Sources The retinol activity equivalent (RAE) is used to express the vitamin A value of food. One RAE is defined as 1 μg of retinol (0.003491 mmol), 12 μg of β-carotene, and 24 μg of other provitamin A carotenoids. In older literature, vitamin A was often expressed in international units (IU), with 1 RAE being equal to 3.33 IU of retinol and 20 IU of β-carotene, but these units are no longer in current scientific use.

Liver, fish, and eggs are excellent food sources for preformed vitamin A; vegetable sources of provitamin A carotenoids include dark green and deeply colored fruits and vegetables. Moderate cooking of vegetables enhances carotenoid release for uptake in the gut. Carotenoid absorption is also aided by some fat in a meal. Infants are particularly susceptible to vitamin A deficiency because neither breast nor cow's milk supplies enough vitamin A to prevent deficiency. In developing countries, chronic dietary deficit is the main cause of vitamin A deficiency and is exacerbated by infection. In early childhood, low vitamin A status results from inadequate intakes of animal food sources and edible oils, both of which are expensive, coupled with seasonal unavailability of vegetables and fruits, and lack of marketed fortified food products. Concurrent zinc deficiency can interfere with the mobilization of vitamin A from liver stores. Alcohol interferes with the conversion of retinol to retinaldehyde in the eye by competing for alcohol (retinol) dehydrogenase. Drugs that interfere with the absorption of vitamin A include mineral oil, neomycin, and cholestyramine.

Deficiency Vitamin A deficiency is endemic where diets are chronically poor, especially in Southern Asia, Sub-Saharan Africa, some areas of Latin America, and the Western Pacific, including parts of China. Vitamin A status is usually assessed by measuring serum retinol [normal range, 1.05–3.50 μmol/L (30–100 μg/dL)] or blood spot retinol or by tests of dark adaptation. Stable isotopic or invasive liver biopsy methods exist to estimate total body stores of vitamin A. Based on deficient serum retinol [<0.70 μmol/L (20 μg/dL)], there are more than 125 million preschool-age children with vitamin A deficiency, among whom ~4 million have an ocular manifestation of deficiency termed *xerophthalmia*. This condition includes milder stages of night blindness and conjunctival xerosis (dryness) with Bitot's spots (white patches of keratinized epithelium appearing on the sclera) as well as rare, potentially blinding corneal ulceration and necrosis. Keratomalacia (softening of the cornea) leads to corneal scarring that blinds at least a quarter of a million children each year and is associated with a fatality rate of 4–25%. However, vitamin A deficiency at any stage poses an increased risk of mortality from diarrhea, dysentery, measles, malaria, and respiratory disease. Vitamin A deficiency can compromise barrier and innate and acquired immune defenses to infection. Vitamin A supplementation can markedly reduce risk of child mortality (23–34%, on average) where deficiency is widely prevalent. About 10% of pregnant women in undernourished settings also develop night blindness, assessed by history, during the latter half of pregnancy and this moderate vitamin A deficiency is associated with an increased risk of maternal infection and mortality.

℞ VITAMIN A DEFICIENCY

Any stage of xerophthalmia should be treated with 60 mg of vitamin A in oily solution, usually contained in a soft-gel capsule. The same dose is repeated 1 and 14 days later. Doses should be reduced by half for patients 6–11 months of age. Mothers with night blindness or Bitot's spots should be given vitamin A orally, either 3 mg daily or 7.5 mg twice a week for 3 months. These regimens are efficacious, and they are less expensive and more widely available than injectable water-miscible vitamin A. A common approach to prevention is to supplement young children living in high-risk areas with 60 mg every 4–6 months, with a half-dose given to infants 6–11 months of age.

Uncomplicated vitamin A deficiency rarely occurs in industrialized countries. One high-risk group, extremely low-birth-weight infants (<1000 g), is likely to be vitamin A–deficient and should be supplemented with 1500 μg (or RAE) of vitamin A, three times a week for 4 weeks. Severe measles in any society can lead to secondary vitamin A deficiency. Children hospitalized with measles should receive two 60-mg doses of vitamin A on two consecutive days. Vitamin A deficiency most often occurs in patients with malabsorptive diseases (e.g., celiac sprue, short-bowel syndrome), who have abnormal dark adaptation or symptoms of night blindness without other ocular changes. Typically, such patients are treated for 1 month with 15 mg/d of a water-miscible preparation of vitamin A. This is followed by a lower maintenance dose with the exact amount determined by monitoring serum retinol.

There are no specific deficiency signs or symptoms that result from carotenoid deficiency. It was postulated that β-carotene would be an effective chemopreventive agent for cancer because numerous epidemiologic studies had shown that diets high in β-carotene were associated with lower incidences of cancers of the respiratory and digestive systems. However, intervention studies in smokers found that treatment with high doses of β-carotene actually resulted in more lung cancers than did treatment with placebo. Non–provitamin A carotenoids, such as lutein and zeaxanthin, have been suggested to protect against macular degeneration. The non–provitamin A carotenoid lycopene has been proposed to protect against prostate cancer. However, the effectiveness of these agents has not been proven by intervention studies, and the mechanisms underlying these purported biologic actions are unknown.

Toxicity Acute toxicity of vitamin A was first noted in Arctic explorers who ate polar bear liver and has also been seen after administration of 150 mg in adults or 100 mg in children. Acute toxicity is manifested by increased intracranial pressure, vertigo, diplopia, bulging fontanels in children, seizures, and exfoliative dermatitis; it may result in death. In children being treated for vitamin A deficiency according to the protocols outlined above, transient bulging of fontanels occurs in 2% of infants, and transient nausea, vomiting, and headache occur in 5% of preschoolers. Chronic vitamin A intoxication is largely a concern in industrialized countries and has been seen in normal adults who ingest 15 mg/d and children who ingest 6 mg/d of vitamin A over a period of several months. Manifestations include dry skin, cheilosis, glossitis, vomiting, alopecia, bone demineralization and pain, hypercalcemia, lymph node enlargement, hyperlipidemia, amenorrhea, and features of pseudotumor cerebri with increased intracranial pressure and papilledema. Liver fibrosis with portal hypertension and bone demineralization may result from chronic vitamin A intoxication. When vitamin A is provided in excess to pregnant women, congenital malformations have included spontaneous abortions, craniofacial abnormalities, and valvular heart disease. In pregnancy, the daily dose of vitamin A should not exceed 3 mg. Commercially available retinoid derivatives are also toxic, including 13-*cis*-retinoic acid, which has been associated with birth defects. As a result, contraception should be continued for a least 1 year, and possibly longer, in women who have taken 13-*cis* retinoic acid.

High doses of carotenoids do not result in toxic symptoms but should be avoided in smokers due to an increased risk of lung cancer. Carotenemia, which is characterized by a yellowing of the skin (creases of the palms and soles) but not the sclerae, may be present after ingestion of >30 mg of β-carotene daily. Hypothyroid patients are particularly susceptible to the development of carotenemia due to impaired breakdown of carotene to vitamin A. Reduction of carotenes from the diet results in the disappearance of skin yellowing and carotenemia over a period of 30–60 days.

VITAMIN D

See Chap. 346, Fig. 71-1, and Table 71-1.

VITAMIN E

Vitamin E is a collective name for all stereoisomers of tocopherols and tocotrienols, although only the 2R tocopherols meet human requirements. Vitamin E acts as a chain-breaking antioxidant and is an efficient pyroxyl radical scavenger, which protects low-density lipoproteins (LDLs) and polyunsaturated fats in membranes from oxidation. A network of other antioxidants (e.g., vitamin C, glutathione) and enzymes maintains vitamin E in a reduced state. Vitamin E also inhibits prostaglandin synthesis and the activities of protein kinase C and phospholipase A_2.

Absorption and Metabolism After absorption, vitamin E is taken up from chylomicrons by the liver, and a hepatic α tocopherol transport protein mediates intracellular vitamin E transport and incorporation into very low-density lipoprotein (VLDL). The transport protein has particular affinity for the RRR isomeric form of α tocopherol; thus this natural isomer has the most biologic activity.

Requirement Vitamin E is widely distributed in the food supply and is particularly high in sunflower oil, safflower oil, and wheat germ oil; γ tocotrienols are notably present in soybean and corn oils. Vitamin E is also found in meats, nuts, and cereal grains, and small amounts are present in fruits and vegetables. Vitamin E pills containing doses of 50–1000 mg are ingested by a large fraction of the U.S. population. The RDA for vitamin E is 15 mg/d (34.9 μmol or 22.5 IU) for all adults. Diets high in polyunsaturated fats may necessitate a slightly higher requirement for vitamin E.

Dietary deficiency of vitamin E does not exist. Vitamin E deficiency is seen in only severe and prolonged malabsorptive diseases, such as celiac disease, or after small-intestinal resection. Children with cystic fibrosis or prolonged cholestasis may develop vitamin E deficiency characterized by areflexia and hemolytic anemia. Children with abetalipoproteinemia cannot absorb or transport vitamin E and become deficient quite rapidly. A familial form of isolated vitamin E deficiency also exists; it is due to a defect in the α tocopherol transport protein. Vitamin E deficiency causes axonal degeneration of the large myelinated axons and results in posterior column and spinocerebellar symptoms. Peripheral neuropathy is initially characterized by areflexia, with progression to an ataxic gait, and by decreased vibration and position sensations. Ophthalmoplegia, skeletal myopathy, and pigmented retinopathy may also be features of vitamin E deficiency. Either vitamin E or selenium deficiency in the host has been shown to increase certain viral mutations and, therefore, virulence. The laboratory diagnosis of vitamin E deficiency is made on the basis of low blood levels of α tocopherol (<5 μg/mL, or <0.8 mg of α tocopherol per gram of total lipids).

℞ VITAMIN E DEFICIENCY

Symptomatic vitamin E deficiency should be treated with 800–1200 mg of α tocopherol per day. Patients with abetalipoproteinemia may need as much as 5000–7000 mg/d. Children with symptomatic vitamin E deficiency should be treated with 400 mg/d orally of water-miscible esters; alternatively, 2 mg/kg per d may be administered intramuscularly. Vitamin E in high doses may protect against oxygen-induced retrolental fibroplasia and bronchopulmonary dysplasia, as well as intraventricular hemorrhage of prematurity. Vitamin E has been suggested to increase sexual performance, to treat intermittent claudication, and to slow the aging process, but evidence for these properties is lacking. When given in combination with other antioxidants, vitamin E may help to prevent macular degeneration. High doses (60–800 mg/d) of vitamin E have been shown in controlled trials to improve parameters of immune function and to reduce colds in nursing home residents, but intervention studies using vitamin E to prevent cardiovascular disease or cancer have not shown efficacy and, at doses >400 mg/d, may even increase all-cause mortality.

Toxicity All forms of vitamin E are absorbed and could contribute to toxicity. High doses of vitamin E (>800 mg/d) may reduce platelet aggregation and interfere with vitamin K metabolism and are therefore contraindicated in patients taking warfarin. Nausea, flatulence, and diarrhea have been reported at doses >1 g/d.

VITAMIN K

There are two natural forms of vitamin K: vitamin K_1, also known as *phylloquinone*, from vegetable and animal sources, and vitamin K_2, or *menaquinone*, which is synthesized by bacterial flora and found in hepatic tissue. Phylloquinone can be converted to menaquinone in some organs.

Vitamin K is required for the posttranslational carboxylation of glutamic acid, which is necessary for calcium binding to γ-carboxylated proteins such as prothrombin (factor II); factors VII, IX, and X; protein C; protein S; and proteins found in bone (osteocalcin) and vascular smooth muscle (e.g., matrix Gla protein). However, the importance of vitamin K for bone mineralization and prevention of vascular calcification is not known. Warfarin-type drugs inhibit γ-carboxylation by preventing the conversion of vitamin K to its active hydroquinone form.

Dietary Sources Vitamin K is found in green leafy vegetables such as kale and spinach, and appreciable amounts are also present in margarine and liver. Vitamin K is present in vegetable oils and is particularly rich in olive, canola, and soybean oils. The average daily intake by Americans is estimated to be approximately 100 μg/d.

Deficiency The symptoms of vitamin K deficiency are due to hemorrhage, and newborns are particularly susceptible because of low fat stores, low breast milk levels of vitamin K, sterility of the infantile intestinal tract, liver immaturity, and poor placental transport. Intracranial bleeding, as well as gastrointestinal and skin bleeding, can occur in vitamin K–deficient infants 1–7 days after birth. Thus, vitamin K (1 mg IM) is given prophylactically at the time of delivery.

Vitamin K deficiency in adults may be seen in patients with chronic small-intestinal disease (e.g., celiac disease, Crohn's disease), in those with obstructed biliary tracts, or after small-bowel resection. Broad-spectrum antibiotic treatment can precipitate vitamin K deficiency by reducing gut bacteria, which synthesize menaquinones, and by inhibiting the metabolism of vitamin K. In patients with warfarin therapy, the antiobesity drug orlistat can lead to INR changes due to vitamin K malabsorption. The diagnosis of vitamin K deficiency is usually made on the basis of an elevated prothrombin time or reduced clotting factors, although vitamin K may also be measured directly by HPLC. Vitamin K deficiency is treated using a parenteral dose of 10 mg. For patients with chronic malabsorption, 1–2 mg/d of vitamin K should be given orally, or 1–2 mg/week can be taken parenterally. Patients with liver disease may have an elevated prothrombin time because of liver cell destruction as well as vitamin K deficiency. If an elevated prothrombin time does not improve on vitamin K therapy, it can be deduced that it is not the result of vitamin K deficiency.

Toxicity Toxicity from dietary phylloquinones and menaquinones has not been described. High doses of vitamin K can impair the actions of oral anticoagulants.

MINERALS

Table 71-2.

CALCIUM

See Chap. 346.

ZINC

Zinc is an integral component of many metalloenzymes in the body; it is involved in the synthesis and stabilization of proteins, DNA, and

RNA and plays a structural role in ribosomes and membranes. Zinc is necessary for the binding of steroid hormone receptors and several other transcription factors to DNA. Zinc is absolutely required for normal spermatogenesis, fetal growth, and embryonic development.

Absorption The absorption of zinc from the diet is inhibited by dietary phytate, fiber, oxalate, iron, and copper, as well as by certain drugs including penicillamine, sodium valproate, and ethambutol. Meat, shellfish, nuts, and legumes are good sources of bioavailable zinc, whereas zinc in grains and legumes is less available for absorption.

Deficiency Mild zinc deficiency has been described in many diseases, including diabetes mellitus, HIV/AIDS, cirrhosis, alcoholism, inflammatory bowel disease, malabsorption syndromes, and sickle cell disease. In these diseases, mild chronic zinc deficiency can cause stunted growth in children, decreased taste sensation (hypogeusia), and impaired immune function. Severe chronic zinc deficiency has been described as a cause of hypogonadism and dwarfism in several Middle Eastern countries. In these children, hypopigmented hair is also part of the syndrome. Acrodermatitis enteropathica is a rare autosomal recessive disorder characterized by abnormalities in zinc absorption. Clinical manifestations include diarrhea, alopecia, muscle wasting, depression, irritability, and a rash involving the extremities, face, and perineum. The rash is characterized by vesicular and pustular crusting with scaling and erythema. Occasional patients with Wilson's disease have developed zinc deficiency as a consequence of penicillamine therapy (Chap. 354).

The diagnosis of zinc deficiency is usually made by a serum zinc level of <12 μmol/L (<70 μg/dL). Pregnancy and birth control pills may cause a slight depression in serum zinc levels, and hypoalbuminemia from any cause can result in hypozincemia. In acute stress situations, zinc may be redistributed from serum into tissues. Zinc deficiency may be treated with 60 mg elemental zinc, orally twice a day. Zinc gluconate lozenges (13 mg elemental zinc every 2 h while awake) have been reported to reduce the duration and symptoms of the common cold in adults, but studies are conflicting.

Zinc deficiency is prevalent in many developing countries and usually coexists with other micronutrient deficiencies (especially iron). Zinc (20 mg/d) may be an effective adjunctive therapeutic strategy for diarrheal disease in children.

Toxicity Acute zinc toxicity after oral ingestion causes nausea, vomiting, and fever. Zinc fumes from welding may also be toxic and cause fever, respiratory distress, excessive salivation, sweating, and headache. Chronic large doses of zinc may depress immune function and cause hypochromic anemia as a result of copper deficiency.

COPPER

Copper is an integral part of numerous enzyme systems including amine oxidases, ferroxidase (ceruloplasmin), cytochrome-*c* oxidase, superoxide dismutase, and dopamine hydroxylase. Copper is also a component of ferroprotein, a transport protein involved in the basolateral transfer of iron during absorption from the enterocyte. As such, copper plays a role in iron metabolism, melanin synthesis, energy production, neurotransmitter synthesis, and CNS function; the synthesis and cross-linking of elastin and collagen; and the scavenging of superoxide radicals. Dietary sources of copper include shellfish, liver, nuts, legumes, bran, and organ meats.

Deficiency Dietary copper deficiency is relatively rare, although it has been described in premature infants who are fed milk diets and in infants with malabsorption (Table 71-2). Copper-deficiency anemia has been reported in patients with malabsorptive diseases and nephrotic syndrome and in patients treated for Wilson's disease with chronic high doses of oral zinc, which can interfere with copper absorption. Menkes kinky hair syndrome is an X-linked metabolic disturbance of copper metabolism characterized by mental retardation, hypocupremia, and decreased circulating ceruloplasmin (Chap. 357). It is caused by mutations in the copper-transporting *ATP7A* gene. Children with this disease often die within 5 years because of dissecting aneurysms or cardiac rupture. Aceruloplasminemia is a rare autosomal recessive disease characterized by tissue iron overload, mental deterioration, microcytic anemia, and low serum iron and copper concentrations.

The diagnosis of copper deficiency is usually made on the basis of low serum levels of copper (<65 μg/dL) and low ceruloplasmin levels (<20 mg/dL). Serum levels of copper may be elevated in pregnancy or stress conditions since ceruloplasmin is an acute-phase reactant and 90% of circulating copper is bound to ceruloplasmin.

Toxicity Copper toxicity is usually accidental (Table 71-2). In severe cases, kidney failure, liver failure, and coma may ensue. In Wilson's disease, mutations in the copper-transporting *ATP7B* gene lead to accumulation of copper in the liver and brain, with low blood levels due to decreased ceruloplasmin (Chap. 354).

SELENIUM

Selenium, in the form of selenocysteine, is a component of the enzyme glutathione peroxidase, which serves to protect proteins, cell membranes, lipids, and nucleic acids from oxidant molecules. As such, selenium is being actively studied as a chemopreventive agent against certain cancers, such as prostate. Selenocysteine is also found in the deiodinase enzymes, which mediate the deiodination of thyroxine to triiodothyronine (Chap. 335). Rich dietary sources of selenium include seafood, muscle meat, and cereals, although the selenium content of cereal is determined by the soil concentration. Countries with low soil concentrations include parts of Scandinavia, China, and New Zealand. *Keshan disease* is an endemic cardiomyopathy found in children and young women residing in regions of China where dietary intake of selenium is low (<20 μg/d). Concomitant deficiencies of iodine and selenium may worsen the clinical manifestations of cretinism. Chronic ingestion of high amounts of selenium leads to selenosis characterized by hair and nail brittleness and loss, garlic breath odor, skin rash, myopathy, irritability, and other abnormalities of the nervous system.

CHROMIUM

Chromium potentiates the action of insulin in patients with impaired glucose tolerance, presumably by increasing insulin receptor–mediated signaling, although its usefulness in treating type II diabetes is uncertain. In addition, improvement in blood lipid profiles has been reported in some patients. The usefulness of chromium supplements in muscle building is not substantiated. Rich food sources of chromium include yeast, meat, and grain products. Chromium in the trivalent state is found in supplements and is largely nontoxic; however, chromium-6 is a product of stainless steel welding and is a known pulmonary carcinogen, as well as a cause of liver, kidney, and CNS damage.

MAGNESIUM

See Chap. 346.

FLUORIDE, MANGANESE, AND ULTRATRACE ELEMENTS

An essential function for fluoride in humans has not been described, although it is useful for the maintenance of structure in teeth and bone. Adult fluorosis results in mottled and pitted defects in tooth enamel as well as brittle bone (skeletal fluorosis).

Manganese and molybdenum deficiencies have been reported in patients with rare genetic abnormalities and in a few patients receiving prolonged total parenteral nutrition. Several manganese-specific enzymes have been identified (e.g., manganese superoxide dismutase). Deficiencies of manganese have been reported to result in bone demineralization, poor growth, ataxia, disturbances in carbohydrate and lipid metabolism, and convulsions.

Ultratrace elements are defined as those needed in amounts <1 mg/d. Essentiality has not been established for most ultratrace elements, al-

though selenium, chromium, and iodine are clearly essential (Chap. 335). *Molybdenum* is necessary for the activity of sulfite and xanthine oxidase, and molybdenum deficiency may result in skeletal and brain lesions.

72 Malnutrition and Nutritional Assessment

Douglas C. Heimburger

Malnutrition can arise from primary or secondary causes, with the former resulting from inadequate or poor-quality food intake and the latter from diseases that alter food intake or nutrient requirements, metabolism, or absorption. Primary malnutrition occurs mainly in developing countries and under conditions of war or famine. Secondary malnutrition, the main form encountered in industrialized countries, was largely unrecognized until the early 1970s, when it became appreciated that persons with adequate food supplies can become malnourished as a result of acute or chronic diseases that alter nutrient intake or metabolism. Various studies have shown that protein-energy malnutrition (PEM) affects one-third to one-half of patients on general medical and surgical wards in teaching hospitals. The consistent finding that nutritional status influences patient prognosis underscores the importance of preventing, detecting, and treating malnutrition.

PROTEIN-ENERGY MALNUTRITION

The two major types of PEM are *marasmus* and *kwashiorkor*. These conditions are compared in Table 72-1. Marasmus and kwashiorkor can occur singly or in combination, as *marasmic kwashiorkor*. Kwashiorkor can occur rapidly, whereas marasmus is the end result of a gradual wasting process that passes through stages of underweight, then mild, moderate, and severe cachexia.

MARASMUS

The end stage of cachexia, marasmus is a state in which virtually all available body fat stores have been exhausted due to starvation. Conditions that produce marasmus in developed countries tend to be chronic and indolent, such as cancer, chronic pulmonary disease, and anorexia nervosa. Marasmus is easy to detect because of the patient's starved appearance. The diagnosis is based on severe fat and muscle wastage resulting from prolonged calorie deficiency. Diminished skin-fold thickness reflects the loss of fat reserves; reduced arm muscle circumference with temporal and interosseous muscle wasting reflects the catabolism of protein throughout the body, including vital organs such as the heart, liver, and kidneys.

The laboratory findings in marasmus are relatively unremarkable. The creatinine-height index (the 24-h urinary creatinine excretion compared with normal values based on height) is low, reflecting the loss of muscle mass. Occasionally, the serum albumin level is reduced, but it stays above 2.8 g/dL in uncomplicated cases. Despite a morbid appearance, immunocompetence, wound healing, and the ability to handle short-term stress are reasonably well preserved in most patients with marasmus.

Marasmus is a chronic, fairly well-adapted form of starvation rather than an acute illness; it should be treated cautiously, in an attempt to reverse the downward trend gradually. Although nutritional support is necessary, overly aggressive repletion can result in severe, even life-threatening metabolic imbalances such as hypophosphatemia and cardiorespiratory failure. When possible, oral or enteral nutritional support is preferred; treatment started slowly allows readaptation of metabolic and intestinal functions (Chap. 73).

KWASHIORKOR

In contrast to marasmus, kwashiorkor in developed countries occurs mainly in connection with acute, life-threatening illnesses such as trauma and sepsis, and chronic illnesses that involve acute-phase in-

TABLE 72-1 COMPARISON OF MARASMUS AND KWASHIORKOR

	Marasmus	Kwashiorkor[a]
Clinical setting	↓ Energy intake	↓ Protein intake during stress state
Time course to develop	Months or years	Weeks
Clinical features	Starved appearance Weight <80% standard for height Triceps skinfold <3 mm Mid-arm muscle circumference <15 cm	Well-nourished appearance Easy hair pluckability[b] Edema
Laboratory findings	Creatinine-height index <60% standard	Serum albumin <2.8 g/dL Total iron-binding capacity <200 μg/dL Lymphocytes <1500/μL Anergy
Clinical course	Reasonably preserved responsiveness to short-term stress	Infections Poor wound healing, decubitus ulcers, skin breakdown
Mortality	Low unless related to underlying disease	High
Diagnostic criteria	Triceps skinfold <3 mm Mid-arm muscle circumference <15 cm	Serum albumin <2.8 g/dL At least one of the following: Poor wound healing, decubitus ulcers, or skin breakdown Easy hair pluckability[b] Edema

[a]The findings used to diagnose kwashiorkor must be unexplained by other causes.
[b]Tested by *firmly* pulling a lock of hair from the top (not the sides or back), grasping with the thumb and forefinger. An average of three or more hairs removed easily and painlessly is considered abnormal hair pluckability.

flammatory responses. The physiologic stress produced by these illnesses increases protein and energy requirements at a time when intake is often limited. A classic scenario for kwashiorkor is the acutely stressed patient who receives only 5% dextrose solutions for periods as brief as 2 weeks. Although the etiologic mechanisms are not clear, the protein-sparing response normally seen in starvation is blocked by the stressed state and by carbohydrate infusion.

In its early stages, the physical findings of kwashiorkor are few and subtle. Fat reserves and muscle mass are initially unaffected, giving the deceptive appearance of adequate nutrition. Signs that support the diagnosis of kwashiorkor include easy hair pluckability, edema, skin breakdown, and poor wound healing. The major *sine qua non* is severe reduction of levels of serum proteins such as albumin (<2.8 g/dL) and transferrin (<150 mg/dL) or iron-binding capacity (<200 µg/dL). Cellular immune function is depressed, reflected by lymphopenia (<1500 lymphocytes/µL in adults and older children) and lack of response to skin test antigens (anergy).

The prognosis of adult patients with full-blown kwashiorkor is not good, even with aggressive nutritional support. Surgical wounds often dehisce (fail to heal), pressure sores develop, gastroparesis and diarrhea can occur with enteral feeding, the risk of gastrointestinal bleeding from stress ulcers is increased, host defenses are compromised, and death from overwhelming infection may occur despite antibiotic therapy. Unlike treatment in marasmus, aggressive nutritional support is indicated to restore better metabolic balance rapidly (Chap. 73). Although kwashiorkor in children is less foreboding, perhaps because a lesser degree of stress is required to precipitate the disorder, it is still a serious condition.

MARASMIC KWASHIORKOR

Marasmic kwashiorkor, the combined form of PEM, develops when the cachectic or marasmic patient experiences acute stress such as surgery, trauma, or sepsis, superimposing kwashiorkor onto chronic starvation. An extremely serious, life-threatening situation can occur because of the high risk of infection and other complications. It is important to determine the major component of PEM so that the appropriate nutritional plan can be developed. If kwashiorkor predominates, the need for vigorous nutritional therapy is urgent; if marasmus predominates, feeding should be more cautious.

PHYSIOLOGIC CHARACTERISTICS OF HYPOMETABOLIC AND HYPERMETABOLIC STATES

The metabolic characteristics and nutritional needs of hypermetabolic patients who are stressed from injury, infection, or chronic inflammatory illness differ from those of hypometabolic patients who are unstressed but chronically starved. In both cases, nutritional support is important, but misjudgments in selecting the appropriate approach may have disastrous consequences.

The hypometabolic patient is typified by the relatively unstressed but mildly catabolic and chronically starved individual who, with time, will develop marasmus. The hypermetabolic patient stressed from injury or infection is catabolic (experiencing rapid breakdown of body mass) and is at high risk for developing kwashiorkor, if nutritional needs are not met and/or the illness does not resolve quickly. As summarized in Table 72-2, the two states are distinguished by differing perturbations of metabolic rate, rates of protein breakdown (proteolysis), and rates of gluconeogenesis. These differences are mediated by proinflammatory cytokines and counterregulatory hormones—tumor necrosis factor, interleukins 1 and 6, C-reactive protein, catecholamines (epinephrine and norepinephrine), glucagon, and cortisol—that are relatively reduced in hypometabolic patients and increased in hypermetabolic patients. Although insulin levels are also elevated in stressed patients, insulin resistance in the target tissues prevents insulin-mediated anabolic actions.

TABLE 72-2 PHYSIOLOGIC CHARACTERISTICS OF HYPOMETABOLIC AND HYPERMETABOLIC STATES

Physiologic Characteristics	Hypometabolic, Nonstressed Patient (Cachectic, Marasmic)	Hypermetabolic, Stressed Patient (Kwashiorkor Risk[a])
Cytokines, catecholamines, glucagon, cortisol, insulin	↓	↑
Metabolic rate, O_2 consumption	↓	↑
Proteolysis, gluconeogenesis	↓	↑
Ureagenesis, urea excretion	↓	↑
Fat catabolism, fatty acid utilization	↑	↑
Adaptation to starvation	Normal	Abnormal

[a]These changes characterize the stressed, kwashiorkor-risk patient seen in developed countries; they differ in some respects from the characteristics of primary kwashiorkor seen in developing countries.

METABOLIC RATE

In starvation and semistarvation, the resting metabolic rate falls between 10% and 30% as an adaptive response to energy restriction, slowing the rate of weight loss. By contrast, resting metabolic rate rises in the presence of physiologic stress in proportion to the degree of the insult. It may increase by about 10% after elective surgery, 20–30% after bone fractures, 30–60% with severe infections such as peritonitis or gram-negative septicemia, and as much as 110% after major burns.

If the metabolic rate (energy requirement) is not matched by energy intake, weight loss results—slowly in hypometabolism and quickly in hypermetabolism. Losses of up to 10% of body weight are unlikely to be detrimental; however, losses greater than this in acutely ill hypermetabolic patients may be associated with rapid deterioration in body function.

PROTEIN CATABOLISM

The rate of endogenous protein breakdown (catabolism) to supply energy needs normally falls during uncomplicated energy deprivation. After about 10 days of total starvation, the unstressed individual loses about 12–18 g/d protein (equivalent to approximately 2 oz of muscle tissue or 2–3 g of nitrogen). By contrast, in injury and sepsis, protein breakdown accelerates in proportion to the degree of stress, to 30–60 g/d after elective surgery, 60–90 g/d with infection, 100–130 g/d with severe sepsis or skeletal trauma, and >175 g/d with major burns or head injuries. These losses are reflected by proportional increases in the excretion of urea nitrogen, the major byproduct of protein breakdown.

GLUCONEOGENESIS

The major aim of protein catabolism during a state of starvation is to provide the glucogenic amino acids (especially alanine and glutamine) that serve as substrates for endogenous glucose production (gluconeogenesis) in the liver. In the hypometabolic/starved state, protein breakdown for gluconeogenesis is minimized, especially as ketones derived from fatty acids become the substrate preferred by certain tissues. In the hypermetabolic/stress state, gluconeogenesis increases dramatically and in proportion to the degree of the insult, to increase the supply of glucose (the major fuel of reparation). Glucose is the only fuel that can be utilized by hypoxic tissues (anaerobic glycolysis), white blood cells, and newly generated fibroblasts. Infusions of glucose partially offset a negative energy balance but do not significantly suppress the high rates of gluconeogenesis in the catabolic patient. Hence, adequate supplies of protein are needed to replace the amino acids utilized for this metabolic response.

In summary, the hypometabolic patient is adapted to starvation and conserves body mass by reducing the metabolic rate and using fat as the primary fuel (rather than glucose and its precursor amino acids). The hypermetabolic patient also uses fat as a fuel but rapidly breaks down body protein to produce glucose, causing loss of muscle and organ tissue and endangering vital body functions.

MICRONUTRIENT MALNUTRITION

The same illnesses and reductions in nutrient intake that lead to PEM often produce deficiencies of vitamins and minerals as well (Chap. 71).

Deficiencies of nutrients that are stored in small amounts (such as the water-soluble vitamins) are lost through external secretions, such as zinc in diarrhea fluid or burn exudate, and are probably more common than generally recognized.

Deficiencies of vitamin C, folic acid, and zinc are reasonably common in sick patients. Signs of scurvy such as corkscrew hairs on the lower extremities are frequently found in chronically ill and/or alcoholic patients. The diagnosis can be confirmed with plasma vitamin C levels. Folic acid intakes and blood levels are often less than optimal, even among healthy persons; when illness, alcoholism, poverty, or poor dentition is present, deficiencies are common. Low blood zinc levels are prevalent in patients with malabsorption syndromes such as inflammatory bowel disease. Patients with zinc deficiency often exhibit poor wound healing, pressure ulcer formation, and impaired immunity. Thiamine deficiency is a common complication of alcoholism, but its manifestations are often prevented by therapeutic doses of thiamine in patients treated for alcohol abuse.

Patients with low plasma vitamin C levels usually respond to the doses found in multivitamin preparations, but patients with deficiencies should be supplemented with 250–500 mg/d. Folic acid is absent from some oral multivitamin preparations; patients with deficiencies should be supplemented with about 1 mg/d. Patients with zinc deficiencies resulting from large external losses sometimes require oral daily supplementation with 220 mg of zinc sulfate one to three times daily. For these reasons, laboratory assessments of the micronutrient status of patients at high risk are desirable.

Hypophosphatemia develops in hospitalized patients with remarkable frequency and generally results from rapid intracellular shifts of phosphate in cachectic or alcoholic patients receiving intravenous glucose (Chap. 46). The adverse clinical sequelae are numerous; some, such as acute cardiopulmonary failure, can be life-threatening.

NUTRITIONAL ASSESSMENT

Because interactions between illness and nutrition are complex, many physical and laboratory findings reflect both underlying disease and nutritional status. Therefore, the nutritional evaluation of a patient requires an integration of the history, physical examination, anthropometrics, and laboratory studies. This approach helps both to detect nutritional problems and to avoid concluding that isolated findings indicate nutritional problems when they do not. For example, hypoalbuminemia caused by an underlying illness does not necessarily indicate malnutrition.

NUTRITIONAL HISTORY

A nutritional history is directed toward identifying underlying mechanisms that put patients at risk for nutritional depletion or excess. These mechanisms include inadequate intake, impaired absorption, decreased utilization, increased losses, and increased requirements of nutrients.

Individuals with the characteristics listed in Table 72-3 are at particular risk for nutritional deficiencies.

PHYSICAL EXAMINATION

Physical findings that suggest vitamin, mineral, and protein-energy deficiencies and excesses are outlined in Table 72-4. Most of the physical findings are not specific for individual nutrient deficiencies, and they must be integrated with the historic, anthropometric, and laboratory findings. For example, the finding of follicular hyperkeratosis on the back of the arms is a fairly common, normal finding. On the other hand, if it is widespread in a person who consumes little fruit and vegetables and smokes regularly (increasing ascorbic acid requirements), vitamin C deficiency is likely. Similarly, easily pluckable hair may be a consequence of chemotherapy, but in a hospitalized patient who has poorly healing surgical wounds and hypoalbuminemia, it suggests kwashiorkor.

TABLE 72-3 THE HIGH-RISK PATIENT

Underweight (body mass index <18.5) and/or recent loss of ≥10% of usual body weight
Poor intake: anorexia, food avoidance (e.g., psychiatric condition), or NPO status for more than about 5 days
Protracted nutrient losses: malabsorption, enteric fistulae, draining abscesses or wounds, renal dialysis
Hypermetabolic states: sepsis, protracted fever, extensive trauma or burns
Alcohol abuse or use of drugs with antinutrient or catabolic properties: steroids, antimetabolites (e.g., methotrexate), immunosuppressants, antitumor agents
Impoverishment, isolation, advanced age

ANTHROPOMETRICS

Anthropometric measurements provide information on body muscle mass and fat reserves. The most practical and commonly used measurements are body weight, height, triceps skinfold (TSF), and mid-arm muscle circumference (MAMC). Body weight is one of the most useful nutritional parameters to follow in patients who are acutely or chronically ill. Unintentional weight loss during illness often reflects loss of lean body mass (muscle and organ tissue), especially if it is rapid and not caused by diuresis. This can be an ominous sign since it indicates use of vital body protein stores as a metabolic fuel. The reference standard for normal body weight, body mass index (BMI, or weight in kilograms divided by height, in meters, squared), is discussed in Chap 75. BMIs <18.5 are considered underweight, 18.5–24.9 are normal, 25–29.9 are overweight, and ≥30 are obese.

Measurement of skinfold thickness is useful for estimating body fat stores, because about 50% of body fat is normally located in the subcutaneous region. Skinfold thicknesses can also permit discrimination of fat mass from muscle mass. The TSF is a convenient site that is generally representative of the body's overall fat level. A thickness of <3 mm suggests virtually complete exhaustion of fat stores. The MAMC, often used to estimate skeletal muscle mass, is calculated as follows:

$$\text{MAMC (cm)} = \text{upper arm circumference (cm)} - [0.314 \times \text{TSF (mm)}]$$

LABORATORY STUDIES

A number of laboratory tests used routinely in clinical medicine can yield valuable information about a patient's nutritional status if a slightly different approach to their interpretation is used. For example, abnormally low serum albumin levels, total iron-binding capacity, and anergy may have a distinct explanation, but collectively they may represent kwashiorkor. In the clinical setting of a hypermetabolic, acutely ill patient who is edematous and has easily pluckable hair and inadequate protein intake, the diagnosis of kwashiorkor is clear-cut. Commonly used laboratory tests for assessing nutritional status are outlined in Table 72-5. The table also provides tips to help avoid assigning nutritional significance to tests that may be abnormal for nonnutritional reasons.

Assessment of Circulating (Visceral) Proteins The serum proteins most used to assess nutritional status include albumin, total iron-binding capacity (or transferrin), thyroxine-binding prealbumin (or transthyretin), and retinol-binding protein. Because they have differing synthesis rates and half-lives—the half-life of serum albumin is about 21 days whereas those of prealbumin and retinol-binding protein are about 2 days and 12 h, respectively—some of these proteins reflect changes in nutritional status more quickly than others. However, rapid fluctuations can also make shorter-half-life proteins less reliable.

Levels of circulating proteins are influenced by their rates of synthesis and catabolism, "third spacing" (loss into interstitial spaces), and, in some cases, external loss. Although an adequate intake of calories and protein is necessary to achieve optimal circulating protein levels, serum protein levels generally do not reflect protein intake. For example, a drop in the serum level of albumin or transferrin often accompanies significant physiologic stress (e.g., from infection

TABLE 72-4 PHYSICAL FINDINGS OF NUTRITIONAL DEFICIENCIES

Clinical Findings	Possible Deficiency[a]	Possible Excess
Hair, Nails		
Corkscrew hairs and unemerged coiled hairs	Vitamin C	
Easily pluckable hair	Protein	
Flag sign (transverse depigmentation of hair)	Protein	
Sparse hair	Protein, biotin, zinc	Vitamin A
Transverse ridging of nails	Protein	
Skin		
Cellophane appearance	Protein	
Cracking (flaky paint or crazy pavement dermatosis)	Protein	
Follicular hyperkeratosis	Vitamins A, C	
Petechiae (especially perifollicular)	Vitamin C	
Purpura	Vitamins C, K	
Pigmentation, scaling of sun-exposed areas	Niacin	
Poor wound healing, decubitus ulcers	Protein, vitamin C, zinc	
Scaling	Vitamin A, essential fatty acids, biotin	Vitamin A
Yellow pigmentation sparing sclerae (benign)	Zinc (hyperpigmented)	Carotene
Eyes		
Night blindness	Vitamin A	
Papilledema		Vitamin A
Perioral		
Angular stomatitis	Riboflavin, pyridoxine, niacin	
Cheilosis (dry, cracking, ulcerated lips)	Riboflavin, pyridoxine, niacin	
Oral		
Atrophic lingual papillae (slick tongue)	Riboflavin, niacin, folate, vitamin B_{12}, protein, iron	
Glossitis (scarlet, raw tongue)	Riboflavin, niacin, pyridoxine, folate, vitamin B_{12}	
Hypogeusesthesia, hyposmia	Zinc	
Swollen, retracted, bleeding gums (if teeth present)	Vitamin C	
Bones, Joints		
Beading of ribs, epiphyseal swelling, bowlegs	Vitamin D	
Tenderness, subperiosteal hemorrhage in children	Vitamin C	
Neurologic		
Confabulation, disorientation	Thiamine (Korsakoff psychosis)	
Drowsiness, lethargy, vomiting		Vitamin A
Dementia	Niacin, vitamin B_{12}, folate	
Headache		Vitamin A
Ophthalmoplegia	Thiamine, phosphorus	
Peripheral neuropathy (e.g., weakness, paresthesias, ataxia, foot drop, and decreased tendon reflexes, fine tactile sense, vibratory sense, and position sense)	Thiamine, pyridoxine, vitamin B_{12}	Pyridoxine
Tetany	Calcium, magnesium	
Other		
Edema	Protein, thiamine	
Heart failure	Thiamine ("wet" beriberi), phosphorus	
Hepatomegaly	Protein	Vitamin A
Parotid enlargement	Protein (consider also bulimia)	
Sudden heart failure, death	Vitamin C	

[a]In this table, "protein deficiency" is used to signify kwashiorkor.

or injury) and is not necessarily an indication of malnutrition or poor intake. A low serum albumin level in a burned patient with both hypermetabolism and increased dermal losses of protein may not indicate malnutrition. On the other hand, adequate nutritional support of the patient's calorie and protein needs is critical for returning circulating proteins to normal levels as stress resolves. Thus low values by themselves do not define malnutrition, but they often point to increased risk of malnutrition because of the hypermetabolic stress state. As long as significant physiologic stress persists, serum protein levels remain low, even with aggressive nutritional support. However, if the levels do not rise after the underlying illness improves, the patient's protein and calorie needs should be reassessed to ensure that intake is sufficient.

Assessment of Vitamin and Mineral Status The use of laboratory tests to confirm suspected micronutrient deficiencies is desirable because the physical findings for these are often equivocal or nonspecific. Low blood micronutrient levels can predate more serious clinical manifestations and may also indicate drug-nutrient interactions.

ESTIMATING ENERGY AND PROTEIN REQUIREMENTS

A patient's basal energy expenditures (BEE, measured in kilocalories per day) can be estimated from height, weight, age, and gender using the Harris-Benedict equations:

$$\text{Men: BEE} = 66.47 + 13.75W + 5.00H - 6.76A$$

$$\text{Women: BEE} = 655.10 + 9.56W + 1.85H - 4.68A$$

where W is weight in kg; H is height in cm, and A is age in years. After solving these equations, total energy requirements are estimated by multiplying the BEE by a factor that accounts for the stress of illness. Multiplying by 1.1–1.4 yields a range 10–40% above basal that estimates the 24-h energy expenditure of the majority of patients. The lower value (1.1) is used for patients without evidence of significant physiologic stress; the higher value (1.4) is appropriate for patients with marked stress such as sepsis or trauma. The result is used as a 24-h energy goal for feeding.

When it is important to have a more accurate assessment of energy expenditure, it can be measured at the bedside using indirect calorimetry. This technique is useful in patients who are believed to be hypermetabolic from sepsis or trauma and whose body weights cannot be obtained accurately. Indirect calorimetry can also be useful in patients having difficulty weaning from a ventilator, as their energy needs should not be exceeded to avoid excessive CO_2 production. Patients at the extremes of weight (e.g., obese persons) and/or age are good candidates as well, because the Harris-Benedict equations were developed from measurements in adults with roughly normal body weights.

Because urea is a major byproduct of protein catabolism, the amount of urea nitrogen excreted each day can be used to estimate the rate of protein catabolism and to determine if protein intake is adequate to offset it. Total protein loss and protein balance can be calculated from the urinary urea nitrogen (UUN) as follows:

$$\text{Protein catabolic rate (g/d)} = [\text{24-h UUN (g)} + 4] \times 6.25 \text{ (g protein/g nitrogen)}$$

The value of 4 g added to the UUN represents a liberal estimate of the unmeasured nitrogen lost in the urine (e.g., creatinine and uric acid), sweat, hair, skin, and feces. When protein intake is low (e.g., less

TABLE 72-5 LABORATORY TESTS FOR NUTRITIONAL ASSESSMENT

Test (Normal Values)	Nutritional Use	Causes of Normal Value Despite Malnutrition	Other Causes of Abnormal Value
Serum albumin (3.5–5.5 g/dL)	2.8–3.5: Compromised protein status <2.8: Possible kwashiorkor Increasing value reflects positive protein balance	Dehydration Infusion of albumin, fresh frozen plasma, or whole blood	**Low** Common: Infection and other stress, especially with poor protein intake Burns, trauma Congestive heart failure Fluid overload Severe liver disease Uncommon: Nephrotic syndrome Zinc deficiency Bacterial stasis/overgrowth of small intestine
Serum prealbumin, also called transthyretin (20–40 mg/dL; lower in prepubertal children)	10–15 mg/dL: Mild protein depletion 5–10 mg/dL: Moderate protein depletion <5 mg/dL: Severe protein depletion Increasing value reflects positive protein balance	Chronic renal failure	Similar to serum albumin
Serum total iron binding capacity (TIBC) 240–450 µg/dL	<200: Compromised protein status, possible kwashiorkor Increasing value reflects positive protein balance More labile than albumin	Iron deficiency	**Low** Similar to serum albumin **High** Iron deficiency
Prothrombin time 12.0–15.5 sec	Prolongation: vitamin K deficiency		**Prolonged** Anticoagulant therapy (warfarin) Severe liver disease
Serum creatinine 0.6–1.6 mg/dL	<0.6: Muscle wasting due to prolonged energy deficit Reflects muscle mass		**High** Despite muscle wasting: Renal failure Severe dehydration
24-h urinary creatinine 500–1200 mg/d (standardized for height and sex)	Low value: muscle wasting due to prolonged energy deficit	>24-h collection Decreasing serum creatinine	**Low** Incomplete urine collection Increasing serum creatinine Neuromuscular wasting
24-h urinary urea nitrogen (UUN) <5 g/d (depends on level of protein intake)	Determine level of catabolism (as long as protein intake is ≥10 g below calculated protein loss or <20 g total, but at least 100 g carbohydrate is provided) 5–10 g/d = mild catabolism or normal fed state 10–15 g/d = moderate catabolism >15 g/d = severe catabolism Estimate protein balance Protein balance = protein intake – protein loss where protein loss (protein catabolic rate) = [24-h UUN (g) + 4] × 6.25 Adjustments required in burn patients and others with large nonurinary nitrogen losses and in patients with fluctuating BUN levels (e.g., renal failure)		
Blood urea nitrogen (BUN) 8–23 mg/dL	<8: Possibly inadequate protein intake 12–23: Possibly adequate protein intake >23: Possibly excessive protein intake If serum creatinine is normal, use BUN If serum creatinine is elevated, use BUN/creatinine ratio (normal range is essentially the same as for BUN)		**Low** Severe liver disease Anabolic state Syndrome of inappropriate antidiuretic hormone **High** Despite poor protein intake: Renal failure (use BUN/creatinine ratio) Congestive heart failure Gastrointestinal hemorrhage

than about 20 g/d), the equation indicates both the patient's protein requirement and the severity of the catabolic state (Table 72-5). More substantial protein intakes can raise the UUN because some of the ingested (or infused) protein is catabolized and converted to UUN. Thus at lower protein intakes the equation is useful for estimating *requirements*, and at higher protein intakes it is useful for assessing protein *balance*.

$$\text{Protein balance (g/d)} = \text{Protein intake} - \text{Protein catabolic rate}$$

73 Enteral and Parenteral Nutrition Therapy

Bruce R. Bistrian, David F. Driscoll

The ability to provide specialized nutritional support (SNS) represents a major advance in medical therapy. Nutritional support, via either enteral or parenteral routes, is used in two main settings: (1) to provide adequate nutritional intake during the recuperative phase of illness or injury, when the patient's ability to ingest or absorb nutrients is impaired, and (2) to support the patient during the systemic response to inflammation, injury, or infection during an extended critical illness. SNS is also used in patients with permanent loss of intestinal length or function. In addition, an increasing number of elderly patients living in nursing homes and chronic care facilities receive enteral feeding, usually as a consequence of inadequate nutritional intake.

Enteral refers to feeding via a tube placed into the gut to deliver liquid formulas containing all essential nutrients. *Parenteral* refers to the infusion of complete nutrient solutions into the bloodstream via a peripheral vein or, more commonly, by central venous access to meet nutritional needs. Enteral feeding is generally the preferred route because of benefits derived from maintaining the digestive, absorptive, and immunologic barrier functions of the gastrointestinal tract. Small-bore pliable tubes have largely replaced large-bore rubber tubes, making placement easier and more acceptable to patients. Infusion pumps have also improved the delivery of nutrient solutions.

For short-term use, enteral tubes can be placed via the nose into the stomach, duodenum, or jejunum. For long-term use, these sites can be accessed through the abdominal wall using endoscopic, radiologic, or surgical procedures. Intestinal tolerance of tube feeding may be limited during acute illness by gastric retention or diarrhea. Parenteral feeding has greater risk of infection, reflecting the need for venous access, and a greater propensity for inducing hyperglycemia. However, these risks can generally be managed successfully by SNS teams. For the postoperative patient with preexisting malnutrition, or in trauma patients who were previously well nourished, SNS is strikingly cost-effective. In the most critically ill patient in the intensive care unit, SNS can dramatically enhance survival. Although enteral nutrition (EN) can be provided by most health care teams caring for hospitalized patients, safe and effective parenteral nutrition (PN) usually requires specialized teams.

APPROACH TO THE PATIENT: Requirements for Specialized Nutritional Support

INDICATIONS FOR SPECIALIZED NUTRITIONAL SUPPORT Although at least 15–20% of patients in acute care hospitals have evidence of significant malnutrition, only a small fraction will benefit from SNS. For others, wasting is an inevitable component of a terminal disease and the course of the disease will not be altered by SNS. The decision to use SNS should be based on the likelihood that preventing protein-calorie malnutrition (PCM) will increase the likelihood of recovery, reduce infection rates, improve healing, or otherwise shorten the hospital stay. In the case of the elderly or chronically ill patient for whom full recovery is not anticipated, the decision to feed is usually based on whether SNS will extend the duration and quality of life. The decision-making process used to decide when to use SNS is depicted in Fig. 73-1.

The first step in deciding to administer SNS is to consider the nutritional implications of the disease process. Is the condition or its treatment likely to impair food intake and absorption for a prolonged period of time? For example, a well-nourished individual can tolerate approximately 7 days of starvation while experiencing a systemic response to inflammation (SRI). The second step is to determine if the patient is already significantly malnourished to the degree that critical functions such as wound healing, immune function, or ventilatory function are impaired (Chap. 72). An unintentional weight loss of >10% during the previous 6 months or a weight/height <90% of standard, when associated with physiologic impairment, represents significant PCM. Weight loss >20% of usual or <80% of standard reflects severe PCM. The presence or absence of SRI should be noted, since inflammation, injury, and infection increase the rate of lean tissue loss. SRI also has pathophysiologic effects that influence nutritional responses such as fluid retention and hyperglycemia, as well as impairment of anabolic responses to nutritional support.

Once it is determined that a patient is already or at risk of becoming malnourished, the next step is to decide whether SNS will impact positively on the patient's response to disease. In the end stages of many chronic illnesses with accompanying PCM, particularly those due to cancer or terminal neurologic disorders, nutrition may not reverse the PCM or improve quality of life. While the provision of food and water is part of basic medical care, nutrition delivered by tube or catheter, either enterally or parenterally, is associated with risk and discomfort. Thus, SNS should be recommended only when potential benefits exceed risks, and should be undertaken with the consent of the patient. Like other life support measures, enteral or parenteral therapy is difficult to withdraw once started. Initiating nutrition support may be appropriate before a final prognosis can be determined, but this should not preclude its subsequent withdrawal. If preventing or treating PCM with SNS is appropriate, nutritional requirements and the method of delivery should be determined. The optimal route depends on the degree of gut function and somewhat on the available technical resources.

The timing of nutritional support is based on evaluation of the preexisting nutritional status, the presence and extent of SRI, and the anticipated clinical course. SRI is identified by the standard clinical signs of leukocytosis, tachycardia, tachypnea, and/or temperature elevation or depression. Although the degree of hypoalbuminemia provides an estimate of SRI severity, normal serum albumin levels will not be restored by adequate nutritional support until the SRI remits, even though nutritional benefits can be achieved by adequate feeding.

The SRI can be graded as severe, moderate, or mild. Examples of severe SRI include sepsis or other inflammatory conditions like pancreatitis requiring ICU care, multiple trauma with an Injury Severity Score > 20–25 or APACHE II > 25, closed head injury with a Glasgow Coma Scale < 8, or major third-degree burns of >40% of body surface area. Moderate SRI includes less severe infections, injuries, or inflammatory conditions like pneumonia, major surgery, acute hepatic or renal insufficiency, and exacerbations of ulcerative colitis or regional enteritis requiring hospitalization. PCM should also be defined as severe, moderate, or minimal as assessed by weight/height, percent recent weight loss, and body mass index. The body mass index in relation to nutritional status is listed in Table 73-1. A patient with a severe SRI requires early feeding within the first several days of care because the condition is likely to produce inadequate spontaneous intake over the next 7 days. A moderate SRI, as commonly seen during a postoperative period without oral intake that exceeds 5 days, benefits from adequate feeding by day 5–7 if the patient was initially well nourished. If severely malnourished, candidates for elective major surgery benefit from preoperative nutritional repletion for 5–7 days. However, this is not often possible. Thus, early postoperative feeding is indicated. Patients with a moderate SRI and moderate PCM also benefit from earlier feeding within the first several days.

EFFICACY OF SNS IN DIFFERENT DISEASE STATES Efficacy studies have shown that malnourished patients undergoing major thoracoabdominal surgery benefit from SNS. Critical illness requiring ICU care including major burns, major trauma, severe sepsis, closed

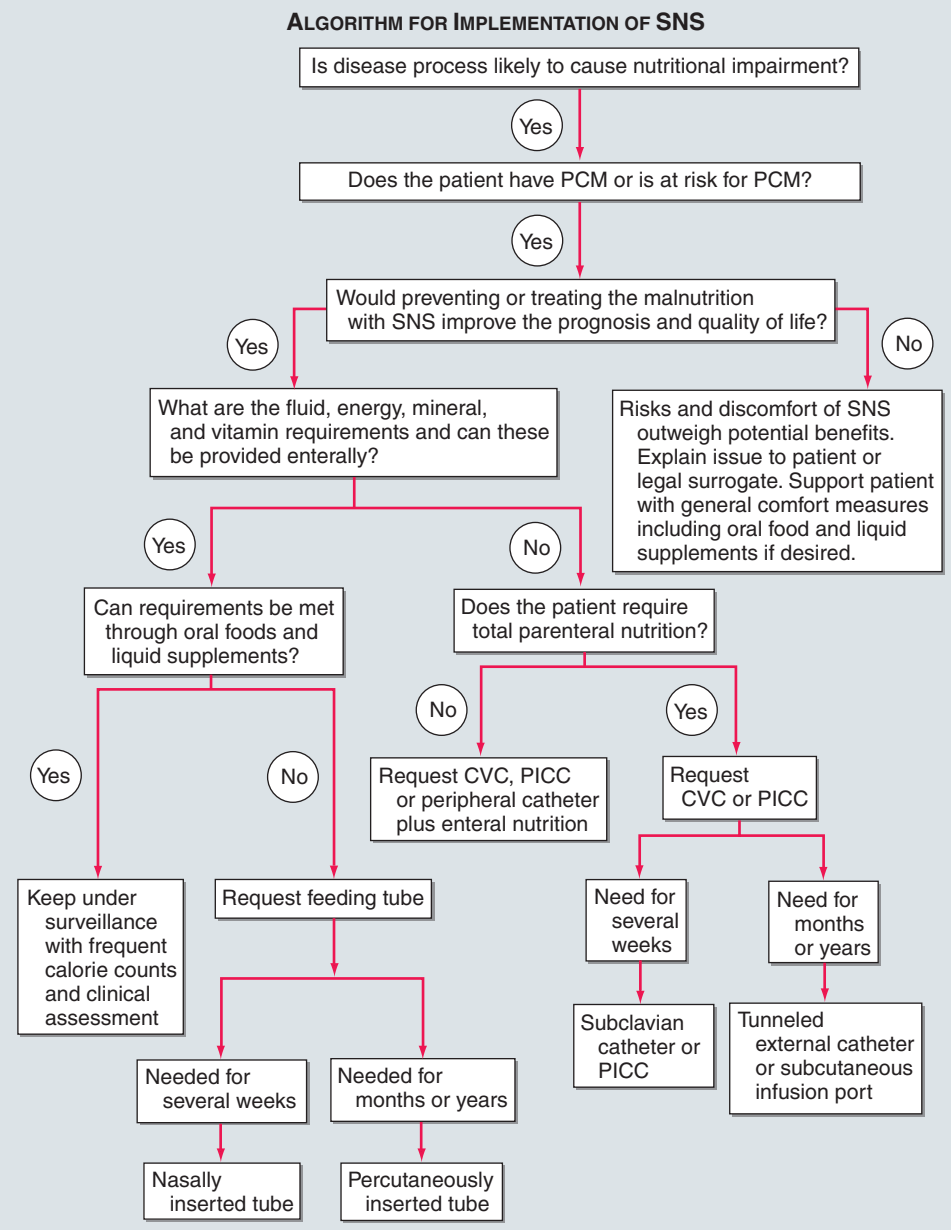

FIGURE 73-1 Decision-making for the implementation of specialized nutrition support (SNS). CVC, central venous catheter; PICC, peripherally inserted central catheter. *(Adapted from previous chapter by Lyn Howard, MD.)*

head injury, and severe pancreatitis [positive CT scan and Acute Physiology and Chronic Health Evaluation II (APACHE II) > 10] all benefit by early SNS, as indicated by reduced mortality and morbidity. In critical illness, initiation of SNS within 24 h of injury or ICU admission is associated with a ~50% reduction in mortality. Patients with nitrogen accumulation disorders of renal and hepatic failure have a likelihood of PCM of >50% and at least a moderate SRI. Improvements in morbidity, including infection rates, encephalopathy, liver or renal function, and length of hospital stay have been found with SNS. Inflammatory bowel disease—including Crohn's disease particularly, and, to a lesser degree, ulcerative colitis—often produce PCM. In the outpatient setting, SNS in Crohn's disease can improve nutritional status, quality of life, and the likelihood of remission. With pulmonary disease in the critically ill, SNS improves ventilatory status, and in acute lung injury the use of omega 3 fats as a component of SNS improves gas exchange and respiratory dynamics and reduces the need for mechanical ventilation. Low body weight in chronic obstructive pulmonary disease is associated with diminished pulmonary status and exercise capacity and higher mortality rates. However, there is little convincing evidence that SNS as caloric supplementation improves nutrition or pulmonary function. PCM is also common in the course of cancer and HIV disease, although less so in the latter with the advent of highly active antiretroviral therapy. When PCM develops as a consequence of SRI in these conditions, there is limited likelihood of substantial efficacy or benefit from SNS. However, when PCM develops as a consequence of gastrointestinal dysfunction, SNS can be effective. Although no randomized trials have been performed for SNS provided for hyperemesis gravidarum, there is considerable clinical evidence that it improves pregnancy outcomes.

RISKS AND BENEFITS OF SPECIALIZED NUTRITION SUPPORT The risks are determined primarily by patient factors such as state of alertness, swallowing competence, the route of delivery, underlying conditions, and the experience of the supervising clinical team. The safest and least costly approach is to avoid SNS by close attention to oral food intake, by adding an oral liquid supplement, or in certain chronic conditions by using medications to stimulate appetite. Nutrient intake monitoring by frequent calorie counts or oral formula selection is best performed by a nutritionist.

Enteral tube feeding is often required in patients with anorexia, impaired swallowing, or bowel disease. The bowel and its associated digestive organs derive 70% of their required nutrients directly from food in the lumen. Arginine, glutamine, short-chain fatty acids, long-chain omega 3 fatty acids, and nucleotides available in some specialty enteral formulas are particularly important for maintaining immunity. Enteral feeding also supports gut function by stimulating splanchnic blood flow, neuronal activity, IgA antibody release, and secretion of gastrointestinal hormones that stimulate gut trophic activity. These factors

TABLE 73-1 BODY MASS INDEX (BMI) AND NUTRITIONAL STATUS

BMI	Nutritional Status
>30 kg/m^2	Obese
>25–30 kg/m^2	Overweight
20–25 kg/m^2	Normal
<18.5 kg/m^2	Moderate malnutrition
<16 kg/m^2	Severe malnutrition
<13 kg/m^2	Lethal in males
<11 kg/m^2	Lethal in females

support the gut as an immunologic barrier against enteric pathogens. For these reasons, some luminal nutrition should be provided, even when PN is required to provide most of the nutritional support. The combination of some enteral feeding either by mouth or by enteral tube with parenteral feeding often shortens the transition to full enteral feeding, which can generally be used when >50% of requirements can be met enterally. Substantial nutritional benefit can be achieved by providing ~50% of energy needs for periods of up to 10 days, if protein and other essential nutrient requirements are met. For longer periods of time, it may be preferable to provide 75–80% of energy needs, rather than full feeding, if this improves gastrointestinal tolerance, glycemic control, and avoidance of excess fluid administration.

In the past, bowel rest through PN was the cornerstone of treatment for many severe gastrointestinal disorders. However, the value of providing even minimal amounts of EN is now widely accepted. The development of protocols to facilitate more widespread use of EN include initiation within 24 h of ICU admission; aggressive use of the head-upright position; postpyloric and nasojejunal feeding tubes; prokinetic agents; more rapid increases in feeding rates; tolerance of higher gastric residuals; and nurse-administered algorithms. PN alone is generally necessary only for severe gut dysfunction due to prolonged ileus, obstruction, or severe hemorrhagic pancreatitis. In the critically ill, feeding adequately by PN beginning within the first 24 h of care improves mortality and is more effective than delayed EN. Early feeding of the critically ill in the ICU is associated with a 50% reduction in mortality, but there is also a 50% increase in infection risk. Much of the increase in morbidity related to PN and EN is due to hyperglycemia, which can be significantly reduced by insulin therapy. The level of glycemia necessary to accomplish this goal, whether <110 mg/dL or only <150 mg/dL, is not yet defined.

Although PN was initially relatively expensive, its components are often less expensive than specialty enteral formulas. Percutaneous placement of a central venous catheter into the subclavian or internal jugular vein with advancement into the superior vena cava can be accomplished at the bedside by trained personnel using sterile techniques. Peripherally inserted central catheters can also be placed within the lumen in the central vein, but this technique is usually more appropriate for non-ICU patients. The subclavian or internal jugular lines can be changed over a wire, but this carries a greater risk of pneumothorax or serious vascular damage. The peripherally inserted catheters are subject to position-related flow, and the catheter cannot be changed over a wire. Inserting a nasogastric tube is a bedside procedure, but many critically ill patients have impaired gastric emptying that increases the risk of aspiration pneumonia. This risk can be reduced by feeding directly into the jejunum beyond the ligament of Treitz. This usually requires fluoroscopic guidance or endoscopic placement. In patients who have planned laparotomies or other conditions likely to require a prolonged need for SNS, it is advantageous to place a jejunal feeding tube at the time of surgery.

Although most SNS is delivered in hospitals, some patients require it on a long-term basis. If they have a safe environment and a willingness to learn the self-care techniques, SNS can be administered at home. The clinical outcomes of patients with severe intestinal disorders treated with home PN or EN are summarized in Table 73-2. PN infused at home is usually cycled overnight to give greater daytime freedom. Other important considerations in determining the appropriateness of home PN or EN are that the patient's prognosis is longer than several months and that the therapy benefits quality of life.

DISEASE-SPECIFIC NUTRITIONAL SUPPORT SNS is basically a support therapy and is primary therapy only for the treatment or prevention of malnutrition. Certain conditions require modification of nutritional support because of organ or system impairment. For instance, in nitrogen accumulation disorders, protein intake may need to be reduced. However, in renal disease, except for brief periods of several days, protein intakes should approach requirement levels of at least 0.8 g/kg or higher up to 1.2 g/kg as long as the

[a]Survival rates on therapy are values at 1 year, calculated by the life table method. This will differ from the percentage listed as died under Therapy Status, since all patients with known end points are considered in this latter measure. The ratio of observed versus expected deaths is equivalent to a Standard Mortality Ratio.

[b]Not shown are those patients who were back in hospital or who had changed therapy type by 12 months.

[c]Rehabilitation is designated complete (C), partial (P), or minimal (M), relative to the patient's ability to sustain normal age-related activity.

[d]Complications refer only to those complications that resulted in rehospitalization.

Source: Derived from North American HPEN Registry.

Table taken from previous chapter by Lyn Howard, MD.

blood urea nitrogen does not exceed 100 mg/dL. If this is not possible, then dialysis or hemofiltration should be considered to allow better feeding. In hepatic failure, intakes of 1.2–1.4 g/kg up to the optimal 1.5 g/kg should be attempted, as long as encephalopathy due to protein intolerance is not encountered. In the presence of protein intolerance, formulas containing 33–50% branched-chain amino acids are available at the 1.2–1.4-g/kg level. Cardiac patients, and many severely stressed patients, often benefit from fluid and sodium restriction to levels of 1000 mL of total parenteral nutrition (TPN) formula and 5–20 meq of sodium per day. In patients with severe chronic PCM characterized by severe weight loss and tissue wasting, TPN must be instituted gradually because of the profound antinatriuresis, antidiuresis, and intracellular accumulation of potassium, magnesium, and phosphorus. This is usually accomplished by limiting fluid intakes initially to about 1000 mL containing modest carbohydrate content of 10–20% dextrose, low sodium, and ample potassium, magnesium, and phosphorus, with careful assessment of fluid and electrolyte status. Protein need not be restricted.

THE DESIGN OF INDIVIDUAL REGIMENS

FLUID REQUIREMENTS

The normal daily requirement for fluid is 30 mL/kg of body weight from all sources (IV infusions, per tube, or oral intake), plus any replacement of abnormal losses such as an osmotic diuresis, nasogastric drainage, wound output, or diarrheal/ostomy losses. Electrolyte and mineral losses can be estimated or measured and also need to be replaced (Table 73-3). Fluid restriction may be necessary in patients with fluid overload, and fluid inputs can be limited to 1200 mL/d if urine is the only significant fluid output. When severe fluid overload occurs, the optimal PN solution for central venous administration is a concentrated 1-L solution of 7% crystalline amino acids (70 g) and 21% dextrose (210 g), which provides an amount of nitrogen and glucose that is effective at protein-sparing.

Patients requiring PN or EN in the acute care setting generally have some element of associated hormonal adaptations (e.g., increased secretion of antidiuretic hormone, aldosterone, insulin, glucagon, or cortisol) that cause fluid retention and hyperglycemia. Weight gain in the critically ill, whether receiving SNS or not, is invariably the consequence of fluid retention, since lean tissue accretion is minimal in the acute phase of illness. Because excess fluid removal can be difficult, limiting fluid intake to allow for balanced intake and output is more effective.

ENERGY REQUIREMENTS

Total energy expenditure comprises resting energy expenditure (two-thirds) plus activity energy expenditure (one-third) (Chap. 72). Resting energy expenditure includes the calories necessary for basal metabolism at bed rest. Activity energy expenditure represents one-fourth to one-third of the total, and the thermal effect of feeding is about 10% of the total energy expenditure. For normally nourished healthy individuals, the total energy expenditure is about 30–35 kcal/kg. Although critical illness increases resting energy expenditure, only in initially well-nourished individuals with the highest systemic inflammatory response, such as that from severe multiple trauma, burns, closed head injury, or sepsis, do total energy expenditures reach 40–45 kcal/kg. The chronically ill patient with lean tissue loss has reduced basal energy expenditure, and inactivity which results in a total energy expenditure of about 20–25 kcal/kg. About 95% of such patients need <30 kcal/kg to achieve energy balance. Because providing about 50% of measured energy expenditure as SNS is at least equally efficacious for the first 10 days of critical illness, actual measurement of energy expenditure is not generally necessary in the early period of SNS. However, in patients who remain critically ill beyond several weeks, in the severely malnourished for whom estimates of energy expenditure are unreliable, or in those who are difficult to wean from ventilators, it is reasonable to actually measure energy expenditure and to aim for energy balance with SNS.

Insulin resistance is associated with increased gluconeogenesis and reduced glucose utilization, predisposing a patient to hyperglycemia. This is aggravated in patients receiving exogenous carbohydrate from SNS. Normalization of blood glucose levels by insulin infusion in critically ill patients receiving SNS reduces morbidity and mortality. In mild or moderately malnourished patients, a reasonable goal is to provide metabolic support to improve protein synthesis and maintain metabolic homeostasis. Hypocaloric nutrition providing only about 1000 kcal/d and 70 g protein for up to 10 days requires less fluid and reduces the likelihood of poor glycemic control. Energy content can be advanced to 20–25 kcal/kg with 1.5 g protein/kg as conditions permit and definitely during the second week of SNS. Patients with multiple trauma, closed head injury, and severe burns often have much higher energy expenditures, but there is little evidence that providing more than 30 kcal/kg has additional benefit, and it risks hyperglycemia.

Generally, because glucose is an essential tissue fuel, glucose and amino acids are provided parenterally until the level of resting energy expenditure is reached. At this point, adding fat becomes beneficial, since more parenteral glucose stimulates de novo lipogenesis by the liver—an energy-inefficient process. Polyunsaturated long-chain triglycerides are the chief ingredient in most parenteral fat emulsions and the majority of the fat in enteral feeding formulas. These vegetable oil–based emulsions provide essential fatty acids. Enteral feeding formulas have fat content that ranges from 3% of calories up to as much as 50% of calories, while parenteral fat comes in separate containers as 10, 20, and 30% emulsions that can be infused separately or mixed by the pharmacy under controlled conditions as all-in-one or total nutrient admixture with glucose, amino acids, lipid, electrolytes, vitamins, and minerals. Although parenteral fat is required at only about 3% of energy requirements to meet essential fatty acid requirements, when provided as an all-in-one mixture of carbohydrate, fat, and protein, 2–3% fat in the TPN mixtures, representing about 20–30% of calories as fat, is provided to ensure emulsion stability. If given separately, parenteral fat should not be provided at rates exceeding 0.11 g/kg body weight per h or about 100 g over 12 h—equivalent to 1 L of 10% parenteral fat and 500 mL of 20% parenteral fat.

Medium-chain triglycerides, which contain saturated fatty acids with chain lengths of 6, 8, 10, or 12 carbons, are provided in a number of enteral feeding formulas because they are absorbed preferentially. Fish oil contains polyunsaturated fatty acids of the omega 3 family, which have been shown to improve immune function and reduce the inflammatory response. Parenteral emulsions containing medium-chain triglycerides, olive oil, and fish oil are available in Europe and Japan but not yet in the United States.

Carbohydrates are provided as hydrous glucose providing 3.4 kcal/g in PN formulas. In enteral formulas, glucose is the carbohydrate source in so-called monomeric diets. These diets provide protein as amino acids and fat in minimal amounts (3%) to meet essential fatty acid requirements. Monomeric formulas are designed to optimize absorption in the seriously compromised gut. These formulas, like the im-

TABLE 73-3 ENTERIC FLUID VOLUMES AND THEIR ELECTROLYTE CONTENT[a]

	L/d	Na	K	Cl	HCO_3	H

mune-enhancing diets, are quite expensive. In polymeric diets, the carbohydrate source is usually an osmotically less active polysaccharide, protein is usually soy or casein protein, and fat is present in amounts from 25 to 50%. Such formulas are usually well tolerated by patients with normal intestinal length, and some are acceptable for oral consumption.

PROTEIN OR AMINO ACID REQUIREMENTS

Although the recommended dietary allowance for protein is 0.8 g/kg per d, maximal rates of repletion occur with 1.5 g/kg in the malnourished. In the severely catabolic patient, this higher level minimizes protein loss. In patients requiring SNS in the acute care setting, at least 1 g/kg is recommended, with greater amounts up to 1.5 g/kg as volume, renal, and hepatic tolerances allow. The standard parenteral and enteral formulas contain protein of high biologic value and meet the requirements for the eight essential amino acids. In protein-intolerant conditions such as renal and hepatic failure, modified amino acid formulas should be considered. In hepatic failure, higher branched-chain amino acid–enriched formulas appear to improve outcomes. Conditionally essential amino acids like arginine and glutamine may also have some benefit in supplemental amounts.

Protein (nitrogen) balance provides a measure of feeding efficacy of PN or EN. It is calculated as protein intake/6.25 because proteins are on average 16% nitrogen (N), minus the 24-h urine urea N (UUN) plus 4 g N, which reflects other N losses. In the critically ill, a mild negative balance of 2–4 g N/d is usually achievable with a similarly mild positive balance in the recuperating patient. Each g N represents approximately 30 g lean tissue.

MINERAL AND VITAMIN REQUIREMENTS

Parenteral electrolyte, vitamin, and trace mineral requirements are summarized in Tables 73-4, 73-5, and 73-6. Electrolyte modifications are necessary with substantial gastrointestinal losses from nasogastric drainage or intestinal losses from fistulas, diarrhea or ostomy outputs. Such losses also imply extra calcium, magnesium, and zinc losses. Excessive urine or potassium losses with amphotericin, or magnesium losses with cisplatin or in renal failure, necessitate adjustments in sodium, potassium, magnesium, phosphorus, and acid-base balance. Vitamin and trace element requirements are met by the daily provision of a complete parenteral vitamin supplement and trace elements for PN, and with the provision of adequate amounts of enteral feeding formulas that contain these micronutrients.

PARENTERAL NUTRITION

INFUSION TECHNIQUE AND PATIENT MONITORING

Parenteral feeding through a peripheral vein is limited by osmolality and volume constraints. Solutions that contain more than 3% amino acids and 5% glucose (290 kcal/L) are poorly tolerated peripherally. Parenteral fat (20%) can be given to increase the calories delivered. The total volume required to provide a marginal protein intake of 60 g and 1680 total kcal is 2.5 L. However, the risk of significant morbidity and mortality from incompatibilities of calcium and phosphate salts is greatest in these low-osmolality, low-glucose regimens. Parenteral feeding via a peripheral vein is generally intended as a supplement to oral feeding and is not optimal for the critically ill. Peripheral parenteral nutrition may benefit from small amounts of heparin at 1000 U/L and co-infusion with parenteral fat to reduce osmolality, but volume constraints still limit the value of this therapy. Peripherally inserted central catheters (PICCs) can be used for the short term to provide concentrated glucose parenteral solutions of 20–25% dextrose and 4–7% amino acids, while avoiding some of the complications of catheter placement via a large central vein. With PICC lines, however, flow can be position-related, and the lines cannot be exchanged over a wire for infection monitoring. For these reasons, in the critically ill, centrally placed catheters are preferred. The subclavian approach is best tolerated by the patient and is the easiest to dress. The jugular approach is less likely to lead to a pneumothorax. The femoral approach is discouraged because of the greater risk of catheter infection. For long-term feeding in the home, tunneled catheters and implanted ports reduce infection risk and are more acceptable to patients. However, tunneled catheters require placement in the operating room.

Catheters are made of silastic, polyurethane, or polyvinyl chloride. Silastic catheters are less thrombogenic and are best for tunneled catheters. Polyurethane is best for temporary catheters. Dressing changes with dry gauze at regular intervals should be performed by nurses skilled in catheter care to avoid infection. Chlorhexidine solution is more effective than alcohol or iodine compounds. Appropriate monitoring for patients receiving PN is summarized in Table 73-7.

TABLE 73-4 USUAL DAILY ELECTROLYTE ADDITIONS TO PARENTERAL NUTRITION

Electrolyte	Parenteral Equivalent of RDA	Usual Intake
Sodium		1–2 meq/kg + replacement, but can be as low as 5–40 meq/d
Potassium		40–100 meq/d + replacement of unusual losses
Chloride		As needed for acid-base balance, but usually 2:1 to 1:1 with acetate
Acetate		As needed for acid-base balance
Calcium	10 meq	10–20 meq/d
Magnesium	10 meq	8–16 meq/d
Phosphorus	30 mmol	20–40 mmol

TABLE 73-5 PARENTERAL MULTIVITAMIN REQUIREMENTS FOR ADULTS

Vitamin	Recently Revised Value
Vitamin A	3300 IU
Thiamin (B_1)	6 mg
Riboflavin (B_2)	3.6 mg
Niacin (B_3)	40 mg
Folic acid	600 μg
Pantothenic acid	15 mg
Pyridoxine (B_6)	6 mg
Cyanocobalamin (B_{12})	5 μg
Biotin	60 μg
Ascorbic acid (C)	200 mg
Vitamin D	200 IU
Vitamin E	10 IU
Vitamin K[a]	150 μg

[a]A product is available that does not contain vitamin K. Vitamin K supplementation is recommended at 2–4 mg/week in patients not receiving oral anticoagulation therapy if using this product.

TABLE 73-6 PARENTERAL TRACE METAL SUPPLEMENTATION FOR ADULTS[a]

Trace Mineral	Intake
Zinc	2.5–4 mg/d, an additional 10–15 mg/d per L of stool or ileostomy output
Copper	0.5–1.5 mg/d, possibility of retention in biliary tract obstruction
Manganese	0.1–0.3 mg/d, possibility of retention in biliary tract obstruction
Chromium	10–15 μg/d
Selenium	20–100 μg/d, necessary for long-term PN, optional for short-term TPN
Molybdenum	20–120 μg/d, necessary for long-term PN, optional for short-term PN
Iodine	75–150 μg/d, necessary for long-term PN, optional for short-term PN

[a]Commercial products are available that have the first four, first five, and all seven of these metals in recommended amounts.
Note: PN, parenteral nutrition; TPN, total parenteral nutrition.

TABLE 73-7 MONITORING THE PATIENT ON PARENTERAL NUTRITION

Clinical Data Monitored Daily	
General sense of well-being	
Strength as evidenced in getting out of bed, walking, resistance exercise as appropriate	
Vital signs including temperature, blood pressure, pulse, and respiratory rate	
Fluid balance: weight at least several times weekly, fluid intake (parenteral and enteral) vs fluid output (urine, stool, gastric drainage, wound, ostomy)	
Parenteral nutrition delivery equipment: tubing, pump, filter, catheter, dressing	
Nutrient solution composition	
Laboratory Daily	
Finger-stick glucose	Three times daily until stable
Blood glucose, Na, K, Cl, HCO_3, BUN	Daily until stable and fully advanced, then twice weekly
Serum creatinine, albumin, PO_4, Ca, Mg, Hb/Hct, WBC	Baseline, then twice weekly
INR	Baseline, then weekly
Micronutrient tests	As indicated

Note: Hb, hemoglobin; Hct, hematocrit; INR, international normalized ratio; WBC, white blood cell count.

COMPLICATIONS

Mechanical The insertion of a central venous catheter should be performed by trained and experienced personnel using aseptic techniques to limit the major common complications of pneumothorax and inadvertent arterial puncture or injury. Catheter position should be radiographically confirmed to be in the superior vena cava distal to the junction with the jugular or subclavian vein and not directly against the vessel wall. Thrombosis related to the catheter may occur at the site of entry into the vein and extend to encase the catheter. Catheter infection predisposes to thrombosis, as does the systemic inflammatory response. The addition of 6000 U of heparin in the daily parenteral formula in hospitalized patients with temporary catheters reduces the risk of fibrin sheath formation and catheter infection. Temporary catheters that develop a thrombus should be removed and, based on clinical findings, treated with anticoagulants. Thrombolytic therapy can be considered for patients with permanent catheters depending on the ease of replacement and presence of alternate, reasonably acceptable venous access sites. Low-dose warfarin therapy of 1 mg/d reduces the risk of thrombosis in permanent catheters used for home PN, but full anticoagulation may be required in patients who have recurrent thrombosis related to permanent catheters. A recent U.S. Food and Drug Administration mandate to reformulate parenteral multivitamins to include vitamin K at a dose of 150 μg daily may affect the efficacy of low-dose warfarin therapy. There is a "no vitamin K" version available for patients receiving this therapy. Catheters can become mechanically occluded and may also become occluded by fibrin at the tip, or by fat, minerals, or drugs intraluminally. These occlusions can be managed with low-dose alteplase for fibrin, with indwelling 70% alcohol for fat, with 0.1 *N* hydrochloric acid for mineral precipitates, and with either 0.1 *N* hydrochloric acid or 0.1 *N* sodium hydroxide for drugs, depending on their pH.

Metabolic The most common problems related to PN are fluid overload and hyperglycemia (Table 73-8). Hypertonic dextrose stimulates a much higher insulin level than meal feeding. Because insulin is a potent antinatriuretic and antidiuretic hormone, hyperinsulinemia leads to sodium and fluid retention. In the absence of gastrointestinal losses or renal dysfunction, net fluid retention is likely when total fluid intake exceeds 2000 mL/d. Close monitoring of body weight, as well as fluid intake and output, is necessary to prevent this complication. In the absence of significant renal impairment, the sodium content of the urine is likely to be <10 meq/L. Providing sodium in limited amounts of 40 meq/d and the use of both glucose and fat in the PN mixture to lower total glucose and sodium will help reduce fluid retention. The elevated insulin also increases the intracellular transport of potassium, magnesium, and phosphorus, which can precipitate a dangerous refeeding syndrome if the total glucose content of the PN solution is advanced too quickly in severely malnourished patients. It is generally best to start PN with <200 g glucose/d to assess glucose tolerance. Regular insulin can be added to the PN formula to establish glycemic control, and the insulin doses can be increased proportionately as the glucose is advanced. As a general rule, patients with insulin-dependent diabetes require about twice their usual home insulin doses when they are receiving TPN at 20–25 kcal/kg, largely as a consequence of parenteral glucose administration and some loss of insulin to the TPN container. As a rough estimate, the amount of insulin can be provided in a similar proportion to the amount of calories provided as TPN relative to full feeding, and the insulin can be placed in the TPN formula. Subcutaneous regular insulin can be provided to improve glucose control as assessed by measurements of blood glucose every 6 h. About two-

TABLE 73-8 SELECTED METABOLIC DISTURBANCES AND THEIR CORRECTION

Disturbance	Cause	Corrective Action with PN
Hyponatremia	Increased total body water or decreased total body sodium	Decrease free water or increase sodium
Hypernatremia	Occurs commonly with excessive isotonic or hypertonic fluid followed by diuretic administration with free water clearance; can also occur with dehydration and normal total body sodium	Increase free water to produce net positive fluid balance maintaining sodium and chloride balance
Hypokalemia	Inadequate intake relative to need	Use supplements
	Excessive diuresis, tubular dysfunction	Use supplements
	Magnesium deficiency	Increase PN magnesium
	Metabolic alkalosis	Correct alkalosis
	Hyperinsulinemia	Maintain constant PN, increase potassium
Hyperkalemia	Excessive provision	Reduce supplements
	Metabolic acidosis	Evaluate alkalosis, treat with PN acetate salt and decrease potassium
	Renal deterioration	Evaluate patient and adjust PN as indicated
Hypocalcemia	Reciprocal response to phosphorus repletion	Increase calcium
	Critical illness effect	Increase calcium
	Severe malabsorption	Supplement calcium
Hypercalcemia	Excessive administration or pathologic (cancer, hyperparathyroidism)	Reduce or eliminate calcium
Hypomagnesemia	Increased requirements due to diuretic use, alcoholism, malabsorption, malnutrition	Supplement magnesium
	Critical illness	Supplement magnesium
Hypophosphatemia	Inadequate intake relative to needs related to malnutrition, alcohol use	Supplement phosphorus
	Increased calcium intake	Use supplements
Hyperphosphatemia	Excessive administration or worsening renal function	Reduce phosphorus
Azotemia	Excessive amino acid infusion or worsening renal function	Reduce amino acid level but consider renal replacement therapy if cannot provide 1 g protein per kg for prolonged periods

Note: PN, parenteral nutrition.

thirds of the total 24-h amount can be added to the next day's order, with subcutaneous insulin supplements as needed. Advances in TPN concentration should be made when reasonable glucose control is established, and the insulin dose adjusted proportionately to the calories added as glucose and amino acids. These are general rules, and they are conservative. Given the adverse clinical impact of hyperglycemia, it may be necessary to use continuous insulin therapy as a separate infusion with a standard protocol to initially establish control. Once established, this insulin dose can be added to the PN formula. Acid-base imbalance is also common during PN therapy. Amino acid formulas are buffered, but critically ill patients are prone to metabolic acidosis, often due to renal tubular impairment. The use of sodium and potassium acetate salts in the PN formula may address this problem. Bicarbonate salts should not be used because they are incompatible with TPN formulations. Nasogastric drainage produces a hypochloremic alkalosis that can be managed by attention to chloride balance. Occasionally, hydrochloric acid may be required for a more rapid response or when diuretic therapy limits the ability to provide substantial sodium chloride. Up to 100 meq/L and up to 150 meq of hydrochloric acid per day may be placed in a fat-free PN formula.

Infectious Infections of the central access catheter rarely occur in the first 72 h. Fever during this period is usually from infection elsewhere or another cause. Fever that develops during PN can be addressed by checking the catheter site and, if the site looks clean, exchanging the catheter over a wire with cultures taken through the catheter and at the catheter tip. If these cultures are negative, as they are most of the time, the new catheter can continue to be used. If a culture is positive for a relatively nonpathogenic bacteria like *Staphylococcus epidermidis*, consider a second exchange over a wire with repeat cultures or replace the catheter depending on the clinical circumstances. If cultures are positive for more pathogenic bacteria, or for fungi like *Candida albicans*, it is generally best to replace the catheter at a new site. Whether antibiotic treatment is required is a clinical decision, but *C. albicans* grown from the blood culture in a patient receiving PN should always be treated because the consequences of failure to treat can be dire.

Catheter infections can be minimized by dedicating the feeding catheter to PN, without blood sampling or medication administration. Central catheter infections are a serious complication with an attributed mortality of 12–25%. Infections in central venous catheters dedicated to feeding should occur less frequently than 3 per 1000 catheter-days. Home PN catheters that become infected may be treated through the catheter without removal of the catheter, particularly if the offending organism is *S. epidermidis*. Clearing of the biofilm and fibrin sheath by local treatment of the catheter with indwelling alteplase may increase the likelihood of eradication. Antibiotic lock therapy with high concentrations of antibiotic, with or without heparin in addition to systemic therapy, may improve efficacy. Sepsis with hypotension should precipitate catheter removal in either the temporary or permanent PN setting.

ENTERAL NUTRITION

TUBE PLACEMENT AND PATIENT MONITORING

The types of enteral feeding tubes, methods of insertion, their clinical uses, and potential complications are outlined in Table 73-9. The different types of enteral formulas are listed in Table 73-10. Patients receiving EN are at risk for many of the same metabolic complications as those who receive PN and should be monitored in the same manner. EN can be a source of similar problems, but not to the same degree, because the insulin response to EN is about half of that seen with PN. Enteral feeding formulas have fixed electrolyte compositions that are generally modest in sodium and somewhat higher in potassium content. Acid-base disturbances can be addressed to a more limited extent with EN. Acetate salts can be added to the formula to treat chronic metabolic acidosis. Calcium chloride can be added to treat mild chronic metabolic alkalosis. Medications and other additives to enteral feeding formulas can clog the tubes (e.g., calcium chloride may interact with casein-based formulas to produce insoluble calcium caseinate products) and may reduce the efficacy of some drugs (e.g., phenytoin). Since small-bore tubes are easily displaced, tube position should be checked at intervals by aspirating and measuring the pH of the gut fluid (<4 in the stomach, >6 in the jejunum).

COMPLICATIONS

Aspiration The debilitated patient with poor gastric emptying and impairment of swallowing and cough is at risk for aspiration; this is particularly true for those who are mechanically ventilated. Tracheal suctioning induces coughing and gastric regurgitation, and cuffs on endotracheal or tracheostomy tubes seldom protect against aspiration. Preventive measures include elevating the head of the bed to 30 degrees,

TABLE 73-9 ENTERAL FEEDING TUBES

Type/Insertion Technique	Clinical Uses	Potential Complications
Nasogastric Tube		
External measurement: nostril, ear, xiphisternum; tube stiffened by ice water or stylet; position verified by injecting air and auscultating, or by x-ray	Short-term clinical situation (weeks) or longer periods with intermittent insertion; bolus feeding simpler, but continuous drip with pump better tolerated	Aspiration; ulceration of nasal and esophageal tissues, leading to stricture
Nasoduodenal Tube		
External measurement: nostril, ear, anterior superior iliac spine; tube stiffened by stylet and passed through pylorus under fluoroscopy or with endoscopic loop	Short-term clinical situations where gastric emptying impaired or proximal leak suspected; requires continuous drip with pump	Spontaneous pulling back into stomach (position verified by aspirating content, pH > 6); diarrhea common, fiber-containing formulas may help
Gastrostomy Tube		
Percutaneous placement endoscopically, radiologically, or surgically; after tract established, can be converted to a gastric "button"	Long-term clinical situations, swallowing disorders, or impaired small-bowel absorption requiring continuous drip	Aspiration; irritation around tube exit site; peritoneal leak; balloon migration and obstruction of pylorus
Jejunostomy Tube		
Percutaneous placement endoscopically or radiologically via pylorus or endoscopically or surgically directly into the jejunum	Long-term clinical situations where gastric emptying impaired; requires continuous drip with pump; direct endoscopic placement (PEJ) is the most comfortable for patient	Clogging or displacement of tube; jejunal fistula if large-bore tube used; diarrhea from dumping; irritation of surgical anchoring suture
Combined Gastrojejunostomy Tube		
Percutaneous placement endoscopically, radiologically, or surgically; intragastric arm for continuous or intermittent gastric suction; jejunal arm for enteral feeding	Used for patients with impaired gastric emptying and at high risk for aspiration or patients with acute pancreatitis or proximal leaks	Clogging: especially of small bore jejunal tube

Note: All small tubes are at risk for clogging, especially if used for crushed medications. In long-term enteral patients, gastrostomy and jejunostomy tubes can be exchanged for a low-profile "button" once the tract is established.

TABLE 73-10 ENTERAL FORMULAS

Composition Characteristics	Clinical Indications
Standard Enteral Formula	
1. Complete dietary products (+)[a] a. Caloric density 1 kcal/mL b. Protein ~14% cals, caseinates, soy, lactalbumin c. CHO ~60% cals, hydrolyzed corn starch, maltodextrin, sucrose d. Fat ~30% cals, corn, soy, safflower oils e. Recommended daily intake of all minerals and vitamins in >1500 kcal/d f. Osmolality (mosmol/kg): ~300	Suitable for most patients requiring tube feeding; some can be used orally
Modified Enteral Formulas	
1. Caloric density 1.5–2 kcal/mL (+)	Fluid-restricted patients
2. a. High protein ~20–25% protein (+)	Critically ill patients
b. Hydrolyzed protein to small peptides (+)	Impaired absorption
c. ↑ Arginine, glutamine, nucleotides, ω3 fat (+++)	Immune-enhancing diets
d. ↑ Branched-chain amino acids, ↓ aromatic amino acids (+++)	Liver failure patients intolerant of 0.8 g/kg protein
e. Low protein of high biologic value	Renal failure patient for brief periods if critically ill
3. a. Low fat, partial MCT substitution (+)	Fat malabsorption
b. ↑ Fat >40% cals (++)	Pulmonary failure with CO_2 retention on standard formula, limited utility
c. ↑ Fat from MUFA (++)	Improvement in glycemic index control in diabetes
d. ↑ Fat from ω3 and ↓ ω6 linoleic acid (+++)	Improved ventilation in ARDS
4. Fiber provided as soy polysaccharide (+)	Improved laxation

Cost: + inexpensive; ++ moderately expensive; +++ very expensive.

Note: ARDS, acute respiratory distress syndrome; CHO, carbohydrate; MCT, medium-chain triglyceride; MUFA, monounsaturated fatty acids; ω3 or ω6, polyunsaturated fat with first double bond at carbon 3 (fish oils) or carbon 6 (vegetable oils).

using nurse-directed algorithms for formula advancement, combining enteral with parenteral feeding, and using post–ligament of Treitz feeding. Tube feeding should not be discontinued for gastric residuals of <300 mL unless there are other signs of gastrointestinal intolerance such as nausea, vomiting, or abdominal distention. Continuous feeding using pumps is better tolerated intragastrically and is essential for feeding into the jejunum. For small-bowel feeding, residuals are not assessed but abdominal pain and distention should be monitored.

Diarrhea Enteral feeding often leads to diarrhea, especially if bowel function is compromised by disease or drugs, particularly broad-spectrum antibiotics. Diarrhea may be controlled by the use of a continuous drip, with a fiber-containing formula, or by adding an antidiarrheal agent to the formula. However, *Clostridium difficile*, which is a common cause of diarrhea in patients being tube fed, should be ruled out before using antidiarrheal agents. H2 blockers may also assist in reducing the net fluid presented to the colon. Diarrhea associated with enteral feeding does not necessarily imply inadequate absorption of nutrients other than water and electrolytes. Amino acids and glucose are particularly well absorbed in the upper small bowel except in the most diseased or shortest bowel. Since luminal nutrients exert trophic effects on the gut mucosa, it is often appropriate to persist with tube feeding, despite the diarrhea, even when this necessitates supplemental parenteral fluid support.

74 Biology of Obesity

Jeffrey S. Flier, Eleftheria Maratos-Flier

In a world where food supplies are intermittent, the ability to store energy in excess of what is required for immediate use is essential for survival. Fat cells, residing within widely distributed adipose tissue depots, are adapted to store excess energy efficiently as triglyceride and, when needed, to release stored energy as free fatty acids for use at other sites. This physiologic system, orchestrated through endocrine and neural pathways, permits humans to survive starvation for as long as several months. However, in the presence of nutritional abundance and a sedentary lifestyle, and influenced importantly by genetic endowment, this system increases adipose energy stores and produces adverse health consequences.

DEFINITION AND MEASUREMENT

Obesity is a state of excess adipose tissue mass. Although often viewed as equivalent to increased body weight, this need not be the case—lean but very muscular individuals may be overweight by numerical standards without having increased adiposity. Body weights are distributed continuously in populations, so that choice of a medically meaningful distinction between lean and obese is somewhat arbitrary. Obesity is therefore more effectively defined by assessing its linkage to morbidity or mortality.

Although not a direct measure of adiposity, the most widely used method to gauge obesity is the *body mass index* (BMI), which is equal to weight/height^2 (in kg/m^2) (Fig. 74-1). Other approaches to quantifying obesity include anthropometry (skin-fold thickness), densitometry (underwater weighing), CT or MRI, and electrical impedance. Using data from the Metropolitan Life Tables, BMIs for the midpoint of all heights and frames among both men and women range from 19–26 kg/m^2; at a similar BMI, women have more body fat than men. Based on data of substantial morbidity, a BMI of 30 is most commonly used as a threshold for obesity in both men and women. Large-scale epidemiologic studies suggest that all-cause, metabolic, cancer, and cardiovascular morbidity begin to rise (albeit at a slow rate) when BMIs are ≥ 25, suggesting that the cut-off for obesity should be low-

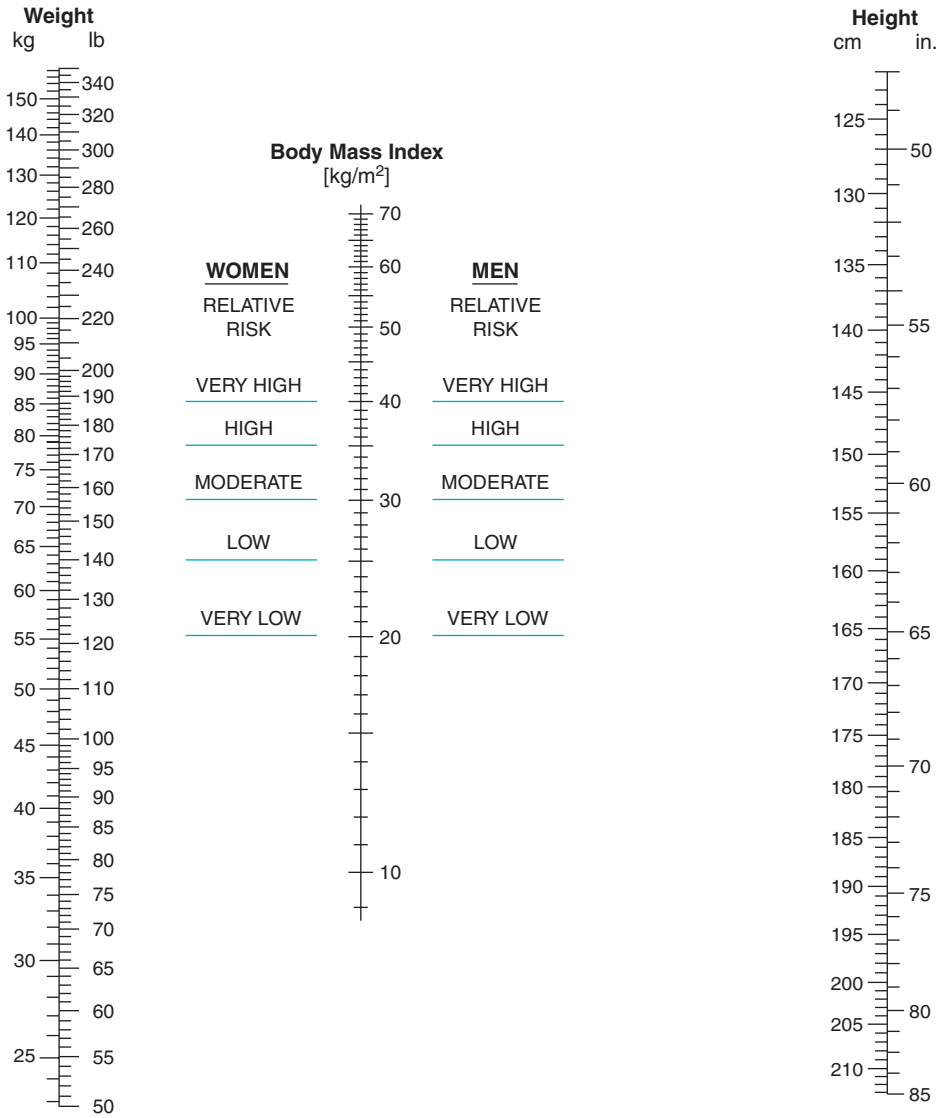

FIGURE 74-1 Nomogram for determining body mass index. To use this nomogram, place a ruler or other straight edge between the body weight (without clothes) in kilograms or pounds located on the left-hand line and the height (without shoes) in centimeters or inches located on the right-hand line. The body mass index is read from the middle of the scale and is in metric units. (*Copyright 1979, George A. Bray, M.D.; used with permission.*)

PREVALENCE

Data from the National Health and Nutrition Examination Surveys (NHANES) show that the percent of the American adult population with obesity (BMI > 30) has increased from 14.5% (between 1976 and 1980) to 30.5% (between 1999 and 2000). As many as 64% of U.S. adults ≥20 years of age were overweight (defined as BMI > 25) between the years of 1999 and 2000. Extreme obesity (BMI ≥40) has also increased and affects 4.7% of the population. The increasing prevalence of medically significant obesity raises great concern. Obesity is more common among women and in the poor; the prevalence in children is also rising at a worrisome rate.

PHYSIOLOGIC REGULATION OF ENERGY BALANCE

Substantial evidence suggests that body weight is regulated by both endocrine and neural components that ultimately influence the effector arms of energy intake and expenditure. This complex regulatory system is necessary because even small imbalances between energy intake and expenditure will ultimately have large effects on body weight. For example, a 0.3% positive imbalance over 30 years would result in a 9-kg (20-lb) weight gain. This exquisite regulation of energy balance cannot be monitored easily by calorie-counting in relation to physical activity. Rather, body weight regulation or dysregulation depends on a complex interplay of hormonal and neural signals. Alterations in stable weight by forced overfeeding or food deprivation induce physiologic changes that resist these perturbations: with weight loss, appetite increases and energy expenditure falls; with overfeeding, appetite falls and energy expenditure increases. This latter compensatory mechanism frequently fails, however, permitting obesity to develop when food is abundant and physical activity is limited. A major regulator of these adaptive responses is the adipocyte-derived hormone leptin, which acts through brain circuits (predominantly in the hypothalamus) to influence appetite, energy expenditure, and neuroendocrine function (see below).

Appetite is influenced by many factors that are integrated by the brain, most importantly within the hypothalamus (Fig. 74-2). Signals that impinge on the hypothalamic center include neural afferents, hormones, and metabolites. Vagal inputs are particularly important, bringing information from viscera, such as gut distention. Hormonal signals include leptin, insulin, cortisol, and gut peptides. Among the latter are ghrelin, which is made in the stomach and stimulates feeding, and peptide YY (PYY) and cholecystokinin, which are made in the small intestine and signal to the brain through direct action on hypothalamic control centers and/or via the vagus nerve. Metabolites, including glucose, can influence appetite, as seen by the effect of hypoglycemia to induce hunger; however, glucose is not normally a major regulator of appetite. These diverse hormonal, metabolic, and neural signals act by influencing the expression and release of various hypothalamic peptides [e.g., neuropeptide Y (NPY), Agouti-related peptide (AgRP), α-melanocyte-stimulating hormone (α-MSH), and melanin-concentrating hormone (MCH)] that are integrated with serotonergic, catecholaminergic, endocannabinoid,

ered. Most authorities use the term *overweight* (rather than obese) to describe individuals with BMIs between 25 and 30. A BMI between 25 and 30 should be viewed as medically significant and worthy of therapeutic intervention, especially in the presence of risk factors that are influenced by adiposity, such as hypertension and glucose intolerance.

The distribution of adipose tissue in different anatomic depots also has substantial implications for morbidity. Specifically, intraabdominal and abdominal subcutaneous fat have more significance than subcutaneous fat present in the buttocks and lower extremities. This distinction is most easily made clinically by determining the waist-to-hip ratio, with a ratio >0.9 in women and >1.0 in men being abnormal. Many of the most important complications of obesity, such as insulin resistance, diabetes, hypertension, hyperlipidemia, and hyperandrogenism in women, are linked more strongly to intraabdominal and/or upper body fat than to overall adiposity (Chap. 236). The mechanism underlying this association is unknown but may relate to the fact that intraabdominal adipocytes are more lipolytically active than those from other depots. Release of free fatty acids into the portal circulation has adverse metabolic actions, especially on the liver. Whether adipokines and cytokines secreted by visceral adipocytes play an additional role in systemic complications of obesity is an area of active investigation.

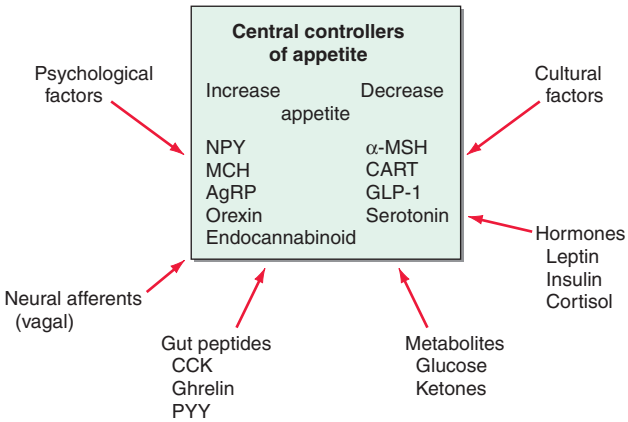

FIGURE 74-2 The factors that regulate appetite through effects on central neural circuits. Some factors that increase or decrease appetite are listed. NPY, neuropeptide Y; MCH, melanin-concentrating hormone; AgRP, Agouti-related peptide; MSH, melanocyte-stimulating hormone; CART, cocaine- and amphetamine-related transcript; GLP-1, glucagon-related peptide-1; CCK, cholecystokinin.

and opioid signaling pathways (see below). Psychological and cultural factors also play a role in the final expression of appetite. Apart from rare genetic syndromes involving leptin, its receptor, and the melanocortin system, specific defects in this complex appetite control network that influence common cases of obesity are not well defined.

Energy expenditure includes the following components: (1) resting or basal metabolic rate; (2) the energy cost of metabolizing and storing food; (3) the thermic effect of exercise; and (4) adaptive thermogenesis, which varies in response to chronic caloric intake (rising with increased intake). Basal metabolic rate accounts for ~70% of daily energy expenditure, whereas active physical activity contributes 5–10%. Thus, a significant component of daily energy consumption is fixed.

Genetic models in mice indicate that mutations in certain genes (e.g., targeted deletion of the insulin receptor in adipose tissue) protect against obesity, apparently by increasing energy expenditure. Adaptive thermogenesis occurs in *brown adipose tissue* (BAT), which plays an important role in energy metabolism in many mammals. In contrast to white adipose tissue, which is used to store energy in the form of lipids, BAT expends stored energy as heat. A mitochondrial *uncoupling protein* (UCP-1) in BAT dissipates the hydrogen ion gradient in the oxidative respiration chain and releases energy as heat. The metabolic activity of BAT is increased by a central action of leptin, acting through the sympathetic nervous system, which heavily innervates this tissue. In rodents, BAT deficiency causes obesity and diabetes; stimulation of BAT with a specific adrenergic agonist (β_3 agonist) protects against diabetes and obesity. Although BAT exists in humans (especially neonates), its physiologic role is not yet established. Homologues of UCP-1 (UCP-2 and -3) may mediate uncoupled mitochondrial respiration in other tissues.

THE ADIPOCYTE AND ADIPOSE TISSUE

Adipose tissue is composed of the lipid-storing adipose cell and a stromal/vascular compartment in which cells including preadipocytes and macrophages reside. Adipose mass increases by enlargement of adipose cells through lipid deposition, as well as by an increase in the number of adipocytes. Obese adipose tissue is also characterized by increased numbers of infiltrating macrophages. The process by which adipose cells are derived from a mesenchymal preadipocyte involves an orchestrated series of differentiation steps mediated by a cascade of specific transcription factors. One of the key transcription factors is *peroxisome proliferator-activated receptor* γ (PPARγ), a nuclear receptor that binds the thiazolidinedione class of insulin-sensitizing drugs used in the treatment of type 2 diabetes (Chap. 338).

Although the adipocyte has generally been regarded as a storage depot for fat, it is also an endocrine cell that releases numerous molecules in a regulated fashion (Fig. 74-3). These include the energy balance–regulating hormone leptin, cytokines such as tumor necrosis factor (TNF) α and interleukin (IL)-6, complement factors such as factor D (also known as *adipsin*), prothrombotic agents such as plasminogen activator inhibitor I, and a component of the blood pressure regulating system, angiotensinogen. Adiponectin, an abundant adipose-derived protein whose levels are reduced in obesity, enhances insulin sensitivity and lipid oxidation and it has vascular protective effects, whereas resistin and RBP4, whose levels are increased in obesity, may induce insulin resistance. These factors, and others not yet identified, play a role in the physiology of lipid homeostasis, insulin sensitivity, blood pressure control, coagulation, and vascular health, and are likely to contribute to obesity-related pathologies.

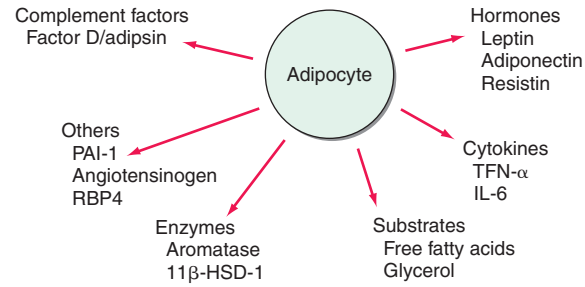

FIGURE 74-3 Factors released by the adipocyte that can affect peripheral tissues. PAI, plasminogen activator inhibitor; TNF, tumor necrosis factor; RBP4, retinal binding protein 4.

ETIOLOGY OF OBESITY

Though the molecular pathways regulating energy balance are beginning to be illuminated, the causes of obesity remain elusive. In part, this reflects the fact that obesity is a heterogeneous group of disorders. At one level, the pathophysiology of obesity seems simple: a chronic excess of nutrient intake relative to the level of energy expenditure. However, due to the complexity of the neuroendocrine and metabolic systems that regulate energy intake, storage, and expenditure, it has been difficult to quantitate all the relevant parameters (e.g., food intake and energy expenditure) over time in human subjects.

Role of Genes versus Environment Obesity is commonly seen in families, and the heritability of body weight is similar to that for height. Inheritance is usually not Mendelian, however, and it is difficult to distinguish the role of genes and environmental factors. Adoptees more closely resemble their biologic than adoptive parents with respect to obesity, providing strong support for genetic influences. Likewise, identical twins have very similar BMIs whether reared together or apart, and their BMIs are much more strongly correlated than those of dizygotic twins. These genetic effects appear to relate to both energy intake and expenditure.

Whatever the role of genes, it is clear that the environment plays a key role in obesity, as evidenced by the fact that famine prevents obesity in even the most obesity-prone individual. In addition, the recent increase in the prevalence of obesity in the United States is far too rapid to be due to changes in the gene pool. Undoubtedly, genes influence the susceptibility to obesity in response to specific diets and availability of nutrition. Cultural factors are also important—these relate to both availability and composition of the diet and to changes in the level of physical activity. In industrial societies, obesity is more common among poor women, whereas in underdeveloped countries, wealthier women are more often obese. In children, obesity correlates to some degree with time spent watching television. Although the role of diet composition in obesity continues to generate controversy, it appears that high-fat diets may promote obesity, especially when combined with diets rich in simple (as opposed to complex) carbohydrates.

Additional environmental factors may contribute to the increasing obesity prevalence. Both epidemiologic correlations and experimental data suggest that sleep deprivation leads to increased obesity. Less well

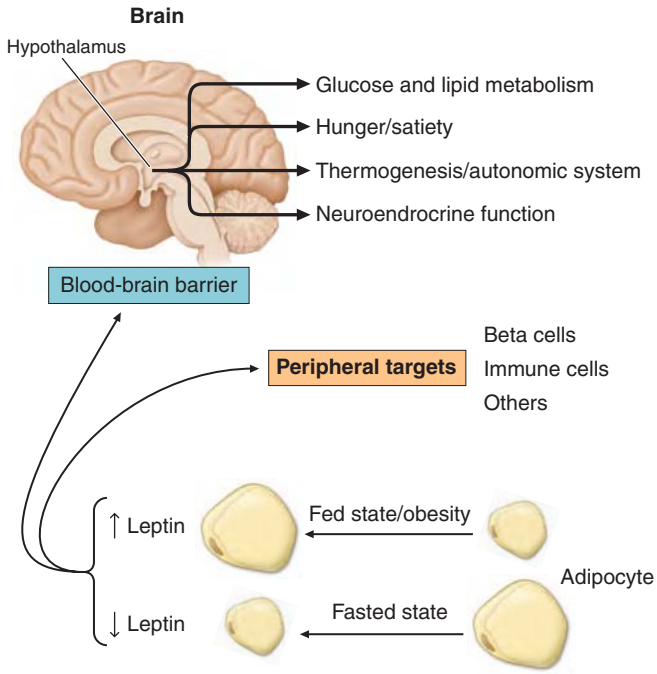

FIGURE 74-4 The physiologic system regulated by leptin. Rising or falling leptin levels act through the hypothalamus to influence appetite, energy expenditure, and neuroendocrine function and through peripheral sites to influence systems such as the immune system.

supported in humans are potential changes in gut flora with capacity to alter energy balance and a possible role for obesigenic viral infections.

Specific Genetic Syndromes For many years obesity in rodents has been known to be caused by a number of distinct mutations distributed through the genome. Most of these single-gene mutations cause both hyperphagia and diminished energy expenditure, suggesting a physiologic link between these two parameters of energy homeostasis. Identification of the *ob* gene mutation in genetically obese (ob/ob) mice represented a major breakthrough in the field. The ob/ob mouse develops severe obesity, insulin resistance, and hyperphagia, as well as efficient metabolism (e.g., it gets fat even when ingesting the same number of calories as lean litter mates). The product of the *ob* gene is the peptide leptin, a name derived from the Greek root *leptos*, meaning thin. Leptin is secreted by adipose cells and acts primarily through the hypothalamus. Its level of production provides an index of adipose energy stores (Fig. 74-4). High leptin levels decrease food intake and increase energy expenditure. Another mouse mutant, db/db, which is resistant to leptin, has a mutation in the leptin receptor and develops a similar syndrome. The *OB* gene is present in humans and expressed in fat. Several families with morbid, early-onset obesity caused by inactivating mutations in either leptin or the leptin receptor have been described, thus demonstrating the biologic relevance of leptin in humans. The obesity in these individuals begins shortly after birth, is severe, and is accompanied by neuroendocrine abnormalities. The most prominent of these is hypogonadotropic hypogonadism, which is reversed by leptin replacement. Central hypothyroidism and growth retardation are seen in the mouse model, but their occurrence in leptin-deficient humans is less clear. To date, there is no evidence to suggest that mutations or polymorphisms in the leptin or leptin receptor genes play a prominent role in common forms of obesity.

Mutations in several other genes cause severe obesity in humans (Table 74-1); each of these syndromes is rare. Mutations in the gene encoding proopiomelanocortin (POMC) cause severe obesity through failure to synthesize α-MSH, a key neuropeptide that inhibits appetite in the hypothalamus. The absence of POMC also causes secondary adrenal insufficiency due to absence of adrenocorticotropic hormone (ACTH), as well as pale skin and red hair due to absence of α-MSH. Proenzyme convertase 1 (PC-1) mutations are thought to cause obesity by preventing synthesis of α-MSH from its precursor peptide, POMC. α-MSH binds to the type 4 melanocortin receptor (MC4R), a key hypothalamic receptor that inhibits eating. Heterozygous loss-of-function mutations of this receptor account for as much as 5% of severe obesity. These five genetic defects define a pathway through which leptin (by stimulating POMC and increasing α-MSH) restricts food intake and limits weight (Fig. 74-5).

In addition to these human obesity genes, studies in rodents reveal several other molecular candidates for hypothalamic mediators of human obesity or leanness. The *tub* gene encodes a hypothalamic peptide of unknown function; mutation of this gene causes late-onset obesity. The *fat* gene encodes carboxypeptidase E, a peptide-processing enzyme; mutation of this gene is thought to cause obesity by disrupting production of one or more neuropeptides. AgRP is coexpressed with NPY in arcuate nucleus neurons. AgRP antagonizes α-MSH action at MC4 receptors, and its overexpression induces obesity. In contrast, a mouse deficient in the peptide MCH, whose administration causes feeding, is lean.

A number of complex human syndromes with defined inheritance are associated with obesity (Table 74-2). Although specific genes are undefined at present, their identification will likely enhance our understanding of more common forms of human obesity. In the Prader-Willi syndrome, obesity coexists with short stature, mental retardation, hypogonadotropic hypogonadism, hypotonia, small hands and feet, fish-shaped mouth, and hyperphagia. Most patients have a chromosome 15 deletion, and reduced expression of the signaling protein necdin may be an important cause of defective hypothalamic neural development in this disorder (Chap. 63). Bardet-Biedl syndrome

TABLE 74-1 SOME OBESITY GENES IN HUMANS AND MICE

Gene	Gene Product	Mechanism of Obesity	In Human	In Rodent
Lep (*ob*)	Leptin, a fat-derived hormone	Mutation prevents leptin from delivering satiety signal; brain perceives starvation	Yes	Yes
LepR (*db*)	Leptin receptor	Same as above	Yes	Yes
POMC	Proopiomelanocortin, a precursor of several hormones and neuropeptides	Mutation prevents synthesis of melanocyte-stimulating hormone (MSH), a satiety signal	Yes	Yes
MC4R	Type 4 receptor for MSH	Mutation prevents reception of satiety signal from MSH	Yes	Yes
AgRP	Agouti-related peptide, a neuropeptide expressed in the hypothalamus	Overexpression inhibits signal through MC4R	No	Yes
PC-1	Prohormone convertase 1, a processing enzyme	Mutation prevents synthesis of neuropeptide, probably MSH	Yes	No
Fat	Carboxypeptidase E, a processing enzyme	Same as above	No	Yes
Tub	Tub, a hypothalamic protein of unknown function	Hypothalamic dysfunction	No	Yes
TrkB	TrkB, a neurotrophin receptor	Hyperphagia due to uncharacterized hypothalamic defect	Yes	Yes

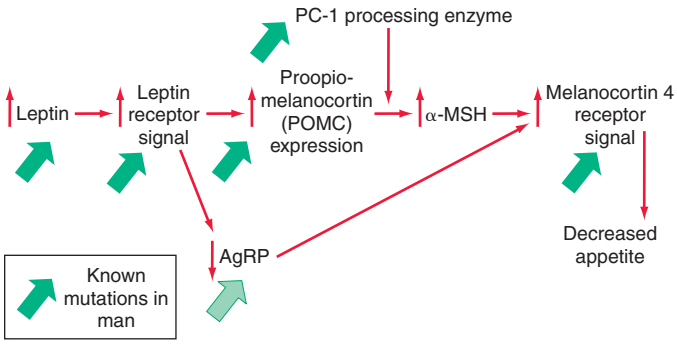

FIGURE 74-5 A central pathway through which leptin acts to regulate appetite and body weight. Leptin signals through pro-opiomelanocortin (POMC) neurons in the hypothalamus to induce increased production of α-melanocyte-stimulating hormone (α-MSH), requiring the processing enzyme PC-1 (proenzyme convertase 1). α-MSH acts as an agonist on melanocortin-4 receptors to inhibit appetite, and the neuropeptide AgRp (Agouti-related peptide) acts as an antagonist of this receptor. Mutations that cause obesity in humans are indicated by the solid green arrows.

(BBS) is a genetically heterogeneous disorder characterized by obesity, mental retardation, retinitis pigmentosa, renal and cardiac malformations, polydactyly, and hypogonadotropic hypogonadism. At least eight genetic loci have been identified, and BBS may involve defects in ciliary function.

Other Specific Syndromes Associated with Obesity • ***CUSHING'S SYNDROME*** Although obese patients commonly have central obesity, hypertension, and glucose intolerance, they lack other specific stigmata of Cushing's syndrome (Chap. 336). Nonetheless, a potential diagnosis of Cushing's syndrome is often entertained. Cortisol production and urinary metabolites (17OH steroids) may be increased in simple obesity. Unlike in Cushing's syndrome, however, cortisol levels in blood and urine in the basal state and in response to corticotropin-releasing hormone (CRH) or ACTH are normal; the overnight 1-mg dexamethasone suppression test is normal in 90%, with the remainder being normal on a standard 2-day low-dose dexamethasone suppression test. Obesity may be associated with excessive local reactivation of cortisol in fat by 11β-hydroxysteroid dehydrogenase 1, an enzyme that converts inactive cortisone to cortisol.

HYPOTHYROIDISM The possibility of hypothyroidism should be considered, but it is an uncommon cause of obesity; hypothyroidism is easily ruled out by measuring thyroid-stimulating hormone (TSH). Much of the weight gain that occurs in hypothyroidism is due to myxedema (Chap. 335).

INSULINOMA Patients with insulinoma often gain weight as a result of overeating to avoid hypoglycemic symptoms (Chap. 339). The increased substrate plus high insulin levels promote energy storage in fat. This can be marked in some individuals but is modest in most.

CRANIOPHARYNGIOMA AND OTHER DISORDERS INVOLVING THE HYPOTHALAMUS Whether through tumors, trauma, or inflammation, hypothalamic dysfunction of systems controlling satiety, hunger, and energy expenditure can cause varying degrees of obesity (Chap. 333). It is uncommon to identify a discrete anatomic basis for these disorders. Subtle hypothalamic dysfunction is probably a more common cause of obesity than can be documented using currently available imaging techniques. Growth hormone (GH), which exerts lipolytic activity, is diminished in obesity and is increased with weight loss. Despite low GH levels, insulin-like growth factor (IGF) I (somatomedin) production is normal, suggesting that GH suppression is a compensatory response to increased nutritional supply.

Pathogenesis of Common Obesity Obesity can result from increased energy intake, decreased energy expenditure, or a combination of the two. Thus, identifying the etiology of obesity should involve measurements of both parameters. However, it is nearly impossible to perform direct and accurate measurements of energy intake in free-living individuals, and the obese, in particular, often underreport intake. Measurements of chronic energy expenditure have only recently become available using doubly labeled water or metabolic chamber/rooms. In subjects at stable weight and body composition, energy intake equals expenditure. Consequently, these techniques allow assessment of energy intake in free-living individuals. The level of energy expenditure differs in established obesity, during periods of weight gain or loss, and in the pre- or postobese state. Studies that fail to take note of this phenomenon are not easily interpreted.

TABLE 74-2 A COMPARISON OF SYNDROMES OF OBESITY—HYPOGONADISM AND MENTAL RETARDATION

Feature	Syndrome				
	Prader-Willi	Laurence-Moon-Biedl	Ahlstrom	Cohen	Carpenter
Inheritance	Sporadic; two-thirds have defect	Autosomal recessive	Autosomal recessive	Probably autosomal recessive	Autosomal recessive
Stature	Short	Normal; infrequently short	Normal; infrequently short	Short or tall	Normal
Obesity	Generalized Moderate to severe Onset 1–3 yrs	Generalized Early onset, 1–2 yrs	Truncal Early onset, 2–5 yrs	Truncal Mid-childhood, age 5	Truncal, gluteal
Craniofacies	Narrow bifrontal diameter Almond-shaped eyes Strabismus V-shaped mouth High-arched palate	Not distinctive	Not distinctive	High nasal bridge Arched palate Open mouth Short philtrum	Acrocephaly Flat nasal bridge High-arched palate
Limbs	Small hands and feet Hypotonia	Polydactyly	No abnormalities	Hypotonia Narrow hands and feet	Polydactyly Syndactyly Genu valgum
Reproductive status	1° Hypogonadism	1° Hypogonadism	Hypogonadism in males but not in females	Normal gonadal function or hypogonadotrophic hypogonadism	2° Hypogonadism
Other features	Enamel hypoplasia Hyperphagia Temper tantrums Nasal speech			Dysplastic ears Delayed puberty	
Mental retardation	Mild to moderate		Normal intelligence	Mild	Slight

There is continued interest in the concept of a body weight "set point." This idea is supported by physiologic mechanisms centered around a sensing system in adipose tissue that reflects fat stores and a receptor, or "adipostat," that is in the hypothalamic centers. When fat stores are depleted, the adipostat signal is low, and the hypothalamus responds by stimulating hunger and decreasing energy expenditure to conserve energy. Conversely, when fat stores are abundant, the signal is increased, and the hypothalamus responds by decreasing hunger and increasing energy expenditure. The recent discovery of the *ob* gene, and its product leptin, and the *db* gene, whose product is the leptin receptor, provides important elements of a molecular basis for this physiologic concept (see above).

What Is the Status of Food Intake in Obesity? (Do the Obese Eat More Than the Lean?) This question has stimulated much debate, due in part to the methodologic difficulties inherent in determining food intake. Many obese individuals believe that they eat small quantities of food, and this claim has often been supported by the results of food intake questionnaires. However, it is now established that average energy expenditure increases as individuals get more obese, due primarily to the fact that metabolically active lean tissue mass increases with obesity. Given the laws of thermodynamics, the obese person must therefore eat more than the average lean person to maintain their increased weight. It may be the case, however, that a subset of individuals who are predisposed to obesity have the capacity to become obese initially without an absolute increase in caloric consumption.

What Is the State of Energy Expenditure in Obesity? The average total daily energy expenditure is higher in obese than lean individuals when measured at stable weight. However, energy expenditure falls as weight is lost, due in part to loss of lean body mass and to decreased sympathetic nerve activity. When reduced to near-normal weight and maintained there for a while, (some) obese individuals have lower energy expenditure than (some) lean individuals. There is also a tendency for those who will develop obesity as infants or children to have lower resting energy expenditure rates than those who remain lean.

The physiologic basis for variable rates of energy expenditure (at a given body weight and level of energy intake) is essentially unknown. A mutation in the human β_3-adrenergic receptor may be associated with increased risk of obesity and/or insulin resistance in certain (but not all) populations. Homologues of the BAT uncoupling protein, named UCP-2 and UCP-3, have been identified in both rodents and humans. UCP-2 is expressed widely, whereas UCP-3 is primarily expressed in skeletal muscle. These proteins may play a role in disordered energy balance.

One newly described component of thermogenesis, called *nonexercise activity thermogenesis* (NEAT), has been linked to obesity. It is the thermogenesis that accompanies physical activities other than volitional exercise, such as the activities of daily living, fidgeting, spontaneous muscle contraction, and maintaining posture. NEAT accounts for about two-thirds of the increased daily energy expenditure induced by overfeeding. The wide variation in fat storage seen in overfed individuals is predicted by the degree to which NEAT is induced. The molecular basis for NEAT and its regulation is unknown.

Leptin in Typical Obesity The vast majority of obese persons have increased leptin levels but do not have mutations of either leptin or its receptor. They appear, therefore, to have a form of functional "leptin resistance." Data suggesting that some individuals produce less leptin per unit fat mass than others or have a form of relative leptin deficiency that predisposes to obesity are at present contradictory and unsettled. The mechanism for leptin resistance, and whether it can be overcome by raising leptin levels, is not yet established. Some data suggest that leptin may not effectively cross the blood-brain barrier as levels rise. It is also apparent from animal studies that leptin signaling inhibitors, such as SOCS3 and PTP1b, are involved in the leptin-resistant state.

PATHOLOGIC CONSEQUENCES OF OBESITY

(See also Chap. 75) Obesity has major adverse effects on health. Obesity is associated with an increase in mortality, with a 50–100% increased risk of death from all causes compared to normal-weight individuals, mostly due to cardiovascular causes. Obesity and overweight together are the second leading cause of preventable death in the United States, accounting for 300,000 deaths per year. Mortality rates rise as obesity increases, particularly when obesity is associated with increased intraabdominal fat (see above). Life expectancy of a moderately obese individual could be shortened by 2–5 years, and a 20- to 30-year-old male with a BMI > 45 may lose 13 years of life. It is also apparent that the degree to which obesity affects particular organ systems is influenced by susceptibility genes that vary in the population.

Insulin Resistance and Type 2 Diabetes Mellitus Hyperinsulinemia and insulin resistance are pervasive features of obesity, increasing with weight gain and diminishing with weight loss (Chap. 236). Insulin resistance is more strongly linked to intraabdominal fat than to fat in other depots. The molecular link between obesity and insulin resistance in tissues such as fat, muscle, and liver has been sought for many years. Major factors under investigation include: (1) insulin itself, by inducing receptor downregulation; (2) free fatty acids, known to be increased and capable of impairing insulin action; (3) intracellular lipid accumulation; and (4) various circulating peptides produced by adipocytes, including the cytokines TNF-α and IL-6, RBP4, and the "adipokines" adiponectin and resistin, which are produced by adipocytes, have altered expression in obese adipocytes, and are capable of modifying insulin action. Despite nearly universal insulin resistance, most obese individuals do not develop diabetes, suggesting that the onset of diabetes requires an interaction between obesity-induced insulin resistance and other factors that predispose to diabetes, such as impaired insulin secretion (Chap. 338). Obesity, however, is a major risk factor for diabetes, and as many as 80% of patients with type 2 diabetes mellitus are obese. Weight loss and exercise, even of modest degree, are associated with increased insulin sensitivity and often improve glucose control in diabetes.

Reproductive Disorders Disorders that affect the reproductive axis are associated with obesity in both men and women. Male hypogonadism is associated with increased adipose tissue, often distributed in a pattern more typical of females. In men >160% ideal body weight, plasma testosterone and sex hormone–binding globulin (SHBG) are often reduced, and estrogen levels (derived from conversion of adrenal androgens in adipose tissue) are increased (Chap. 340). Gynecomastia may be seen. However, masculinization, libido, potency, and spermatogenesis are preserved in most of these individuals. Free testosterone may be decreased in morbidly obese men whose weight is >200% ideal body weight.

Obesity has long been associated with menstrual abnormalities in women, particularly in women with upper body obesity (Chap. 341). Common findings are increased androgen production, decreased SHBG, and increased peripheral conversion of androgen to estrogen. Most obese women with oligomenorrhea have the polycystic ovarian syndrome (PCOS), with its associated anovulation and ovarian hyperandrogenism; 40% of women with PCOS are obese. Most nonobese women with PCOS are also insulin-resistant, suggesting that insulin resistance, hyperinsulinemia, or the combination of the two are causative or contribute to the ovarian pathophysiology in PCOS in both obese and lean individuals. In obese women with PCOS, weight loss or treatment with insulin-sensitizing drugs often restores normal menses. The increased conversion of androstenedione to estrogen, which occurs to a greater degree in women with lower body obesity, may contribute to the increased incidence of uterine cancer in postmenopausal women with obesity.

Cardiovascular Disease The Framingham Study revealed that obesity was an independent risk factor for the 26-year incidence of cardiovascular disease in men and women [including coronary disease, stroke, and congestive heart failure (CHF)]. The waist/hip ratio may be the best predictor of these risks. When the additional effects of hypertension and glucose intolerance associated with obesity are included, the adverse impact of obesity is even more evident. The effect of obesity

on cardiovascular mortality in women may be seen at BMIs as low as 25. Obesity, especially abdominal obesity, is associated with an atherogenic lipid profile; with increased low-density lipoprotein (LDL) cholesterol, very low density lipoprotein, and triglyceride; and with decreased high-density lipoprotein cholesterol and decreased levels of the vascular protective adipokine adiponectin (Chap. 350). Obesity is also associated with hypertension. Measurement of blood pressure in the obese requires use of a larger cuff size to avoid artifactual increases. Obesity-induced hypertension is associated with increased peripheral resistance and cardiac output, increased sympathetic nervous system tone, increased salt sensitivity, and insulin-mediated salt retention; it is often responsive to modest weight loss.

Pulmonary Disease Obesity may be associated with a number of pulmonary abnormalities. These include reduced chest wall compliance, increased work of breathing, increased minute ventilation due to increased metabolic rate, and decreased functional residual capacity and expiratory reserve volume (Chap. 246). Severe obesity may be associated with obstructive sleep apnea and the "obesity hypoventilation syndrome" with attenuated hypoxic and hypercapnic ventilatory responses (Chap. 258). Sleep apnea can be obstructive (most common), central, or mixed and is associated with hypertension. Weight loss (10–20 kg) can bring substantial improvement, as can major weight loss following gastric bypass or restrictive surgery. Continuous positive airway pressure has been used with some success.

Gallstones Obesity is associated with enhanced biliary secretion of cholesterol, supersaturation of bile, and a higher incidence of gallstones, particularly cholesterol gallstones (Chap. 305). A person 50% above ideal body weight has about a sixfold increased incidence of symptomatic gallstones. Paradoxically, fasting increases supersaturation of bile by decreasing the phospholipid component. Fasting-induced cholecystitis is a complication of extreme diets.

Cancer Obesity in males is associated with higher mortality from cancer, including cancer of the esophagus, colon, rectum, pancreas, liver, and prostate; obesity in females is associated with higher mortality from cancer of the gallbladder, bile ducts, breasts, endometrium, cervix, and ovaries. Some of the latter may be due to increased rates of conversion of androstenedione to estrone in adipose tissue of obese individuals. It was recently estimated that obesity accounts for 14% of cancer deaths in men and 20% in women in the United States.

Bone, Joint, and Cutaneous Disease Obesity is associated with an increased risk of osteoarthritis, no doubt partly due to the trauma of added weight bearing and joint malalignment. The prevalence of gout may also be increased (Chap. 327). Among the skin problems associated with obesity is acanthosis nigricans, manifested by darkening and thickening of the skin folds on the neck, elbows, and dorsal interphalangeal spaces. Acanthosis reflects the severity of underlying insulin resistance and diminishes with weight loss. Friability of skin may be increased, especially in skin folds, enhancing the risk of fungal and yeast infections. Finally, venous stasis is increased in the obese.

75 Evaluation and Management of Obesity

Robert F. Kushner

Over 66% of U.S. adults are currently categorized as overweight or obese, and the prevalence of obesity is increasing rapidly throughout most of the industrialized world. Based on statistics from the World Health Organization, overweight and obesity may soon replace more traditional public health concerns such as undernutrition and infectious diseases as the most significant contributors to ill health. Children and adolescents are also becoming more obese, indicating that the current trends will accelerate over time. Obesity is associated with an increased risk of multiple health problems, including hypertension, type 2 diabetes, dyslipidemia, degenerative joint disease, and some malignancies. Thus, it is important for physicians to routinely identify, evaluate, and treat patients for obesity and associated comorbid conditions.

EVALUATION

The U.S. Preventive Services Task Force recommends that physicians screen all adult patients for obesity and offer intensive counseling and behavioral interventions to promote sustained weight loss. This recommendation is consistent with previously released guidelines from the National Heart, Lung, and Blood Institute (NHLBI) and a number of medical societies. The five main steps in the evaluation of obesity are described below and include (1) focused obesity-related history, (2) physical examination to determine the degree and type of obesity, (3) comorbid conditions, (4) fitness level, and (5) the patient's readiness to adopt lifestyle changes.

The Obesity-Focused History Information from the history should address the following six questions:

- What factors contribute to the patient's obesity?
- How is the obesity affecting the patient's health?
- What is the patient's level of risk from obesity?
- What are the patient's goals and expectations?
- Is the patient motivated to begin a weight management program?
- What kind of help does the patient need?

Although the vast majority of obesity can be attributed to behavioral features that affect diet and physical activity patterns, the history may suggest secondary causes that merit further evaluation. Disorders to consider include polycystic ovarian syndrome, hypothyroidism, Cushing's syndrome, and hypothalamic disease. Drug-induced weight gain should also to be considered. Common causes include antidiabetes agents (insulin, sulfonylureas, thiazolidinediones); steroid hormones; psychotropic agents; mood stabilizers (lithium); antidepressants (tricyclics, monoamine oxidase inhibitors, paraxetine, mirtazapine); and antiepileptic drugs (valproate, gabapentin, carbamazapine). Other medications such as nonsteroidal anti-inflammatory drugs and calcium-channel blockers may cause peripheral edema, but they do not increase body fat.

The patient's current diet and physical activity patterns may reveal factors that contribute to the development of obesity in addition to identifying behaviors to target for treatment. This type of historical information is best obtained by using a questionnaire in combination with an interview.

BMI and Waist Circumference Three key anthropometric measurements are important to evaluate the degree of obesity—weight, height, and waist circumference. The body mass index (BMI), calculated as weight (kg)/height (m)^2, or as weight (lbs)/height (inches)^2 × 703, is used to classify weight status and risk of disease (Tables 75-1 and 75-2). BMI is used since it provides an estimate of body fat and is related to risk of disease. Lower BMI thresholds for overweight and obesity have been proposed for the Asia-Pacific region since this population appears to be at-risk at lower body weights for glucose and lipid abnormalities.

Excess abdominal fat, assessed by measurement of waist circumference or waist-to-hip ratio, is independently associated with higher risk for diabetes mellitus and cardiovascular disease. Measurement of the waist circumference is a surrogate for visceral adipose tissue and should be performed in the horizontal plane above the iliac crest. Cut points that define higher risk for men and women based on ethnicity have been proposed by the International Diabetes Federation (Table 75-3).

TABLE 75-2 CLASSIFICATION OF WEIGHT STATUS AND RISK OF DISEASE

	BMI (kg/m^2)	Obesity Class	Risk of Disease
Underweight	<18.5		
Healthy weight	18.5–24.9		
Overweight	25.0–29.9		Increased
Obesity	30.0–34.9	I	High
Obesity	35.0–39.9	II	Very high
Extreme Obesity	≥40	III	Extremely high

Physical Fitness Several prospective studies have demonstrated that physical fitness, reported by questionnaire or measured by a maximal treadmill exercise test, is an important predictor of all-cause mortality independent of BMI and body composition. These observations highlight the importance of taking an exercise history during examination as well as emphasizing physical activity as a treatment approach.

Obesity-Associated Comorbid Conditions The evaluation of comorbid conditions should be based on presentation of symptoms, risk factors, and index of suspicion. All patients should have a fasting lipid panel (total, LDL, and HDL cholesterol and triglyceride levels) and blood glucose measured at presentation along with blood pressure determination. Symptoms and diseases that are directly or indirectly related to obesity are listed in Table 75-4. Although individuals vary, the number and severity of organ-specific comorbid conditions usually rise with increasing levels of obesity. Patients at very high absolute risk include the following: established coronary heart disease; presence of other atherosclerotic diseases such as peripheral arterial disease, abdominal aortic aneurysm, and symptomatic carotid artery disease; type 2 diabetes; and sleep apnea.

Assessing the Patient's Readiness to Change An attempt to initiate lifestyle changes when the patient is not ready usually leads to frustration and may hamper future weight-loss efforts. Assessment includes patient motivation and support, stressful life events, psychiatric status, time availability and constraints, and appropriateness of goals and expectations. Readiness can be viewed as the balance of two opposing forces: (1) motivation, or the patient's desire to change; and (2) resistance, or the patient's resistance to change.

A helpful method to begin a readiness assessment is to "anchor" the patient's interest and confidence to change on a numerical scale. Using this technique, the patient is asked to rate his or her level of interest and confidence on a scale from 0 to 10, with 0 being not so important (or confident) and 10 being very important (or confident) to lose weight at this time. This exercise helps to establish readiness to change and also serves as a basis for further dialogue.

℞ OBESITY

THE GOAL OF THERAPY The primary goal of treatment is to improve obesity-related comorbid conditions and reduce the risk of developing future comorbidities. Information obtained from the history, physical examination, and diagnostic tests is used to determine risk and develop a treatment plan **(Fig. 75-1)**. The decision of how aggressively to treat the patient, and which modalities to use, is determined by the patient's risk status, expectations, and available resources. Therapy for obesity always begins with lifestyle management and may include pharmacotherapy or surgery, depending on BMI risk category **(Table 75-5)**. Setting an initial weight-loss goal of 10% over 6 months is a realistic target.

LIFESTYLE MANAGEMENT Obesity care involves attention to three essential elements of lifestyle: dietary habits, physical activity, and behavior modification. Because obesity is fundamentally a disease of energy imbalance, all patients must learn how and when energy is consumed (diet), how and when energy is expended (physical activity), and how to incorporate this information into their daily life (behavior therapy). Lifestyle management has been shown to result in a modest (typically 3–5 kg) weight loss compared to no treatment or usual care.

Diet Therapy The primary focus of diet therapy is to reduce overall calorie consumption. The NHLBI guidelines recommend initiating treatment with a calorie deficit of 500–1000 kcal/d compared to the patient's habitual diet. This reduction is consistent with a goal of losing approximately 1–2 lb per week. This calorie deficit can be accomplished by suggesting substitutions or alternatives to the diet. Examples include choosing smaller portion sizes, eating more fruits and vegetables, consuming more whole-grain cereals, selecting leaner cuts of meat and skimmed dairy products, reducing fried foods and other added fats and oils, and drinking water instead of caloric beverages. It is important that the dietary counseling remains patient-centered and that the goals are practical, realistic, and achievable.

The macronutrient composition of the diet will vary depending on the patient's preference and medical condition. The 2005 U.S. Department of Agriculture Dietary Guidelines for Americans (Chap. 70), which focus on health promotion and risk reduction, can be applied to treatment of the overweight or obese patient. The recommendations include maintaining a diet rich in whole grains, fruits, vegetables, and dietary fiber; consuming two servings (8 oz) of fish high in omega 3 fatty acids per week; decreasing sodium to <2300 mg/d; consuming 3 cups of milk (or equivalent low-fat or fat-free dairy products) per day; limiting cholesterol to <300 mg/d; and keeping total fat between 20 and 35% of daily calories and saturated fats to <10% of daily calories. Application of these guidelines to specific calorie goals can be found on the website *www.mypyramid.gov*. The revised Dietary Reference Intakes for Macronutrients released by the Institute of Medicine recommends 45–65% of calories from carbohydrates, 20–35% from fat, and 10–35% from protein. The guidelines also recommend daily fiber intake of 38 g (men) and 25 g (women) for persons over 50 years of age and 30 g (men) and 21 g (women) for those under 50.

Since portion control is one of the most difficult strategies for patients to manage, the use of pre-prepared products, such as meal replacements, is a simple and convenient suggestion. Examples include frozen entrees, canned beverages and bars. Use of meal replacements in the diet has been shown to result in a 7–8% weight loss.

A current area of controversy is the use of low-carbohydrate, high-protein diets for weight loss. These diets are based on the concept that carbohydrates are the primary cause of obesity and lead to insulin resistance. Most low-carbohydrate diets (e.g., South Beach, Zone, and Sugar Busters!) recommend a carbohydrate level of approximately 40–46% of energy. The Atkins diet contains 5–15% carbohydrate, depending on the phase of the diet. Several randomized, controlled trials of these low-carbohydrate diets have demonstrated greater weight loss at 6 months with improvement in coronary heart disease risk factors, including an increase in HDL cholesterol and a decrease in triglyceride levels. Weight loss between groups did not remain statistically significant at 1 year; however, low-carbohydrate diets appear to be at least as effective as low-fat diets in inducing weight loss for up to 1 year.

Another dietary approach to consider is the concept of energy density, which refers to the number of calories (energy) a food contains per unit of weight. People tend to ingest a constant volume of food, regardless of caloric or macronutrient content. Adding water or fiber to a food decreases its energy density by increasing weight without affecting caloric content. Examples of foods with low-energy density include soups, fruits, vegetables, oatmeal, and lean meats. Dry foods and high-fat foods such as pret-

zels, cheese, egg yolks, potato chips, and red meat have a high-energy density. Diets containing low-energy dense foods have been shown to control hunger and result in decreased caloric intake and weight loss.

Occasionally, very-low-calorie diets (VLCDs) are prescribed as a form of aggressive dietary therapy. The primary purpose of a VLCD is to promote a rapid and significant (13–23 kg) short-term weight loss over a 3–6 month period. These propriety formulas typically supply ≤800 kcal, 50–80 g protein, and 100% of the recommended daily intake for vitamins and minerals. According to a review by the National Task Force on the Prevention and Treatment of Obesity, indications for initiating a VLCD include well-motivated individuals who are moderately to severely obese (BMI >30), have failed at more conservative approaches to weight loss, and have a medical condition that would be immediately improved with rapid weight loss. These conditions include poorly controlled type 2 diabetes, hypertriglyceridemia, obstructive sleep apnea, and symptomatic peripheral edema. The risk for gallstone formation increases exponentially at rates of weight loss >1.5 kg/week (3.3 lb/week). Prophylaxis against gallstone formation with ursodeoxycholic acid, 600 mg/d, is effective in reducing this risk. Because of the

need for close metabolic monitoring, these diets are usually prescribed by physicians specializing in obesity care.

Physical Activity Therapy Although exercise alone is only moderately effective for weight loss, the combination of dietary modification and exercise is the most effective behavioral approach for the treatment of obesity. The most important role of exercise appears to be in the maintenance of the weight loss. Currently, the *minimum* public health recommendation for physical activity is 30 min of moderate intensity physical activity on most, and preferably all, days of the week. Focusing on simple ways to add physical activity into the normal daily routine through leisure activities, travel, and domestic work should be suggested. Examples include walking, using the stairs, doing home and yard work, and engaging in sport activities. Asking the patient to wear a pedometer to monitor total accumulation of steps as part of the activities of daily living is a useful strategy. Step counts are highly correlated with activity level. Studies have demonstrated that lifestyle activities are as effective as structured exercise programs for improving cardiorespiratory fitness and weight loss. The Dietary Guidelines for Americans 2005 summarizes compelling evidence that at least 60–90 min of daily moderate-intensity physical activity (420–630 min per week) is needed to sustain weight loss (*http://www.health.gov/dietaryguidelines/dga2005/*). The American College of Sports Medicine recommends that overweight and obese individuals progressively increase to a minimum of 150 min of moderate intensity physical activity per week as a first goal. However, for long-term weight loss, a higher level of exercise (e.g., 200–300 min or ≥2000 kcal per week) is needed. These recommendations are daunting to most patients and need to be implemented gradually. Consultation with an exercise physiologist or personal trainer may be helpful.

Behavioral Therapy Cognitive behavioral therapy is used to help change and reinforce new dietary and physical activity behaviors. Strategies include self-monitoring techniques (e.g., journaling, weighing, and measuring food and activity); stress management; stimulus control (e.g., using smaller plates, not eating in front of the television or in the car); social support; problem solving; and cognitive restructuring to help patients develop more positive and realistic thoughts about themselves. When recommending any behavioral lifestyle change, have the patient identify what, when, where, and how the behavioral change will be performed. The patient should keep a record of the anticipated behavioral change so that progress can be reviewed at the next office visit. Because these techniques are time-consuming to implement, they are often provided by ancillary office staff such as a nurse clinician or registered dietitian.

PHARMACOTHERAPY Adjuvant pharmacologic treatments should be considered for patients with a BMI >30 kg/m^2 or with a BMI >27 kg/m^2 who also have concomitant obesity-related diseases and for whom dietary and physical activity therapy has not been successful. When prescribing an antiobesity medication, patients should be actively engaged in a lifestyle program that provides the strategies and skills needed to effectively use the drug since this support increases total weight loss.

There are several potential targets of pharmacologic therapy for obesity. The most thoroughly explored treatment is suppression of appetite via centrally active medications that alter monoamine neurotransmitters. A second strategy is to reduce the absorption of selective macronutrients from the gastrointestinal (GI) tract, such as fat. These two mechanisms form the basis for all currently prescribed antiobesity agents. A third target, selective blocking of the endocannabinoid system, has recently been identified.

Centrally Acting Anorexiant Medications Appetite-suppressing drugs, or anorexiants, affect satiety—the absence of hunger after eating—and hunger—a biologic sensation that initiates eating. By increasing satiety and decreasing hunger, these agents help patients reduce caloric intake without a sense of deprivation. The target site for the actions of anorexiants is the ventromedial and lateral hypothalamic regions in the central nervous system (Chap. 74). Their biological effect on appetite regulation is produced by augmenting the neurotransmission of three monoamines: norepinephrine; serotonin [5-hydroxytryptamine (5-HT)]; and, to a lesser degree, dopamine. The classic sympathomimetic adrenergic agents (benzphetamine, phendimetrazine, diethylpropion, mazindol, and phentermine) function by stimulating norepinephrine release or by blocking its reuptake. In contrast, sibutramine (Meridia) functions as a serotonin and norepinephrine reuptake inhibitor. Unlike other previously used anorexiants, sibutramine is not pharmacologically related to amphetamine and has no addictive potential.

Sibutramine is the only anorexiant that is currently approved by the Food and Drug Administration (FDA) for long-term use. It produces an average loss of about 5–9% of initial body weight at 12 months. Sibutramine has been demonstrated to maintain weight loss for up to 2 years. The most commonly reported adverse events of sibutramine are headache, dry mouth, insomnia, and constipation. These are generally mild and well-tolerated. The principal concern is a dose-related increase in blood pressure and heart rate that may require discontinuation of the medication. A dose of 10–15 mg/d causes an average increase in systolic and diastolic blood pressure of 2–4 mmHg and an increase in heart rate of 4–6 beats/min. For this reason, all patients should be monitored closely and evaluated within 1 month after initiating therapy. The risk of adverse effects on blood pressure are no greater in patients with controlled hypertension than in those who do not have hypertension, and the drug does not appear to cause cardiac valve dysfunction. Contraindications to sibutramine use include uncontrolled hypertension, congestive heart failure, symptomatic coronary heart disease, arrhythmias, or history of stroke. Similar to other antiobesity medications, weight reduction is enhanced when the drug is used along with behavioral therapy, and body weight increases when the medication is discontinued.

Peripherally Acting Medications Orlistat (Xenical) is a synthetic hydrogenated derivative of a naturally occurring lipase inhibitor, lipostatin, produced by the mold *Streptomyces toxytricini*. Orlistat is a potent, slowly reversible inhibitor of pancreatic, gastric, and carboxylester lipases and phospholipase A2, which are required for the hydrolysis of dietary fat into fatty acids and monoacylglycerols. The drug acts in the lumen of the stomach and small intestine by forming a covalent bond with the active site of these lipases. Taken at a therapeutic dose of 120 mg tid, orlistat blocks the digestion and absorption of about 30% of dietary fat. After discontinuation of the drug, fecal fat usually returns to normal concentrations within 48–72 h.

Multiple randomized, 1–2 year double-blind, placebo-controlled studies have shown that after one year, orlistat produces a weight loss of about 9–10%, compared with a 4–6% weight loss in the placebo-treated groups. Because orlistat is minimally (<1%) absorbed from the GI tract, it has no systemic side effects. Tolerability to the drug is related to the malabsorption of dietary fat and subsequent passage of fat in the feces. GI tract adverse effects are reported in at least 10% of orlistat-treated patients. These include flatus with discharge, fecal urgency, fatty/oily stool, and increased defecation. These side effects are generally experienced early, diminish as patients control their dietary fat intake, and infrequently cause patients to withdraw from clinical trials. Psyllium mucilloid is helpful in controlling the orlistat-induced GI side effects when taken concomitantly with the medication. Serum concentrations of the fat-soluble vitamins D and E and β–carotene may be reduced, and vitamin supplements are recommended to prevent potential deficiencies. Orlistat was approved for other-the-counter use in 2007.

The Endocannabinoid System Cannabinoid receptors and their endogenous ligands have been implicated in a variety of physiologic functions, including feeding, modulation of pain, emotional behavior, and peripheral lipid metabolism. Cannabis and its main ingredient, Δ^9-tetrahydrocannabinol (THC), is an exogenous cannabinoid compound. Two endocannabinoids have been identified, anandamide and 2-arachidonyl glyceride. Two cannabinoid receptors have been identified: CB_1 (abundant in the brain) and CB_2 (present in immune cells). The brain endocannabinoid system is thought to control food intake through reinforcing motivation to find and consume foods with high incentive value and to regulate actions of other mediators of appetite. The first selective cannabinoid CB_1 receptor antagonist, rimonabant, was discovered in 1994. The medication antagonizes the orexigenic effect of THC and suppresses appetite when given alone in animal models. Several large prospective, randomized controlled trials have demonstrated the effectiveness of rimonabant as a weight-loss agent. Taken as a 20 mg dose, subjects lost an average of 6.5 kg (14.32 lb) compared to 1.5 kg (3.3 lb) for placebo at 1 year. Concomitant improvements were seen in waist circumference and cardiovascular risk factors. The most common reported side effects include depression, anxiety, and nausea. FDA approval of Rimonabant is still pending.

SURGERY Bariatric surgery can be considered for patients with severe obesity (BMI ≥40 kg/m^2) or those with moderate obesity (BMI ≥35 kg/m^2) associated with a serious medical condition. Surgical weight loss functions by reducing caloric intake and, depending on the procedure, macronutrient absorption.

Weight-loss surgeries fall into one of two categories: restrictive and restrictive-malabsorptive **(Fig. 75-2)**. Restrictive surgeries limit the amount of food the stomach can hold and slow the rate of gastric emptying. The vertical

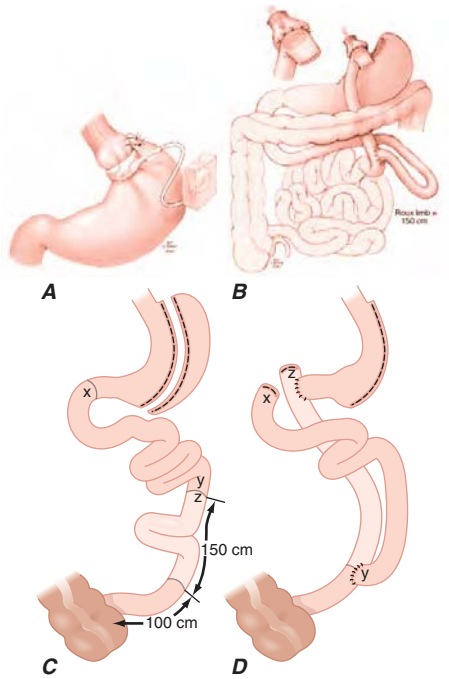

FIGURE 75-2 Bariatric surgical procedures. Examples of operative interventions used for surgical manipulation of the gastrointestinal tract. ***A.*** Laparoscopic gastric band (LAGB). ***B.*** The Roux-en-Y gastric bypass. ***C.*** Biliopancreatic diversion with duodenal switch. ***D.*** Biliopancreatic diversion. *(From ML Kendrick, GF Dakin. Surgical approaches to obesity. Mayo Clin Proc 815:518, 2006; with permission.)*

banded gastroplasty (VBG) is the prototype of this category but is currently performed on a very limited basis due to lack of effectiveness in long-term trials. Laparoscopic adjustable silicone gastric banding (LASGB) has replaced the VBG as the most commonly performed restrictive operation. The first banding device, the lap-band, was approved for use in the United States in 2001. In contrast to previous devices, the diameter of this band is adjustable by way of its connection to a reservoir that is implanted under the skin. Injection or removal of saline into the reservoir tightens or loosens the band's internal diameter, thus changing the size of the gastric opening.

The three restrictive-malabsorptive bypass procedures combine the elements of gastric restriction and selective malabsorption. These procedures include Roux-en-Y gastric bypass (RYGB), biliopancreatic diversion (BPD), and biliopancreatic diversion with duodenal switch (BPDDS) (Fig. 75-2). RYGB is the most commonly performed and accepted bypass procedure. It may be performed with an open incision or laparoscopically.

Although no recent randomized controlled trials compare weight loss after surgical and nonsurgical interventions, data from meta-analyses and large databases, primarily obtained from observational studies, suggest that bariatric surgery is the most effective weight-loss therapy for those with clinically severe obesity. These procedures generally produce a 30–35% average total body weight loss that is maintained in nearly 60% of patients at 5 years. In general, mean weight loss is greater after the combined restrictive-malabsorptive procedures compared to the restrictive procedures. An abundance of data supports the positive impact of bariatric surgery on obesity-related morbid conditions, including diabetes mellitus, hypertension, obstructive sleep apnea, dyslipidemia, and nonalcoholic fatty liver disease.

Surgical mortality from bariatric surgery is generally <1% but varies with the procedure, patient's age and comorbid conditions, and experience of the surgical team. The most common surgical complications include stomal stenosis or marginal ulcers (occurring in 5–15% of patients) that present as prolonged nausea and vomiting after eating or inability to advance the diet to solid foods. These complications are typically treated by endoscopic balloon dilatation and acid suppression therapy, respectively. For patients who undergo LASGB, there are no intestinal absorptive abnormalities other than mechanical reduction in gastric size and outflow. Therefore, selective deficiencies occur uncommonly unless eating habits become unbalanced. In contrast, the restrictive-malabsorptive procedures increase risk for micronutrient deficiencies of vitamin B_{12}, iron, folate, calcium, and vitamin D. Patients with restrictive-malabsorptive procedures require lifelong supplementation with these micronutrients.

76 Eating Disorders

B. Timothy Walsh

Anorexia nervosa and bulimia nervosa are characterized by severe disturbances of eating behavior. The salient feature of *anorexia nervosa* (AN) is a refusal to maintain a minimally normal body weight. *Bulimia nervosa* (BN) is characterized by recurrent episodes of binge eating followed by abnormal compensatory behaviors, such as self-induced vomiting. AN and BN are distinct clinical syndromes but share certain features in common. Both disorders occur primarily among previously healthy young women who become overly concerned with body shape and weight. Many patients with BN have past histories of anorexia nervosa, and many patients with AN engage in binge eating and purging behavior. In the current diagnostic system, the critical distinction between AN and BN depends on body weight: patients with AN are, by definition, significantly underweight, whereas patients with BN have body weights in the normal range or above.

Binge eating disorder (BED) is a more recently described syndrome characterized by repeated episodes of binge eating, similar to those of BN, in the absence of inappropriate compensatory behavior. Patients with BED are typically middle-aged men or women with significant obesity. They have an increased frequency of anxiety and depression compared to similarly obese patients without BED. It is not established that patients with BED are at increased risk for medical complications or that they require specific treatment interventions.

EPIDEMIOLOGY

Among women, the lifetime prevalence of the full syndrome of AN is approximately 1%. AN is much less common in males. AN is more prevalent in cultures where food is plentiful and in which being thin is associated with attractiveness. Individuals who pursue interests that place a premium on thinness, such as ballet and modeling, are at greater risk. The incidence of AN has increased in recent decades.

ETIOLOGY

The etiology of AN is unknown but appears to involve a combination of psychological, biologic, and cultural risk factors. Risk factors, such as sexual or physical abuse and a family history of mood disturbance, are best viewed as nonspecific risk factors that increase vulnerability to a range of psychiatric disorders, including AN.

Patients who develop AN are inclined to be more obsessional and perfectionist than their peers. The disorder often begins as a diet not distinguishable at the outset from those undertaken by many adolescents and young women. As weight loss progresses, the fear of gaining weight grows; dieting becomes stricter; and psychological, behavioral, and medical aberrations increase. Eating disorders, including AN, may develop among individuals with type 1 diabetes mellitus and are associated with poorer glycemic control and an increased frequency of complications (Chap. 338).

Numerous physiologic disturbances, including abnormalities in a variety of neurotransmitter systems, have been described in AN (see below). It is difficult to distinguish neurochemical, metabolic, and hormonal changes that may have a role in the initiation or perpetuation of the syndrome from those that are secondary to the disorder. The resolution of most of these abnormalities with weight restoration argues against an etiologic role.

Genetic factors contribute to the risk of development of AN, as its incidence is greater in families with one affected member and the concordance in monozygotic twins is greater than in dizygotic twins. However, specific genes have not been identified.

CLINICAL FEATURES

AN typically begins in mid to late adolescence, sometimes in association with a stressful life event such as leaving home for school (Table 76-1). The disorder occasionally develops in early puberty, before menarche, but seldom begins after age 40. Despite being underweight, patients with AN are irrationally afraid of gaining weight, often out of a concern that weight gain will get "out of control." They also exhibit a distortion of body image, which may express itself in several ways. For example, despite being emaciated, patients with AN may believe that their body as a whole, or some part of their body, is too fat. Further weight loss is viewed by the patient as a fulfilling accomplishment, while weight gain is seen as a personal failure. Patients with AN rarely complain of hunger or fatigue and often exercise extensively. Despite the denial of hunger, one-quarter to one-half of patients with AN engage in eating binges. Patients tend to become socially withdrawn and increasingly committed to work or study, dieting, and exercise. As weight loss progresses, thoughts of food dominate mental life and idiosyncratic rules develop around eating. Patients with AN may obsessively collect cookbooks and recipes and be drawn to food-related occupations.

Physical Features Patients with AN typically have few physical complaints but may note cold intolerance. Gastrointestinal motility is diminished, leading to reduced gastric emptying and constipation. Some women who develop AN after menarche report that their menses ceased before significant weight loss occurred. Weight and height should be measured to allow calculation of body mass index (BMI; kg/m^2). Vital signs may reveal bradycardia, hypotension, and mild hypothermia. Soft, downy hair growth (lanugo) sometimes occurs, and alopecia may be seen. Salivary gland enlargement, which is associated with starvation as well as with binge eating and vomiting, may make the face appear surprisingly full in contrast to the marked general wasting. Acrocyanosis of the digits is common, and peripheral edema can be seen in the absence of hypoalbuminemia, particularly when the patient begins to regain weight. Consumption of large amounts of vegetables containing vitamin A can result in a yellow tint to the skin (*hypercarotenemia*), which is especially notable on the palms.

Laboratory Abnormalities Mild normochromic, normocytic anemia is frequent, as is mild to moderate leukopenia, with a disproportionate reduction of polymorphonuclear leukocytes. Dehydration may result in slightly increased levels of blood urea nitrogen and creatinine. Serum transaminase levels may increase, especially during the early phases of refeeding. The level of serum proteins is usually normal. Blood sugar is often low and serum cholesterol may be moderately elevated. Hypokalemic alkalosis suggests self-induced vomiting or the use

TABLE 76-1 COMMON CHARACTERISTICS OF ANOREXIA NERVOSA AND BULIMIA NERVOSA

	Anorexia Nervosa[a]	Bulimia Nervosa
Clinical Characteristics		
Onset	Mid-adolescence	Late adolescence/early adulthood
Female:male	10:1	10:1
Lifetime prevalence in women	1%	1–3%
Weight	Markedly decreased	Usually normal
Menstruation	Absent	Usually normal
Binge eating	25–50%	Required for diagnosis
Mortality	~5% per decade	Low
Physical and Laboratory Findings[a]		
Skin/extremities	Lanugo Acrocyanosis Edema	
Cardiovascular	Bradycardia Hypotension

Abbreviations: BUN, blood urea nitrogen; LH, luteinizing hormone; FSH, follicle stimulating hormone; TSH, thyroid stimulating hormone.

of diuretics. Hyponatremia is common and may result from excess fluid intake and disturbances in the secretion of antidiuretic hormone.

Endocrine Abnormalities The regulation of virtually every endocrine system is altered in AN, but the most striking changes occur in the reproductive system. Amenorrhea is hypothalamic in origin and reflects diminished production of gonadotropin-releasing hormone (GnRH). When exogenous GnRH is administered in a pulsatile manner, pituitary responses of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) are normalized, indicating the absence of a primary pituitary abnormality. The resulting gonadotropin deficiency causes low plasma estrogen in women and reduced testosterone in men. The hypothalamic GnRH pulse generator is exquisitely sensitive, particularly in women, to body weight, stress, and exercise, each of which may contribute to *hypothalamic amenorrhea* in AN (Chap. 341).

Serum leptin levels are markedly reduced in AN as a result of undernutrition and decreased body fat mass. The reduction in leptin appears to be the primary factor responsible for the disturbances of the hypothalamic-pituitary-gonadal axis, and to be an important mediator of the other neuroendocrine abnormalities characteristic of AN (Chap. 74).

Serum cortisol and 24-h urine free cortisol levels are generally elevated but without characteristic clinical signs of cortisol excess. Thyroid function tests resemble the pattern seen in euthyroid sick syndrome (Chap. 335). Thyroxine (T_4) and free T_4 levels are usually in the low-normal range, triiodothyronine (T_3) levels are reduced, and reverse T_3 (rT_3) is elevated. The level of thyroid-stimulating hormone (TSH) is normal or partially suppressed. Growth hormone is increased, but insulin-like growth factor 1 (IGF-1), which is produced mainly by the liver, is reduced, as in other conditions of starvation. Diminished bone density is routinely observed in AN and reflects the effects of multiple nutritional deficiencies, reduced gonadal steroids, and increased cortisol. The degree of bone density reduction is proportional to the length of the illness, and patients are at risk for the development of symptomatic fractures. The occurrence of AN during adolescence may lead to the premature cessation of linear bone growth and a failure to achieve expected adult height.

Cardiac Abnormalities Cardiac output is reduced, and congestive heart failure occurs rarely during rapid refeeding. The electrocardiogram usually shows sinus bradycardia, reduced QRS voltage, and nonspecific ST-T-wave abnormalities. Some patients develop a prolonged QT_c interval, which may predispose to serious arrhythmias, particularly when electrolyte abnormalities also are present.

DIAGNOSIS

The diagnosis of AN is based on the presence of characteristic behavioral, psychological, and physical attributes (Table 76-2). Widely accepted diagnostic criteria are provided by the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV). These criteria include weight <85% of that expected for age and height, which is roughly equivalent to a BMI of 18.5 kg/m^2 for adult women. This weight criterion is somewhat arbitrary, so that a patient who meets all other diagnostic criteria but weighs between 85 and 90% of expected would still merit the diagnosis of AN. The current diagnostic criteria require that women with AN not have spontaneous menses, but occasional patients with the characteristics and complications of AN describe regular menstruation. Two mutually exclusive subtypes of AN are specified in DSM-IV. Patients whose weight loss is maintained primarily by caloric restriction, perhaps augmented by excessive exercise, are considered to have the "restricting" subtype of AN. The "binge eating/purging" subtype is characterized by binge eating and self-induced vomiting and/or laxative abuse. Patients with the binge/purge subtype are more prone to develop electrolyte imbalances, are more emotionally labile, and are more likely to have other problems with impulse control, such as drug abuse.

TABLE 76-2 DIAGNOSTIC FEATURES OF ANOREXIA NERVOSA

Refusal to maintain body weight at or above a minimally normal weight for age and height. (This includes a failure to achieve weight gain expected during a period of growth leading to an abnormally low body weight.)
Intense fear of weight gain or becoming fat.
Distortion of body image (e.g., feeling fat despite an objectively low weight or minimizing the seriousness of low weight).
Amenorrhea. (This criterion is met if menstrual periods occur only following hormone—e.g., estrogen—administration.)

The diagnosis of AN can usually be made confidently in a patient with a history of weight loss accomplished by restrictive dieting and excessive exercise, accompanied by a marked reluctance to gain weight. Patients with AN often deny that they have a serious problem and may be brought to medical attention by concerned family or friends. In atypical presentations, other causes of significant weight loss in previously healthy young people should be considered, including inflammatory bowel disease, gastric outlet obstruction, diabetes mellitus, central nervous system (CNS) tumors, or neoplasm (Chap. 41).

PROGNOSIS

The course and outcome of AN are highly variable. One-quarter to one-half of patients eventually recover fully, with few psychological or physical sequelae. However, many patients have persistent difficulties with weight maintenance, depression, and eating disturbances, including BN. The development of obesity following AN is rare. The long-term mortality of AN is among the highest associated with any psychiatric disorder. Approximately 5% of patients die per decade of follow-up, primarily due to the physical effects of chronic starvation or by suicide.

Virtually all of the physiologic abnormalities associated with AN are observed in other forms of starvation and markedly improve or disappear with weight gain. A worrisome exception is the reduction in bone mass, which may not recover fully, particularly when AN occurs during adolescence when peak bone mass is normally achieved.

℞ ANOREXIA NERVOSA

Because of the profound physiologic and psychological effects of starvation, there is a broad consensus that weight restoration to at least 90% of predicted weight is the primary goal in the treatment of AN. Unfortunately, because most patients resist this goal, the management of AN is often accompanied by frustration for the patient, the family, and the physician. Patients typically exaggerate their food intake and minimize their symptoms. Some patients resort to subterfuge to make their weights appear higher, for example, by water-loading before they are weighed. In attempting to engage the patient in treatment, it may be useful for the physician to elicit the patient's physical concerns (e.g., about osteoporosis, weakness, or fertility) and, provide education about the importance of normalizing nutritional status in order to address those concerns. The physician should reassure the patient that weight gain will not be permitted to get "out of control" but simultaneously emphasize that weight restoration is medically and psychologically imperative.

The intensity of the initial treatment, including the need for hospitalization, is determined by the patient's current weight, the rapidity of recent weight loss, and the severity of medical and psychological complications (Fig. 76-1). Hospitalization should be strongly considered for patients weighing <75% of expected, even if the results of routine blood studies are within normal limits. Acute medical problems, such as severe electrolyte imbalances, should be identified and addressed. Nutritional restoration can almost always be successfully accomplished by oral feeding, and parenteral methods are rarely required. For severely underweight patients, sufficient calories (approximately 1200–1800 kcal/d) should be provided initially in divided meals as food or liquid supplements to maintain weight and to permit stabilization of fluid and electrolyte balance. Calories can then be gradually increased to achieve a weight gain of 1–2 kg (2–4 lb) per week, typically requiring an intake of 3000–4000 kcal/d. Meals must be supervised, ideally by personnel who are firm regarding the necessity of food consumption, empathic regarding the challenges entailed, and reassuring about the patient's eventual recovery. Patients have great psychological difficulty complying with the need for increased caloric consumption, and the assistance of psychiatrists or psychologists experienced in the treatment of AN is usually necessary.

Less severely affected patients may be treated in a partial hospitalization program where medical and psychiatric supervision is available and

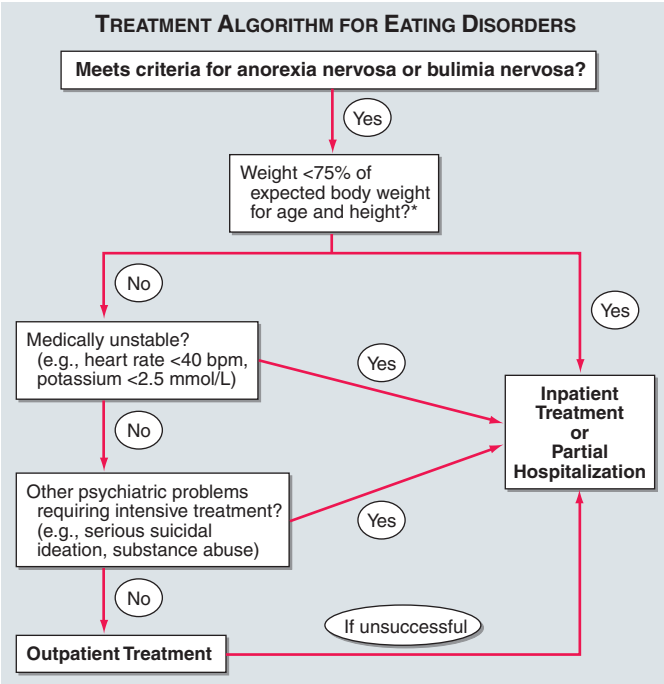

FIGURE 76-1 An algorithm for basic treatment decisions regarding patients with anorexia nervosa or bulimia nervosa. Based on the American Psychiatric Association's practice guidelines for the treatment of patients with eating disorders. *Although outpatient management may be considered for patients with anorexia nervosa weighing more than 75% of expected, there should be a low threshold for using more intensive interventions if the weight loss has been rapid or if current weight is <80% of expected.

several meals can be monitored each day. Outpatient treatment may suffice for mildly ill patients. Weight must be monitored at frequent intervals, and explicit goals agreed on for weight gain, with the understanding that more intensive treatment will be required if the level of care initially employed is not successful. For younger patients, the active involvement of the family in treatment is crucial regardless of the treatment venue.

Psychiatric treatment focuses primarily on two issues. First, patients require much emotional support during the period of weight gain. Patients often intellectually agree with the need to gain weight, but strenuously resist increases in caloric intake, and often surreptitiously discard food that is provided. Second, patients must learn to base their self-esteem not on the achievement of an inappropriately low weight, but on the development of satisfying personal relationships and the attainment of reasonable academic and occupational goals. While this is often possible, some patients with AN develop other serious emotional and behavioral symptoms such as depression, self-mutilation, obsessive-compulsive behavior, and suicidal ideation. These symptoms may require additional therapeutic interventions, in the form of psychotherapy, medication, or hospitalization.

Medical complications occasionally occur during refeeding. Especially in the early stages of treatment, severely malnourished patients may develop a "refeeding syndrome" characterized by hypophosphatemia, hypomagnesemia, and cardiovascular instability. Acute gastric dilatation has been described when refeeding is rapid. As in other forms of malnutrition, fluid retention and peripheral edema may occur, but they generally do not require specific treatment in the absence of cardiac, renal, or hepatic dysfunction. Transient modest elevations in serum liver enzyme levels occasionally occur. Multivitamins should be given, and an adequate intake of vitamin D (400 IU/d) and calcium (1500 mg/d) should be provided to minimize bone loss.

No psychotropic medications are of established value in the treatment of AN; tricyclic antidepressants are contraindicated when there is prolongation of the QT_c interval. The alterations of cortisol and thyroid hormone metabolism do not require specific treatment and are corrected by weight gain. Estrogen treatment appears to have minimal impact on bone density in underweight patients, and the small benefit of bisphosphonate treatment appears to be outweighed by the potential risks of such agents in young women.

BULIMIA NERVOSA

EPIDEMIOLOGY

In women, the full syndrome of BN occurs with a lifetime prevalence of 1–3%. Variants of the disorder, such as occasional binge eating or purging, are much more common and occur in 5–10% of young women. The frequency of BN among men is less than one-tenth of that among women. The prevalence of BN increased dramatically in the early 1970s and 1980s but may have leveled off or declined somewhat in recent years.

ETIOLOGY

As with AN, the etiology of BN is likely to be multifactorial. Patients who develop BN describe a higher-than-expected prevalence of childhood and parental obesity, suggesting that a predisposition toward obesity may increase vulnerability to this eating disorder. The marked increase in the number of cases of BN during the past 25 years and the rarity of BN in underdeveloped countries suggest that cultural factors are important. Several biologic abnormalities in patients with BN may perpetuate this disorder once it has begun. These include abnormalities of CNS serotonergic function, which is involved in eating behavior, and disruption of peripheral satiety mechanisms, including the release of cholecystokinin (CCK) from the small intestine.

CLINICAL FEATURES

The typical patient presenting for treatment of BN is a woman of normal weight in her mid-twenties who reports binge eating and purging 5–10 times a week for 5–10 years (Table 76-3). The disorder usually begins in late adolescence or early adulthood during or following a diet, often in association with depressed mood. The self-imposed caloric restriction leads to increased hunger and to overeating. In an attempt to avoid weight gain, the patient induces vomiting, takes laxatives or diuretics, or engages in some other form of compensatory behavior. During binges, patients with this disorder tend to consume large amounts of sweet foods with a high fat content, such as dessert items. The most frequent compensatory behaviors are self-induced vomiting and laxative abuse, but a wide variety of techniques have been described, including the omission of insulin injections by individuals with type 1 diabetes mellitus. Initially, patients may experience a sense of satisfaction that appealing food can be eaten without weight gain. However, as the disorder progresses, patients perceive diminished control over eating. Binges increase in size and frequency and are provoked by a variety of stimuli, such as transient depression, anxiety, or a sense that too much food has been consumed in a normal meal. Between binges, patients restrict caloric intake, which increases hunger and sets the stage for the next binge. Typically, patients with BN are ashamed of their behavior and endeavor to keep their disorder hidden from family and friends. Like patients with AN, those with BN place an unusual emphasis on weight and shape as a basis for their self-esteem. Many patients with BN have mild symptoms of depression. Some patients exhibit serious mood and behavioral disturbances, such as suicide attempts, sexual promiscuity, and drug and alcohol abuse. Although vomiting may be

TABLE 76-3 DIAGNOSTIC FEATURES OF BULIMIA NERVOSA

Recurrent episodes of binge eating, which is characterized by the consumption of a large amount of food in a short period of time and a feeling that the eating is out of control.
Recurrent inappropriate behavior to compensate for the binge eating, such as self-induced vomiting.
The occurrence of both the binge eating and the inappropriate compensatory behavior at least twice weekly, on average, for 3 months.
Overconcern with body shape and weight.

Note: If the diagnostic criteria for anorexia nervosa are simultaneously met, only the diagnosis of anorexia nervosa is given.

triggered initially by manual stimulation of the gag reflex, most patients with BN develop the ability to induce vomiting at will. Rarely, patients resort to the regular use of syrup of ipecac. Laxatives and diuretics are frequently taken in impressive quantities, such as 30 or 60 laxative pills on a single occasion. The resulting fluid loss produces dehydration and a feeling of emptiness but has little impact on caloric balance.

The physical abnormalities associated with BN primarily result from the purging behavior. Painless bilateral salivary gland hypertrophy (sialadenosis) may be noted. A scar or callus on the dorsum of the hand may develop due to repeated trauma from the teeth among patients who manually stimulate the gag reflex. Recurrent vomiting and the exposure of the lingual surfaces of the teeth to stomach acid lead to loss of dental enamel and eventually to chipping and erosion of the front teeth. Laboratory abnormalities are surprisingly infrequent, but hypokalemia, hypochloremia, and hyponatremia are observed occasionally. Repeated vomiting may lead to alkalosis, whereas repeated laxative abuse may produce a mild metabolic acidosis. Serum amylase may be slightly elevated due to an increase in the salivary isoenzyme.

Serious physical complications resulting from BN are rare. Oligomenorrhea and amenorrhea are more frequent than among women without eating disorders. Arrhythmias occasionally occur secondary to electrolyte disturbances. Tearing of the esophagus and rupture of the stomach have been reported and constitute life-threatening events. Some patients who chronically abuse laxatives or diuretics develop transient peripheral edema when this behavior ceases, presumably due to high levels of aldosterone secondary to persistent fluid and electrolyte depletion.

DIAGNOSIS

The critical diagnostic features of BN are repeated episodes of binge eating followed by inappropriate and abnormal behaviors aimed at avoiding weight gain (Table 76-3). The diagnosis of BN requires a candid history from the patient detailing frequent, large eating binges followed by the purposeful use of inappropriate mechanisms to avoid weight gain. Most patients with BN who present for treatment are distressed by their inability to control their eating behavior but are able to provide such details if queried in a supportive and nonjudgmental fashion.

As in AN, there are two subtypes of BN. Patients with the "purging" subtype utilize compensatory behaviors that directly rid the body of calories or fluids (e.g., self-induced vomiting, laxative, or diuretic abuse), whereas those with the "nonpurging" subtype attempt to compensate for binges by fasting or by excessive exercise. Patients with the nonpurging subtype tend to be heavier and are less prone to fluid and electrolyte disturbances.

PROGNOSIS

The prognosis of BN is much more favorable than that of AN. Mortality is low, and full recovery occurs in approximately 50% of patients within 10 years. Approximately 25% of patients have persistent symptoms of BN over many years. Few patients progress from BN to AN.

Rx BULIMIA NERVOSA

BN can usually be treated on an outpatient basis (Fig. 76-1). Cognitive behavioral therapy (CBT) is a short-term (4–6 months) psychological treatment that focuses on the intense concern with shape and weight, the persistent dieting, and the binge eating and purging that characterize this disorder. Patients are directed to monitor the circumstances, thoughts, and emotions associated with binge/purge episodes, to eat regularly, and to challenge their assumptions linking weight to self-esteem. CBT produces symptomatic remission in 25–50% of patients.

Numerous double-blind, placebo-controlled trials have documented that antidepressant medications are useful in the treatment of BN but are probably somewhat less effective than CBT. Although efficacy has been established for virtually all chemical classes of antidepressants, only the selective serotonin reuptake inhibitor fluoxetine (Prozac) has been approved for use in BN by the U.S. Food and Drug Administration. Antidepressant medications are helpful even for patients with BN who are not depressed, and the dose of fluoxetine recommended for BN (60 mg/d) is higher than that typically used to treat depression. These observations suggest that different mechanisms may underlie the utility of these medications in BN and in depression.

A subset of patients does not respond to CBT, antidepressant medication, or their combination. More intensive forms of treatment, including hospitalization, may be required.

77 Approach to the Patient with Cancer

Dan L. Longo

The application of current treatment techniques (surgery, radiation therapy, chemotherapy, and biological therapy) results in the cure of nearly two of three patients diagnosed with cancer. Nevertheless, patients experience the diagnosis of cancer as one of the most traumatic and revolutionary events that has ever happened to them. Independent of prognosis, the diagnosis brings with it a change in a person's self-image and in his or her role in the home and workplace. The prognosis of a person who has just been found to have pancreatic cancer is the same as the prognosis of the person with aortic stenosis who develops the first symptoms of congestive heart failure (median survival, ~8 months). However, the patient with heart disease may remain functional and maintain a self-image as a fully intact person with just a malfunctioning part, a diseased organ ("a bum ticker"). By contrast, the patient with pancreatic cancer has a completely altered self-image and is viewed differently by family and anyone who knows the diagnosis. He or she is being attacked and invaded by a disease that could be anywhere in the body. Every ache or pain takes on desperate significance. Cancer is an exception to the coordinated interaction among cells and organs. In general, the cells of a multicellular organism are programmed for collaboration. Many diseases occur because the specialized cells fail to perform their assigned task. Cancer takes this malfunction one step further. Not only is there a failure of the cancer cell to maintain its specialized function, but it also strikes out on its own; the cancer cell competes to survive using natural mutability and natural selection to seek advantage over normal cells in a recapitulation of evolution. One consequence of the traitorous behavior of cancer cells is that the patient feels betrayed by his or her body. The cancer patient feels that he or she, and not just a body part, is diseased.

THE MAGNITUDE OF THE PROBLEM

No nationwide cancer registry exists; therefore, the incidence of cancer is estimated on the basis of the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) database, which tabulates cancer incidence and death figures from nine sites, accounting for about 10% of the U.S. population, and from population data from the U.S. Census Bureau. In 2007, 1.445 million new cases of invasive cancer (766,860 men, 678,060 women) were diagnosed and 559,650 persons (289,550 men, 270,100 women) died from cancer. The percent distribution of new cancer cases and cancer deaths by site for men and women are shown in Table 77-1. Cancer incidence has been declining by about 2% each year since 1992.

The most significant risk factor for cancer overall is age; two-thirds of all cases were in those over age 65. Cancer incidence increases as the third, fourth, or fifth power of age in different sites. For the interval between birth and age 39, 1 in 72 men and 1 in 51 women will develop cancer; for the interval between ages 40 and 59, 1 in 12 men and 1 in 11 women will develop cancer; and for the interval between ages 60 and 79, 1 in 3 men and 1 in 5 women will develop cancer. Overall, men have a 45% risk of developing cancer at some time during their lives; women have a 37% lifetime risk.

Cancer is the second leading cause of death behind heart disease. Deaths from heart disease have declined 45% in the United States since 1950 and continue to decline. Cancer has overtaken heart disease as the number one cause of death in persons under age 85 years (Fig. 77-1). After a 70-year period of increases, cancer deaths began to decline in 1997 (Fig. 77-2). The five leading causes of cancer deaths are shown for various populations in Table 77-2. Along with the decrease in incidence has come an increase in survival for cancer patients. The 5-year survival for white patients was 39% in 1960–1963 and 68% in 1996–2002. Cancers are more often deadly in blacks; the 5-year survival was 57% for the 1996–2002 interval. Incidence and mortality vary among racial and ethnic groups (Table 77-3). The basis for these differences is unclear.

CANCER AROUND THE WORLD

In 2002, 11 million new cancer cases and 7 million cancer deaths were estimated worldwide. When broken down by region of the world, ~45% of cases were in Asia, 26% in Europe, 14.5% in North America, 7.1% in Central/South America, 6% in Africa, and 1% in Australia/New Zealand (Fig. 77-3). Lung cancer is the most common cancer and the most common cause of cancer death in the world. Its incidence is highly variable, affecting only 2 per 100,000 African women but as many as 61 per 100,000 North American men. Breast cancer is the second most common cancer worldwide; however, it ranks fifth as a cause of death behind lung, stomach, liver, and colorectal cancer. Among the eight most common forms of cancer, lung (2-fold), breast (3-fold), prostate (2.5-fold), and colorectal (3-fold) cancers are more common in more developed countries than in less developed countries. By contrast, liver (2-fold), cervical (2-fold), and esophageal (2- to 3-fold) cancers are more common in less developed

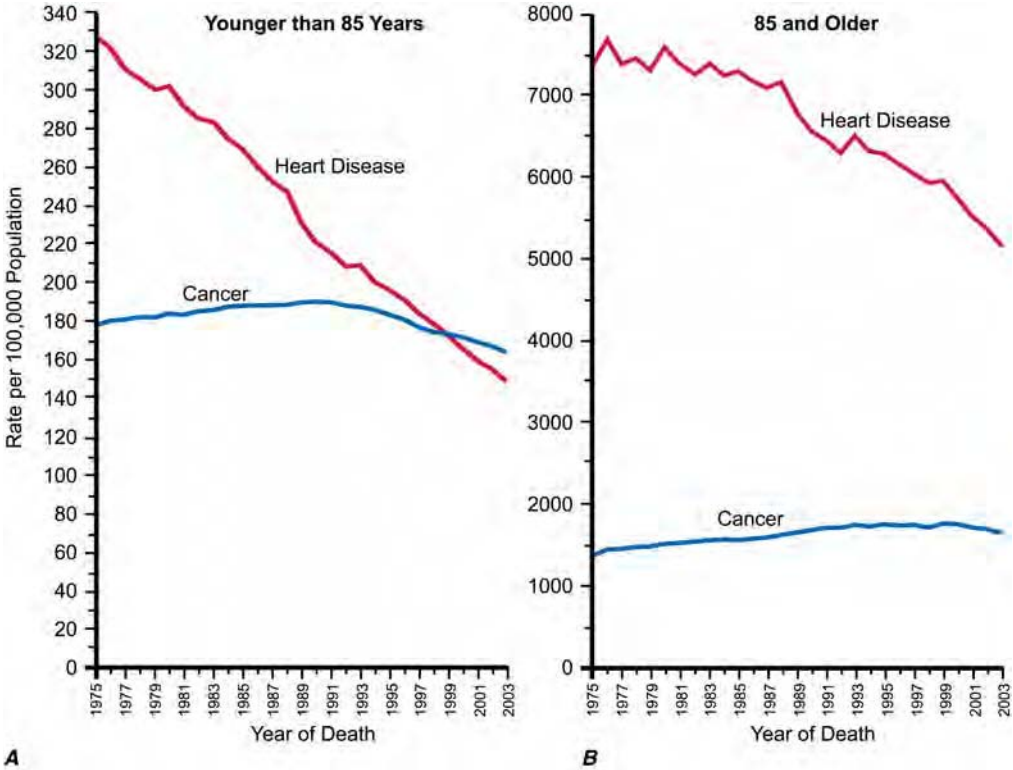

FIGURE 77-1 Death rates for heart disease and cancer among people younger and older than age 85. ***A.*** In people younger than 85 years, cancer has overtaken heart disease as the largest cause of death. ***B.*** In people over 85 years, heart disease is by far the major cause of death. *(From Jemal et al.)*

countries. Stomach cancer incidence is similar in more and less developed countries but is much more common in Asia than North America or Africa. The most common cancers in Africa are cervical, breast, and liver cancers. It has been estimated that nine modifiable risk factors are responsible for more than one-third of cancers worldwide. These include smoking, alcohol consumption, obesity, physical inactivity, low fruit and vegetable consumption, unsafe sex, air pollution, indoor smoke from household fuels, and contaminated injections.

PATIENT MANAGEMENT

Important information is obtained from every portion of the routine history and physical examination. The duration of symptoms may reveal the chronicity of disease. The past medical history may alert the physician to the presence of underlying diseases that may affect the choice of therapy or the side effects of treatment. The social history may reveal occupational exposure to carcinogens or habits, such as smoking or alcohol consumption, that may influence the course of disease and its treatment. The family history may suggest an underlying familial cancer predisposition and point out the need to begin surveillance or other preventive therapy for unaffected siblings of the patient. The review of systems may suggest early symptoms of metastatic disease or a paraneoplastic syndrome.

DIAGNOSIS

The diagnosis of cancer relies most heavily on invasive tissue biopsy and should never be made without obtaining tissue; no noninvasive diagnostic test is sufficient to define a disease process as cancer. Although in rare clinical settings (e.g., thyroid nodules) fine-needle aspiration is an acceptable diagnostic procedure, the diagnosis generally depends on obtaining adequate tissue to permit careful evaluation of the histology of the tumor, its grade, and its invasiveness and to yield further molecular diagnostic information, such as the expression of cell-surface markers or intracellular proteins that typify a particular cancer, or the presence of a molecular marker, such as the t(8;14) translocation of Burkitt's lymphoma. Increasing evidence links the expression of certain genes with the prognosis and response to therapy (Chaps. 79, 80).

Occasionally a patient will present with a metastatic disease process that is defined as cancer on biopsy but has no apparent primary site of disease. Efforts should be made to define the primary site based on age, sex, sites of involvement, histology and tumor markers, and personal and family history. Particular attention should be focused on ruling out the most treatable causes (Chap. 95).

Once the diagnosis of cancer is made, the management of the patient is best undertaken as a multidisciplinary collaboration among the primary care physician, medical oncologists, surgical oncologists, radiation oncologists, oncology nurse specialists, pharmacists, social workers, rehabilitation medicine specialists, and a number of other consulting professionals working closely with each other and with the patient and family.

DEFINING THE EXTENT OF DISEASE AND THE PROGNOSIS

The first priority in patient management after the diagnosis of cancer is established and shared with the patient is to determine the extent of disease. The curability of a tumor usually is inversely proportional to the tumor burden. Ideally, the tumor will be diagnosed before symptoms develop or as a consequence of screening efforts (Chap. 78). A very high proportion of such patients can be cured. However, most patients with cancer present with symptoms related to the cancer, caused either by mass effects of the tumor or by alterations associated with the production of cytokines or hormones by the tumor.

For most cancers, the extent of disease is evaluated by a variety of noninvasive and invasive diagnostic tests and procedures. This process is called *staging*. There are two types. *Clinical staging* is based on physical examination, radiographs, isotopic scans, CT scans, and other imaging procedures; *pathologic staging* takes into account information obtained during a surgical procedure, which might include intraoperative palpation, resection of regional lymph nodes and/or tissue adjacent to the tumor, and inspection and biopsy of organs commonly involved in disease spread. Pathologic staging includes histologic examination of all tissues removed during the surgical procedure. Surgical procedures performed may include a simple lymph node biopsy or more extensive procedures such as thoracotomy, mediastinoscopy, or laparotomy. Surgical staging may occur in a separate procedure or may be done at the time of definitive surgical resection of the primary tumor.

Knowledge of the predilection of particular tumors for spread to adjacent or distant organs helps direct the staging evaluation.

Information obtained from staging is used to define the extent of disease either as localized, as exhibiting spread outside of the organ of origin to regional but not distant sites, or as metastatic to distant sites. The most widely used system of staging is the TNM (tumor, node, metastasis) system codified by the International Union Against Cancer and the American Joint Committee on Cancer (AJCC). The TNM classification is an anatomically based system that categorizes the tumor on the basis of the size of the primary tumor lesion (T1–4, where a higher number indicates a tumor of larger size), the presence of nodal involvement (usually N0 and N1 for the absence and presence, respectively, of involved nodes, although some tumors have more elaborate

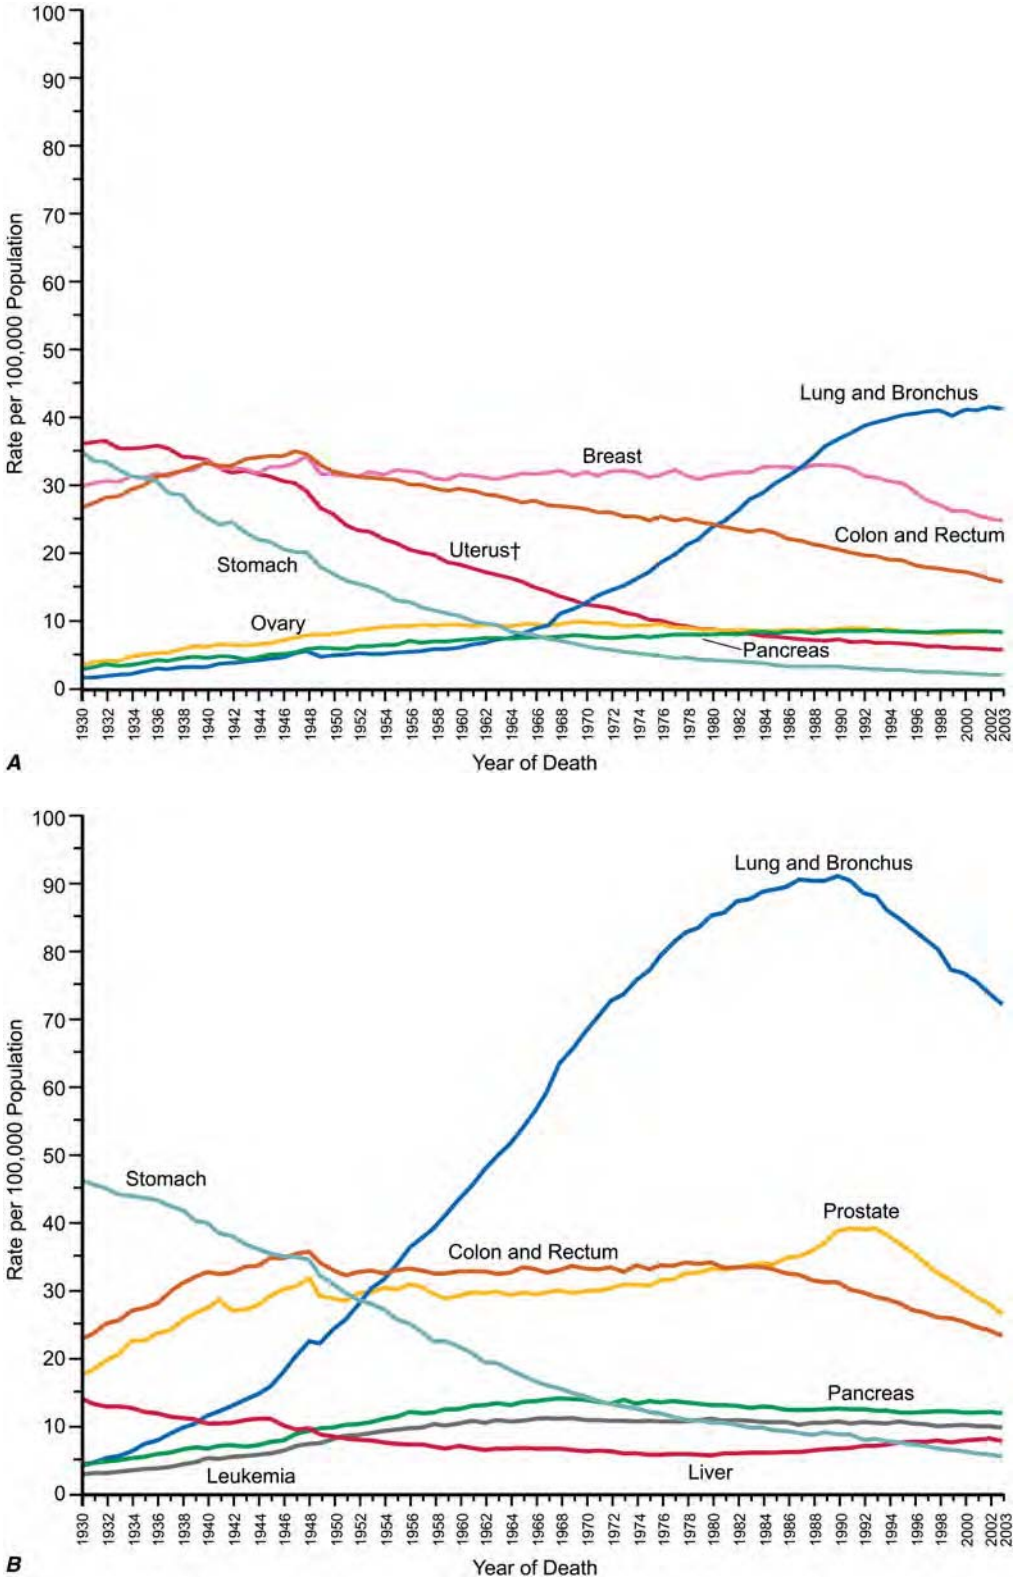

FIGURE 77-2 Sixty-year trend in cancer death rates for (***A***) women and (***B***) men, by site in the United States, 1930–2003. Rates are per 100,000 age-adjusted to the 2000 U.S. standard population. (*From Jemal et al.*)

systems of nodal grading), and the presence of metastatic disease (M0 and M1 for the absence and presence, respectively, of metastases). The various permutations of T, N, and M scores (sometimes including tumor histologic grade G) are then broken into stages, usually designated by the roman numerals I through IV. Tumor burden increases and curability decreases with increasing stage. Other anatomic staging systems are used for some tumors, e.g., the Dukes classification for colorectal cancers, the International Federation of Gynecologists and Obstetricians (FIGO) classification for gynecologic cancers, and the Ann Arbor classification for Hodgkin's disease.[1]

Certain tumors cannot be grouped on the basis of anatomic considerations. For example, hematopoietic tumors such as leukemia, myeloma, and lymphoma are often disseminated at presentation and do not spread like solid tumors. For these tumors, other prognostic factors have been identified (Chaps. 104–106).

In addition to tumor burden, a second major determinant of treatment outcome is the physiologic reserve of the patient. Patients who are bedridden before developing cancer are likely to fare worse, stage for stage, than fully active patients. Physiologic reserve is a determinant of how a patient is likely to cope with the physiologic stresses imposed by the cancer and its treatment. This factor is difficult to assess directly. Instead, surrogate markers for physiologic reserve are used, such as the patient's age or Karnofsky performance status (Table 77-4). Older patients and those with a Karnofsky performance status <70 have a poor prognosis unless the poor performance is a reversible consequence of the tumor.

Increasingly, biologic features of the tumor are being related to prognosis. The expression of particular oncogenes, drug-resistance genes, apoptosis-related genes, and genes involved in metastasis are being found to influence response to therapy and prognosis. The presence of selected cytogenetic abnormalities may influence survival. Tumors with higher growth fractions, as assessed by expression of proliferation-related markers such as proliferating cell nuclear antigen (PCNA), behave more aggressively than tumors with lower growth fractions. Information obtained from studying the tumor itself will increasingly be used to influence treatment decisions. Host genes involved in drug metabolism can influence the safety and efficacy of particular treatments.

MAKING A TREATMENT PLAN

From information on the extent of disease and the prognosis and in conjunction with the patient's wishes, it is determined whether the treatment approach should be curative or palliative in intent. Cooperation among the various professionals involved in cancer treat-

[1]The AJCC *Manual for Staging Cancer*, 5th edition, can be obtained from the AJCC at 55 East Erie Street, Chicago, IL, 60611.

TABLE 77-2 THE FIVE LEADING PRIMARY TUMOR SITES FOR PATIENTS DYING OF CANCER BASED ON AGE AND SEX IN 2004

Rank		All Ages	Age, years: Under 20	20–39	40–59	60–79	>80
1	M	Lung	Leukemia	Leukemia	Lung	Lung	Lung

ment is of the utmost importance in treatment planning. For some cancers, chemotherapy or chemotherapy plus radiation therapy delivered before the use of definitive surgical treatment (so-called neoadjuvant therapy) may improve the outcome, as seems to be the case for locally advanced breast cancer and head and neck cancers. In certain settings in which combined modality therapy is intended, coordination among the medical oncologist, radiation oncologist, and surgeon is crucial to achieving optimal results. Sometimes the chemotherapy and radiation therapy need to be delivered sequentially, and other times concurrently. Surgical procedures may precede or follow other treatment approaches. It is best for the treatment plan either to follow a standard protocol precisely or else to be part of an ongoing clinical research protocol evaluating new treatments. Ad hoc modifications of standard protocols are likely to compromise treatment results.

The choice of treatment approaches was formerly dominated by the local culture in both the university and the practice settings. However, it is now possible to gain access electronically to standard treatment protocols and to every approved clinical research study in North America through a personal computer interface with the Internet.[2]

The skilled physician also has much to offer the patient for whom curative therapy is no longer an option. Often a combination of guilt and frustration over the inability to cure the patient and the pressure of a busy schedule greatly limit the time a physician spends with a patient who is receiving only palliative care. Resist these forces. In addition to the medicines administered to alleviate symptoms (see below), it is important to remember the comfort that is provided by holding the patient's hand, continuing regular examinations, and taking time to talk.

MANAGEMENT OF DISEASE AND TREATMENT COMPLICATIONS

Because cancer therapies are toxic (Chap. 81), patient management involves addressing complications of both the disease and its treatment as well as the complex psychosocial problems associated with cancer. In the short term during a course of curative therapy, the patient's functional status may decline. Treatment-induced toxicity is less acceptable if the goal of therapy is palliation. The most common side effects of treatment are nausea and vomiting (see below), febrile neutropenia (Chap. 82), and myelosuppression (Chap. 81). Tools are now available to minimize the acute toxicity of cancer treatment.

New symptoms developing in the course of cancer treatment should always be assumed to be reversible until proven otherwise. The fatalistic attribution of anorexia, weight loss, and jaundice to recurrent or progressive tumor could result in a patient dying from a reversible intercurrent cholecystitis. Intestinal obstruction may be due to reversible adhesions rather than progressive tumor. Systemic infections, sometimes with unusual pathogens, may be a consequence of the immunosuppression associated with cancer therapy. Some drugs used to treat cancer or its complications (e.g., nausea) may produce central nervous system symptoms that look like metastatic disease or may mimic paraneoplastic syndromes such as the syndrome of inappropriate antidiuretic hormone. A definitive diagnosis should be pursued and may even require a repeat biopsy.

A critical component of cancer management is assessing the response to treatment. In addition to a careful physical examination in which all sites of disease are physically measured and recorded in a flow chart by date, response assessment usually requires periodic repeating of imaging

[2]The National Cancer Institute maintains a database called PDQ (Physician Data Query) that is accessible on the Internet under the name CancerNet at *wwwicic.nci.nih.gov/health.htm*. Information can be obtained through a facsimile machine using CancerFax by dialing 301-402-5874. Patient information is also provided by the National Cancer Institute in at least three formats: on the Internet via CancerNet at *wwwicic.nci.nih.gov/patient.htm*, through the CancerFax number listed above, or by calling 1-800-4-CANCER. The quality control for the information provided through these services is rigorous.

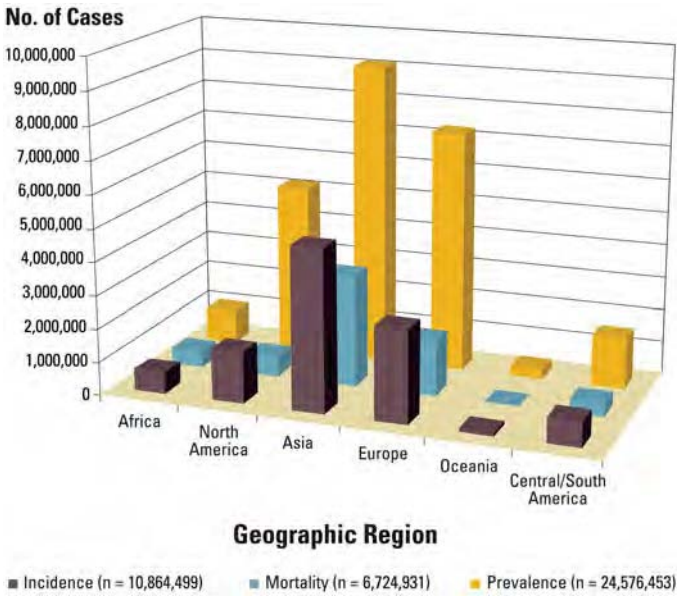

FIGURE 77-3 Worldwide overall annual cancer incidence, mortality and 5-year prevalence for the period of 1993–2001. (*From Kamangar et al.*)

tests that were abnormal at the time of staging. If imaging tests have become normal, repeat biopsy of previously involved tissue is performed to document complete response by pathologic criteria. Biopsies are not usually required if there is macroscopic residual disease. A *complete response* is defined as disappearance of all evidence of disease, and a *partial response* as >50% reduction in the sum of the products of the perpendicular diameters of all measurable lesions. The determination of partial response may also be based on a 30% decrease in the sums of the longest diameters of lesions (Response Evaluation Criteria in Solid Tumors, or RECIST, criteria). *Progressive disease* is defined as the appearance of any new lesion or an increase of >25% in the sum of the products of the perpendicular diameters of all measurable lesions (or an increase of 20% in the sums of the longest diameters by RECIST). Tumor shrinkage or growth that does not meet any of these criteria is considered *stable disease*. Some sites of involvement (e.g., bone) or patterns of involvement (e.g., lymphangitic lung or diffuse pulmonary infiltrates) are considered unmeasurable. No response is complete without biopsy documentation of their resolution, but partial responses may exclude their assessment unless clear objective progression has occurred.

Tumor markers may be useful in patient management in certain tumors. Response to therapy may be difficult to gauge with certainty. However, some tumors produce or elicit the production of markers that can be measured in the serum or urine and, in a particular patient, rising and falling levels of the marker are usually associated with increasing or decreasing tumor burden, respectively. Some clinically useful tumor markers are shown in Table 77-5. Tumor markers are not in themselves specific enough to permit a diagnosis of malignancy to be made, but once a malignancy has been diagnosed and shown to be associated with elevated levels of a tumor marker, the marker can be used to assess response to treatment.

TABLE 77-4 KARNOFSKY PERFORMANCE INDEX

Performance Status	Functional Capability of the Patient
100	Normal; no complaints; no evidence of disease
90	Able to carry on normal activity; minor signs or symptoms of disease
80	Normal activity with effort; some signs or symptoms of disease
70	Cares for self; unable to carry on normal activity or do active work
60	Requires occasional assistance but is able to care for most needs
50	Requires considerable assistance and frequent medical care
40	Disabled; requires special care and assistance
30	Severely disabled; hospitalization is indicated although death is not imminent
20	Very sick; hospitalization necessary; active supportive treatment is necessary
10	Moribund, fatal processes progressing rapidly
0	Dead

The recognition and treatment of depression are important components of management. The incidence of depression in cancer patients is ~25% overall and may be greater in patients with greater debility. This diagnosis is likely in a patient with a depressed mood (dysphoria) and/or a loss of interest in pleasure (anhedonia) for at least 2 weeks. In addition, three or more of the following symptoms are usually present: appetite change, sleep problems, psychomotor retardation or agitation, fatigue, feelings of guilt or worthlessness, inability to concentrate, and suicidal ideation. Patients with these symptoms should receive therapy. Medical therapy with a serotonin reuptake inhibitor such as fluoxetine (10–20 mg/d), sertraline (50–150 mg/d), or paroxetine (10–20 mg/d) or a tricyclic antidepressant such as amitriptyline (50–100 mg/d) or desipramine

TABLE 77-5 TUMOR MARKERS

Tumor Markers	Cancer	Non-Neoplastic Conditions
Hormones		
Human chorionic gonadotropin	Gestational trophoblastic disease, gonadal germ cell tumor	Pregnancy
Calcitonin	Medullary cancer of the thyroid	
Catecholamines	Pheochromocytoma	
Oncofetal Antigens		
Alphafetoprotein	Hepatocellular carcinoma, gonadal germ cell tumor	Cirrhosis, hepatitis
Carcinoembryonic antigen	Adenocarcinomas of the colon, pancreas, lung, breast, ovary	Pancreatitis, hepatitis, inflammatory bowel disease, smoking
Enzymes		
Prostatic acid phosphatase	Prostate cancer	Prostatitis, prostatic hypertrophy
Neuron-specific enolase	Small cell cancer of the lung, neuroblastoma	
Lactate dehydrogenase	Lymphoma, Ewing's sarcoma	Hepatitis, hemolytic anemia, many others
Tumor-Associated Proteins		
Prostate-specific antigen	Prostate cancer	Prostatitis, prostatic hypertrophy
Monoclonal immunoglobulin	Myeloma	Infection, MGUS[a]
CA-125	Ovarian cancer, some lymphomas	Menstruation, peritonitis, pregnancy
CA 19-9	Colon, pancreatic, breast cancer	Pancreatitis, ulcerative colitis
CD30	Hodgkin's disease, anaplastic large cell lymphoma	—
CD25	Hairy cell leukemia, adult T cell leukemia/lymphoma	—

[a]MGUS, monoclonal gammopathy of uncertain significance.

(75–150 mg/d) should be tried, allowing 4–6 weeks for response. Effective therapy should be continued at least 6 months after resolution of symptoms. If therapy is unsuccessful, other classes of antidepressants may be used. In addition to medication, psychosocial interventions such as support groups, psychotherapy, and guided imagery may be of benefit.

Many patients opt for unproven or unsound approaches to treatment when it appears that conventional medicine is unlikely to be curative. Those seeking such alternatives are often well educated and may be early in the course of their disease. Unsound approaches are usually hawked on the basis of unsubstantiated anecdotes and not only cannot help the patient but may be harmful. Physicians should strive to keep communications open and nonjudgmental, so that patients are more likely to discuss with the physician what they are actually doing. The appearance of unexpected toxicity may be an indication that a supplemental therapy is being taken.[3]

LONG-TERM FOLLOW-UP/LATE COMPLICATIONS

At the completion of treatment, sites originally involved with tumor are reassessed, usually by radiography or imaging techniques, and any persistent abnormality is biopsied. If disease persists, the multidisciplinary team discusses a new salvage treatment plan. If the patient has been rendered disease-free by the original treatment, the patient is followed regularly for disease recurrence. The optimal guidelines for follow-up care are not known. For many years, a routine practice has been to follow the patient monthly for 6–12 months, then every other month for a year, every 3 months for a year, every 4 months for a year, every 6 months for a year, and then annually. At each visit, a battery of laboratory and radiographic and imaging tests were obtained on the assumption that it is best to detect recurrent disease before it becomes symptomatic. However, where follow-up procedures have been examined, this assumption has been found to be untrue. Studies of breast cancer, melanoma, lung cancer, colon cancer, and lymphoma have all failed to support the notion that asymptomatic relapses are more readily cured by salvage therapy than symptomatic relapses. In view of the enormous cost of a full battery of diagnostic tests and their manifest lack of impact on survival, new guidelines are emerging for less frequent follow-up visits, during which the history and physical examination are the major investigations performed.

As time passes, the likelihood of recurrence of the primary cancer diminishes. For many types of cancer, survival for 5 years without recurrence is tantamount to cure. However, important medical problems can occur in patients treated for cancer and must be examined (**Chap. e13**). Some problems emerge as a consequence of the disease and some as a consequence of the treatment. An understanding of these disease- and treatment-related problems may help in their detection and management.

Despite these concerns, most patients who are cured of cancer return to normal lives.

SUPPORTIVE CARE

In many ways, the success of cancer therapy depends on the success of the supportive care. Failure to control the symptoms of cancer and its treatment may lead patients to abandon curative therapy. Of equal importance, supportive care is a major determinant of quality of life. Even when life cannot be prolonged, the physician must strive to preserve its quality. Quality-of-life measurements have become common endpoints of clinical research studies. Furthermore, palliative care has been shown to be cost-effective when approached in an organized fashion. A credo for oncology could be to cure sometimes, to extend life often, and to comfort always.

Pain Pain occurs with variable frequency in the cancer patient: 25–50% of patients present with pain at diagnosis, 33% have pain associated with treatment, and 75% have pain with progressive disease. The pain may have several causes. In ~70% of cases, pain is caused by the tumor itself—by invasion of bone, nerves, blood vessels, or mucous membranes or obstruction of a hollow viscus or duct. In ~20% of cases, pain is related to a surgical or invasive medical procedure, to radiation injury (mucositis, enteritis, or plexus or spinal cord injury), or to chemotherapy injury (mucositis, peripheral neuropathy, phlebitis, steroid-induced aseptic necrosis of the femoral head). In 10% of cases, pain is unrelated to cancer or its treatment.

Assessment of pain requires the methodical investigation of the history of the pain, its location, character, temporal features, provocative and palliative factors, and intensity (Chap. 12); a review of the oncologic history and past medical history as well as personal and social history; and a thorough physical examination. The patient should be given a 10-division visual analogue scale on which to indicate the severity of the pain. The clinical condition is often dynamic, making it necessary to reassess the patient frequently. Pain therapy should not be withheld while the cause of pain is being sought.

A variety of tools are available with which to address cancer pain. About 85% of patients will have pain relief from pharmacologic intervention. However, other modalities, including antitumor therapy (such as surgical relief of obstruction, radiation therapy, and strontium-89 or samarium-153 treatment for bone pain), neurostimulatory techniques, regional analgesia, or neuroablative procedures are effective in an additional 12% or so. Thus, very few patients will have inadequate pain relief if appropriate measures are taken. **A specific approach to pain relief is detailed in Chap. 11.**

Nausea Emesis in the cancer patient is usually caused by chemotherapy (Chap. 81). Its severity can be predicted from the drugs used to treat the cancer. Three forms of emesis are recognized on the basis of their timing with regard to the noxious insult. *Acute emesis*, the most common variety, occurs within 24 h of treatment. *Delayed emesis* occurs 1–7 days after treatment; it is rare, but, when present, usually follows cisplatin administration. *Anticipatory emesis* occurs before administration of chemotherapy and represents a conditioned response to visual and olfactory stimuli previously associated with chemotherapy delivery.

Acute emesis is the best understood form. Stimuli that activate signals in the chemoreceptor trigger zone in the medulla, the cerebral cortex, and peripherally in the intestinal tract lead to stimulation of the vomiting center in the medulla, the motor center responsible for coordinating the secretory and muscle contraction activity that leads to emesis. Diverse receptor types participate in the process, including dopamine, serotonin, histamine, opioid, and acetylcholine receptors. The serotonin receptor antagonists ondansetron and granisetron are the most effective drugs against highly emetogenic agents, but they are expensive.

As with the analgesia ladder, emesis therapy should be tailored to the situation. For mildly and moderately emetogenic agents, prochlorperazine, 5–10 mg PO or 25 mg PR, is effective. Its efficacy may be enhanced by administering the drug before the chemotherapy is delivered. Dexamethasone, 10–20 mg IV, is also effective and may enhance the efficacy of prochlorperazine. For highly emetogenic agents such as cisplatin, mechlorethamine, dacarbazine, and streptozocin, combinations of agents work best and administration should begin 6–24 h before treatment. Ondansetron, 8 mg PO every 6 h the day before therapy and IV on the day of therapy, plus dexamethasone, 20 mg IV before treatment, is an effective regimen. Addition of oral aprepitant (a substance P/neurokinin 1 receptor antagonist) to this regimen (125 mg on day 1, 80 mg on days 2 and 3) further decreases the risk of both acute and delayed vomiting. Like pain, emesis is easier to prevent than to alleviate.

Delayed emesis may be related to bowel inflammation from the therapy and can be controlled with oral dexamethasone and oral metoclopramide, a dopamine receptor antagonist that also blocks serotonin receptors at high dosages. The best strategy for preventing anticipatory emesis is to control emesis in the early cycles of therapy to prevent the conditioning from taking place. If this is unsuccessful, pro-

[3]Information about unsound methods may be obtained from the National Council Against Health Fraud, Box 1276, Loma Linda, CA 92354, or from the Center for Medical Consumers and Health Care Information, 237 Thompson Street, New York, NY 10012.

phylactic antiemetics the day before treatment may help. Experimental studies are evaluating behavior modification.

Effusions Fluid may accumulate abnormally in the pleural cavity, pericardium, or peritoneum. Asymptomatic malignant effusions may not require treatment. Symptomatic effusions occurring in tumors responsive to systemic therapy usually do not require local treatment but respond to the treatment for the underlying tumor. Symptomatic effusions occurring in tumors unresponsive to systemic therapy may require local treatment in patients with a life expectancy of at least 6 months.

Pleural effusions due to tumors may or may not contain malignant cells. Lung cancer, breast cancer, and lymphomas account for ~75% of malignant pleural effusions. Their exudative nature is usually gauged by an effusion/serum protein ratio of ≥0.5 or an effusion/serum lactate dehydrogenase ratio of ≥0.6. When the condition is symptomatic, thoracentesis is usually performed first. In most cases, symptomatic improvement occurs for <1 month. Chest tube drainage is required if symptoms recur within 2 weeks. Fluid is aspirated until the flow rate is <100 mL in 24 h. Then either 60 units of bleomycin or 1 g of doxycycline is infused into the chest tube in 50 mL of 5% dextrose in water; the tube is clamped; the patient is rotated on four sides, spending 15 min in each position; and, after 1–2 h, the tube is again attached to suction for another 24 h. The tube is then disconnected from suction and allowed to drain by gravity. If <100 mL drains over the next 24 h, the chest tube is pulled, and a radiograph taken 24 h later. If the chest tube continues to drain fluid at an unacceptably high rate, sclerosis can be repeated. Bleomycin may be somewhat more effective than doxycycline but is very expensive. Doxycycline is usually the drug of first choice. If neither doxycycline nor bleomycin is effective, talc can be used.

Symptomatic pericardial effusions are usually treated by creating a pericardial window or by stripping the pericardium. If the patient's condition does not permit a surgical procedure, sclerosis can be attempted with doxycycline and/or bleomycin.

Malignant ascites is usually treated with repeated paracentesis of small volumes of fluid. If the underlying malignancy is unresponsive to systemic therapy, peritoneovenous shunts may be inserted. Despite the fear of disseminating tumor cells into the circulation, widespread metastases are an unusual complication. The major complications are occlusion, leakage, and fluid overload. Patients with severe liver disease may develop disseminated intravascular coagulation.

Nutrition Cancer and its treatment may lead to a decrease in nutrient intake of sufficient magnitude to cause weight loss and alteration of intermediary metabolism. The prevalence of this problem is difficult to estimate because of variations in the definition of cancer cachexia, but most patients with advanced cancer experience weight loss and decreased appetite. A variety of both tumor-derived factors (e.g., bombesin, adrenocorticotropic hormone) and host-derived factors (e.g., tumor necrosis factor, interleukins 1 and 6, growth hormone) contribute to the altered metabolism, and a vicious cycle is established in which protein catabolism, glucose intolerance, and lipolysis cannot be reversed by the provision of calories.

It remains controversial how to assess nutritional status and when and how to intervene. Efforts to make the assessment objective have included the use of a prognostic nutritional index based on albumin levels, triceps skin fold thickness, transferrin levels, and delayed-type hypersensitivity skin testing. However, a simpler approach has been to define the threshold for nutritional intervention as >10% unexplained body weight loss, serum transferrin level <1500 mg/L (150 mg/dL), and serum albumin <34 g/L (3.4 g/dL).

The decision is important, because it appears that cancer therapy is substantially more toxic and less effective in the face of malnutrition. Nevertheless, it remains unclear whether nutritional intervention can alter the natural history. Unless some pathology is affecting the absorptive function of the gastrointestinal tract, enteral nutrition provided orally or by tube feeding is preferred over parenteral supplementation. However, the risks associated with the tube may outweigh the benefits. Megestrol acetate, a progestational agent, has been advocated as a pharmacologic intervention to improve nutritional status. Research in this area may provide more tools in the future as cytokine-mediated mechanisms are further elucidated.

Psychosocial Support The psychosocial needs of patients vary with their situation. Patients undergoing treatment experience fear, anxiety, and depression. Self-image is often seriously compromised by deforming surgery and loss of hair. Women who receive cosmetic advice that enables them to look better also feel better. Loss of control over how one spends time can contribute to the sense of vulnerability. Juggling the demands of work and family with the demands of treatment may create enormous stresses. Sexual dysfunction is highly prevalent and needs to be discussed openly with the patient. An empathetic health care team is sensitive to the individual patient's needs and permits negotiation where such flexibility will not adversely affect the course of treatment.

Cancer survivors have other sets of difficulties. Patients may have fears associated with the termination of a treatment they associate with their continued survival. Adjustments are required to physical losses and handicaps, real and perceived. Patients may be preoccupied with minor physical problems. They perceive a decline in their job mobility and view themselves as less desirable workers. They may be victims of job and/or insurance discrimination. Patients may experience difficulty reentering their normal past life. They may feel guilty for having survived and may carry a sense of vulnerability to colds and other illnesses. Perhaps the most pervasive and threatening concern is the ever-present fear of relapse (the Damocles syndrome).

Patients in whom therapy has been unsuccessful have other problems related to the end of life.

Death and Dying The most common causes of death in patients with cancer are infection (leading to circulatory failure), respiratory failure, hepatic failure, and renal failure. Intestinal blockage may lead to inanition and starvation. Central nervous system disease may lead to seizures, coma, and central hypoventilation. About 70% of patients develop dyspnea preterminally. However, many months usually pass between the diagnosis of cancer and the occurrence of these complications, and during this period the patient is severely affected by the possibility of death. The path of unsuccessful cancer treatment usually occurs in three phases. First, there is optimism at the hope of cure; when the tumor recurs, there is the acknowledgment of an incurable disease, and the goal of palliative therapy is embraced in the hope of being able to live with disease; finally, at the disclosure of imminent death, another adjustment in outlook takes place. The patient imagines the worst in preparation for the end of life and may go through stages of adjustment to the diagnosis. These stages include denial, isolation, anger, bargaining, depression, acceptance, and hope. Of course, patients do not all progress through all the stages or proceed through them in the same order or at the same rate. Nevertheless, developing an understanding of how the patient has been affected by the diagnosis and is coping with it is an important goal of patient management.

It is best to speak frankly with the patient and the family regarding the likely course of disease. These discussions can be difficult for the physician as well as for the patient and family. The critical features of the interaction are to reassure the patient and family that everything that can be done to provide comfort will be done. They will not be abandoned. Many patients prefer to be cared for in their homes or in a hospice setting rather than a hospital. The American College of Physicians has published a book called *Home Care Guide for Cancer: How to Care for Family and Friends at Home* that teaches an approach to successful problem-solving in home care. With appropriate planning, it should be possible to provide the patient with the necessary medical care as well as the psychological and spiritual support that will prevent the isolation and depersonalization that can attend in-hospital death.

The care of dying patients may take a toll on the physician. A "burnout" syndrome has been described that is characterized by fatigue, disengagement from patients and colleagues, and a loss of self-fulfillment. Efforts at stress reduction, maintenance of a balanced life, and setting realistic goals may combat this disorder.

End-of-Life Decisions Unfortunately, a smooth transition in treatment goals from curative to palliative may not be possible in all cases because of the occurrence of serious treatment-related complications or rapid disease progression. Vigorous and invasive medical support for a reversible disease or treatment complication is assumed to be justified. However, if the reversibility of the condition is in doubt, the patient's wishes determine the level of medical care. These wishes should be elicited before the terminal phase of illness and reviewed periodically. Information about advance directives can be obtained from the American Association of Retired Persons, 601 E Street, NW, Washington, DC 20049, 202-434-2277 or Choice in Dying, 250 West 57th Street, New York, NY 10107, 212-366-5540. **A full discussion of end-of-life management is in Chap. 11.**

78 Prevention and Early Detection of Cancer

Otis W. Brawley, Barnett S. Kramer

Improved understanding of carcinogenesis has allowed cancer prevention and early detection (also known as cancer control) to expand beyond the identification and avoidance of carcinogens. Specific interventions to prevent cancer in those at risk, and more sensitive and specific screening for early detection of cancer are the goals.

Carcinogenesis is not simply an event but a process, a continuum of discrete cellular changes over time resulting in more autonomous cellular processes. Prevention concerns the identification and manipulation of the genetic, biologic, and environmental factors in the causal pathway of cancer.

EDUCATION AND HEALTHFUL HABITS

Public education on the avoidance of identified risk factors for cancer and encouraging healthy habits contributes to cancer prevention and control. The physician is a powerful messenger in this education campaign. The patient-physician encounter provides an opportunity to teach patients about the hazards of smoking, the features of a healthy lifestyle (including diet and exercise), use of proven cancer screening methods, and sun avoidance.

Smoking Cessation Tobacco smoking is the most modifiable risk factor for cardiovascular disease, pulmonary disease, and cancer. Smokers have a 33% lifetime risk of dying prematurely from a tobacco-related cancer, cardiovascular, or pulmonary disease. Tobacco use causes more deaths from cardiovascular disease than from cancer. Lung cancer and cancers of the larynx, oropharynx, esophagus, kidney, bladder, pancreas, and stomach are all tobacco-related.

The degree of smoke exposure, meaning the number of cigarettes smoked per day as well as the level of inhalation of cigarette smoke, is correlated with risk of lung cancer mortality. Light- and low-tar cigarettes are not safer because smokers tend to inhale them more frequently and deeply.

Those who stop smoking have a 30–50% lower 10-year lung cancer mortality rate compared to those who continue smoking, despite the fact that some carcinogen-induced gene mutations persist for years after smoking cessation. Smoking cessation and avoidance have the potential to save more lives than any other public health activity.

The risk of tobacco smoke is not limited to the smoker. Environmental tobacco smoke, known as second hand or passive smoke, causes lung cancer and other cardiopulmonary diseases in nonsmokers.

Tobacco prevention is a pediatric issue. Over 80% of adult American smokers began smoking before the age of 18. Nearly 20% of Americans aged 12–18 have smoked a cigarette in the past month. Counseling of adolescents and young adults is critical to prevent smoking. A physician's simple advice to not start smoking or to quit smoking can be of benefit. Physicians should query patients on tobacco use on every office visit, record the answer with the vital signs, and ask smokers if they would like assistance in quitting.

Current approaches to smoking cessation recognize that smoking is an addiction (Chap. 390). The smoker who is quitting goes through a process with identifiable stages that include contemplation of quitting, an action phase in which the smoker quits, and a maintenance phase. Smokers who quit completely are more likely to be successful than those who gradually reduce the number of cigarettes smoked or change to lower tar or nicotine cigarettes. More than 90% of the Americans who have successfully quit smoking did so on their own without participation in an organized cessation program, but cessation programs are helpful for some smokers. The Community Intervention Trial for Smoking Cessation (COMMIT) was a 4-year program; it demonstrated that light smokers (<25 cigarettes per day) were more likely to benefit from simple cessation messages and cessation programs. Quit rates were 30.6% in the intervention group and 27.5% in the control group. The COMMIT interventions were not successful in heavy smokers (>25 cigarettes per day). Heavy smokers may need an intensive broad-based cessation program that includes counseling, behavioral strategies, and pharmacologic adjuncts, such as nicotine replacement (gum, patches, sprays, lozenges, and inhalers) and bupropion.

Cigar smoking has increased in the past decade. The health risks of cigars are similar to those of cigarettes. Smoking one or two cigars daily doubles the risk for oral and esophageal cancers; three or four cigars daily increases the risk of oral cancers more than eightfold and esophageal cancer fourfold. The risks of occasional use are unknown.

Smokeless tobacco is the fastest growing part of the tobacco industry and represents a substantial health risk. Chewing tobacco is a carcinogen linked to dental caries, gingivitis, oral leukoplakia, and oral cancer. The systemic effects of smokeless tobacco may increase risks for other cancers. Esophageal cancer is linked to carcinogens in tobacco being dissolved in saliva, swallowed, and coming into contact with the esophagus.

Physical Activity Physical activity is associated with a decreased risk of colon and breast cancer. A variety of mechanisms have been pro-

posed. However, such studies are prone to confounding factors such as recall bias, association of exercise with other health-related practices, and effects of preclinical cancers on exercise habits (reverse causality). Recommending adults to engage in at least 30 min of vigorous activity for ≥3 days a week is good health advice, though its effects on cancer incidence are unproven.

Diet Modification International epidemiologic studies suggest that diets high in fat are associated with increased risk for cancers of the breast, colon, prostate, and endometrium. These cancers have their highest incidence and mortalities in western culture where fat comprises an average of 40–45% of the total calories consumed. In populations at low risk for these cancers, fat accounts for <20% of dietary calories.

Despite correlations, dietary fat has not been proven to cause cancer. Case-control and cohort epidemiologic studies give conflicting results. In addition, diet is a highly complex exposure to many nutrients and chemicals. Low-fat diets are associated with many dietary changes beyond simple subtraction of fat. Other lifestyle changes are also associated with adherence to a low-fat diet. The Women's Intervention Nutrition Study (WINS) evaluated the effects of low-fat diet on breast cancer recurrence in previously treated postmenopausal breast cancer patients. Breast cancer patients, mean age 62 years, were randomly assigned to a standard diet (40% fat) or a low-fat diet (26% fat). At 5 years, breast cancer had recurred in 9.8% of women in the low-fat diet group compared to 12.4% of women on the standard diet.

In observational studies, dietary fiber lowers the risk of colonic polyps and invasive cancer of the colon. However, cancer protective effects of increasing fiber and lowering dietary fat have not been proven in the context of a prospective clinical trial. The putative protective mechanisms are complex and speculative. Fiber binds oxidized bile acids and generates soluble fiber products, such as butyrate, that may have differentiating properties. Fiber does not increase bowel transit times. High-fiber diets could lower the risk of breast and prostate cancer by absorbing and inactivating dietary estrogenic and androgenic cancer promoters. However, two large prospective cohort studies of >100,000 health professionals showed no association between fruit and vegetable intake and risk of cancer.

The Polyp Prevention Trial randomly assigned 2000 elderly persons, who had polyps removed, to a low-fat, high-fiber diet versus routine diet for 4 years. No differences were noted in polyp formation.

The U.S. National Institutes of Health Women's Health Initiative, launched in 1994, is a long-term clinical trial enrolling >100,000 women aged 45–69. It placed women in 22 intervention groups. Participants received calcium/vitamin D supplementation, hormone-replacement therapy, and counseling to increase exercise, eat a low-fat diet, and cease smoking. The study showed that while dietary fat intake was significantly lower in the diet intervention group, invasive breast cancers were not reduced over an 8-year follow-up period compared to the control group. The difference in dietary fat averaged ~10% between the two groups. Scientific evidence does not currently establish the anticarcinogenic value of vitamin, mineral, or nutritional supplements in amounts greater than those provided by a balanced diet. However, consuming at least five servings of fruits and vegetables a day decreases dietary fat and increases fiber; such a diet may lower the risk of cardiovascular disease even if it does not influence cancer.

Energy Balance Risk of cancer increases as body mass index increases over 25 kg/m^2. Obesity increases risks for cancers of the colon, breast (female postmenopausal), endometrium, kidney (renal cell), and esophagus, although causality is not established.

Relative risks of colon cancer are increased in obesity by 1.5–2.0 for men and 1.2–1.5 for women. Obese postmenopausal women have a 30–50% increased risk of breast cancer. A hypothesis for the association is that adipose tissue serves as a depot for aromatase that facilitates estrogen production. Adiposity is also associated with poorer survival and increased risk of recurrence after treatment.

Sun Avoidance Nonmelanoma skin cancers (basal cell and squamous cell) are induced by cumulative exposure to ultraviolet (UV) radiation. Intermittent acute sun exposure and sun damage have been linked to melanoma. Sunburns, especially in childhood and adolescence, are associated with increased risk of melanoma in adulthood. Reduction of sun exposure through use of protective clothing and changing patterns of outdoor activities can reduce skin cancer risk. Sunscreens decrease the risk of actinic keratoses, the precursor to squamous cell skin cancer, but melanoma risk may be increased. Sunscreens prevent burning, but they may encourage more prolonged exposure to the sun and may not filter out wavelengths of energy that cause melanoma.

Educational interventions to help individuals accurately assess their risk of developing skin cancer have some impact. Self examination for skin pigment characteristics associated with melanoma, such as freckling, may be useful in identifying people at high risk. Those who recognize themselves as being at risk tend to be more compliant with sun-avoidance recommendations. Risk factors for melanoma include a propensity to sunburn, a large number of benign melanocytic nevi, and atypical nevi.

CANCER CHEMOPREVENTION

Chemoprevention involves the use of specific natural or synthetic chemical agents to reverse, suppress, or prevent carcinogenesis before the development of invasive malignancy.

Cancer develops through an accumulation of genetic and epigenetic changes that are potential points of intervention to prevent cancer. The initial changes are termed *initiation*. The alteration can be inherited or acquired through the action of physical, infectious, or chemical carcinogens. Like most human diseases, cancer arises from an interaction between genetics and environmental exposures (Table 78-1). Influences that cause the initiated cell to progress through the carcinogenic process and change

TABLE 78-1 SUSPECTED CARCINOGENS

Carcinogens[a]	Associated Cancer or Neoplasm
Alkylating agents	Acute myeloid leukemia, bladder cancer
Androgens	Prostate cancer
Aromatic amines (dyes)	Bladder cancer
Arsenic	Cancer of the lung, skin
Asbestos	Cancer of the lung, pleura, peritoneum
Benzene	Acute myelocytic leukemia
Chromium	Lung cancer
Diethylstilbestrol (prenatal)	Vaginal cancer (clear cell)
Epstein-Barr virus	Burkitt's lymphoma, nasal T cell lymphoma
Estrogens	Cancer of the endometrium, liver, breast
Ethyl alcohol	Cancer of the liver, esophagus, head and neck
Helicobacter pylori	Gastric cancer, gastric MALT lymphoma
Hepatitis B or C virus	Liver cancer
Human immunodeficiency virus	Non-Hodgkin's lymphoma, Kaposi's sarcoma, squamous cell carcinomas (especially of the urogenital tract)
Human papilloma virus	Cervix cancer, head and neck cancer
Human T cell lymphotropic virus type I (HTLV-I)	Adult T cell leukemia/lymphoma
Immunosuppressive agents (azathioprine, cyclosporine, glucocorticoids)	Non-Hodgkin's lymphoma
Nitrogen mustard gas	Cancer of the lung, head and neck, nasal sinuses
Nickel dust	Cancer of the lung, nasal sinuses
Phenacetin	Cancer of the renal pelvis and bladder
Polycyclic hydrocarbons	Cancer of the lung, skin (especially squamous cell carcinoma of scrotal skin)
Schistosomiasis	Bladder cancer (squamous cell)
Sunlight (ultraviolet)	Skin cancer (squamous cell and melanoma)
Tobacco (including smokeless)	Cancer of the upper aerodigestive tract, bladder
Vinyl chloride	Liver cancer (angiosarcoma)

[a]Agents that are thought to act as cancer initiators and/or promoters.

phenotypically are termed *promoters*. Promoters include hormones such as androgens, linked to prostate cancer, and estrogen, linked to breast and endometrial cancer. The distinction between an initiator and promoter is sometimes arbitrary; some components of cigarette smoke are "complete carcinogens," acting as both initiators and promoters. Cancer can be prevented or controlled through interference with the factors that cause cancer initiation, promotion, or progression. Compounds of interest in chemoprevention often have antimutagenic, antioxidant, anti-inflammatory, antiproliferative, or pro-apoptotic activity (or a combination).

Chemoprevention of Cancers of the Upper Aerodigestive Tract Smoking causes diffuse epithelial injury in the head, neck, esophagus, and lung. Patients cured of squamous cell cancers of the lung, esophagus, head, and neck are at risk (as high as 5% per year) of developing second cancers of the upper aerodigestive tract. Cessation of cigarette smoking does not markedly decrease the cured cancer patient's risk of second malignancy, even though it does lower the cancer risk in those who have never developed a malignancy. Smoking cessation may halt the early stages of the carcinogenic process (such as metaplasia), but it may have no effect on late stages of carcinogenesis. This "field carcinogenesis" hypothesis for upper aerodigestive tract cancer has made "cured" patients an important population for chemoprevention of second malignancies.

Oral leukoplakia, a premalignant lesion commonly found in smokers, has been used as an intermediate marker allowing demonstration of chemopreventive activity in smaller shorter duration, randomized, placebo-controlled trials. Response was associated with upregulation of retinoic acid receptor-β (RAR-β). Therapy with high, relatively toxic doses of isoretinoin (13-*cis*-retinoic acid) causes regression of oral leukoplakia. However, the lesions recur when the therapy is withdrawn, suggesting the need for chronic administration. More tolerable doses of isoretinoin have not proven beneficial in the prevention of head and neck cancer. Isoretinoin also failed to prevent second malignancies in patients cured of early-stage non-small cell lung cancer; mortality rates were actually increased in current smokers.

Premalignant lesions in the oropharyngeal area have also responded to retinol, α-tocopherol (vitamin E), and selenium. Further study to define the activity of these drugs is ongoing.

Several large-scale trials have assessed agents in the chemoprevention of lung cancer in patients at high risk. In the α-tocopherol/β-carotene (ATBC) Lung Cancer Prevention Trial participants were male smokers, age 50–69 at entry. Participants had smoked an average of one pack of cigarettes per day for 35.9 years. Participants received α-tocopherol, β-carotene, and/or placebo in a randomized, 2×2 factorial design. After median follow-up of 6.1 years, lung cancer incidence and mortality were statistically significantly increased in those receiving β-carotene. α-Tocopherol had no effect on lung cancer mortality, and no evidence suggested interaction between the two drugs. Patients receiving α-tocopherol had a higher incidence of hemorrhagic stroke.

The β-Carotene and Retinol Efficacy Trial (CARET) involved 17,000 American smokers and workers with asbestos exposure. Entrants were randomly assigned to one of four arms and received β-carotene, retinol, and/or placebo in a 2×2 factorial design. This trial also demonstrated harm from β-carotene: a lung cancer rate of 5 per 1000 subjects per year for those taking placebo and of 6 per 1000 subjects per year for those taking β-carotene.

The ATBC and CARET results demonstrate the importance of testing chemoprevention hypotheses thoroughly before their widespread implementation as the results contradict a number of observational studies. In the ATBC trial, those taking α-tocopherol had a one-third reduction in the incidence of prostate cancer, compared to those not taking α-tocopherol. The Physicians' Health Trial showed no change in the risk of lung cancer for those taking β-carotene; fewer of its participants were smokers than those in the ATBC and CARET studies.

Chemoprevention of Colon Cancer Many of the current colon cancer prevention trials are based on the premise that most colorectal cancers develop from adenomatous polyps. These trials use adenoma recurrence or disappearance as a surrogate endpoint for colon cancer prevention. Early clinical trial results suggest that nonsteroidal anti-inflammatory drugs (NSAIDs), such as piroxicam, sulindac, and aspirin, may prevent adenoma formation or cause regression of adenomatous polyps. The mechanism of action of NSAIDs is unknown, but they are presumed to work through the cyclooxygenase pathway. In the Physicians' Health Trial, aspirin had no effect on colon cancer incidence, although the 6-year assessment period may not have been long enough to evaluate this endpoint definitively. A number of studies suggest that NSAID use is associated with a lower risk of adenomatous polyps and invasive cancer. However, prospective trials have not shown that NSAIDs prevent colon cancer.

Cyclooxygenase-2 (COX-2) inhibitors may be even more effective. In a placebo-controlled trial, high-dose celecoxib reduced the recurrence of colorectal polyps in patients with familial adenomatous polyposis. The effect on colon cancer occurrence is unknown. Trials for prevention of sporadic colorectal cancers with COX-2 inhibitors were initiated but have been complicated by the association of these drugs with cardiovascular disease.

Epidemiologic studies suggest that diets high in calcium lower colon cancer risk. Calcium binds bile and fatty acids, which cause proliferation of colonic epithelium. It is hypothesized that calcium reduces intraluminal exposure to these compounds. Calcium supplementation decreases the risk of adenomatous polyp recurrence by ~20%. Trials of calcium with cancer-incidence endpoints are underway.

The Women's Health Initiative demonstrated that postmenopausal women taking premarin plus progestin have a 44% lower risk of colorectal cancer compared to women taking placebo. Of >16,600 women randomized and followed for a median of 5.6 years, 43 invasive colorectal cancers occurred in the hormone group and 72 in the placebo group. The positive effect on colon cancer is mitigated by the modest increase in cardiovascular and breast cancer risks associated with combined estrogen plus progestin therapy. Colorectal cancers diagnosed in women taking estrogen and progestin were in more advanced stage than those in women taking placebo.

A case-control study suggested that statins decrease the incidence of colorectal cancer. However, a meta-analysis of statin use showed no protective effect of statins on overall cancer incidence or death.

Chemoprevention of Breast Cancer Hormonal manipulation is being tested in the primary prevention of breast cancer. Tamoxifen is an antiestrogen with partial estrogen agonistic activity in some tissues, such as endometrium and bone. One of its actions is to upregulate transforming growth factor β, which decreases breast cell proliferation. In randomized placebo-controlled trials to assess tamoxifen as adjuvant therapy for breast cancer, tamoxifen reduced the number of new breast cancers in the opposite breast by more than a third. In a randomized placebo-controlled prevention trial involving >13,000 women at high risk, tamoxifen decreased the risk of developing breast cancer by 49% (from 43.4 to 22.0 per 1000 women) after a median follow-up of nearly 6 years. The International Breast Cancer Intervention Study (IBIS-I) trial had similar findings. In both studies tamoxifen also reduced bone fractures; a small increase in risk of endometrial cancer, stroke, pulmonary emboli, and deep vein thrombosis was noted. Tamoxifen has been approved by the U.S. Food and Drug Administration for reduction of breast cancer in women at high risk for the disease (1.66% risk at 5 years based on the Gail risk model: *http://www.nci.nih.gov/cancertopics/pdq/genetics/breast-and-ovarian/healthprofessional#Section_66*).

A trial comparing tamoxifen with another selective estrogen receptor modulator, raloxifene, showed that raloxifene is comparable to tamoxifen in cancer prevention. Raloxifene is associated with more noninvasive breast cancer than tamoxifen; the drugs are similar in risks of other cancers, fractures, ischemic heart disease, and stroke. Because the aromatase inhibitors are even more effective than tamoxifen in adjuvant breast cancer therapy, it is hoped that they also are more effective in breast cancer prevention. However, no data are available on this point.

Chemoprevention of Prostate Cancer Finasteride is a 5-α-reductase inhibitor. It inhibits conversion of testosterone to dihydrotestosterone

(DHT), a potent stimulator of prostate cell proliferation. The Prostate Cancer Prevention Trial randomly assigned men ≥55 years at average risk of prostate cancer to finasteride or placebo. After 7 years of therapy, the incidence of prostate cancer was 18.4% in the finasteride arm and 24.8% in the placebo arm, a statistically significant difference. However, the finasteride group had more patients with tumors of Gleason score 7 and higher compared to the placebo arm (6.4% vs 5.1%). The clinical significance of this finding, if any, is unknown.

Selenium is being tested as a prostate cancer preventive based on laboratory studies, epidemiologic data, and a small randomized skin cancer prevention trial that showed a significantly decreased number of prostate cancers in men taking selenium. In the placebo group, 16 prostate cancers were diagnosed versus 4 in the treatment group among the 843 men who began the study with a serum prostate specific antigen level <4 ng/mL.

The ATBC study cited above showed in secondary analysis that the risk of prostate cancer was reduced 33% in men taking α-tocopherol (99 cases in those on the drug; 151 cases on placebo). A prospective randomized trial to assess these drugs is ongoing.

Vaccines and Cancer Prevention A number of infectious agents cause cancer. Hepatitis B and C are linked to liver cancer, some human papilloma virus (HPV) strains are linked to cervical and head and neck cancer, and *Helicobacter pylori* is associated with gastric cancer and lymphoma. Vaccines to protect against these agents may reduce the risk of their associated cancers.

The hepatitis B vaccine is effective in preventing hepatitis and hepatomas due to chronic hepatitis B infection. Public health officials are encouraging widespread administration of the hepatitis B vaccine, especially in Asia, where the disease is epidemic.

A four-valent HPV vaccine (Gardasil) is 100% effective at preventing infection with any of the four component strains (6, 11, 16, 18). The vaccine is recommended for girls and women ages 9–26 years. Reduction in these HPV types could prevent >70% of the cervical cancers worldwide.

SURGICAL PREVENTION OF CANCER

Some organs in some individuals are at such high risk of developing cancer that surgical removal of the organ at risk is recommended. Women with severe cervical dysplasia are treated with conization and occasionally even hysterectomy. Colectomy is used to prevent colon cancer in patients with familial polyposis or ulcerative colitis.

Prophylactic bilateral mastectomy is chosen for breast cancer prevention among women with genetic predisposition to breast cancer. In a prospective series of 139 women with *BRCA1* and *BRCA2* mutations, 76 chose to undergo prophylactic mastectomy and 63 chose close surveillance. At 3 years, no cases of breast cancer had been diagnosed in those opting for surgery, but eight in the surveillance group had developed breast cancer. A larger retrospective cohort study reported that prophylactic mastectomy could reduce risk of breast cancer by 90%. The effect of the procedure on mortality is unknown. Observational studies are prone to a variety of biases associated with the choice to undergo prophylactic surgery; thus, such studies can give an overestimate of the magnitude of benefit.

Surgery is also used to manage hormonal cancers. Orchiectomy is an effective method of androgen deprivation in prostate cancer, and oophorectomy is effective in hormone-dependent breast cancer.

CANCER SCREENING

Screening is a means of detecting disease early in asymptomatic individuals, with the goal of decreasing morbidity and mortality. While screening can potentially save lives and has been shown to do so in cervical, colon, and probably breast cancer, it is also subject to a number of biases that can suggest a benefit when actually there is none. Biases can even mask net harm. Early detection does not in itself confer benefit. To be of value, screening must detect disease earlier, and treatment of earlier disease must yield a better outcome than treatment at the onset of symptoms. Cause-specific mortality, rather than survival after diagnosis, is the preferred endpoint (see below).

Because screening is done on asymptomatic, healthy persons, it should offer substantial likelihood of benefit that outweighs harm. Screening tests and their appropriate use should be carefully evaluated before their use is widely encouraged in screening programs, as a matter of public policy.

Screening examinations, tests, or procedures are usually not diagnostic of cancer but instead indicate that a cancer may be present. The diagnosis is then made following a workup that includes a biopsy and pathologic confirmation.

A number of genes have been identified that predispose for a disease, and many more will be identified in the near future. Testing for these genes can define a high-risk population. The ability to predict the development of a particular cancer may some day present therapeutic options as well as ethical dilemmas. It may eventually allow for early intervention to prevent a cancer or limit its severity. People at high risk may be ideal candidates for chemoprevention and screening; however, efficacy of these interventions in the high-risk population should be investigated. Currently, persons at high risk for a particular cancer can engage in intensive screening. While this course is clinically prudent, it is not known if it saves lives in these populations.

The Accuracy of Screening A screening test's accuracy or ability to discriminate disease is described by four indices: sensitivity, specificity, positive predictive value, and negative predictive value (Table 78-2). *Sensitivity*, also called the true positive rate, is the proportion of persons with the disease testing positive in the screen (i.e., the ability of the test to detect disease when it is present). *Specificity*, or 1-false positive rate, is the proportion of persons who do not have the disease and test negative in the screening test (i.e., the ability of a test to correctly identify that the disease is not present). The *positive predictive value* is the proportion of persons that test positive who actually have the disease. Similarly, *negative predictive value* is the proportion testing negative who do not have the disease. The sensitivity and specificity of a test are relatively independent of the underlying prevalence (or risk) of the disease in the population screened, but the predictive values depend strongly on the prevalence of the disease.

Screening is most beneficial, efficient, and economical when the target disease is common in the population being screened. To be valuable, the screening test should have a high specificity; sensitivity need not be very high.

Potential Biases of Screening Tests The common biases of screening are lead time, length-biased sampling, and selection. These biases can

TABLE 78-2 ASSESSMENT OF THE VALUE OF A DIAGNOSTIC TEST[a]

	Condition Present	Condition Absent
Positive test	*a*	*b*
Negative test	*c*	*d*
a = true positive *b* = false positive *c* = false negative *d* = true negative		
Sensitivity	The proportion of persons with the condition who test positive: $a/(a+c)$	
Specificity	The proportion of persons without the condition who test negative: $d/(b+d)$	
Positive predictive value (PPV)	The proportion of persons with a positive test who have the condition: $a/(a+b)$	
Negative predictive value	The proportion of persons with a negative test who do not have the condition: $d/(c+d)$	
Prevalence, sensitivity, and specificity determine PPV $\text{PPV} = \frac{\text{prevalence} \times \text{sensitivity}}{(\text{prevalence} \times \text{sensitivity}) + (1 - \text{prevalence})(1 - \text{specificity})}$		

[a]For diseases of low prevalence, such as cancer, poor specificity has a dramatic adverse effect on PPV such that only a small fraction of positive tests are true positives.

TABLE 78-3 SCREENING RECOMMENDATIONS FOR ASYMPTOMATIC NORMAL-RISK SUBJECTS[a]

Test or Procedure	USPSTF	ACS	CTFPHC
Sigmoidoscopy	Fair evidence to recommend	≥50, every 5 years	Fair evidence to consider
Fecal occult blood testing	≥50, good evidence for every 1–2 years	≥50, every year	Good evidence, age ≥50
Colonoscopy	No direct evidence	≥50, every 10 years	No direct evidence
Digital rectal examination	No recommendation	No recommendation	No recommendation
Prostate-specific antigen	Insufficient evidence to recommend	M: ≥50, every year	Recommendation against
Pap test	F: 18–65, every 1–3 years	F: with uterine cervix, beginning 3 years after first intercourse or by age 21. Yearly for standard Pap; every 2 years with liquid test.	Fair evidence to include in examination of sexually active women
Pelvic examination	No recommendation, advise adnexal palpation during exam for other reasons	F: 18–40, every 1–3 years with Pap test; >40, every year	Not considered
Breast self-examination	No recommendation	≥20, monthly	Fair evidence to exclude
Breast clinical examination	Insufficient evidence as a stand-alone without mammography	F: 20–40, every 3 years; >40, yearly	F: 50–69, every 1–2 years
Mammography	F: 40–75, every 1–2 years (fair evidence)	F: ≥40, every year	F: 50–69, every 1–2 years
