The activity of miltefosine is attributed to interaction with cell signal transduction pathways and inhibition of phospholipid and sterol biosynthesis. Resistance to miltefosine has not been observed clinically. The drug is readily absorbed from the GI tract, is widely distributed, and accumulates in several tissues. The efficacy of a 28-day treatment course in Indian visceral leishmaniasis is equivalent to that of amphotericin B therapy; however, it appears that a shortened course of 21 days may be equally efficacious.

General recommendations for the use of miltefosine are limited by the exclusion of specific groups from the published clinical trials: persons <12 or >65 years of age, persons with the most advanced disease, breast-feeding women, HIV-infected patients, and individuals with significant renal or hepatic insufficiency.

Niclosamide Niclosamide is active against a wide variety of adult tapeworms but not against tissue cestodes. It is also a molluscacide and is used in snail-control programs. The drug uncouples oxidative phosphorylation in parasite mitochondria, thereby blocking the uptake of glucose by the intestinal tapeworm and resulting in the parasite's death. Niclosamide rapidly causes spastic paralysis of intestinal cestodes in vitro. Its use is limited by its side effects, the necessarily long duration of therapy, the recommended use of purgatives, and—most important—limited availability (i.e., on a named-patient basis from the manufacturer).

Niclosamide is poorly absorbed. Tablets are given on an empty stomach in the morning after a liquid meal the night before, and this dose is followed by another 1 h later. For treatment of hymenolepiasis, the drug is administered for 7 days. A second course is often prescribed. The scolex and proximal segments of the tapeworms are killed on contact with niclosamide and may be digested in the gut. However, disintegration of the adult tapeworm results in the release of viable ova, which theoretically can result in autoinfection. Although fears of the development of cysticercosis in patients with *Taenia solium* infections have proved unfounded, it is still recommended that a brisk purgative be given 2 h after the first dose.

Nifurtimox* This nitrofuran compound is a cheap and effective oral agent for the treatment of acute Chagas' disease. Trypanosomes lack catalase and have very low levels of peroxidase; as a result, they are very vulnerable to by-products of oxygen reduction. When nifurtimox is reduced in the trypanosome, a nitro anion radical is formed and undergoes autooxidation, resulting in the generation of the superoxide anion O_2^-, hydrogen peroxide (H_2O_2), hydroperoxyl radical (HO_2), and other highly reactive and cytotoxic molecules. Despite the abundance of catalases, peroxidases, and superoxide dismutases that neutralize these destructive radicals in mammalian cells, nifurtimox has a poor therapeutic index. Prolonged use is required, but the course may have to be interrupted because of drug toxicity, which develops in 40–70% of recipients. Nifurtimox is well absorbed and undergoes rapid and extensive biotransformation; <0.5% of the original drug is excreted in urine.

Nitazoxanide Nitazoxanide is a 5-nitrothiazole compound used for the treatment of cryptosporidiosis and giardiasis; it is active against other intestinal protozoa as well. The drug is approved for use in children 1–11 years of age.

The antiprotozoal activity of nitazoxanide is believed to be due to interference with the pyruvate-ferredoxin oxidoreductase (PFOR) enzyme–dependent electron transfer reaction that is essential to anaerobic energy metabolism. Studies have shown that the PFOR enzyme from *G. lamblia* directly reduces nitazoxanide by transfer of electrons in the absence of ferredoxin. The DNA-derived PFOR protein sequence of *Cryptosporidium parvum* appears to be similar to that of *G. lamblia*. Interference with the PFOR enzyme–dependent electron transfer reaction may not be the only pathway by which nitazoxanide exerts antiprotozoal activity.

After oral administration, nitazoxanide is rapidly hydrolyzed to an active metabolite, tizoxanide (desacetyl-nitazoxanide). Tizoxanide then undergoes conjugation, primarily by glucuronidation. It is recommended that nitazoxanide be taken with food; however, no studies have been conducted to determine whether the pharmacokinetics of

Copyright © 2008 The McGraw-Hill Companies. All rights reserved.

tizoxanide and tizoxanide glucuronide differ in fasted versus fed subjects. Tizoxanide is excreted in urine, bile, and feces, and tizoxanide glucuronide is excreted in urine and bile. The pharmacokinetics of nitazoxanide in patients with impaired hepatic and/or renal function have not been studied. Tizoxanide is highly bound to plasma protein (>99.9%). Therefore, caution should be used when administering this agent concurrently with other highly plasma protein–bound drugs with narrow therapeutic indices, as competition for binding sites may occur.

Oxamniquine This tetrahydroquinoline derivative is an effective alternative agent for the treatment of *Schistosoma mansoni*, although susceptibility to this drug exhibits regional variation. Oxamniquine exhibits anticholinergic properties, but its primary mode of action seems to rely on ATP-dependent enzymatic drug activation generating an intermediate that alkylates essential macromolecules, including DNA. In treated adult schistosomes, oxamniquine produces marked tegumental alterations that are similar to those seen with praziquantel but that develop less rapidly, becoming evident 4–8 days after treatment.

Oxamniquine is administered orally as a single dose and is well absorbed. Food retards absorption and reduces bioavailability. About 70% of an administered dose is excreted in urine as a mixture of pharmacologically inactive metabolites. Patients should be warned that their urine might have an intense orange-red color. Side effects are uncommon and usually mild, although hallucinations and seizures have been reported.

Paromomycin (Aminosidine) First isolated in 1956, this aminoglycoside is an effective oral agent for the treatment of infections due to intestinal protozoa. Parenteral paromomycin appears to be effective against visceral leishmaniasis in India.

Paromomycin inhibits protozoan protein synthesis by binding to the 30S ribosomal RNA in the aminoacyl-tRNA site, causing misreading of mRNA codons. Paromomycin is less active against *G. lamblia* than standard agents; however, like other aminoglycosides, paromomycin is poorly absorbed from the intestinal lumen, and the high levels of drug in the gut compensate for this relatively weak activity. If absorbed or administered systemically, paromomycin can cause ototoxicity and nephrotoxicity. However, systemic absorption is very limited, and toxicity should not be a concern in persons with normal kidneys. Topical formulations are not generally available.

Pentamidine Isethionate This diamidine is an effective alternative agent for some forms of leishmaniasis and trypanosomiasis. It is available for parenteral and aerosolized administration. While its mechanism of action remains undefined, it is known to exert a wide range of effects, including interaction with trypanosomal kinetoplast DNA; interference with polyamine synthesis by a decrease in the activity of ornithine decarboxylase; and inhibition of RNA polymerase, ribosomal function, and the synthesis of nucleic acids and proteins.

Pentamidine isethionate is well absorbed, is highly tissue bound, and is excreted slowly over several weeks, with an elimination half-life of 12 days. No steady-state plasma concentration is attained in persons given daily injections; the result is extensive accumulation of pentamidine in tissues, primarily the liver, kidney, adrenal, and spleen. Pentamidine does not penetrate well into the CNS. Pulmonary concentrations of pentamidine are increased when the drug is delivered in aerosolized form.

Piperazine The antihelminthic activity of piperazine is confined to ascariasis and enterobiasis. Piperazine acts as an agonist at extrasynaptic γ-aminobutyric acid (GABA) receptors, causing an influx of chloride ions in the nematode somatic musculature. The ultimate effect is flaccid paralysis of the muscle fibers, leading to the expulsion of live but mostly paralyzed worms. Patients should be warned, as this occurrence can be unsettling.

Praziquantel This heterocyclic pyrazinoisoquinoline derivative is highly active against a broad spectrum of trematodes and cestodes. It is the mainstay of treatment for schistosomiasis and is a critical part of community-based control programs.

All of the effects of praziquantel can be attributed either directly or indirectly to an alteration of intracellular calcium concentrations. Although the exact mechanism of action remains unclear, the major mechanism is disruption of the parasite tegument, causing tetanic contractures with loss of adherence to host tissues and, ultimately, disintegration or expulsion. Praziquantel induces changes in the antigenicity of the parasite by causing the exposure of concealed antigens. Praziquantel also produces alterations in schistosomal glucose metabolism, including decreases in glucose uptake, lactate release, glycogen content, and ATP levels.

Praziquantel exerts its parasitic effects directly and does not need to be metabolized to be effective. It is well absorbed but undergoes extensive first-pass hepatic clearance. Levels of the drug are increased when it is taken with food, particularly carbohydrates, or with cimetidine. Serum levels are reduced by glucocorticoids, chloroquine, carbamazepine, and phenytoin. Praziquantel is completely metabolized in humans, with 80% of the dose recovered as metabolites in urine within 4 days. It is not known to what extent praziquantel crosses the placenta.

Patients with schistosomiasis who have heavy parasite burdens may develop abdominal discomfort, nausea, headache, dizziness, and drowsiness. Symptoms begin 30 min after ingestion, may require spasmolytics for relief, and usually disappear spontaneously after a few hours.

Primaquine Phosphate Primaquine, an 8-aminoquinoline, has a broad spectrum of activity against all stages of plasmodial development in humans but has been used most effectively for eradication of the hepatic stage of these parasites. Despite its toxicity, it remains the drug of choice for radical cure of *P. vivax* infections. Primaquine must be metabolized by the host to be effective. It is, in fact, rapidly metabolized; only a small fraction of the dose of the parent drug is excreted unchanged. Although the parasiticidal activity of the three oxidative metabolites remains unclear, they are believed to affect both pyrimidine synthesis and the mitochondrial electron transport chain. The metabolites appear to have significantly less antimalarial activity than primaquine; however, their hemolytic activity is greater than that of the parent drug.

Primaquine causes marked hypotension after parenteral administration and therefore is given only by the oral route. It is rapidly and almost completely absorbed from the GI tract.

Patients should be tested for G6PD deficiency before they receive primaquine. The drug may induce the oxidation of hemoglobin into methemoglobin, irrespective of the G6PD status of the patient. Primaquine is otherwise well tolerated.

Proguanil (Chloroguanide) Proguanil inhibits plasmodial dihydrofolate reductase and is used with atovaquone for oral treatment of uncomplicated malaria or with chloroquine for malaria prophylaxis in parts of Africa without widespread chloroquine-resistant *P. falciparum*.

Proguanil exerts its effect primarily by means of the metabolite cycloguanil, whose inhibition of dihydrofolate reductase in the parasite disrupts deoxythymidylate synthesis, thus interfering with a key pathway involved in the biosynthesis of pyrimidines required for nucleic acid replication. There are no clinical data indicating that folate supplementation diminishes drug efficacy; women of childbearing age for whom atovaquone/proguanil is prescribed should continue taking folate supplements to prevent neural-tube birth defects.

Proguanil is extensively absorbed regardless of food intake. The drug is 75% protein-bound. The main routes of elimination are hepatic biotransformation and renal excretion; 40–60% of the proguanil dose is excreted by the kidneys. Drug levels are increased and elimination is impaired in patients with hepatic insufficiency.

Pyrantel Pamoate Pyrantel is a tetrahydropyrimidine formulated as pamoate. This safe, well-tolerated, inexpensive drug is used to treat a variety of intestinal nematode infections but is ineffective in trichuriasis. Pyrantel pamoate is usually effective in a single dose. Like levami-

Copyright © 2008 The McGraw-Hill Companies. All rights reserved.

sole, the drug has as its target the nicotinic acetylcholine receptor on the surface of nematode somatic muscle. Pyrantel depolarizes the neuromuscular junction of the nematode, resulting in its irreversible paralysis and allowing the natural expulsion of the worm.

Pyrantel pamoate is poorly absorbed from the intestine; >85% of the dose is passed unaltered in feces. The absorbed portion is metabolized and excreted in urine. Piperazine, which produces hyperpolarization of muscle cells in intestinal helminths, is antagonistic to pyrantel pamoate and should not be used concomitantly.

Pyrantel pamoate has minimal toxicity at the oral doses used to treat intestinal helminthic infection. It is not recommended for pregnant women or for children <12 months old.

Pyrimethamine When combined with short-acting sulfonamides, this diaminopyrimidine is effective in malaria, toxoplasmosis, and isosporiasis. Unlike mammalian cells, the parasites that cause these infections cannot utilize preformed pyrimidines obtained through salvage pathways but rather rely completely on de novo pyrimidine synthesis, for which folate derivatives are essential cofactors. The efficacy of pyrimethamine is increasingly limited by the development of resistant strains of *P. falciparum* and *P. vivax*. Single amino acid substitutions to parasite dihydrofolate reductase confer resistance to pyrimethamine by decreasing the enzyme's binding affinity for the drug.

Pyrimethamine is well absorbed; the drug is 87% bound to human plasma proteins. In healthy volunteers, drug concentrations remain at therapeutic levels for up to 2 weeks; drug levels are lower in patients with malaria.

At the usual dosage, pyrimethamine alone causes little toxicity except for occasional skin rashes and, more rarely, blood dyscrasias. Bone marrow suppression sometimes occurs at the higher doses used for toxoplasmosis; at these doses, the drug should be administered with folinic acid.

Quinacrine* First introduced as an antimalarial agent in 1930, quinacrine is the only drug approved by the FDA for the treatment of giardiasis. Its production was discontinued in 1992. Although not commercially available, quinacrine can be obtained from alternative sources through the CDC Drug Service. The antiprotozoal mechanism of quinacrine has not been fully elucidated. The drug inhibits NADH oxidase—the same enzyme that activates furazolidone. The differing relative quinacrine uptake rate between human cells and *G. lamblia* may explain the selective toxicity of the drug. Resistance correlates with decreased drug uptake.

Quinacrine is rapidly absorbed from the intestinal tract and is widely distributed in body tissues. Alcohol is best avoided due to a disulfiram-like effect.

Quinine and Quinidine When combined with another agent, the cinchona alkaloid quinine is effective for the oral treatment of both uncomplicated, chloroquine-resistant malaria and babesiosis. Quinine acts rapidly against the asexual blood stages of all forms of human malaria. For severe malaria, only quinidine (the dextroisomer of quinine) is available in the United States. Quinine concentrates in the acidic food vacuoles of *Plasmodium* spp. The drug inhibits the nonenzymatic polymerization of the highly reactive, toxic heme molecule into the nontoxic polymer pigment hemozoin.

Quinine is readily absorbed when given orally. In patients with malaria, the elimination half-life of quinine increases according to the severity of the infection. However, toxicity is avoided by an increase in the concentration of plasma glycoproteins. The cinchona alkaloids are extensively metabolized, particularly by CYP3A4; only 20% of the dose is excreted unchanged in urine. The drug's metabolites are also excreted in urine and may be responsible for toxicity in patients with renal failure. Renal excretion of quinine is decreased when cimetidine is taken and increased when the urine is acidic. The drug readily crosses the placenta.

Quinidine is both more potent as an antimalarial and more toxic than quinine. Its use requires cardiac monitoring. Dose reduction is necessary in persons with severe renal impairment.

Spiramycin† This macrolide is used to treat acute toxoplasmosis in pregnancy and congenital toxoplasmosis. While the mechanism of action is similar to that of other macrolides, the efficacy of spiramycin in toxoplasmosis appears to stem from its rapid and extensive intracellular penetration, which results in macrophage drug concentrations 10–20 times greater than serum concentrations.

Spiramycin is rapidly and widely distributed throughout the body and reaches concentrations in the placenta up to five times those in serum. This agent is excreted mainly in bile. Indeed, in humans, the urinary excretion of active compounds represents only 20% of the administered dose.

Serious reactions to spiramycin are rare. Of the available macrolides, spiramycin appears to have the lowest risk of drug interactions. Complications of treatment are rare but, in neonates, can include life-threatening ventricular arrhythmias that disappear with drug discontinuation.

Sulfonamides See Table 201-1 and Chap. 127.

Suramin* This derivative of urea is the drug of choice for the early stage of African trypanosomiasis. The drug is polyanionic and acts by forming stable complexes with proteins, thus inhibiting multiple enzymes essential to parasite energy metabolism. Suramin appears to inhibit all trypanosome glycolytic enzymes more effectively than it inhibits the corresponding host enzymes.

Suramin is parenterally administered. It binds to plasma proteins and persists at low levels for several weeks after infusion. Its metabolism is negligible. This drug does not penetrate the CNS.

Tafenoquine Tafenoquine is an 8-aminoquinoline with causal prophylactic activity. Its prolonged half-life (2–3 weeks) allows longer dosing intervals when the drug is used for prophylaxis. Tafenoquine has been well tolerated in clinical trials. When tafenoquine is taken with food, its absorption is increased by 50% and the most commonly reported adverse event—mild GI upset—is diminished. Like primaquine, tafenoquine is a potent oxidizing agent, causing hemolysis in patients with G6PD deficiency as well as methemoglobinemia.

Tetracyclines See Table 201-1 and Chap. 127.

Thiabendazole Discovered in 1961, thiabendazole remains one of the most potent of the numerous benzimidazole derivatives. However, its use has declined significantly because of a higher frequency of adverse effects than is seen with other, equally effective agents.

Thiabendazole is active against most intestinal nematodes that infect humans. Although the exact mechanism of its antihelminthic activity has not been fully elucidated, it is likely to be similar to that of other benzimidazole drugs: namely, inhibition of polymerization of parasite β-tubulin. The drug also inhibits the helminth-specific enzyme fumarate reductase. In animals, thiabendazole has anti-inflammatory, antipyretic, and analgesic effects, which may explain its usefulness in dracunculiasis and trichinosis. Thiabendazole also suppresses egg and/or larval production by some nematodes and may inhibit the subsequent development of eggs or larvae passed in feces. Despite the emergence and global spread of thiabendazole-resistant trichostrongyliasis among sheep, there have been no reports of drug resistance in humans.

Thiabendazole is available in tablet form and as an oral suspension. The drug is rapidly absorbed from the GI tract but can also be absorbed through the skin. Thiabendazole should be taken after meals. This agent is extensively metabolized in the liver before ultimately being excreted; most of the dose is excreted within the first 24 h. The usual dose of thiabendazole is determined by the patient's weight, but some treatment regimens are parasite specific. No particular adjustments are recommended in patients with renal or hepatic failure; only cautious use is advised.

Coadministration of thiabendazole in patients taking theophylline can result in an increase in theophylline levels by >50%. Therefore, serum levels of theophylline should be monitored closely in this situation.

Copyright © 2008 The McGraw-Hill Companies. All rights reserved.

Tinidazole This nitroimidazole is effective for the treatment of amebiasis, giardiasis, and trichomoniasis. Like metronidazole, tinidazole must undergo reductive activation by the parasite's metabolic system before it can act on protozoal targets. Tinidazole inhibits the synthesis of new DNA in the parasite and causes degradation of existing DNA. The reduced free-radical derivatives alkylate DNA, with consequent cytotoxic damage to the parasite. This damage appears to be produced by short-lived reduction intermediates, resulting in helix destabilization and strain breakage of DNA. The mechanism of action and side effects of tinidazole are similar to those of metronidazole, but adverse events appear to be less frequent and severe with tinidazole. In addition, the significantly longer half-life of tinidazole (>12 h) offers potential cure with a single dose.

Triclabendazole While most benzimidazoles have broad-spectrum antihelminthic activity, they exhibit minimal or no activity against *F. hepatica*. In contrast, the antihelminthic activity of triclabendazole is highly specific for *Fasciola* spp. and *Paragonimus* spp., with little activity against nematodes, cestodes, and other trematodes. Triclabendazole is effective against all stages of *Fasciola* spp. The active sulfoxide metabolite of triclabendazole binds to fluke tubulin by assuming a unique nonplanar configuration and disrupts microtubule-based processes. Resistance to triclabendazole in veterinary use has been reported in Australia and Europe; however, no resistance has been documented in humans.

Triclabendazole is rapidly absorbed after oral ingestion; administration with food enhances its absorption and shortens the elimination half-life of the active metabolite. Both the sulfoxide and the sulfone metabolites are highly protein bound (>99%). Treatment with triclabendazole is typically given in one or two doses. No clinical data are available regarding dose adjustment in renal or hepatic insufficiency; however, given the short course of therapy and extensive hepatic metabolism of triclabendazole, dose adjustment is unlikely to be necessary. No information exists on drug interactions.

Trimethoprim-Sulfamethoxazole See Table 201-1 and Chap. 127.

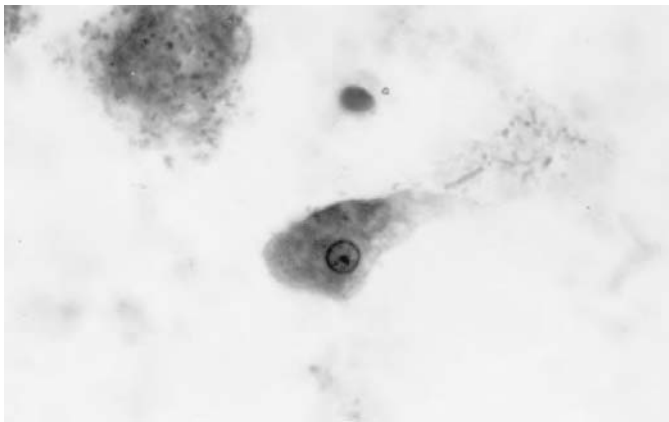

FIGURE 202-1 Trophozoite of *E. histolytica* demonstrating a single nucleus with a central, dot-like nucleolus (trichrome stain).

patients with AIDS. However, host factors play a role as well. In one study, 10% of asymptomatic patients who were colonized with *E. histolytica* went on to develop amebic colitis, while the rest remained asymptomatic and cleared the infection within 1 year.

Areas of highest incidence (due to inadequate sanitation and crowding) include most developing countries in the tropics, particularly Mexico, India, and nations of Central and South America, tropical Asia, and Africa. In a 4-year follow-up study of preschool children in a highly endemic area of Bangladesh, 80% of children had at least one episode of infection with *E. histolytica* and 53% had more than one episode. Naturally acquired immunity did develop but was usually short-lived and correlated with the presence in the stool of secretory IgA antibody to the major adherence lectin galactose *N*-acetylgalactosamine (Gal/GalNAc). The main groups at risk for amebiasis in developed countries are returned travelers, recent immigrants, homosexual men, and inmates of institutions.

PATHOGENESIS AND PATHOLOGY

Both trophozoites (Fig. 202-1) and cysts (Fig. 202-2) are found in the intestinal lumen, but only trophozoites of *E. histolytica* invade tissue. The trophozoite is 20–60 μm in diameter and contains vacuoles and a nucleus with a characteristic central nucleolus. In animals, depletion of intestinal mucus, diffuse inflammation, and disruption of the epithelial barrier occur before trophozoites actually come into contact with the colonic mucosa. Trophozoites attach to colonic mucus and epithelial cells by Gal/GalNAc. The earliest intestinal lesions are microulcerations of the mucosa of the cecum, sigmoid colon, or rectum that release erythrocytes, inflammatory cells, and epithelial cells. Proctoscopy reveals small ulcers with heaped-up margins and normal intervening mucosa. Submucosal extension of ulcerations under viable-appearing surface mucosa causes the classic "flask-shaped" ulcer containing trophozoites at the margins of dead and viable tissues. Although neutrophilic infiltrates may accompany the early lesions in animals, human intestinal infection is marked by a paucity of inflammatory cells, probably in part because of the killing of neutrophils by trophozoites (Fig. 202-3). Treated ulcers characteristically heal with little or no scarring. Occasionally, however, full-thickness necrosis and perforation occur.

Rarely, intestinal infection results in the formation of a mass lesion, or *ameboma*, in the bowel lumen. The overlying mucosa is usually thin and ulcerated, while other layers of the wall are thickened, edematous, and hemorrhagic; this condition results in exuberant formation of granulation tissue with little fibrous-tissue response.

A number of virulence factors have been linked to the ability of *E. histolytica* to invade through the interglandular epithelium. One consists of the extracellular cysteine proteinases that degrade collagen, elastin, IgA, IgG, and the anaphylatoxins C3a and C5a. Other enzymes may disrupt glycoprotein bonds between mucosal epithelial cells in the gut. Amebas can lyse neutrophils, monocytes, lymphocytes, and cells of colonic and hepatic lines. The cytolytic effect of amebas appears to require direct contact with target cells and may be linked to the release of phospholipase A and pore-forming peptides. *E. histolytica* trophozoites also cause apoptosis of human cells.

Liver abscesses are always preceded by intestinal colonization, which may be asymptomatic. Blood vessels may be compromised early by wall lysis and thrombus formation. Trophozoites invade veins to reach the liver through the portal venous system. *E. histolytica* is resistant to complement-mediated lysis—a property critical to survival in the bloodstream. In contrast, *E. dispar* is rapidly lysed by complement and is thus restricted to the bowel lumen. Inoculation of amebas into the portal system of hamsters results in an acute cellular infiltrate consisting predominantly of neutrophils. Later, the neutrophils are lysed by contact with amebas, and the release of neutrophil toxins may contribute to necrosis of hepatocytes. The liver parenchyma is replaced by necrotic material that is surrounded by a thin rim of congested liver tissue. The necrotic contents of a liver abscess are classically described as "anchovy paste," although the fluid is variable in color and is composed of bacteriologically sterile granular debris with few or no cells. Amebas, if seen, tend to be found near the capsule of the abscess.

A study in Bangladeshi schoolchildren revealed that an intestinal IgA response to Gal/GalNAc reduced the risk of new *E. histolytica* infection by 64%. Serum IgG antibody is not protective; titers correlate with the duration of illness rather than with the severity of disease. Indeed, Bangladeshi children with a serum IgG response were more likely than those without such a response to develop new *E. histolytica* infection. Studies of animals suggest that cell-mediated immunity may

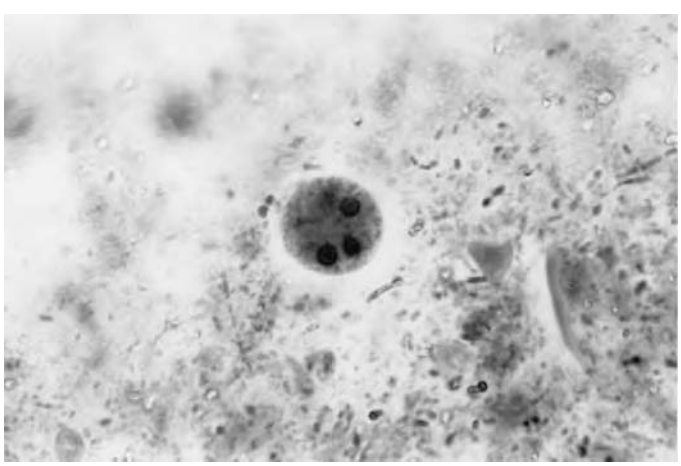

FIGURE 202-2 Cyst of *E. histolytica* showing three of the four nuclei (trichrome stain).

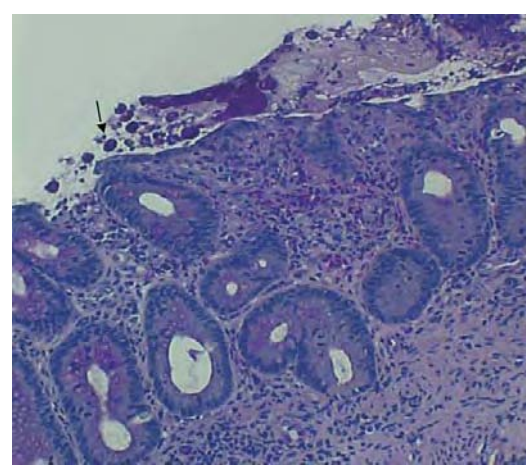

FIGURE 202-3 Pathology of amebic ulcer with colonic invasion. Arrow points to trophozoites (hematoxylin and eosin, 400X).

be important for protection, although patients with AIDS appear not to be predisposed to more severe disease.

CLINICAL SYNDROMES

Intestinal Amebiasis

The most common type of amebic infection is asymptomatic cyst passage. Even in highly endemic areas, most patients harbor *E. dispar*.

Symptomatic amebic colitis develops 2–6 weeks after the ingestion of infectious cysts. A gradual onset of lower abdominal pain and mild diarrhea is followed by malaise, weight loss, and diffuse lower abdominal or back pain. Cecal involvement may mimic acute appendicitis. Patients with full-blown dysentery may pass 10–12 stools per day. The stools contain little fecal material and consist mainly of blood and mucus. In contrast to those with bacterial diarrhea, fewer than 40% of patients with amebic dysentery are febrile. Virtually all patients have heme-positive stools.

More fulminant intestinal infection, with severe abdominal pain, high fever, and profuse diarrhea, is rare and occurs predominantly in children. Patients may develop toxic megacolon, in which there is severe bowel dilation with intramural air. Patients receiving glucocorticoids are at risk for severe amebiasis. Uncommonly, patients develop a chronic form of amebic colitis, which can be confused with inflammatory bowel disease. The association between severe amebiasis complications and glucocorticoid therapy emphasizes the importance of excluding amebiasis when inflammatory bowel disease is suspected. An occasional patient presents with only an asymptomatic or tender abdominal mass caused by an ameboma, which is easily confused with cancer on barium studies. A positive serologic test or biopsy can prevent unnecessary surgery in this setting. The syndrome of postamebic colitis—persistent diarrhea following documented cure of amebic colitis—is controversial; no evidence of recurrent amebic infection can be found, and re-treatment usually has no effect.

Amebic Liver Abscess

Extraintestinal infection by *E. histolytica* most often involves the liver. Of travelers who develop an amebic liver abscess after leaving an endemic area, 95% do so within 5 months. Young patients with an amebic liver abscess are more likely than older patients to present in the acute phase with prominent symptoms of <10 days' duration. Most patients are febrile and have right-upper-quadrant pain, which may be dull or pleuritic in nature and may radiate to the shoulder. Point tenderness over the liver and right-sided pleural effusion are common. Jaundice is rare. Although the initial site of infection is the colon, fewer than one-third of patients with an amebic abscess have active diarrhea. Older patients from endemic areas are more likely to have a subacute course lasting 6 months, with weight loss and hepatomegaly. About one-third of patients with chronic presentations are febrile. Thus, the clinical diagnosis of an amebic liver abscess may be difficult to establish because the symptoms and signs are often nonspecific. Since 10–15% of patients present only with fever, amebic liver abscess must be considered in the differential diagnosis of fever of unknown origin (Chap. 19).

Complications of Amebic Liver Abscess

Pleuropulmonary involvement, which is reported in 20–30% of patients, is the most frequent complication of amebic liver abscess. Manifestations include sterile effusions, contiguous spread from the liver, and rupture into the pleural space. Sterile effusions and contiguous spread usually resolve with medical therapy, but frank rupture into the pleural space requires drainage. A hepatobronchial fistula may cause cough productive of large amounts of necrotic material that may contain amebas. This dramatic complication carries a good prognosis. Abscesses that rupture into the peritoneum may present as an indolent leak or an acute abdomen and require both percutaneous catheter drainage and medical therapy. Rupture into the pericardium, usually from abscesses of the left lobe of the liver, carries the gravest prognosis; it can occur during medical therapy and requires surgical drainage.

Other Extraintestinal Sites

The genitourinary tract may become involved by direct extension of amebiasis from the colon or by hematogenous spread of the infection. Painful genital ulcers, characterized by a punched-out appearance and profuse discharge, may develop secondary to extension from either the intestine or the liver. Both these conditions respond well to medical therapy. Cerebral involvement has been reported in fewer than 0.1% of patients in large clinical series. Symptoms and prognosis depend on the size and location of the lesion.

DIAGNOSTIC TESTS

Laboratory Diagnosis

Stool examinations, serologic tests, and noninvasive imaging of the liver are the most important procedures in the diagnosis of amebiasis. Fecal findings suggestive of amebic colitis include a positive test for heme, a paucity of neutrophils, and amebic cysts or trophozoites. The definitive diagnosis of amebic colitis is made by the demonstration of hematophagous trophozoites of *E. histolytica* (Fig. 202-1). Because trophozoites are killed rapidly by water, drying, or barium, it is important to examine at least three fresh stool specimens. Examination of a combination of wet mounts, iodine-stained concentrates, and trichrome-stained preparations of fresh stool and concentrates for cysts (Fig. 202-2) or trophozoites (Fig. 202-1) confirms the diagnosis in 75–95% of cases. Cultures of amebas are more sensitive but are not routinely available. If stool examinations are negative, sigmoidoscopy with biopsy of the edge of ulcers may increase the yield, but this procedure is dangerous during fulminant colitis because of the risk of perforation. Trophozoites in a biopsy specimen from a colonic mass confirm the diagnosis of ameboma, but trophozoites are rare in liver aspirates because they are found in the abscess capsule and not in the readily aspirated necrotic center. Accurate diagnosis requires experience, since the trophozoites may be confused with neutrophils and the cysts must be differentiated morphologically from *Entamoeba hartmanni*, *Entamoeba coli*, and *Endolimax nana*, which do not cause clinical disease and do not warrant therapy. Unfortunately, the cysts of *E. histolytica* cannot be distinguished microscopically from those of *E. dispar*. Therefore, the microscopic diagnosis of *E. histolytica* can be made only by the detection of *Entamoeba* trophozoites that have ingested erythrocytes. In terms of sensitivity, stool diagnostic tests based on the detection of the Gal/GalNAc lectin of *E. histolytica* compare favorably with the polymerase chain reaction and with isolation in culture followed by isoenzyme analysis.

Serology is an important addition to the methods used for parasitologic diagnosis of invasive amebiasis. Enzyme-linked immunosorbent assays (ELISAs) and agar gel diffusion assays are positive in more than 90% of patients with colitis, amebomas, or liver abscess. Positive results in conjunction with the appropriate clinical syndrome suggest active disease because serologic findings usually revert to negative within 6–12 months. Even in highly endemic areas such as South Africa, fewer than 10% of asymptomatic individuals have a positive amebic serology. The interpretation of the indirect hemagglutination test is more difficult because titers may remain positive for as long as 10 years.

Up to 10% of patients with acute amebic liver abscess may have negative serologic findings; in suspected cases with an initially negative result, testing should be repeated in a week. In contrast to carriers of *E. dispar*, most asymptomatic carriers of *E. histolytica* develop antibodies. Thus, serologic tests are helpful in assessing the risk of invasive amebiasis in asymptomatic, cyst-passing individuals in nonendemic areas. Serologic tests also should be performed in patients with ulcerative colitis before the institution of glucocorticoid therapy to prevent the development of severe colitis or toxic megacolon owing to unsuspected amebiasis.

Routine hematology and chemistry tests usually are not very helpful in the diagnosis of invasive amebiasis. About three-fourths of patients with an amebic liver abscess have leukocytosis (>10,000 cells/μL); this condition is particularly likely if symptoms are acute or complications have developed. Invasive amebiasis does not elicit eosinophilia. Anemia, if present, is usually multifactorial. Even with large liver abscesses, liver enzyme levels are normal or minimally elevated. The alkaline phosphatase level is most often elevated and may remain so for months. Aminotransferase elevations suggest acute disease or a complication.

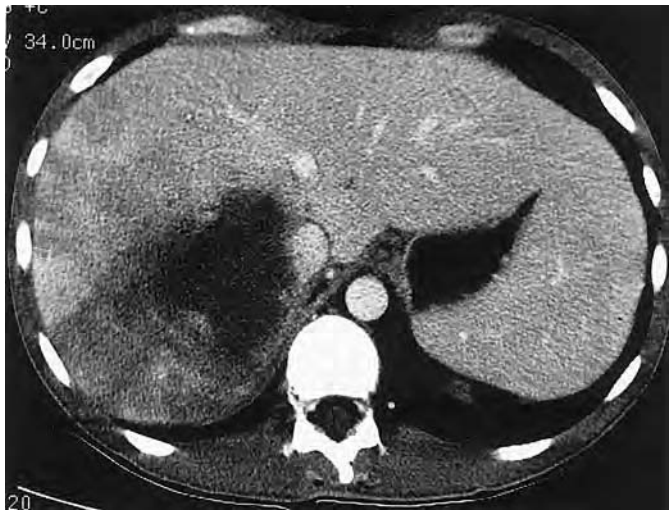

FIGURE 202-4 Abdominal CT scan of a large amebic abscess of the right lobe of the liver. *(Courtesy of the Department of Radiology, UCSD Medical Center, San Diego; with permission.)*

Radiographic Studies Radiographic barium studies are potentially dangerous in acute amebic colitis. Amebomas are usually identified first by a barium enema, but biopsy is necessary for differentiation from carcinoma.

Radiographic techniques such as ultrasonography, CT, and MRI are all useful for detection of the round or oval hypoechoic cyst. More than 80% of patients who have had symptoms for >10 days have a single abscess of the right lobe of the liver (Fig. 202-4). Approximately 50% of patients who have had symptoms for <10 days have multiple abscesses. Findings associated with complications include large abscesses (>10 cm) in the superior part of the right lobe, which may rupture into the pleural space; multiple lesions, which must be differentiated from pyogenic abscesses; and lesions of the left lobe, which may rupture into the pericardium. Because abscesses resolve slowly and may increase in size in patients who are responding clinically to therapy, frequent follow-up ultrasonography may prove confusing. Complete resolution of a liver abscess within 6 months can be anticipated in two-thirds of patients, but 10% may have persistent abnormalities for a year.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of intestinal amebiasis includes bacterial diarrheas (Chap. 122) caused by *Campylobacter* (Chap. 148); enteroinvasive *Escherichia coli* (Chap. 143); and species of *Shigella* (Chap. 147), *Salmonella* (Chap. 146), and *Vibrio* (Chap. 149). Although the typical patient with amebic colitis has less prominent fever than in these other conditions as well as heme-positive stools with few neutrophils, correct diagnosis requires bacterial cultures, microscopic examination of stools, and amebic serologic testing. As has already been mentioned, amebiasis must be ruled out in any patient thought to have inflammatory bowel disease.

Because of the variety of presenting signs and symptoms, amebic liver abscess can easily be confused with pulmonary or gallbladder disease or with any febrile illness with few localizing signs, such as malaria (Chap. 203) or typhoid fever (Chap. 146). The diagnosis should be considered in members of high-risk groups who have recently traveled outside the United States (Chap. 117) and in inmates of institutions. Once radiographic studies have identified an abscess in the liver, the most important differential diagnosis is between amebic and pyogenic abscess. Patients with pyogenic abscess typically are older and have a history of underlying bowel disease or recent surgery. Amebic serology is helpful, but aspiration of the abscess, with Gram's staining and culture of the material, may be required for differentiation of the two diseases.

Rx AMEBIASIS

INTESTINAL DISEASE (Table 202-2) The drugs used to treat amebiasis can be classified according to their primary site of action. Luminal amebicides are poorly absorbed and reach high concentrations in the bowel, but their activity is limited to cysts and trophozoites close to the mucosa. Only two luminal drugs are available in the United States: iodoquinol and paromomycin. Indications for the use of luminal agents include eradication of cysts in patients with colitis or a liver abscess and treatment of asymptomatic carriers. The majority of asymptomatic individuals who pass cysts are colonized with *E. dispar*, which does not warrant specific therapy. However, it is prudent to treat asymptomatic individuals who pass cysts unless *E. dispar* colonization can be definitively demonstrated by specific antigen-detection tests.

TABLE 202-2 DRUG THERAPY FOR AMEBIASIS

Indication	Therapy
Asymptomatic carriage	Luminal agent: iodoquinol (650-mg tablets), 650 mg tid for 20 days; *or* paromomycin (250-mg tablets), 500 mg tid for 10 days
Acute colitis	Metronidazole (250- or 500-mg tablets), 750 mg PO or IV tid for 5–10 days, *plus* Luminal agent as above
Amebic liver abscess	Metronidazole, 750 mg PO or IV for 5–10 days, *or* Tinidazole, 2 g PO once, *or* Ornidazole,[a] 2 g PO once, *plus* Luminal agent as above

[a]Not available in the United States.

Tissue amebicides reach high concentrations in the blood and tissue after oral or parenteral administration. The development of nitroimidazole compounds, especially metronidazole, was a major advance in the treatment of invasive amebiasis. Patients with amebic colitis should be treated with intravenous or oral metronidazole. Side effects include nausea, vomiting, abdominal discomfort, and a disulfiram-like reaction. Another longer-acting imidazole compound, tinidazole, is also effective and was recently approved in the United States. All patients should also receive a full course of therapy with a luminal agent, since metronidazole does not eradicate cysts. Resistance to metronidazole has been selected in the laboratory but has not been found in clinical isolates. Relapses are not uncommon and probably represent reinfection or failure to eradicate amebas from the bowel because of an inadequate dosage or duration of therapy.

AMEBIC LIVER ABSCESS Metronidazole is the drug of choice for amebic liver abscess. Longer-acting nitroimidazoles (tinidazole and ornidazole) have been effective as single-dose therapy in developing countries. With early diagnosis and therapy, mortality rates from uncomplicated amebic liver abscess are <1%. The second-line therapeutic agents emetine and chloroquine should be avoided if possible because of the potential cardiovascular and gastrointestinal side effects of the former and the higher relapse rates with the latter. There is no evidence that combined therapy with two drugs is more effective than the single-drug regimen. Studies of South Africans with liver abscesses demonstrated that 72% of patients without intestinal symptoms had bowel infection with *E. histolytica*; thus, all treatment regimens should include a luminal agent to eradicate cysts and prevent further transmission. Amebic liver abscess recurs rarely.

ASPIRATION OF LIVER ABSCESSES More than 90% of patients respond dramatically to metronidazole therapy with decreases in both pain and fever within 72 h. Indications for aspiration of liver abscesses are (1) the need to rule out a pyogenic abscess, particularly in patients with multiple lesions; (2) the lack of a clinical response in 3–5 days; (3) the threat of imminent rupture; and (4) the need to prevent rupture of left-lobe abscesses into the pericardium. There is no evidence that aspiration, even of large abscesses (up to 10 cm), accelerates healing. Percutaneous drainage may be successful even if the liver abscess has already ruptured. Surgery should be reserved for instances of bowel perforation and rupture into the pericardium.

PREVENTION

Amebic infection is spread by ingestion of food or water contaminated with cysts. Since an asymptomatic carrier may excrete up to 15 million cysts per day, prevention of infection requires adequate sanitation and

eradication of cyst carriage. In high-risk areas, infection can be minimized by the avoidance of unpeeled fruits and vegetables and the use of bottled water. Because cysts are resistant to readily attainable levels of chlorine, disinfection by iodination (tetraglycine hydroperiodide) is recommended. There is no effective prophylaxis.

INFECTION WITH FREE-LIVING AMEBAS

EPIDEMIOLOGY

Free-living amebas of the genera *Acanthamoeba* and *Naegleria* are distributed throughout the world and have been isolated from a wide variety of fresh and brackish water, including that from lakes, taps, hot springs, swimming pools, and heating and air-conditioning units, and even from the nasal passages of healthy children. Encystation may protect the protozoa from desiccation and food deprivation. The persistence of *Legionella pneumophila* in water supplies may be attributable in part to chronic infection of free-living amebas, particularly *Naegleria*. Free-living amebas of the genus *Balamuthia* have only recently been isolated from soil samples, including a sample from a flowerpot linked to a fatal infection in a child.

NAEGLERIA INFECTIONS

Primary amebic meningoencephalitis caused by *Naegleria fowleri* follows the aspiration of water contaminated with trophozoites or cysts or the inhalation of contaminated dust, leading to invasion of the olfactory neuroepithelium. After an incubation period of 2–15 days, severe headache, high fever, nausea, vomiting, and meningismus develop. Photophobia and palsies of the third, fourth, and sixth cranial nerves are common. Rapid progression to seizures and coma may follow. The prognosis is uniformly poor: most patients die within a week. Only a few survivors, treated with high-dose amphotericin B and rifampin, have been reported. Infection is most common in otherwise-healthy children or young adults, who often report recent swimming in lakes or heated swimming pools.

The diagnosis of *Naegleria* infection should be considered in any patient who has purulent meningitis without evidence of bacteria on Gram's staining, antigen detection assay, and culture. Other laboratory findings resemble those for fulminant bacterial meningitis, with elevated intracranial pressure, high white blood cell counts (up to 20,000/μL), and elevated protein concentrations and low glucose levels in cerebrospinal fluid (CSF). Diagnosis depends on the detection of motile trophozoites in wet mounts of fresh spinal fluid. Antibodies to *Naegleria* spp. have been detected in normal adults; serologic testing is not useful in the diagnosis of acute infection.

ACANTHAMOEBA INFECTIONS

Granulomatous Amebic Encephalitis Infection with *Acanthamoeba* species follows a more indolent course and typically occurs in chronically ill or debilitated patients. Risk factors include lymphoproliferative disorders, chemotherapy, glucocorticoid therapy, lupus erythematosus, and AIDS. Infection usually reaches the central nervous system (CNS) hematogenously from a primary focus in the sinuses, skin, or lungs. In the CNS, the onset is insidious, and the syndrome often mimics a space-occupying lesion. Altered mental status, headache, and stiff neck may be accompanied by focal findings such as cranial nerve palsies, ataxia, and hemiparesis. Cutaneous ulcers or hard nodules containing amebas are frequently detected in AIDS patients with disseminated *Acanthamoeba* infection.

Examination of the CSF for trophozoites may be diagnostically helpful, but lumbar puncture may be contraindicated because of increased intracerebral pressure. CT frequently reveals cortical and subcortical lesions of decreased density consistent with embolic infarcts. In other patients, multiple enhancing lesions with edema may mimic the computed tomographic appearance of toxoplasmosis (Chap. 207). Demonstration of the trophozoites and cysts of *Acanthamoeba* on wet mounts or in biopsy specimens establishes the diagnosis. Culture on nonnutrient agar plates seeded with *E. coli* may also be helpful. Fluorescein-labeled antiserum is available from the Centers for Disease Control and Prevention (CDC) for the detection of protozoa in biopsy specimens. Granulomatous amebic encephalitis in patients with AIDS may have an accelerated course (with survival for only 3–40 days) because of the difficulty these individuals have in forming granulomas. Various antimicrobial agents have been used to treat *Acanthamoeba* infection, including pentamidine, trimethoprim-sulfamethoxazole, and fluconazole, but the infection is almost uniformly fatal.

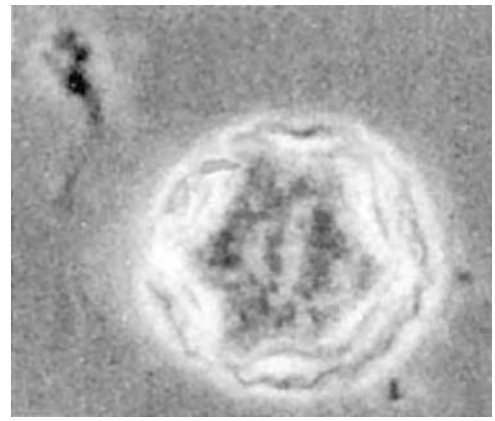

FIGURE 202-5 Double-walled cyst of *Acanthamoeba castellani*, as seen by phase-contrast microscopy. *[From DJ Krogstad et al, in A Balows et al (eds): Manual of Clinical Microbiology, 5th ed. Washington, DC, American Society for Microbiology, 1991.]*

Keratitis The incidence of keratitis caused by *Acanthamoeba* has increased in the past 20 years, in part as a result of improved diagnosis. Earlier infections were associated with trauma to the eye and exposure to contaminated water. At present, most infections are linked to extended-wear contact lenses, and rare cases are associated with laser-assisted in situ keratomileusis (LASIK). Risk factors include the use of homemade saline, the wearing of lenses while swimming, and inadequate disinfection. Since contact lenses presumably cause microscopic trauma, the early corneal findings may be nonspecific. The first symptoms usually include tearing and the painful sensation of a foreign body. Once infection is established, progression is rapid; the characteristic clinical sign is an annular, paracentral corneal ring representing a corneal abscess. Deeper corneal invasion and loss of vision may follow.

The differential diagnosis includes bacterial, mycobacterial, and herpetic infection. The irregular polygonal cysts of *Acanthamoeba* (Fig. 202-5) may be identified in corneal scrapings or biopsy material, and trophozoites can be grown on special media. Cysts are resistant to available drugs, and the results of medical therapy have been disappointing. Some reports have suggested partial responses to propamidine isethionate eyedrops. Severe infections usually require keratoplasty.

BALAMUTHIA INFECTIONS

Balamuthia mandrillaris, a free-living ameba previously referred to as a leptomyxid ameba, is an important etiologic agent of amebic meningoencephalitis in immunocompetent hosts. The course is typically subacute, with focal neurologic signs, fever, seizures, and headaches leading to death within 1 week to several months after onset. Examination of CSF reveals mononuclear or neutrophilic pleocytosis, elevated protein levels, and normal to low glucose concentrations. Multiple hypodense lesions are usually detected with imaging studies. This mixed picture of space-occupying lesions with CSF pleocytosis is suggestive of *Balamuthia.* Detection of an indirect fluorescent antibody response may be helpful in noninvasive diagnosis, but usually a definitive diagnosis is made post-mortem. Fluorescent antibody is available from the CDC. The variety of drugs used to treat the few surviving patients (numbering fewer than five in the United States) include pentamidine, flucytosine, sulfadiazine, and macrolides. The differential diagnosis includes tuberculomas (Chap. 158) and neurocysticercosis (Chap. 213).

203 Malaria

Nicholas J. White, Joel G. Breman

Humanity has but three great enemies: Fever, famine and war; of these by far the greatest, by far the most terrible, is fever.

William Osler

Malaria is a protozoan disease transmitted by the bite of infected *Anopheles* mosquitoes. It is the most important of the parasitic diseases of humans, with transmission in 107 countries containing 3 billion people and causing 1–3 million deaths each year. Malaria has now been eliminated from the United States, Canada, Europe, and Russia but, despite enormous control efforts, has resurged in many parts of the tropics. Added to this resurgence are the increasing problems of drug resistance of the parasite and insecticide resistance of the vectors. Occasional local transmission after importation of malaria has occurred recently in several southern and eastern areas of the United States and in Europe, indicating the continual danger to nonmalarious countries. Although there are promising new control and research initiatives, malaria remains today, as it has been for centuries, a heavy burden on tropical communities, a threat to nonendemic countries, and a danger to travelers.

ETIOLOGY AND PATHOGENESIS

Four species of the genus *Plasmodium* cause nearly all malarial infections in humans (although rare infections involve species normally affecting other primates). These are *P. falciparum*, *P. vivax*, *P. ovale*, and *P. malariae* (Table 203-1). Almost all deaths are caused by falciparum malaria. Human infection begins when a female anopheline mosquito inoculates plasmodial *sporozoites* from its salivary gland during a blood meal (Fig. 203-1). These microscopic motile forms of the malarial parasite are carried rapidly via the bloodstream to the liver, where they invade hepatic parenchymal cells and begin a period of asexual reproduction. By this amplification process (known as *intrahepatic* or *preerythrocytic schizogony* or *merogony*), a single sporozoite eventually may produce from 10,000 to >30,000 daughter merozoites. The swollen infected liver cell eventually bursts, discharging motile *merozoites* into the bloodstream. These then invade the red blood cells (RBCs) and multiply six- to twentyfold every 48–72 h. When the parasites reach densities of ~50/μL of blood, the symptomatic stage of the infection begins. In *P. vivax* and *P. ovale* infections, a proportion of the intrahepatic forms do not divide immediately but remain dormant for a period ranging from 3 weeks to a year or longer before reproduction begins. These dormant forms, or *hypnozoites*, are the cause of the relapses that characterize infection with these two species.

After entry into the bloodstream, merozoites rapidly invade erythrocytes and become *trophozoites*. Attachment is mediated via a specific erythrocyte surface receptor. In the case of *P. vivax*, this receptor is related to the Duffy blood-group antigen Fy^a or Fy^b. Most West Africans and people with origins in that region carry the Duffy-negative FyFy phenotype and are therefore resistant to *P. vivax* malaria. During the early stage of intraerythrocytic development, the small "ring forms" of the four parasitic species appear similar under light microscopy. As the trophozoites enlarge, species-specific characteristics become evident, pigment becomes visible, and the parasite assumes an irregular or ameboid shape. By the end of the 48-h intraerythrocytic life cycle (72 h for *P. malariae*), the parasite has consumed nearly all the hemoglobin and grown to occupy most of the RBC. It is now called a *schizont*. Multiple nuclear divisions have taken place (*schizogony* or *merogony*), and the RBC then ruptures to release 6–30 daughter merozoites, each potentially capable of invading a new RBC and repeating the cycle. The disease in human beings is caused by the direct effects of RBC invasion and destruction by the asexual parasite and the host's reaction. After a series of asexual cycles (*P. falciparum*) or immediately after release from the liver (*P. vivax*, *P. ovale*, *P. malariae*), some of the para-

TABLE 203-1 CHARACTERISTICS OF *PLASMODIUM* SPECIES INFECTING HUMANS

Characteristic	Finding for Indicated Species			
	P. falciparum	***P. vivax***	***P. ovale***	***P. malariae***
Duration of intrahepatic phase (days)	5.5	8	9	15
Number of merozoites released per infected hepatocyte	30,000	10,000	15,000	15,000
Duration of erythrocytic cycle (hours)	48	48	50	72
Red cell preference	Younger cells (but can invade cells of all ages)	Reticulocytes and cells up to 2 weeks old	Reticulocytes	Older cells
Morphology	Usually only ring forms[a]; banana-shaped gametocytes	Irregularly shaped large rings and trophozoites; enlarged erythrocytes; Schüffner's dots	Infected erythrocytes, enlarged and oval with tufted ends; Schüffner's dots	Band or rectangular forms of trophozoites common
Pigment color	Black	Yellow-brown	Dark brown	Brown-black
Ability to cause relapses	No	Yes	Yes	No

[a]Parasitemias of >2% are suggestive of *P. falciparum* infection.

sites develop into morphologically distinct, longer-lived sexual forms (*gametocytes*) that can transmit malaria.

After being ingested in the blood meal of a biting female anopheline mosquito, the male and female gametocytes form a zygote in the insect's midgut. This zygote matures into an ookinete, which penetrates and encysts in the mosquito's gut wall. The resulting oocyst expands by asexual division until it bursts to liberate myriad motile sporozoites, which then migrate in the hemolymph to the salivary gland of the mosquito to await inoculation into another human at the next feeding.

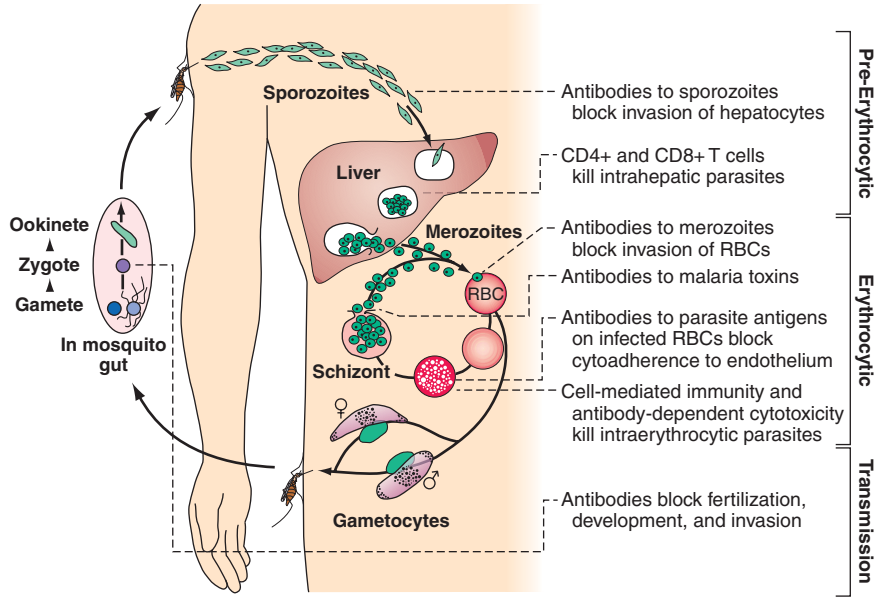

FIGURE 203-1 The malaria transmission cycle from mosquito to human. RBC, red blood cell.

EPIDEMIOLOGY

Malaria occurs throughout most of the tropical regions of the world (Fig. 203-2). *P. falciparum* predominates in Africa, New Guinea, and Haiti; *P. vivax* is more common in Central America. The prevalence of these two species is approximately equal in South America, the Indian subcontinent, eastern Asia, and Oceania. *P. malariae* is found in most endemic areas, especially throughout sub-Saharan Africa, but is much less common. *P. ovale* is relatively unusual outside of Africa and, where it is found, comprises <1% of isolates.

The epidemiology of malaria is complex and may vary considerably even within relatively small geographic areas. Endemicity traditionally has been defined in terms of parasitemia rates or palpable-spleen rates in children 2–9 years of age as hypoendemic (<10%), mesoendemic (11–50%), hyperendemic (51–75%), and holoendemic (>75%); however, it is uncommon to use these indices for planning control programs. In holo- and hyperendemic areas (e.g., certain regions of tropical Africa or coastal New Guinea) where there is intense *P. falciparum* transmission, people may sustain more than one infectious mosquito bite per day and are infected repeatedly throughout their lives. In such settings, rates of morbidity and mortality due to malaria are considerable during childhood. Immunity against disease is hard won in these areas, and the burden of disease in young children is high; by adulthood, however, most malarial infections are asymptomatic. Constant, frequent, year-round infection is termed *stable transmission*. In areas where transmission is low, erratic, or focal, full protective immunity is not acquired, and symptomatic disease may occur at all ages. This situation usually exists in hypoendemic areas and is termed *unstable transmission*. Even in stable transmission areas, there is often an increased incidence of symptomatic malaria coinciding with increased mosquito breeding and transmission during the rainy season. Malaria behaves like an epidemic disease in some areas, particularly those with unstable malaria, such as northern India, Sri Lanka, Southeast Asia, Ethiopia, Eritrea, Rwanda, Burundi, southern Africa, and Madagascar. An epidemic can develop when there are changes in environmental, economic, or social conditions, such as heavy rains following drought or migrations (usually of refugees or workers) from a nonmalarious region to an area of high transmission; a breakdown in malaria control and prevention services can intensify epidemic conditions. This situation usually results in considerable mortality among all age groups.

The principal determinants of the epidemiology of malaria are the number (density), the human-biting habits, and the longevity of the anopheline mosquito vectors. Not all of the >400 anophelines can transmit malaria, and those that do vary considerably in their efficiency as malaria vectors. More specifically, the transmission of malaria is directly proportional to the density of the vector, the square of the number of human bites per day per mosquito, and the tenth power of the probability of the mosquito's surviving for 1 day. Mosquito longevity is particularly important, because the portion of the parasite's life cycle that takes place within the mosquito—from gametocyte ingestion to subsequent inoculation (*sporogony*)—lasts 8–30 days, depending on ambient temperature; thus, to transmit malaria, the mosquito must survive for >7 days. In general, at temperatures below 16°–18°C, sporogony is not completed and transmission does not occur, although malaria outbreaks and transmission have recently occurred in the highlands of east Africa—areas (>1500 m) previously free of vectors. The most effective mosquito vectors of malaria are those, such as *Anopheles gambiae* in Africa, which are long-lived, occur in high densities in tropical climates, breed readily, and bite humans in preference to other animals. The entomologic inoculation rate (the number of sporozoite-positive mosquito bites per person per year) is the most common measure of malaria transmission and varies from <1 in some parts of Latin America and Southeast Asia to >300 in parts of tropical Africa.

ERYTHROCYTE CHANGES IN MALARIA

After invading an erythrocyte, the growing malarial parasite progressively consumes and degrades intracellular proteins, principally hemoglobin. The potentially toxic heme is detoxified by polymerization to biologically inert hemozoin (malaria pigment). The parasite also alters the RBC membrane by changing its transport properties, exposing cryptic surface antigens, and inserting new parasite-derived proteins. The RBC becomes more irregular in shape, more antigenic, and less deformable.

In *P. falciparum* infections, membrane protuberances appear on the erythrocyte's surface 12–15 h after the cell's invasion. These "knobs" extrude a high-molecular-weight, antigenically variant, strain-specific erythrocyte membrane adhesive protein (PfEMP1) that mediates attachment to receptors on venular and capillary endothelium—an event termed *cytoadherence*. Several vascular receptors have been identified, of which intercellular adhesion molecule 1 (ICAM-1) is probably the most important in the brain, chondroitin sulfate B in the placenta, and CD36 in most other organs. Thus, the infected erythrocytes stick inside and eventually block capillaries and venules. At the same stage, these *P. falciparum*–infected RBCs may also adhere to uninfected RBCs (to form rosettes) and to other parasitized erythrocytes (agglutination). The processes of cytoadherence, rosetting, and agglutination are central to the pathogenesis of falciparum malaria. They result in the sequestration of RBCs containing mature forms of the parasite in vital organs (particularly the brain), where they interfere with microcirculatory flow and metabolism. Sequestered parasites continue to develop out of reach of the principal host defense mechanism: splenic processing and filtration. As a consequence, only the younger ring forms of the asexual parasites are seen circulating in the peripheral blood in falciparum malaria, and the level of peripheral parasitemia underestimates the true number of par-

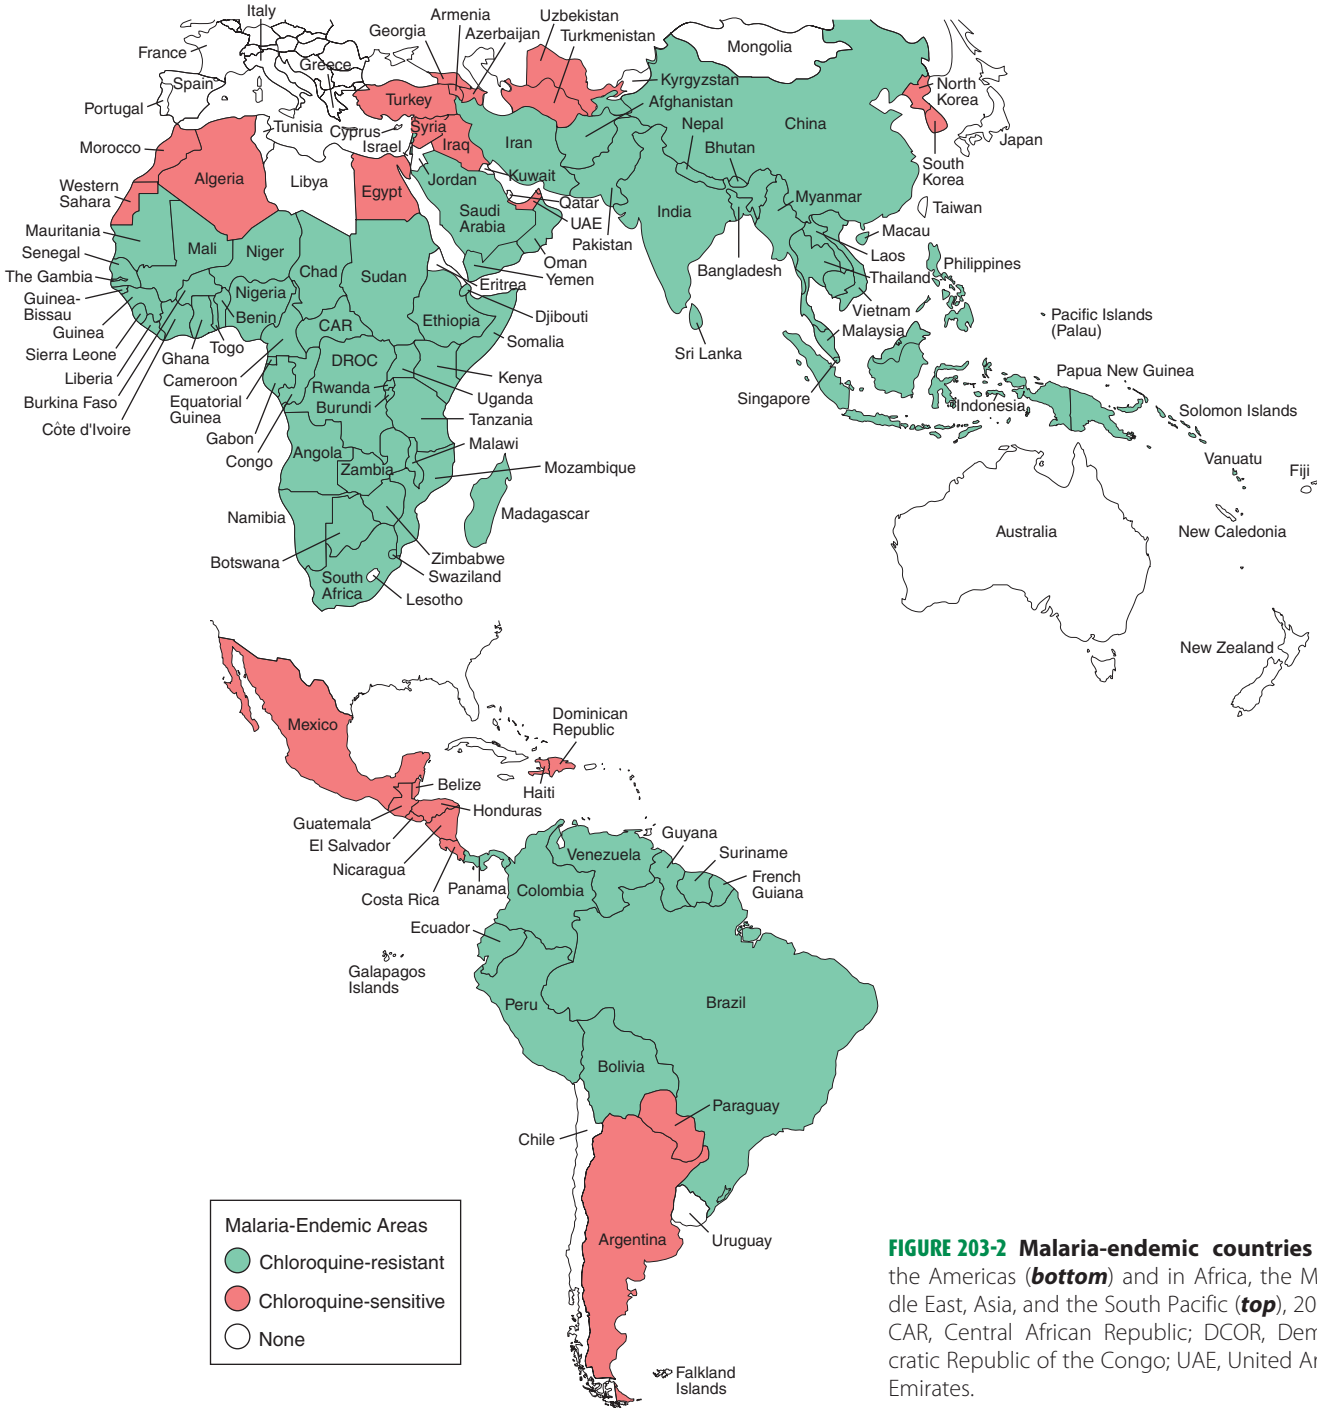

FIGURE 203-2 Malaria-endemic countries in the Americas (***bottom***) and in Africa, the Middle East, Asia, and the South Pacific (***top***), 2007. CAR, Central African Republic; DCOR, Democratic Republic of the Congo; UAE, United Arab Emirates.

asites within the body. Severe malaria is also associated with reduced deformability of the uninfected erythrocytes, which compromises their passage through the partially obstructed capillaries and venules and shortens RBC survival.

In the other three ("benign") malarias, sequestration does not occur, and all stages of the parasite's development are evident on peripheral blood smears. Whereas *P. vivax*, *P. ovale*, and *P. malariae* show a marked predilection for either young RBCs (*P. vivax*, *P. ovale*) or old cells (*P. malariae*) and produce a level of parasitemia that is seldom >2%, *P. falciparum* can invade erythrocytes of all ages and may be associated with very high levels of parasitemia.

HOST RESPONSE

Initially, the host responds to plasmodial infection by activating nonspecific defense mechanisms. Splenic immunologic and filtrative clearance functions are augmented in malaria, and the removal of both parasitized and uninfected erythrocytes is accelerated. The parasitized cells escaping splenic removal are destroyed when the schizont ruptures. The material released induces the activation of macrophages and the release of proinflammatory mononuclear cell–derived cytokines, which cause fever and exert other pathologic effects. Temperatures of ≥40°C damage mature parasites; in untreated infections, the effect of such temperatures is to further synchronize the parasitic cycle, with eventual production of the regular fever spikes and rigors that originally served to characterize the different malarias. These regular fever patterns (tertian, every 2 days; quartan, every 3 days) are seldom seen today in patients who receive prompt and effective antimalarial treatment.

The geographic distributions of sickle cell disease, ovalocytosis, thalassemia, and glucose-6-phosphate dehydrogenase (G6PD) deficiency closely resemble that of malaria before the introduction of control measures. This similarity suggests that these genetic disor-

ders confer protection against death from falciparum malaria. For example, HbA/S heterozygotes (sickle cell trait) have a sixfold reduction in the risk of dying from severe falciparum malaria. This decrease in risk appears to be related to impaired parasite growth at low oxygen tensions. Parasite multiplication in HbA/E heterozygotes is reduced at high parasite densities. In Melanesia, children with α-thalassemia appear to have more frequent malaria (both vivax and falciparum) in the early years of life, and this pattern of infection appears to protect against severe disease. In Melanesian ovalocytosis, rigid erythrocytes resist merozoite invasion, and the intraerythrocytic milieu is hostile.

Nonspecific host defense mechanisms stop the infection's expansion, and the subsequent specific immune response controls the infection. Eventually, exposure to sufficient strains confers protection from high-level parasitemia and disease but not from infection. As a result of this state of infection without illness (*premunition*), asymptomatic parasitemia is common among adults and older children living in regions with stable and intense transmission (i.e., holo- or hyperendemic areas). Immunity is mainly specific for both the species and the strain of infecting malarial parasite. Both humoral immunity and cellular immunity are necessary for protection, but the mechanisms of each are incompletely understood (Fig. 203-1). Immune individuals have a polyclonal increase in serum levels of IgM, IgG, and IgA, although much of this antibody is unrelated to protection. Antibodies to a variety of parasitic antigens presumably act in concert to limit in vivo replication of the parasite. In the case of falciparum malaria, the most important of these antigens is the surface adhesin—the variant protein PfEMP1 mentioned above. Passively transferred IgG from immune adults has been shown to reduce levels of parasitemia in children; although parasitemia in very young infants can occur, passive transfer of maternal antibody contributes to the relative (but not complete) protection of infants from severe malaria in the first months of life. This complex immunity to disease declines when a person lives outside an endemic area for several months or longer.

Several factors retard the development of cellular immunity to malaria. These factors include the absence of major histocompatibility antigens on the surface of infected RBCs, which precludes direct T cell recognition; malaria antigen–specific immune unresponsiveness; and the enormous strain diversity of malarial parasites, along with the ability of the parasites to express variant immunodominant antigens on the erythrocyte surface that change during the period of infection. Parasites may persist in the blood for months (or, in the case of *P. malariae*, for many years) if treatment is not given. The complexity of the immune response in malaria, the sophistication of the parasites' evasion mechanisms, and the lack of a good in vitro correlate with clinical immunity have all slowed progress toward an effective vaccine.

CLINICAL FEATURES

Malaria is a very common cause of fever in tropical countries. The first symptoms of malaria are nonspecific; the lack of a sense of well-being, headache, fatigue, abdominal discomfort, and muscle aches followed by fever are all similar to the symptoms of a minor viral illness. In some instances, a prominence of headache, chest pain, abdominal pain, arthralgia, myalgia, or diarrhea may suggest another diagnosis. Although headache may be severe in malaria, there is no neck stiffness or photophobia resembling that in meningitis. While myalgia may be prominent, it is not usually as severe as in dengue fever, and the muscles are not tender as in leptospirosis or typhus. Nausea, vomiting, and orthostatic hypotension are common. The classic malarial paroxysms, in which fever spikes, chills, and rigors occur at regular intervals, are relatively unusual and suggest infection with *P. vivax* or *P. ovale*. The fever is irregular at first (that of falciparum malaria may never become regular); the temperature of nonimmune individuals and children often rises above 40°C in conjunction with tachycardia and sometimes delirium. Although childhood febrile convulsions may occur with any of the malarias, generalized seizures are specifically associated with falciparum malaria and may herald the development of cerebral disease. Many clinical abnormalities have been described in acute malaria, but most patients with uncomplicated infections have few abnormal physical findings other than fever, malaise, mild anemia, and (in some cases) a palpable spleen. Anemia is common among young children living in areas with stable transmission, particularly where resistance has compromised the efficacy of antimalarial drugs. In nonimmune individuals with acute malaria, the spleen takes several days to become palpable, but splenic enlargement is found in a high proportion of otherwise healthy individuals in malaria-endemic areas and reflects repeated infections. Slight enlargement of the liver is also common, particularly among young children. Mild jaundice is common among adults; it may develop in patients with otherwise uncomplicated falciparum malaria and usually resolves over 1–3 weeks. Malaria is not associated with a rash like those seen in meningococcal septicemia, typhus, enteric fever, viral exanthems, and drug reactions. Petechial hemorrhages in the skin or mucous membranes—features of viral hemorrhagic fevers and leptospirosis—develop only rarely in severe falciparum malaria.

SEVERE FALCIPARUM MALARIA

Appropriately and promptly treated, uncomplicated falciparum malaria (i.e., the patient can swallow medicines and food) carries a mortality rate of ~0.1%. However, once vital-organ dysfunction occurs or the total proportion of erythrocytes infected increases to >2% (a level corresponding to $>10^{12}$ parasites in an adult), mortality risk rises steeply. The major manifestations of severe falciparum malaria are shown in Table 203-2, and features indicating a poor prognosis are listed in Table 203-3.

Cerebral Malaria Coma is a characteristic and ominous feature of falciparum malaria and, despite treatment, is associated with death rates of ~20% among adults and 15% among children. Any obtundation, delirium, or abnormal behavior should be taken very seriously. The onset may be gradual or sudden following a convulsion.

Cerebral malaria manifests as diffuse symmetric encephalopathy; focal neurologic signs are unusual. Although some passive resistance to head flexion may be detected, signs of meningeal irritation are lacking. The eyes may be divergent and a pout reflex is common, but other primitive reflexes are usually absent. The corneal reflexes are preserved, except in deep coma. Muscle tone may be either increased or decreased. The tendon reflexes are variable, and the plantar reflexes may be flexor or extensor; the abdominal and cremasteric reflexes are absent. Flexor or extensor posturing may be seen. Approximately 15% of patients have retinal hemorrhages; with pupillary dilatation and indirect ophthalmoscopy, this figure increases to 30–40%. Other funduscopic abnormalities (Fig. 203-3) include discrete spots of retinal opacification (30–60%), papilledema (8% among children, rare among adults), cotton wool spots (<5%), and decolorization of a retinal vessel or segment of vessel (occasional cases). Convulsions, usually generalized and often repeated, occur in up to 50% of children with cerebral malaria. More covert seizure activity is also common, particularly among children, and may manifest as repetitive tonic-clonic eye movements or even hypersalivation. Whereas adults rarely (i.e., in <3% of cases) suffer neurologic sequelae, ~15% of children surviving cerebral malaria—especially those with hypoglycemia, severe anemia, repeated seizures, and deep coma—have some residual neurologic deficit when they regain consciousness; hemiplegia, cerebral palsy, cortical blindness, deafness, and impaired cognition and learning (all of varying duration) have been reported. Approximately 10% of children surviving cerebral malaria have a persistent language deficit. The incidence of epilepsy is increased and the life expectancy decreased among these children.

Hypoglycemia Hypoglycemia, an important and common complication of severe malaria, is associated with a poor prognosis and is particularly problematic in children and pregnant women. Hypoglycemia in malaria results from a failure of hepatic gluconeogenesis and an increase in the consumption of glucose by both host and, to a much less-

TABLE 203-2 MANIFESTATIONS OF SEVERE FALCIPARUM MALARIA

Signs	Manifestations
Major	
Unarousable coma/cerebral malaria	Failure to localize or respond appropriately to noxious stimuli; coma persisting for >30 min after generalized convulsion
Acidemia/acidosis	Arterial pH <7.25 or plasma bicarbonate level of <15 mmol/L; venous lactate level of >5 mmol/L; manifests as labored deep breathing, often termed "respiratory distress"
Severe normochromic, normocytic anemia	Hematocrit of <15% or hemoglobin level of <50 g/L (<5 g/dL) with parasitemia level of >100,000/μL
Renal failure	Urine output (24 h) of <400 mL in adults or <12 mL/kg in children; no improvement with rehydration; serum creatinine level of >265 μmol/L (>3.0 mg/dL)
Pulmonary edema/adult respiratory distress syndrome	Noncardiogenic pulmonary edema, often aggravated by overhydration
Hypoglycemia	Plasma glucose level of <2.2 mmol/L (<40 mg/dL)
Hypotension/shock	Systolic blood pressure of <50 mmHg in children 1–5 years or <80 mmHg in adults; core/skin temperature difference of >10°C; capillary refill >2 s
Bleeding/disseminated intravascular coagulation	Significant bleeding and hemorrhage from the gums, nose, and gastrointestinal tract and/or evidence of disseminated intravascular coagulation
Convulsions	More than two generalized seizures in 24 h; signs of continued seizure activity sometimes subtle (e.g., tonic-clonic eye movements without limb or face movement)
Hemoglobinuria[a]	Macroscopic black, brown, or red urine; not associated with effects of oxidant drugs and red blood cell enzyme defects (such as G6PD deficiency)
Other	
Impaired consciousness/arousable	Unable to sit or stand without support
Extreme weakness	Prostration; inability to sit unaided[b]
Hyperparasitemia	Parasitemia level of >5% in nonimmune patients (>20% in any patient)
Jaundice	Serum bilirubin level of >50 mmol/L (>3.0 mg/dL) if combined with other evidence of vital-organ dysfunction

[a]Hemoglobinuria may occur in uncomplicated malaria.
[b]In a child who is normally able to sit.
Note: G6PD, glucose-6-phosphate dehydrogenase.

TABLE 203-3 FEATURES INDICATING A POOR PROGNOSIS IN SEVERE FALCIPARUM MALARIA

Clinical
- Marked agitation
- Hyperventilation (respiratory distress)
- Hypothermia (<36.5°C)
- Bleeding
- Deep coma
- Repeated convulsions
- Anuria
- Shock

Laboratory
- Biochemistry
  - Hypoglycemia (<2.2 mmol/L)
  - Hyperlactatemia (>5 mmol/L)
  - Acidosis (arterial pH <7.3, serum HCO_3 <15 mmol/L)
  - Elevated serum creatinine (>265 μmol/L)
  - Elevated total bilirubin (>50 μmol/L)
  - Elevated liver enzymes (AST/ALT 3 times upper limit of normal, 5-nucleotidase ↑)
  - Elevated muscle enzymes (CPK ↑, myoglobin ↑)
  - Elevated urate (>600 μmol/L)
- Hematology
  - Leukocytosis (>12,000/μL)
  - Severe anemia (PCV <15%)
  - Coagulopathy
    - Decreased platelet count (<50,000/μL)
    - Prolonged prothrombin time (>3 s)
    - Prolonged partial thromboplastin time
    - Decreased fibrinogen (<200 mg/dL)
- Parasitology
  - Hyperparasitemia
    - Increased mortality at >100,000/μL
    - High mortality at >500,000/μL
    - >20% of parasites identified as pigment-containing trophozoites and schizonts
    - >5% of neutrophils with visible pigment

Note: ALT, alanine aminotransferase; AST, aspartate aminotransferase; CPK, creatine phosphokinase; PCV, packed cell volume.

er extent, the malaria parasites. To compound the situation, quinine and quinidine—drugs used for the treatment of severe chloroquine-resistant malaria—are powerful stimulants of pancreatic insulin secretion. Hyperinsulinemic hypoglycemia is especially troublesome in pregnant women receiving quinine treatment. In severe disease, the clinical diagnosis of hypoglycemia is difficult: the usual physical signs (sweating, gooseflesh, tachycardia) are absent, and the neurologic impairment caused by hypoglycemia cannot be distinguished from that caused by malaria.

Acidosis Acidosis, an important cause of death from severe malaria, results from accumulation of organic acids. Hyperlactatemia commonly coexists with hypoglycemia. In adults, coexisting renal impairment often compounds the acidosis; in children, ketoacidosis may also contribute. Other still-unidentified organic acids are major contributors to acidosis. Acidotic breathing, sometimes called respiratory distress, is a sign of poor prognosis. It is often followed by circulatory failure refractory to volume expansion or inotropic drugs and ultimately by respiratory arrest. The plasma concentrations of bicarbonate or lactate are the best biochemical prognosticators in severe malaria. Lactic acidosis is caused by the combination of anaerobic glycolysis in tissues where sequestered parasites interfere with microcirculatory flow, hypovolemia, lactate production by the parasites, and a failure of hepatic and renal lactate clearance. The prognosis of severe acidosis is poor.

Noncardiogenic Pulmonary Edema Adults with severe falciparum malaria may develop noncardiogenic pulmonary edema even after several days of antimalarial therapy. The pathogenesis of this variant of the

FIGURE 203-3 The eye in cerebral malaria: perimacular whitening and pale-centered retinal hemorrhages. *(Courtesy of N. Beare, T. Taylor, S. Harding, S. Lewallen, and M. Molyneux; with permission.)*

adult respiratory distress syndrome is unclear. The mortality rate is >80%. This condition can be aggravated by overly vigorous administration of IV fluid. Noncardiogenic pulmonary edema can also develop in otherwise uncomplicated vivax malaria, where recovery is usual.

Renal Impairment Renal impairment is common among adults with severe falciparum malaria but rare among children. The pathogenesis of renal failure is unclear but may be related to erythrocyte sequestration interfering with renal microcirculatory flow and metabolism. Clinically and pathologically, this syndrome manifests as acute tubular necrosis, although renal cortical necrosis never develops. Acute renal failure may occur simultaneously with other vital-organ dysfunction (in which case the mortality risk is high) or may progress as other disease manifestations resolve. In survivors, urine flow resumes in a median of 4 days, and serum creatinine levels return to normal in a mean of 17 days (Chap. 273). Early dialysis or hemofiltration considerably enhances the likelihood of a patient's survival, particularly in acute hypercatabolic renal failure.

Hematologic Abnormalities Anemia results from accelerated RBC removal by the spleen, obligatory RBC destruction at parasite schizogony, and ineffective erythropoiesis. In severe malaria, both infected and uninfected RBCs show reduced deformability, which correlates with prognosis and development of anemia. Splenic clearance of all RBCs is increased. In nonimmune individuals and in areas with unstable transmission, anemia can develop rapidly and transfusion is often required. As a consequence of repeated malarial infections, children in many areas of Africa may develop severe anemia resulting from both shortened RBC survival and marked dyserythropoiesis. Anemia is a common consequence of antimalarial drug resistance, which results in repeated or continued infection.

Slight coagulation abnormalities are common in falciparum malaria, and mild thrombocytopenia is usual. Of patients with severe malaria, <5% have significant bleeding with evidence of disseminated intravascular coagulation. Hematemesis from stress ulceration or acute gastric erosions may also occur.

Liver Dysfunction Mild hemolytic jaundice is common in malaria. Severe jaundice is associated with *P. falciparum* infections; is more common among adults than among children; and results from hemolysis, hepatocyte injury, and cholestasis. When accompanied by other vital-organ dysfunction (often renal impairment), liver dysfunction carries a poor prognosis. Hepatic dysfunction contributes to hypoglycemia, lactic acidosis, and impaired drug metabolism. Occasional patients with falciparum malaria may develop deep jaundice (with hemolytic, hepatitic, and cholestatic components) without evidence of other vital-organ dysfunction.

Other Complications Septicemia may complicate severe malaria, particularly in children. In endemic areas, *Salmonella* bacteremia has been associated specifically with *P. falciparum* infections. Chest infections and catheter-induced urinary tract infections are common among patients who are unconscious for >3 days. Aspiration pneumonia may follow generalized convulsions. The frequency of complications of severe falciparum malaria is summarized in Table 203-4.

MALARIA IN PREGNANCY

In heavily endemic (hyper- and holoendemic) areas, falciparum malaria in primi- and secundigravid women is associated with low birth weight (average reduction, ~170 g) and consequently increased infant and childhood mortality. In general, infected mothers in areas of stable transmission remain asymptomatic despite intense accumulation of parasitized erythrocytes in the placental microcirculation. Maternal HIV infection predisposes pregnant women to malaria, predisposes their newborns to congenital malarial infection, and exacerbates the reduction in birth weight associated with malaria.

In areas with unstable transmission of malaria, pregnant women are prone to severe infections and are particularly vulnerable to high-

TABLE 203-4 RELATIVE INCIDENCE OF SEVERE COMPLICATIONS OF FALCIPARUM MALARIA

Complication	Nonpregnant Adults	Pregnant Women	Children
Anemia	+	++	+++
Convulsions	+	+	+++
Hypoglycemia	+	+++	+++
Jaundice	+++	+++	+
Renal failure	+++	+++	–
Pulmonary edema	++	+++	+

Key: –, rare; +, infrequent; ++, frequent; +++, very frequent.

edema. Fetal distress, premature labor, and stillbirth or low birth weight are common results. Fetal death is usual in severe malaria. Congenital malaria occurs in <5% of newborns whose mothers are infected; its frequency and the level of parasitemia are related directly to the parasite density in maternal blood and in the placenta. *P. vivax* malaria in pregnancy is also associated with a reduction in birth weight (average, 110 g), but, in contrast to the situation in falciparum malaria, this effect is more pronounced in multigravid than in primigravid women.

MALARIA IN CHILDREN

Most of the estimated 1–3 million persons who die of falciparum malaria each year are young African children. Convulsions, coma, hypoglycemia, metabolic acidosis, and severe anemia are relatively common among children with severe malaria, whereas deep jaundice, acute renal failure, and acute pulmonary edema are unusual. Severely anemic children may present with labored deep breathing, which in the past has been attributed incorrectly to "anemic congestive cardiac failure" but in fact is usually caused by metabolic acidosis, often compounded by hypovolemia. Evidence is accruing that severe malaria can result in long-term neurocognitive and developmental deficits. In general, children tolerate antimalarial drugs well and respond rapidly to treatment.

TRANSFUSION MALARIA

Malaria can be transmitted by blood transfusion, needle-stick injury, sharing of needles by infected injection drug users, or organ transplantation. The incubation period in these settings is often short because there is no preerythrocytic stage of development. The clinical features and management of these cases are the same as for naturally acquired infections. Radical chemotherapy with primaquine is unnecessary for transfusion-transmitted *P. vivax* and *P. ovale* infections.

CHRONIC COMPLICATIONS OF MALARIA

TROPICAL SPLENOMEGALY (HYPERREACTIVE MALARIAL SPLENOMEGALY)

Chronic or repeated malarial infections produce hypergammaglobulinemia; normochromic, normocytic anemia; and, in certain situations, splenomegaly. Some residents of malaria-endemic areas in tropical Africa and Asia exhibit an abnormal immunologic response to repeated infections that is characterized by massive splenomegaly, hepatomegaly, marked elevations in serum titers of IgM and malarial antibody, hepatic sinusoidal lymphocytosis, and (in Africa) peripheral B cell lymphocytosis. This syndrome has been associated with the production of cytotoxic IgM antibodies to CD8+ T lymphocytes, antibodies to CD5+ T lymphocytes, and an increase in the ratio of CD4+ T cells to CD8+ T cells. These events may lead to uninhibited B cell production of IgM and the formation of cryoglobulins (IgM aggregates and immune complexes). This immunologic process stimulates reticuloendothelial hyperplasia and clearance activity and eventually produces splenomegaly. Patients with hyperreactive malarial splenomegaly (HMS) present with an abdominal mass or a dragging sensation in the abdomen and occasional sharp abdominal pains suggesting perisplenitis. Anemia and some degree of pancytopenia are usually evident, and in some cases malarial parasites cannot be found in peripheral-blood smears. Vulnerability to respira-

tory and skin infections is increased; many patients die of overwhelming sepsis. Persons with HMS who are living in endemic areas should receive antimalarial chemoprophylaxis; the results are usually good. In nonendemic areas, antimalarial treatment is advised. In some cases refractory to therapy, clonal lymphoproliferation may develop and then evolve into a malignant lymphoproliferative disorder.

QUARTAN MALARIAL NEPHROPATHY

Chronic or repeated infections with *P. malariae* (and possibly with other malarial species) may cause soluble immune-complex injury to the renal glomeruli, resulting in the nephrotic syndrome. Other unidentified factors must contribute to this process since only a very small proportion of infected patients develop renal disease. The histologic appearance is that of focal or segmental glomerulonephritis with splitting of the capillary basement membrane. Subendothelial dense deposits are seen on electron microscopy, and immunofluorescence reveals deposits of complement and immunoglobulins; in samples of renal tissue from children, *P. malariae* antigens are often visible. A coarse-granular pattern of basement membrane immunofluorescent deposits (predominantly IgG3) with selective proteinuria carries a better prognosis than a fine-granular, predominantly IgG2 pattern with nonselective proteinuria. Quartan nephropathy usually responds poorly to treatment with either antimalarial agents or glucocorticoids and cytotoxic drugs.

BURKITT'S LYMPHOMA AND EPSTEIN-BARR VIRUS INFECTION

It is possible that malaria-related immunosuppression provokes infection with lymphoma viruses. Burkitt's lymphoma is strongly associated with Epstein-Barr virus. The prevalence of this childhood tumor is high in malarious areas of Africa.

DIAGNOSIS

DEMONSTRATION OF THE PARASITE

The diagnosis of malaria rests on the demonstration of asexual forms of the parasite in stained peripheral-blood smears. After a negative blood smear, repeat smears should be made if there is a high degree of suspicion. Of the Romanowsky stains, Giemsa at pH 7.2 is preferred; Wright's, Field's, or Leishman's stain can also be used. Both thin (Figs. 203-4 and 203-5; see also Figs. e18-1 and e18-2) and thick (Figs. 203-6, 203-7, 203-8, and 203-9) blood smears should be examined. The thin blood smear should be rapidly air-dried, fixed in anhydrous methanol, and stained; the RBCs in the tail of the film should then be examined under oil immersion (×1000 magnification). The level

of parasitemia is expressed as the number of parasitized erythrocytes per 1000 RBCs. The thick blood film should be of uneven thickness. The smear should be dried thoroughly and stained without fixing. As many layers of erythrocytes overlie one another and are lysed during the staining procedure, the thick film has the advantage of concentrating the parasites (by 40- to 100-fold compared with a thin blood film) and thus increasing diagnostic sensitivity. Both parasites and white blood cells (WBCs) are counted, and the number of parasites per unit volume is calculated from the total leukocyte count. Alternatively, a WBC count of 8000/μL is assumed. This figure is converted to the number of parasitized erythrocytes per microliter. A minimum of 200 WBCs should be counted under oil immersion. Interpretation of blood smear films requires some experience because artifacts are common. Before a thick smear is judged to be negative, 100–200 fields should be examined under oil immersion. In high-transmission areas, the presence of up to 10,000 parasites/μL of blood may be tolerated without symptoms or signs in partially immune individuals. Thus the detection of malaria parasites is sensitive but only poorly specific in identifying malaria as the cause of illness.

Rapid, simple, sensitive, and specific antibody-based diagnostic stick or card tests that detect *P. falciparum*–specific, histidine-rich protein 2 (PfHRP2) or lactate dehydrogenase antigens in finger-prick blood samples have been introduced (Table 203-5). Some of these tests carry a second antibody, which allows falciparum malaria to be distinguished from the less dangerous malarias. PfHRP2-based tests may remain positive for several weeks after acute infection. This feature is a disadvantage in high-transmission areas where infections are frequent but is of value in the diagnosis of severe malaria in patients who have taken antimalarial drugs and cleared peripheral parasitemia (but in whom the PfHRP2 test remains strongly positive).

The relationship between parasitemia and prognosis is complex; in general, patients with $>10^5$ parasites/μL are at increased risk of dying, but nonimmune patients may die with much lower counts, and partially immune persons may tolerate parasitemia levels many times higher with only minor symptoms. In severe malaria, a poor prognosis is indicated by a predominance of more mature *P. falciparum* parasites (i.e., >20% of parasites with visible pigment) in the peripheral blood film or by the presence of phagocytosed malarial pigment in >5% of neutrophils. In *P. falciparum* infections, gametocytemia peaks 1 week after the peak of asexual parasites. Because the mature gametocytes of *P. falciparum* are not affected by most antimalarial drugs, their persistence does not constitute evidence of drug resistance. Phagocytosed malarial pigment is sometimes seen inside peripheral-blood monocytes or polymorphonuclear leukocytes and may provide a clue to recent infection if malaria parasites are not detectable. After the clearance of the parasites, this intraphagocytic malarial pigment is often evident for several days in the peripheral blood or for longer in bone marrow aspirates or smears of fluid expressed after intradermal puncture. Staining of parasites with the fluorescent dye acridine orange allows more rapid diagnosis of malaria (but not speciation of the infection) in patients with low-level parasitemia.

LABORATORY FINDINGS

Normochromic, normocytic anemia is usual. The leukocyte count is generally normal, although it may be raised in very severe infections. There is slight monocytosis, lymphopenia, and eosinopenia, with reactive lymphocytosis and eosinophilia in the weeks after the acute infection. The erythrocyte

TABLE 203-5 METHODS FOR THE DIAGNOSIS OF MALARIA[a]

Method	Procedure	Advantages	Disadvantages
Thick blood film[b]	Blood should be uneven in thickness but sufficiently thin to read watch hands through part of the spot. Stain dried, unfixed blood spot with Giemsa, Field's, or other Romanowsky stain. Count number of asexual parasites per 200 WBCs (or per 500 at low densities). Count gametocytes separately.[c]	Sensitive (0.001% parasitemia); species specific; inexpensive	Requires experience (artifacts may be misinterpreted as low-level parasitemia); underestimates true count
Thin blood film[d]	Stain fixed smear with Giemsa, Field's, or other Romanowsky stain. Count number of RBCs containing asexual parasites per 1000 RBCs. In severe malaria, assess stage of parasite development and count neutrophils containing malaria pigment.[e] Count gametocytes separately.[c]	Rapid; species specific; inexpensive; in severe malaria, provides prognostic information[e]	Insensitive (<0.05% parasitemia); uneven distribution of *P. vivax*, as enlarged infected red cells concentrate at leading edge
PfHRP2 dipstick or card test	A drop of blood is placed on the stick or card, which is then immersed in washing solutions. Monoclonal antibody captures the parasite antigen and reads out as a colored band.	Robust and relatively inexpensive; rapid; sensitivity similar to or slightly lower than that of thick films (~0.001% parasitemia)	Detects only *Plasmodium falciparum*; remains positive for weeks after infection[f]; does not quantitate *P. falciparum* parasitemia
Plasmodium LDH dipstick or card test	A drop of blood is placed on the stick or card, which is then immersed in washing solutions. Monoclonal antibodies capture the parasite antigens and read out as colored bands. One band is genus specific (all malarias), and the other is specific for *P. falciparum*.	Rapid; sensitivity similar to or slightly lower than that of thick films for *P. falciparum* (~0.001% parasitemia)	Slightly more difficult preparation than PfHRP2 tests; may miss low-level parasitemia with *P. vivax*, *P. ovale*, and *P. malariae* and does not speciate these organisms; does not quantitate *P. falciparum* parasitemia
Microtube concentration methods with acridine orange staining	Blood is collected in a specialized tube containing acridine orange, anticoagulant, and a float. After centrifugation, which concentrates the parasitized cells around the float, fluorescence microscopy is performed.	Sensitivity similar or superior to that of thick films (~0.001% parasitemia); ideal for processing large numbers of samples rapidly	Does not speciate or quantitate; requires fluorescence microscopy

[a]Malaria cannot be diagnosed clinically with accuracy, but treatment should be started on clinical grounds if the laboratory confirmation is likely to be delayed. In areas of the world where malaria is endemic and transmission is high, low-level asymptomatic parasitemia is common in otherwise-healthy people. Thus malaria may not be the cause of a fever, although in this context the presence of >10,000 parasites/μL (~0.2% parasitemia) *does* indicate that malaria is the cause. Antibody and polymerase chain reaction tests have no role in the diagnosis of malaria.

[b]Asexual parasites/200 WBCs × 40 = parasite count/μL (assumes a WBC count of 8000/μL). See Figs. 203-6 through 203-9.

[c]Gametocytemia may persist for days or weeks after clearance of asexual parasites. Gametocytemia without asexual parasitemia does not indicate active infection.

[d]Parasitized RBCs (%) × hematocrit × 1256 = parasite count/μL. See Figs. 203-3 and 203-4.

[e]The presence of >100,000 parasites/μL (~2% parasitemia) is associated with an increased risk of severe malaria, but some patients have severe malaria with lower counts. At any level of parasitemia, the finding that >50% of parasites are tiny rings (cytoplasm width less than half of nucleus width) carries a relatively good prognosis. The presence of visible pigment in >20% of parasites or of phagocytosed pigment in >5% of polymorphonuclear leukocytes (indicating massive recent schizogony) carries a worse prognosis.

[f]Persistence of PfHRP2 is a disadvantage in high-transmission settings, where many asymptomatic people have positive tests, but can be used to diagnostic advantage in low-transmission settings when a sick patient has received previous unknown treatment (which, in endemic areas, often consists of antimalarial drugs). A positive PfHRP2 test indicates that the illness is falciparum malaria, even if the blood smear is negative.

Note: LDH, lactate dehydrogenase; PfHRP2, *P. falciparum* histidine-rich protein 2; RBCs, red blood cells; WBCs, white blood cells.

sedimentation rate, plasma viscosity, and levels of C-reactive protein and other acute-phase proteins are high. The platelet count is usually reduced to ~10^5/μL. Severe infections may be accompanied by prolonged prothrombin and partial thromboplastin times and by more severe thrombocytopenia. Levels of antithrombin III are reduced even in mild infection. In uncomplicated malaria, plasma concentrations of electrolytes, blood urea nitrogen (BUN), and creatinine are usually normal. Findings in severe malaria may include metabolic acidosis, with low plasma concentrations of glucose, sodium, bicarbonate, calcium, phosphate, and albumin together with elevations in lactate, BUN, creatinine, urate, muscle and liver enzymes, and conjugated and unconjugated bilirubin. Hypergammaglobulinemia is usual in immune and semi-immune subjects. Urinalysis generally gives normal results. In adults and children with cerebral malaria, the mean opening pressure at lumbar puncture is ~160 mm of cerebrospinal fluid (CSF); usually the CSF is normal or has a slightly elevated total protein level [<1.0 g/L (<100 mg/dL)] and cell count (<20/μL).

MALARIA

(Table 203-6) When a patient in or from a malarious area presents with fever, thick and thin blood smears should be prepared and examined immediately to confirm the diagnosis and identify the species of infecting parasite (Figs. 203-4 through 203-9). Repeat blood smears should be performed at least every 12–24 h for 2 days if the first smears are negative and malaria is strongly suspected. Alternatively, a rapid antigen detection card or stick test should be performed. Patients with severe malaria or those unable to take oral drugs should receive parenteral antimalarial therapy. If there is any doubt about the resistance status of the infecting organism, it should be considered resistant. Antimalarial susceptibility testing can be performed but is not generally available and yields results too slowly to influence the choice of treatment. Several drugs are available for oral treatment, and the choice of drug depends on the likely sensitivity of the infecting parasites. Despite recent evidence of chloroquine resistance in *P. vivax* (from parts of Indonesia, Oceania, eastern and southern Asia, and Central and South America), chloroquine remains the treatment of choice for the "benign" human malarias (*P. vivax*, *P. ovale*, *P. malariae*) except in Indonesia and Papua New Guinea, where high levels of resistance are prevalent.

The treatment of falciparum malaria has changed radically in recent years. In endemic areas, the World Health Organization now recommends artemisinin-based combinations as first-line treatment for uncomplicated falciparum malaria everywhere. These rapidly and reliably effective drugs are often unavailable in temperate countries (including the United States), where treatment recommendations are limited by the registered available drugs. Fake or substandard drugs, including antimalarial agents, are being sold in many low-income countries; thus, careful attention is required at purchase, especially when the patient fails to respond as expected. Characteristics of antimalarial drugs are shown in **Table 203-7**.

SEVERE MALARIA In large studies conducted in Asia, parenteral artesunate, a water-soluble artemisinin derivative, has been shown to reduce mortality rates in severe falciparum malaria by 35% from rates obtained with quinine. Artesunate has therefore become the drug of choice. Artesunate is given by the IV route but can also be given by IM injection. Artemether and

Type of Disease or Treatment	Regimen(s)
Uncomplicated Malaria	
Known chloroquine-sensitive strains of *Plasmodium vivax*, *P. malariae*, *P. ovale*, *P. falciparum*[a]	Chloroquine (10 mg of base/kg stat followed by 5 mg/kg at 12, 24, and 36 h or by 10 mg/kg at 24 h and 5 mg/kg at 48 h) *or* Amodiaquine (10–12 mg of base/kg qd for 3 days)
Radical treatment for *P. vivax* or *P. ovale* infection	In addition to chloroquine or amodiaquine as detailed above, primaquine (0.25 mg of base/kg qd; 0.375–0.5 mg of base/kg qd in Southeast Asia and Oceania) should be given for 14 days to prevent relapse. In mild G6PD deficiency, 0.75 mg of base/kg should be given once weekly for 6 weeks. Primaquine should not be given in severe G6PD deficiency.
Sensitive *P. falciparum* malaria[b]	Artesunate[c] (4 mg/kg qd for 3 days) plus sulfadoxine (25 mg/kg)/pyrimethamine (1.25 mg/kg) as a single dose *or* Artesunate[c] (4 mg/kg qd for 3 days) plus amodiaquine (10 mg of base/kg qd for 3 days)[d]
Multidrug-resistant *P. falciparum* malaria	Either artemether-lumefantrine[c] (1.5/9 mg/kg bid for 3 days with food) or artesunate[c] (4 mg/kg qd for 3 days) *plus* Mefloquine (25 mg of base/kg—either 8 mg/kg qd for 3 days or 15 mg/kg on day 2 and then 10 mg/kg on day 3)[d]
Second-line treatment/treatment of imported malaria	Either artesunate[c] (2 mg/kg qd for 7 days) or quinine (10 mg of salt/kg tid for 7 days) *plus 1 of the following 3:* 1. Tetracycline[e] (4 mg/kg qid for 7 days) 2. Doxycycline[e] (3 mg/kg qd for 7 days) 3. Clindamycin (10 mg/kg bid for 7 days) *or* Atovaquone-proguanil (20/8 mg/kg qd for 3 days with food)
Severe Falciparum Malaria[f]	
	Artesunate[c] (2.4 mg/kg stat IV followed by 2.4 mg/kg at 12 and 24 h and then daily if necessary)[g] *or* Artemether[c] (3.2 mg/kg stat IM followed by 1.6 mg/kg qd) *or* Quinine dihydrochloride (20 mg of salt/kg[h] infused over 4 h, followed by 10 mg of salt/kg infused over 2–8 h q8h[i]) *or* Quinidine (10 mg of base/kg[h] infused over 1–2 h, followed by 1.2 mg of base/kg per hour[i] with electrocardiographic monitoring)

[a]Very few areas now have chloroquine-sensitive malaria (Fig. 203-2).
[b]In areas where the partner drug to artesunate is known to be effective.
[c]Artemisinin derivatives are not registered in the United States and some other temperate countries.
[d]Fixed-dose coformulated combinations are available.
[e]Tetracycline and doxycycline should not be given to pregnant women or to children <8 years of age.
[f]Oral treatment should be substituted as soon as the patient recovers sufficiently to take fluids by mouth.
[g]Artesunate is the drug of choice when available. The data from large studies in Southeast Asia showed a 35% reduction in mortality rate from that with quinine. Severe malaria in children in high-transmission settings has different characteristics; thus trials are ongoing in Africa comparing artesunate with quinine to determine whether there is a survival benefit in African children.
[h]A loading dose should not be given if therapeutic doses of quinine or quinidine have definitely been adminstered in the previous 24 h. Some authorities recommend a lower dose of quinidine.
[i]Infusions can be given in 0.9% saline and 5% or 10% dextrose in water. Infusion rates for quinine and quinidine should be carefully controlled.
Note: G6PD, glucose-6-phosphate dehydrogenase.

the closely related drug artemotil (arteether) are oil-based formulations given by IM injection; they are erratically absorbed and do not confer the same survival benefit as artesunate. A rectal formulation of artesunate has been developed as a community-based prereferral treatment for patients in the rural tropics who cannot take oral medications. Although the artemisinin compounds are safer than quinine and considerably safer than quinidine, only one formulation is available in the United States. IV artesunate has recently been approved by the FDA for emergency use for severe malaria through the Centers for Disease Control and Prevention (CDC) Drug Service (see end of chapter for contact information). The antiarrhythmic quinidine gluconate is as effective as quinine and, as it is more readily available, has replaced quinine for the treatment of malaria in the United States. The administration of quinidine must be closely monitored if dysrhythmias and hypotension are to be avoided. Total plasma levels >8 μg/mL, a QT_c interval >0.6 s, or QRS widening beyond 25% of baseline are indications for slowing infusion rates. If arrhythmia or saline-unresponsive hypotension develops, treatment with this drug should be discontinued. Quinine is safer than quinidine; cardiovascular monitoring is not required except when the recipient has cardiac disease.

Severe falciparum malaria constitutes a medical emergency requiring intensive nursing care and careful management. The patient should be weighed and, if comatose, placed on his or her side or prone. Frequent evaluation of the patient's condition is essential. Ancillary drugs such as high-dose glucocorticoids, urea, heparin, dextran, desferrioxamine, antibody to tumor necrosis factor α, and high-dose phenobarbital (20 mg/kg) have proved either ineffective or harmful in clinical trials and should not be used. In acute renal failure or severe metabolic acidosis, hemofiltration or hemodialysis should be started as early as possible.

Parenteral antimalarial treatment should be started as soon as possible. If artemether, quinine, or quinidine is used, an initial loading dose must be given so that therapeutic concentrations are reached as soon as possible. Both quinine and quinidine will cause dangerous hypotension if injected rapidly; when given IV, they must be administered carefully by rate-controlled infusion only. If this approach is not possible, quinine may be given by deep IM injections into the anterior thigh. The optimal therapeutic range for quinine and quinidine in severe malaria is not known with certainty, but total plasma concentrations of 8–15 mg/L for quinine and 3.5–8.0 mg/L for quinidine are effective and do not cause serious toxicity. The systemic clearance and apparent volume of distribution of these alkaloids are markedly reduced and plasma protein binding is increased in severe malaria, so that the blood concentrations attained with a given dose are higher. If the patient remains seriously ill or in acute renal failure for >2 days, maintenance doses of quinine or quinidine should be reduced by 30–50% to prevent toxic accumulation of the drug. The initial doses should never be reduced. If one of the artemisinin derivatives is given, dose reductions are unnecessary, even in renal failure. Exchange transfusion should be considered for severely ill patients, although the precise indications for this procedure have not been agreed upon. It has been recommended that—if safe and feasible—exchange should be considered for patients with severe malaria, but there is no clear evidence that this measure is beneficial. The role of prophylactic anticonvulsants is uncertain. If respiratory support is not available, then a full loading dose of phenobarbital (20 mg/kg) to prevent convulsions should not be given as it may cause respiratory arrest.

When the patient is unconscious, the blood glucose level should be measured every 4–6 h, and values <2.2 mmol/L (40 mg/dL) should mandate treatment with IV dextrose. All patients treated with IV quinine or quinidine should receive a continuous infusion of 5–10% dextrose. The parasite count and hematocrit level should be measured every 6–12 h. Anemia develops rapidly; if the hematocrit falls to <20%, then whole blood (preferably fresh) or packed cells should be transfused slowly, with careful attention to circulatory status. Renal function should be checked daily. Children presenting with severe anemia and acidotic breathing are often

TABLE 203-7 PROPERTIES OF ANTIMALARIAL DRUGS

Drug(s)	Pharmacokinetic Properties	Antimalarial Activity	Minor Toxicity	Major Toxicity
Quinine, quinidine	Good oral and IM absorption (quinine); *Cl* and V_d reduced, but plasma protein binding (principally to ∝1 acid glycoprotein) increased (90%) in malaria; quinine $t_{1/2}$: 16 h in malaria, 11 h in healthy persons; quinidine $t_{1/2}$: 13 h in malaria, 8 h in healthy persons	Acts mainly on trophozoite blood stage; kills gametocytes of *P. vivax*, *P. ovale*, and *P. malariae* (but not *P. falciparum*); no action on liver stages	*Common:* "Cinchonism": tinnitus, high-tone hearing loss, nausea, vomiting, dysphoria, postural hypotension; ECG QT_c interval prolongation (quinine usually by <10% but quinidine by up to 25%) *Rare:* Diarrhea, visual disturbance, rashes *Note:* Very bitter taste	*Common:* Hypoglycemia *Rare:* Hypotension, blindness, deafness, cardiac arrhythmias, thrombocytopenia, hemolysis, hemolytic-uremic syndrome, vasculitis, cholestatic hepatitis, neuromuscular paralysis *Note:* Quinidine more cardiotoxic
Chloroquine	Good oral absorption, very rapid IM and SC absorption; complex pharmacokinetics; enormous *Cl* and V_d (unaffected by malaria); blood concentration profile determined by distribution processes in malaria; $t_{1/2}$: 1–2 months	As for quinine but acts slightly earlier in asexual cycle	*Common:* Nausea, dysphoria, pruritus in dark-skinned patients, postural hypotension *Rare:* Accommodation difficulties, keratopathy, rash *Note:* Bitter taste, well tolerated	*Acute:* Hypotensive shock (parenteral), cardiac arrhythmias, neuropsychiatric reactions *Chronic:* Retinopathy (cumulative dose, >100 g), skeletal and cardiac myopathy
Amodiaquine	Good oral absorption; largely converted to active metabolite desethylamodiaquine	As for chloroquine	Nausea (tastes better than chloroquine)	Agranulocytosis; hepatitis, mainly with prophylactic use
Mefloquine	Adequate oral absorption; no parenteral preparation; $t_{1/2}$: 14–20 days (shorter in malaria)	As for quinine	Nausea, giddiness, dysphoria, fuzzy thinking, sleeplessness, nightmares, sense of dissociation	Neuropsychiatric reactions, convulsions, encephalopathy
Tetracycline, doxycycline[a]	Excellent absorption; $t_{1/2}$: 8 h for tetracycline, 18 h for doxycycline	Weak antimalarial activity; should not be used alone for treatment	Gastrointestinal intolerance, deposition in growing bones and teeth, photosensitivity, moniliasis, benign intracranial hypertension	Renal failure in patients with impaired renal function (tetracycline)
Halofantrine[b]	Highly variable absorption related to fat intake; $t_{1/2}$: 1–3 days (active desbutyl metabolite $t_{1/2}$: 3–7 days)	As for quinine	Diarrhea	Cardiac conduction disturbances; atrioventricular block; ECG QT_c interval prolongation; potentially lethal ventricular tachyarrhythmias
Artemisinin and derivatives (artemether, artesunate)	Good oral absorption, slow and variable absorption of IM artemether; artesunate and artemether biotransformed to active metabolite dihydroartemisinin; all drugs eliminated very rapidly; $t_{1/2}$: <1 h	Broader stage specificity and more rapid than other drugs; no action on liver stages; kills all but fully mature gametocytes of *P. falciparum*	Reduction in reticulocyte count (but not anemia)	Anaphylaxis, urticaria, fever
Pyrimethamine	Good oral absorption, variable IM absorption; $t_{1/2}$: 4 days	For blood stages, acts mainly on mature forms; causal prophylactic	Well tolerated	Megaloblastic anemia, pancytopenia, pulmonary infiltration
Proguanil (chloroguanide)	Good oral absorption; biotransformed to active metabolite cycloguanil; $t_{1/2}$: 16 h; biotransformation reduced by oral contraceptive use and in pregnancy	Causal prophylactic; not used alone for treatment	Well tolerated; mouth ulcers and rare alopecia	Megaloblastic anemia in renal failure
Primaquine	Complete oral absorption; active compound not known; $t_{1/2}$: 7 h	Radical cure; eradicates hepatic forms of *P. vivax* and *P. ovale*; kills all stages of gametocyte development of *P. falciparum*	Nausea, vomiting, diarrhea, abdominal pain, hemolysis, methemoglobinemia	Massive hemolysis in subjects with severe G6PD deficiency
Atovaquone	Highly variable absorption related to fat intake; $t_{1/2}$: 30–70 h	Acts mainly on trophozoite blood stage	None identified	None identified
Lumefantrine	Highly variable absorption related to fat intake; $t_{1/2}$: 3–4 days	As for quinine	None identified	None identified

[a]Tetracycline and doxycycline should not be given to pregnant women or to children <8 years of age.

[b]Halofantrine should not be used by patients with long ECG QT_c intervals or known conduction disturbances or by those taking drugs that may affect ventricular repolarization, e.g., quinidine, quinine, mefloquine, chloroquine, neuroleptics, antiarrhythmics, tricyclic antidepressants, terfenadine, or astemizole.

Abbreviations: *Cl*, systemic clearance; V_d, total apparent volume of distribution; IM, intramuscular; SC, subcutaneous; ECG, electrocardiogram; G6PD, glucose-6-phosphate dehydrogenase.

hypovolemic; in this situation, resuscitation with crystalloids or blood is indicated. Accurate assessment is vital. Management of fluid balance is difficult in severe malaria, particularly in adults, because of the thin dividing line between overhydration (leading to pulmonary edema) and underhydration (contributing to renal impairment). If necessary, central venous pressures should be measured and maintained in the low-normal range. As soon as the patient can take fluids, oral therapy should be substituted for parenteral treatment.

UNCOMPLICATED MALARIA Infections due to *P. vivax*, *P. malariae*, and *P. ovale* should be treated with oral chloroquine (total dose, 25 mg of base/kg). In much of the tropics, drug-resistant *P. falciparum* has been increasing in distribution, frequency, and intensity. Chloroquine-resistant *P. falciparum* is now present throughout most of the tropical world, and resistance to sulfadoxine/pyrimethamine is widespread and increasing. It is now accepted that, to prevent resistance, falciparum malaria should be treated with drug combinations and not with single drugs in endemic areas; the same rationale has been applied successfully to the treatment of tuberculosis and HIV/AIDS. This combination strategy is based on simultaneous use of two or more drugs with different modes of action: one is usually an artemisinin derivative (artesunate, artemether, or dihydroartemisinin) given for 3 days, and the other is usually a slower-acting antimalarial to which *P. falciparum* is sensitive. Artemisinin combination regimens now constitute first-line recommended treatment for falciparum malaria. In areas with multidrug-resistant falciparum malaria (parts of Asia and South America), either artemether-lumefantrine or artesunate-mefloquine should be used. Although significant resistance to mefloquine has been documented in Thailand, Myanmar, Vietnam, Laos, and Cambodia **(Fig. 203-10)**, mefloquine is usually effective against multidrug-resistant strains of *P. falciparum* outside these areas and, in combination with artesunate, achieves cure rates exceeding 90% nearly everywhere. Atovaquone-proguanil is also highly effective. In areas with more drug-sensitive isolates, atovaquone-proguanil, mefloquine, artesunate-amodiaquine, or artesunate-sulfadoxine/pyrimethamine can be used, depending on the prevailing drug susceptibility pattern. These 3-day regimens are all well tolerated, although mefloquine is associated with increased rates of vomiting and dizziness. As second-line treatment for recrudescence following first-line therapy, a 7-day course of either artesunate or quinine plus tetracycline, doxycycline, or clindamycin is effective. Tetracycline and doxycycline cannot be given to pregnant women or to children <8 years of age. Oral quinine is extremely bitter and regularly produces cinchonism comprising tinnitus, high-tone deafness, nausea, vomiting, and dysphoria. Adherence is poor with the required 7-day regimens of quinine.

Patients should be monitored for vomiting for 1 h after the administration of any oral antimalarial drug. If there is vomiting, the dose should be repeated. Symptom-based treatment, with tepid sponging and acetaminophen administration, lowers fever and thereby reduces the patient's propensity to vomit these drugs. Minor central nervous system reactions (nausea, dizziness, sleep disturbances) are common. The incidence of serious adverse neuropsychiatric reactions to mefloquine treatment is ~1 in 1000 in Asia but may be as high as 1 in 200 among Africans and Caucasians. All the antimalarial quinolines (chloroquine, mefloquine, and quinine) exacerbate the orthostatic hypotension associated with malaria, and all are tolerated better by children than by adults. Pregnant women, young children, patients unable to tolerate oral therapy, and nonimmune subjects (e.g., travelers) with suspected malaria should be evaluated carefully and hospitalization considered. If there is any doubt as to the identity of the infecting malarial species, treatment for falciparum malaria should be given. A negative blood smear does not rule out malaria; thick blood films should be checked 1 and 2 days later to exclude the diagnosis. Nonimmune patients receiving treatment for malaria should have daily parasite counts performed until negative thick films indicate clearance of the parasite. If the level of parasitemia does not fall below 25% of the admission value in 48 h or if parasitemia has not cleared by 7 days (and adherence is assured), drug resistance is likely and the regimen should be changed. If treatment failures occur with commonly used antimalarial agents, alternative drugs should be used.

To eradicate persistent liver stages and prevent relapse (radical treatment), primaquine (0.25–0.5 mg of base/kg, adult dose) should be given daily for 14 days to patients with *P. vivax* or *P. ovale* infections after laboratory tests for G6PD deficiency have proved negative. A total dose of 22.5–30 mg for an adult is recommended for infections acquired in Southeast Asia and Oceania. If the patient has a mild variant of G6PD deficiency, primaquine can be given in a dose of 0.75 mg of base/kg (45 mg maximum) once weekly for 6 weeks.

COMPLICATIONS **Acute Renal Failure** If the level of BUN or creatinine rises despite adequate rehydration, fluid administration should be restricted to prevent volume overload. As in other forms of hypercatabolic acute renal failure, renal replacement is best performed early (Chap. 273). Hemofiltration and hemodialysis are more effective than peritoneal dialysis and are associated with lower mortality. Some patients with renal impairment pass small volumes of urine sufficient to allow control of fluid balance; these cases can be managed conservatively if other indications for dialysis do not arise. Renal function usually improves within days, but full recovery may take weeks.

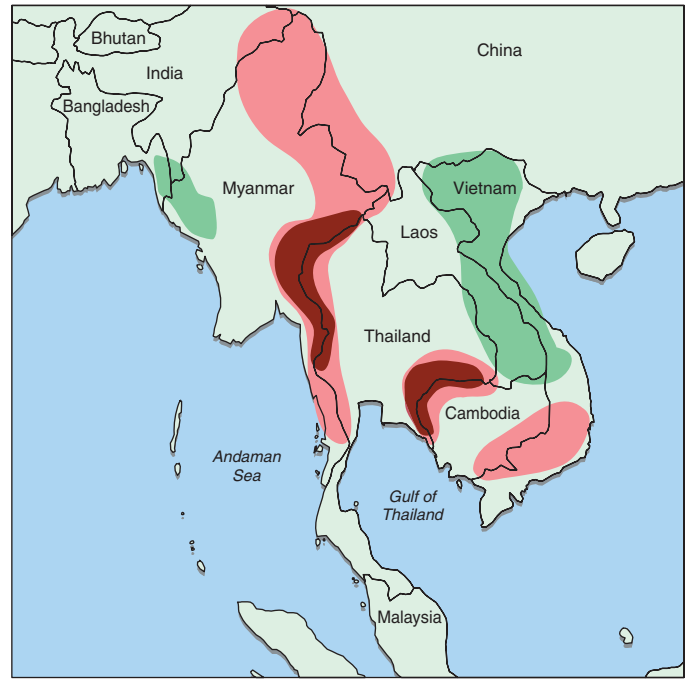

FIGURE 203-10 Mefloquine resistance in *Plasmodium falciparum* in Southeast Asia: high-level mefloquine resistance (*brown*), low-level mefloquine resistance (*red*), and mefloquine sensitivity (failure rate, <20%; *green*). There is insufficient information for the other areas.

Acute Pulmonary Edema Patients should be positioned with the head of the bed at a 45° elevation and given oxygen and IV diuretics. Pulmonary artery occlusion pressures may be normal, indicating increased pulmonary capillary permeability. Positive-pressure ventilation should be started early if the immediate measures fail (Chap. 228).

Hypoglycemia An initial slow injection of 50% dextrose (0.5 g/kg) should be followed by an infusion of 10% dextrose (0.10 g/kg per hour). The blood glucose level should be checked regularly thereafter as recurrent hypoglycemia is common, particularly among patients receiving quinine or quinidine. In severely ill patients, hypoglycemia commonly occurs together with metabolic (lactic) acidosis and carries a poor prognosis.

Other Complications Patients who develop spontaneous bleeding should be given fresh blood and IV vitamin K. Convulsions should be treated with IV or rectal benzodiazepines and, if necessary, respiratory support. Aspiration pneumonia should be suspected in any unconscious patient with convulsions, particularly with persistent hyperventilation; IV antimicrobial agents and oxygen should be administered, and pulmonary toilet should be undertaken. Hypoglycemia or gram-negative septicemia should be suspected when the condition of any patient suddenly deteriorates for no obvious reason during antimalarial treatment. Systemic *Salmonella* infections are common complications among African children with falciparum malaria. Antibiotics should be considered for severely ill patients not responding to antimalarial treatment.

PREVENTION

These are halcyon days for malaria prevention and control. New drugs have been discovered and developed; highly effective drugs, insecticide-treated nets, and insecticides for spraying dwellings are being purchased for endemic countries by the Global Fund to Fight HIV/AIDS, Tuberculosis, and Malaria and the President's Malaria Initiative; and even stronger support is being advocated by the Roll Back Malaria Partnership, the Global Health Council, and other supporters of malaria control and research. Still, the eradication of malaria is not yet feasible because of the widespread distribution of *Anopheles* breeding

TABLE 203-8 DRUGS USED IN THE PROPHYLAXIS OF MALARIA

Drug	Usage	Adult Dose	Pediatric Dose	Comments
Atovaquone/proguanil (Malarone)	Prophylaxis in areas with chloroquine- or mefloquine-resistant *Plasmodium falciparum*	1 adult tablet PO[a]	5–8 kg: 1/2 pediatric tablet[b] daily ≥8–10 kg: 3/4 pediatric tablet daily ≥10–20 kg: 1 pediatric tablet daily ≥20–30 kg: 2 pediatric tablets daily ≥30–40 kg: 3 pediatric tablets daily ≥40 kg: 1 adult tablet daily	Begin 1–2 days before travel to malarious areas. Take daily at the same time each day while in the malarious area and for 7 days after leaving such areas. Atovaquone-proguanil is contraindicated in persons with severe renal impairment (creatinine clearance rate <30 mL/min). It is not recommended for children weighing <5 kg, pregnant women, or women breast-feeding infants weighing <5 kg. Atovaquone/proguanil should be taken with food or a milky drink.
Chloroquine phosphate (Aralen and generic)	Prophylaxis only in areas with chloroquine-sensitive *P. falciparum*[c]	300 mg of base (500 mg of salt) PO once weekly	5 mg/kg of base (8.3 mg of salt/kg) PO once weekly, up to a maximum adult dose of 300 mg of base	Begin 1–2 weeks before travel to malarious areas. Take weekly on the same day of the week while in the malarious areas and for 4 weeks after leaving such areas. Chloroquine phosphate may exacerbate psoriasis.
Doxycycline (many brand names and generic)	Prophylaxis in areas with chloroquine- or mefloquine-resistant *P. falciparum*[c]	100 mg PO qd	≥8 years of age: 2 mg/kg, up to adult dose	Begin 1–2 days before travel to malarious areas. Take daily at the same time each day while in the malarious areas and for 4 weeks after leaving such areas. Doxycycline is contraindicated in children <8 years of age and in pregnant women.
Hydroxychloroquine sulfate (Plaquenil)	An alternative to chloroquine for primary prophylaxis only in areas with chloroquine-sensitive *P. falciparum*[c]	310 mg of base (400 mg of salt) PO once weekly	5 mg of base/kg (6.5 mg of salt/kg) PO once weekly, up to maximum adult dose of 310 mg of base	Begin 1–2 weeks before travel to malarious areas. Take weekly on the same day of the week while in the malarious areas and for 4 weeks after leaving such areas. Hydroxychloroquine may exacerbate psoriasis.
Mefloquine (Lariam and generic)	Prophylaxis in areas with chloroquine-resistant *P. falciparum*	228 mg of base (250 mg of salt) PO once weekly	≤9 kg: 4.6 mg of base/kg (5 mg of salt/kg) PO once weekly 10–19 kg: 1/4 tablet once weekly 20–30 kg: 1/2 tablet once weekly 31–45 kg: 3/4 tablet once weekly ≥46 kg: 1 tablet once weekly	Begin 1–2 weeks before travel to malarious areas. Take weekly on the same day of the week while in the malarious areas and for 4 weeks after leaving such areas. Mefloquine is contraindicated in persons allergic to this drug or related compounds (e.g., quinine and quinidine) and in persons with active or recent depression, generalized anxiety disorder, psychosis, schizophrenia, other major psychiatric disorders, or seizures. Use with caution in persons with psychiatric disturbances or a history of depression. Mefloquine is not recommended for persons with cardiac conduction abnormalities.
Primaquine	An option for prophylaxis in special circumstances	30 mg of base (52.6 mg of salt) PO qd	0.5 mg of base/kg (0.8 mg of salt/kg) PO qd, up to adult dose; should be taken with food	Begin 1–2 days before travel to malarious areas. Take daily at the same time each day while in the malarious areas and for 7 days after leaving such areas. Primaquine is contraindicated in persons with G6PD1 deficiency. It is also contraindicated during pregnancy and in lactation unless the infant being breast-fed has a documented normal G6PD level. Use in consultation with malaria experts.
Primaquine	Used for presumptive antirelapse therapy (terminal prophylaxis) to decrease risk of relapses of *P. vivax* and *P. ovale*.	30 mg of base (52.6 mg of salt) PO qd for 14 days after departure from the malarious area	0.5 mg of base/kg (0.8 mg of salt/kg), up to adult dose, PO qd for 14 days after departure from the malarious area	This therapy is indicated for persons who have had prolonged exposure to *P. vivax* and/or *P. ovale*. It is contraindicated in persons with G6PD1 deficiency as well as during pregnancy and in lactation unless the infant being breast-fed has a documented normal G6PD level.

[a]An adult tablet contains 250 mg of atovaquone and 100 mg of proguanil hydrochloride.
[b]A pediatric tablet contains 62.5 mg of atovaquone and 25 mg of proguanil hydrochloide.
[c]Very few areas now have chloroquine-sensitive malaria (Fig. 203-2).

Source: CDC: *http:/wwwn.cdc.gov/travel/contentMalariaDrugsHC.aspx*, accessed September 13, 2007.

sites; the great number of infected persons; the continued use of ineffective antimalarial drugs; and inadequacies in human and material resources, infrastructure, and control programs. Malaria may be contained by judicious use of insecticides to kill the mosquito vector, rapid diagnosis, appropriate patient management, and—where effective and feasible—administration of intermittent presumptive treatment or chemoprophylaxis to high-risk groups. Malaria researchers are intensifying their efforts to gain a better understanding of parasite-human-mosquito interactions and to develop more effective control and prevention interventions. Despite the enormous investment in efforts to develop a malaria vaccine, no safe, effective, long-lasting vaccine is likely to be available for general use in the near future (Chap. 116). While there is promise for one or more malaria vaccines on the more distant horizon, prevention and control measures continue to rely on antivector and drug-use strategies.

PERSONAL PROTECTION AGAINST MALARIA

Simple measures to reduce the frequency of mosquito bites in malarious areas are very important. These measures include the avoidance of exposure to mosquitoes at their peak feeding times (usually dusk and dawn) and throughout the night as well as the use of insect repellents containing DEET (10–35%) or picaridin (7%; if DEET is unacceptable), suitable clothing, and insecticide-impregnated bed nets or other materials. Widespread use of bed nets treated with residual pyrethroids reduces the incidence of malaria in areas where vectors bite indoors at night and has been shown to reduce mortality rates in western and eastern Africa.

CHEMOPROPHYLAXIS

(Table 203-8; *http://wwwn.cdc.gov/travel/contentMalariaDrugsHC.aspx*; accessed September 13, 2007) Recommendations for prophylaxis depend on knowledge of local patterns of plasmodial drug sensitivity and

the likelihood of acquiring malarial infection. When there is uncertainty, drugs effective against resistant *P. falciparum* should be used [atovaquone-proguanil (Malarone), doxycycline, mefloquine, or primaquine]. Chemoprophylaxis is never entirely reliable, and malaria should always be considered in the differential diagnosis of fever in patients who have traveled to endemic areas, even if they are taking prophylactic antimalarial drugs.

Pregnant women traveling to malarious areas should be warned about the potential risks. All pregnant women at risk in endemic areas should be encouraged to attend regular antenatal clinics. Mefloquine is the only drug advised for pregnant women traveling to areas with drug-resistant malaria; this drug is generally considered safe in the second and third trimesters of pregnancy, and the limited data on first-trimester exposure are reassuring. The safety of other prophylactic antimalarial agents in pregnancy has not been established. Antimalarial prophylaxis has been shown to reduce mortality rates among children between the ages of 3 months and 4 years in malaria-endemic areas; however, it is not a logistically or economically feasible option in many countries. The alternative—to give intermittent treatment doses [intermittent preventive treatment (IPT)]—shows promise for more widespread use in infants, young children, and pregnant women. Children born to nonimmune mothers in endemic areas (usually expatriates moving to malaria-endemic areas) should receive prophylaxis from birth.

Travelers should start taking antimalarial drugs 2 days to 1–2 weeks before departure so that any untoward reactions can be detected and so that therapeutic antimalarial blood concentrations will be present when needed (Table 203-8). Antimalarial prophylaxis should continue for 4 weeks after the traveler has left the endemic area, except if atovaquone-proguanil or primaquine has been taken; these drugs have significant activities against the liver stage of the infection (causal prophylaxis) and can be discontinued 1 week after departure from the endemic area. Presumptive self-treatment for malaria with atovaquone-proguanil (for 3 consecutive days) or another drug can be considered under special circumstances; medical advice on self-treatment should be sought before departure for malarious areas and as soon as possible after illness begins.

Atovaquone-proguanil (Malarone; 3.75/1.5 mg/kg or 250/100 mg, daily adult dose) is a fixed-combination, once-daily prophylactic agent that is very well tolerated by adults and children, with fewer adverse gastrointestinal effects than chloroquine-proguanil and fewer adverse central nervous system effects than mefloquine. It is proguanil itself, rather than the antifolate metabolite cycloguanil, that acts synergistically with atovaquone. This combination is effective against all types of malaria, including multidrug-resistant falciparum malaria. Atovaquone-proguanil is best taken with food or a milky drink to optimize absorption. There are insufficient data on the safety of this regimen in pregnancy.

Mefloquine (250 mg of salt weekly, adult dose) has been widely used for malarial prophylaxis because it is usually effective against multidrug-resistant falciparum malaria and is reasonably well tolerated. Mild nausea, dizziness, fuzzy thinking, disturbed sleep patterns, vivid dreams, and malaise are relatively common. Approximately 1 in every 10,000 recipients develops an acute reversible neuropsychiatric reaction manifested by confusion, psychosis, convulsions, or encephalopathy. The role of mefloquine prophylaxis during pregnancy remains uncertain; in studies in Africa, mefloquine prophylaxis was found to be effective and safe during pregnancy. However, in one study from Thailand, treatment of malaria with mefloquine was associated with an increased risk of stillbirth.

Daily administration of doxycycline (100 mg daily, adult dose) is an effective alternative to atovaquone-proguanil or mefloquine. Doxycycline is generally well tolerated but may cause vulvovaginal thrush, diarrhea, and photosensitivity and cannot be used by children <8 years old or by pregnant women.

Chloroquine remains the drug of choice for the prevention of infection with drug-sensitive *P. falciparum* (now found in very few areas of the world) and with the other human malarial species (although chloroquine-resistant *P. vivax* has been reported from parts of eastern Asia, Oceania, and Central and South America). Chloroquine is generally well tolerated, although some patients cannot take the drug because of malaise, headache, visual symptoms (from reversible keratopathy), gastrointestinal intolerance, or (in dark-skinned patients) pruritus. A concomitant filarial infection may provoke or aggravate chloroquine-induced pruritus. Chloroquine is considered safe in pregnancy. With chronic administration for >5 years, a characteristic dose-related retinopathy may develop, but this condition is rare at the doses used for antimalarial prophylaxis. Idiosyncratic or allergic reactions are also rare. Skeletal and cardiac myopathy are potential problems with protracted prophylactic use; they are more likely to occur with the high doses used in the treatment of rheumatoid arthritis. Neuropsychiatric reactions and skin rashes are unusual. When used continuously, amodiaquine, a related aminoquinoline, is associated with a high risk of agranulocytosis (~1 person in 2000) and hepatotoxicity (~1 person in 16,000) and should not be used for prophylaxis.

Primaquine (0.5 mg of base/kg or 30 mg, daily adult dose taken with food) has proved safe and effective in the prevention of drug-resistant falciparum and vivax malaria in adults. This drug can be considered for persons who are traveling to areas with or without drug-resistant *P. falciparum* and who are intolerant to other recommended drugs. Abdominal pain and oxidant hemolysis—the principal adverse effects—are not common as long as the drug is taken with food and is not given to G6PD-deficient persons. Primaquine should not be given to pregnant women or neonates. Travelers must be tested for G6PD deficiency and be shown to have a level in the normal range before receiving primaquine. In G6PD deficiency, primaquine can cause hemolysis that is sometimes fatal.

In the past, the dihydrofolate reductase inhibitors pyrimethamine and proguanil (chloroguanide) have been administered widely, but the rapid selection of resistance in both *P. falciparum* and *P. vivax* has limited their use. Whereas antimalarial quinolines such as chloroquine act on the erythrocyte stage of parasitic development, the dihydrofolate reductase inhibitors also inhibit preerythrocytic growth in the liver (causal prophylaxis) and development in the mosquito (sporontocidal activity). Proguanil is safe and well tolerated, although mouth ulceration occurs in ~8% of persons using this drug; it is considered safe for antimalarial prophylaxis in pregnancy. The prophylactic use of the combination of pyrimethamine and sulfadoxine is not recommended because of an unacceptable incidence of severe toxicity, principally exfoliative dermatitis and other skin rashes, agranulocytosis, hepatitis, and pulmonary eosinophilia (incidence, 1:7000; fatal reactions, 1:18,000). The combination of pyrimethamine with dapsone (0.2/1.5 mg/kg weekly; 12.5/100 mg, adult dose) is a third-line alternative available in some countries. Dapsone may cause methemoglobinemia and allergic reactions and (at higher doses) may pose a significant risk of agranulocytosis. Proguanil and the pyrimethamine-dapsone combination are not available in the United States.

Because of the increasing spread and intensity of antimalarial drug resistance (Figs. 203-2 and 203-10), the Centers for Disease Control and Prevention (CDC; *http://www.cdc.gov/malaria/index.htm*), which recommends a daily dose of atovaquone-proguanil for all travelers, maintains an updated 24-h travel and malaria information audiotape that can be accessed by touch-tone telephone (877-FYI-TRIP). Regional and disease-specific documents may be requested from the CDC Fax Information Service (888-232-3299). Consultation for the evaluation of prophylaxis failures or treatment of malaria can be obtained from state and local health departments and the CDC Malaria Hotline (770-488-7788) or the CDC Emergency Operations Center (770-488-7100).

204 Babesiosis

Jeffrey A. Gelfand, Edouard Vannier

Babesiosis is an emerging infection transmitted by ticks and caused by intraerythrocytic protozoa of the genus *Babesia*. Wild and domestic animals are natural reservoirs of *Babesia* species. Only in the past 50 years has *Babesia* been appreciated to be a pathogen in humans. Usually a mild flulike illness in young and healthy people, babesiosis may develop into a life-threatening malaria-like syndrome in asplenic, immunocompromised, or elderly patients.

ETIOLOGY AND NATURAL CYCLE

In the northeastern United States, *Babesia microti* is transmitted to humans by the hard-bodied tick *Ixodes scapularis* (*I. dammini*). In the fall, adult ticks feed primarily on white-tailed deer. Deer are incompetent reservoirs for *B. microti* but are essential for the maintenance of *I. scapularis*. Adult ticks overwinter and lay eggs in the spring. The eggs hatch into larvae in late July. In August and September, larvae become infected as they feed on *B. microti*–infected white-footed mice. In the spring of the following year, larvae molt into nymphs that remain infected with *B. microti* (transstadial transmission). Early in the summer, these nymphs feed on white-footed mice that become reservoirs of *B. microti*. Transmission of *B. microti* to humans is incidental and occurs primarily at the nymphal stage.

In Europe, *I. ricinus* is regarded as the main vector for infection of humans with *B. divergens*, a pathogen of cattle. *B. divergens* is maintained in the life cycle of the tick by transstadial and transovarial transmission. Nymphs and adults are considered the primary vectors in bovine and human babesiosis.

As ticks feed, *Babesia*-infected red blood cells (RBCs) accumulate in their gut. Gametes fuse into zygotes that translocate across the epithelium, enter the hemolymph, and become kinetes. Some kinetes reach salivary acini and undergo hypertrophy to become dormant sporoblasts. Upon attachment of the tick to the host, sporogony is initiated. In the last hours of feeding, sporozoites are deposited in the host dermis. Once in the blood, sporozoites invade erythrocytes to become trophozoites. Trophozoites undergo asynchronous schizogony, resulting in the budding of two or four merozoites. Tetrads ("Maltese crosses") are pathognomonic of *B. microti* and other small *Babesia* species (e.g., *B. duncani*) but are seen only rarely in blood smears during infection.

EPIDEMIOLOGY

United States Babesiosis due to *B. microti* is an emerging infection in the United States. Most of the >300 documented cases have occurred in coastal southern New England (from eastern Connecticut to Cape Cod, MA) and the chain of islands off the coast, particularly Nantucket Island and Martha's Vineyard (MA); Block Island (RI); and eastern Long Island, Shelter Island, and Fire Island (NY). Several cases have been reported from upstate New York, New Jersey, and Pennsylvania and from the upper Midwest (Wisconsin, Minnesota). Because babesiosis is not a notifiable disease in every state and asymptomatic infection is common, the incidence of *B. microti* infection is greatly underestimated. In New York state alone, >800 cases have been reported in the past decade. In Washington state and northern California, nine cases have been attributed to *B. duncani* (isolates WA1 and CA5), *B. duncani*–type parasites (WA2 and CA6), and other closely related babesial parasites (CA1–4). These organisms are antigenically distinct from *B. microti* and belong to the clade of piroplasms found in dogs (*B. conradae*) and wild animals in the western United States. As asymptomatic infection may persist for months without detectable parasitemia, babesiosis may be transmitted by blood transfusion, especially in endemic areas. More than 50 transfusion-transmitted cases have been attributed to *B. microti* and two to *B. duncani* (WA1 and WA2). Neonatal babesiosis is rare and has been acquired by vertical transmission, blood transfusion, or tick bite. Lastly, *B. divergens*–like parasites have been implicated in three cases of acute babesiosis (one each in Missouri, Kentucky, and Washington state).

Other Countries Babesiosis is rare in Europe, with half of the >35 cases documented in France and the British Isles. In addition to the original case from Croatia, cases have been reported from the central Alpine region (Austria, Italy, Switzerland) and from southern Europe (Spain, Portugal). Most cases have involved asplenic patients and have been attributed to *B. divergens*. *B. microti* has been implicated in only a handful of cases, although serologic evidence of *B. microti* infection has emerged from Switzerland and midwestern Germany. A study of two patients from Austria and Italy has identified *Babesia* EU1 as a novel pathogen that belongs to the *B. divergens* clade and is closely related to *B. odocoilei*, a parasite of white-tailed deer.

Sporadic cases of human babesiosis have been described in Mexico, Colombia, the Canary Islands, Ivory Coast, Egypt, Mozambique, South Africa, and India. Cases due to *B. microti*–like piroplasms have been reported from Taiwan and Japan.

CLINICAL PRESENTATION

Infections with *B. microti* vary in severity. Asymptomatic infection or self-limiting flulike illness occurs in ~25% of adults and ~50% of children. The incubation period lasts 1–6 weeks. Onset is gradual. The most common manifestations are fever (intermittent or sustained, with temperatures sometimes reaching 40°C), fatigue, malaise, shaking chills, sweats, myalgias, and arthralgias. Less frequent symptoms include shortness of breath, headache, anorexia, and nausea. Malaise, myalgias, arthralgias, and shortness of breath may help differentiate babesiosis from other febrile illnesses. Fever is the salient feature on physical examination. Mild splenomegaly and hepatomegaly may be noted. Jaundice is rare.

Low hematocrit, low hemoglobin, and hemoglobinuria are consistent with hemolytic anemia. The parasitemia level is usually 1–10% in immunocompetent hosts but can reach 85% in asplenic patients. Reticulocyte counts are elevated, white blood cell (WBC) counts are normal or slightly low, and thrombocytopenia is common. Levels of liver enzymes (including alkaline phosphatase, lactate dehydrogenase, aspartate and alanine aminotransferases, and bilirubin) are elevated. With hemolysis, the serum haptoglobin concentration is low, and urinalysis may show hemoglobinuria and proteinuria.

Complications of babesiosis include acute respiratory failure, disseminated intravascular coagulation, congestive heart failure, and renal failure. *B. microti* infection may be fatal in 5–10% of cases in hospitalized patients. Severe anemia (hemoglobin concentration, <10 g/dL) and high-level parasitemia (>10%) are risk factors for complications. Alkaline phosphatase levels of >125 U/L, WBC counts of $>5 \times 10^9$/L, and male gender are strong predictors of severe disease, as defined by death, hospitalization for >2 weeks, or admission to an intensive care unit for >2 days. Severe babesiosis is common among asplenic patients, patients co-infected with *Borrelia burgdorferi* (i.e., those with Lyme disease), persons >50 years of age, and individuals with comorbidities, including HIV infection, cancer, and other diseases associated with immunosuppression. Infection may recrudesce after splenectomy or immunosuppressive therapy.

Babesiosis due to *B. divergens* occurs most often in asplenic patients. After an incubation period of 1–3 weeks, disease suddenly appears. Hemoglobinuria—the presenting symptom—is followed by

jaundice, persistent high fever (40°–41°C), myalgias, shaking chills, and drenching sweats. Babesiosis may evolve into a shocklike syndrome, with renal failure and pulmonary edema. The parasitemia level can reach 80%. Hemoglobin levels may plunge to 4–8 g/dL. The mortality rate remains high (42%).

Infections with *B. duncani* and related parasites range from asymptomatic to severe and are sometimes fatal.

TABLE 204-1 ANTIBIOTIC REGIMENS FOR THE TREATMENT OF BABESIOSIS

Organism	Severity	Adults	Children
B. microti	Mild[a]	Atovaquone (750 mg q12h PO) *plus* Azithromycin (500–1000 mg/d PO on day 1, 250 mg/d PO thereafter)	Atovaquone (20 mg/kg q12h PO; maximum, 750 mg/dose) *plus* Azithromycin [10 mg/kg qd PO on day 1 (maximum, 500 mg/dose), 5 mg/kg qd PO thereafter (maximum, 250 mg/dose)]
	Severe[a]	Clindamycin (300–600 mg q6h IV or 600 mg q8h PO) *plus* Quinine (650 mg q6–8h PO) *plus* Consider RBC exchange transfusion	Clindamycin (7–10 mg/kg q6–8h IV or 7–10 mg/kg q6–8h PO; maximum, 600 mg/dose) *plus* Quinine (8 mg/kg q8h PO; maximum, 650 mg/dose) *plus* Consider RBC exchange transfusion
B. divergens	Mild or severe[b]	Immediate complete RBC exchange transfusion *plus* Clindamycin (600 mg q6–8h IV) *plus* Quinine (650 mg q8h PO)	Immediate complete RBC exchange transfusion *plus* Clindamycin (7–10 mg/kg q6–8h IV; maximum, 600 mg/dose) *plus* Quinine (8 mg/kg q8h PO; maximum, 650 mg/dose)

[a]Treatment duration: 7–10 days.
[b]Treatment duration: generally 7–10 days, but may vary.
Note: RBC, red blood cell.

DIAGNOSIS

A diagnosis of babesiosis should be considered for any symptomatic patient who resides or travels in endemic areas. The tick bite often goes unnoticed. Because symptoms are nonspecific, the diagnosis requires laboratory testing. Babesiosis is diagnosed by microscopic examination of Giemsa-stained thin blood smears. *Babesia* spp. appear annular, oval, or piriform. Ring forms are most common and do not contain the central brownish deposits (hemozoin) typical of *Plasmodium falciparum*. Tetrads are indicative of small babesial parasites, such as *B. microti* and *B. duncani*. An indirect immunofluorescent antibody test (IFAT) for *B. microti* is available from the Centers for Disease Control and Prevention. A serum IgG titer of ≥1:64 is diagnostic. The latter test has good predictive value for infection but must be interpreted in the clinical context; antibodies do not develop until at least 1 week into the illness, and serologic testing does not distinguish prior infection from active infection. Thus, IFAT is ideal for detection of past or persistent infection but not of fulminant acute infection. Antibodies to *B. microti* do not react with *B. divergens* or *B. duncani*. The persistence of low-grade infection is best diagnosed by polymerase chain reaction (PCR)–based amplification of the babesial 18S rRNA gene in blood samples. As primers are species-specific, this assay is a valuable adjunct in the diagnosis of babesiosis.

Rx BABESIOSIS

(See **Table 204-1**) Whether *B. microti* infection should be treated depends on the clinical context. Asymptomatic infections need not be treated, but if *Babesia* organisms continue to be seen on blood smear or by PCR for >3 months, treatment should be considered. Symptomatic infections should not be treated if blood smear and PCR are both negative for *Babesia*. If *Babesia* is detected in blood samples from symptomatic patients, treatment should be initiated.

A combination of atovaquone and azithromycin, given for 7–10 days, constitutes initial therapy for non-life-threatening (mild) babesiosis due to *B. microti*. For immunocompromised patients, higher doses of azithromycin (600–1000 mg/d) than those listed in the table are used. A combination of clindamycin and quinine is given for 7–10 days to patients with severe *B. microti* babesiosis; whenever possible, clindamycin should be given IV rather than PO. Partial or complete RBC exchange transfusion is advised in severe babesiosis, which is defined as a parasitemia level of >10%; significant hemolysis; or renal, hepatic, or pulmonary compromise. Treatment failures have been described with the recommended medical regimens. Other combination therapies may be used. A combination of azithromycin and quinine was effective in two patients with infection refractory to clindamycin plus quinine. One patient with AIDS and chronic babesiosis was treated successfully with a combination of clindamycin, doxycycline, and azithromycin after becoming allergic to quinine.

In patients with mild *B. microti* babesiosis, symptoms should improve within the first 48 h of therapy and should resolve within 3 months. In patients with severe babesiosis, hematocrit and parasitemia should be monitored each day or every other day until symptoms recede and the parasitemia level is <5%. Re-treatment may be required if the babesial parasite or amplifiable babesial DNA is detected for >3 months after initial therapy, but routine testing is not needed for immunocompetent patients who are asymptomatic. Underlying immunodeficiency (such as malignancy or HIV infection) should be considered in patients with severe or prolonged episodes of babesiosis. There is increasing evidence that immunosuppressed patients may need treatment for considerably longer periods.

Patients with babesiosis should be evaluated for Lyme disease (Chap. 166) and human granulocytotropic anaplasmosis (Chap. 167), as all three infections may be acquired from the same tick vector. In endemic areas for these infections, relevant antimicrobial therapy should be considered when an intercurrent infection is strongly suspected.

B. divergens infection is often severe and progresses rapidly. The recommended treatment is immediate complete blood exchange transfusion and medical therapy with IV clindamycin plus oral quinine. Exchange transfusion ensures a complete and rapid removal of parasitized RBCs, RBC debris, and inflammatory mediators. Although uninfected RBCs are introduced by exchange transfusion, anemia may persist for >1 month. If so, additional transfusion is needed.

PREVENTION

Individuals who live or travel in endemic areas, especially those at increased risk for severe babesiosis, should be advised to avoid tick exposure by wearing protective clothing (long sleeves/long pants, with pants tucked into socks); applying tick repellents (such as DEET) to clothing; and limiting outdoor activities, especially between May and September, when infection risk is highest. Thorough skin examination after outdoor exposure allows removal of ticks within 24 h of attachment—i.e., before transmission can occur.

e18 Atlas of Blood Smears of Malaria and Babesiosis

Nicholas J. White, Joel G. Breman

Four species of blood protozoan parasites cause human malaria: the potentially lethal and often drug-resistant *Plasmodium falciparum*; the relapsing parasites *P. vivax* and *P. ovale*; and *P. malariae*, which can persist at low densities for years. Occasional infections in individuals who have been in tropical forests may be caused by monkey parasites—notably, *P. knowlesi*.

The malaria parasites are readily seen under the microscope (×1000 magnification) in thick and thin blood smears stained with supravital dyes (e.g., Giemsa's, Field's, Wright's, Leishman's). The morphologic characteristics of the parasites are summarized in Table e18-1. In the thick film, lysis of red blood cells by water leaves the stained white cells and parasites, allowing detection of densities as low as 50 parasites/μL. This degree of sensitivity is up to 100 times greater than that of the thin film, in which the red cells are fixed and the malaria parasites are seen inside the cells. The thin film is better for speciation and provides useful prognostic information in severe falciparum malaria. Several findings are associated with increased mortality risk: high parasite counts, more mature parasites (>20% containing visible malaria pigment), and phagocytosed malaria pigment in >5% of neutrophils.

Babesia microti appears as a small ring form resembling *P. falciparum*. Unlike *Plasmodium*, *Babesia* does not cause the production of pigment in parasites, nor are schizonts or gametocytes formed.

TABLE e18-1 MORPHOLOGIC CHARACTERISTICS OF HUMAN MALARIA PARASITES

	P. falciparum	*P. vivax*	*P. ovale*	*P. malariae*
Asexual parasites	Usually only fine blue ring forms (some resembling stereo headsets) are seen. Parasitemia level may exceed 2%.	Irregular, large, fairly thick rings become highly pleomorphic as the parasite grows. Parasitemia level is low.	Regular, dense ring enlarges to compact, blue, mature trophozoite (rectangular or band-form). Parasitemia level is low.	Dense, thick rings mature to dense, round trophozoites. Parasitemia level is low.
Schizonts	Rare in peripheral blood; 8–32 merozoites, dark brown-black pigment	Common; 12–18 merozoites, orange-brown pigment	8–14 merozoites, brown or black pigment	8–10 merozoites, dark brown or black pigment
Gametocytes	Banana-shaped; male: light blue; female: darker blue; a few scattered blue-black pigment granules in cytoplasm	Round or oval; male: round, pale blue; female: oval, dark blue; triangular nucleus, a few orange pigment granules	Large, round, dense, and blue (like *P. malariae*), but prominent James's dots; brown pigment	Large, oval; male: pale blue; female: dense blue; large black pigment granules
RBC changes	RBCs are normal in size. As the parasite matures, the RBC cytoplasm becomes pale, the cells become crenated, and a few small red dots may appear over the cytoplasm (Maurer's clefts).	RBCs are enlarged. Pale red Schüffner's dots increase in number as the parasite matures.	RBCs become oval with tufted ends. Red James's dots are prominent.	RBCs are normal in size and shape. No red dots are seen.

Note: RBC, red blood cell.

205 Leishmaniasis

Barbara L. Herwaldt

The term *leishmaniasis* encompasses multiple clinical syndromes. Most notable are visceral, cutaneous, and mucosal leishmaniasis, which result from infection of macrophages throughout the reticuloendothelial system, in the dermis, and in the naso-oropharyngeal mucosa, respectively.

Leishmaniasis, a vector-borne disease caused by obligate intracellular protozoa, is characterized by vast diversity and by specificity within that diversity. The disease is endemic in focal areas of ~90 countries in the tropics, subtropics, and southern Europe, in settings that range from deserts to rain forests and from rural to urban areas. Infection in humans is caused by ~20 *Leishmania* species (*Leishmania* and *Viannia* subgenera) (Table 205-1), which are transmitted by ~30 species of phlebotomine sandflies [*Phlebotomus* (Old World) and *Lutzomyia* (New World)]. Amid this diversity, particular parasite, vector, and host species maintain the transmission cycle in a given setting.

Both the diversity and the specificity of the disease confound attempts to generalize about any aspect of leishmaniasis, including control measures and clinical management. The multitudinous possible combinations of *Leishmania* species/strains, syndromes, and geographic areas—modified by host factors and immunoinflammatory responses—may be associated with clinically relevant differences, such as diverse manifestations of infection and diverse responses to particular therapies. It is essential that clinicians understand the dangers associated with extrapolating data from one setting to another and the importance of individualizing patient care, with expert consultation.

LIFE CYCLE AND IMMUNOREGULATION

Leishmania parasites, which target and persist in tissue macrophages, are transmitted by the bite of female phlebotomine sandflies. While probing for a blood meal, sandflies regurgitate the parasite's flagellated promastigote stage into the host's skin; sandfly salivary components with immunomodulating effects have been shown to promote experimental infection. Promastigotes bind to receptors on macrophages, are phagocytized, and transform within phagolysosomes into nonflagellated amastigotes (Fig. 205-1), which replicate and infect additional macrophages. Amastigotes ingested by sandflies transform back into infective promastigotes. Other modes of transmission include congenital and parenteral (e.g., by blood transfusion or needle sharing).

Leishmaniasis is viewed as a model system for exploring immunoregulatory responses to intracellular pathogens. Murine models of *L. major* infection exemplify the T_H1/T_H2 paradigm, in which polarized T_H1 and T_H2 responses govern resistance and susceptibility, respectively. Production of interferon γ (IFN-γ) by T_H1 and natural killer cells confers resistance; interleukin (IL) 12 induces naïve T cells to differentiate into T_H1 cells and induces T cells and natural killer cells to produce IFN-γ. In contrast, expansion of IL-4-producing T_H2 cells and IL-10 mediate susceptibility.

Although the immunoregulatory responses are more complex and less polarized in humans than in inbred mice, key principles are evident. The immunoinflammatory response is central to pathogenesis, healing is associated with activation of macrophages to kill intracellular amastigotes, and persistent infection is characteristic. Although the correlates of immunity are not fully defined and may differ between treated and untreated persons, nonsterile cure is a mixed blessing: quiescent parasites may help the host maintain a protective T cell–mediated immune response but may also serve as a source for activation of latent or clinically cured infection if the protective mechanisms fail.

TABLE 205-1 *LEISHMANIA* SPECIES THAT CAUSE DISEASE IN HUMANS

Species[a]	Clinical Syndrome[b]	Geographic Distribution[c]
Subgenus *Leishmania*		
L. donovani complex		
L. donovani sensu stricto	VL (PKDL, OWCL)	China, Indian subcontinent (southern Asia), southwestern Asia, Ethiopia,[d] Kenya, Somalia, Sudan, Uganda; possibly sporadic elsewhere in sub-Saharan Africa
L. infantum sensu stricto[e]	VL (OWCL)	China, central and southwestern Asia, Middle East, southern Europe, northern Africa, Ethiopia,[d] Sudan; sporadic elsewhere in sub-Saharan Africa
L. chagasi[e]	VL (NWCL)	Central and South America
L. mexicana complex		
L. mexicana	NWCL (DCL)	Mexico, Central and South America; sporadic in Texas and Oklahoma
L. amazonensis	NWCL (ML, DCL, VL)	Panama and South America
L. tropica	*OWCL (VL)*[f]	*Central Asia, India, Pakistan, southwestern Asia, Middle East, Turkey, Greece, northern Africa, Ethiopia,[d] Kenya, Namibia*
L. major	OWCL	Central Asia, India, Pakistan, southwestern Asia, Middle East, Turkey, northern Africa, Sahel region of north-central Africa, Ethiopia,[d] Sudan, Kenya
L. aethiopica	OWCL (DCL)	Ethiopia,[d] Kenya, Uganda
Subgenus *Viannia*		
L. (V.) braziliensis	NWCL (ML)	Central and South America
L. (V.) guyanensis	NWCL (ML)	South America
L. (V.) panamensis	NWCL (ML)	Central America, Venezuela, Colombia, Ecuador, Peru
L. (V.) peruviana	NWCL[g]	Peru (western slopes of Andes)

[a]Species other than those listed here have been reported to infect humans.
[b]DCL, diffuse cutaneous leishmaniasis; ML, mucosal leishmaniasis; NWCL, New World (American) cutaneous leishmaniasis; OWCL, Old World cutaneous leishmaniasis; PKDL, post–kala-azar dermal leishmaniasis; VL, visceral leishmaniasis. Clinical syndromes less frequently associated with the various species are shown in parentheses.
[c]The geographic distribution is highly focal within countries/regions, and the order in which areas are listed does not reflect the level of endemicity. (See text for further information.) The geographic distribution of cases evaluated in countries such as the United States reflects travel and immigration patterns.
[d]Cutaneous and visceral leishmaniasis also are endemic in parts of Eritrea, but the causative species have not been well established.
[e]"*L. infantum*" and "*L. chagasi*" are considered synonymous.
[f]*L. tropica* also causes leishmaniasis recidivans and viscerotropic leishmaniasis.
[g]The cutaneous leishmaniasis syndrome caused by this species is called *uta*.

EPIDEMIOLOGY, PREVENTION, AND CONTROL

Leishmaniasis is endemic or emerging in focal areas of ~90 countries in Asia, the Middle East, southern Europe, and Africa (Old World disease) and the Americas (New World disease) (Table 205-1). Upwards of several hundred thousand cases of visceral leishmaniasis and 1–1.5 million cases of cutaneous leishmaniasis occur annually. Leishmaniasis is associated with the loss of ~2.4 million disability-adjusted life-years.

More than 90% of the world's cases of visceral leishmaniasis occur in three regions: (1) southern Asia or the Indian subcontinent, particularly in Bihar State in northeastern India and in foci in Bangladesh and Nepal; (2) eastern Africa (Sudan and neighboring countries); and (3) the Americas, particularly in periurban areas of northeastern Brazil.

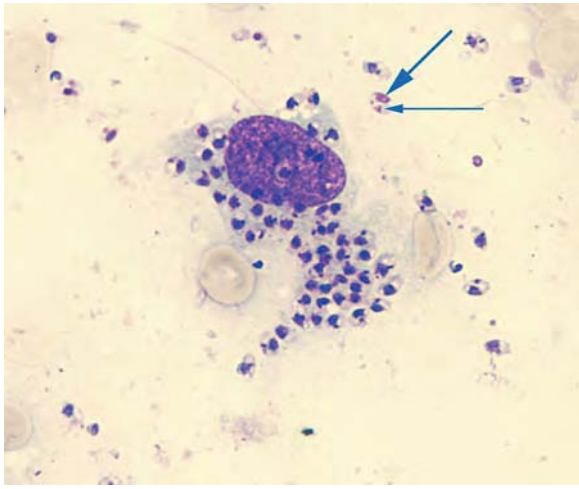

FIGURE 205-1 Amastigotes (the tissue stage of *Leishmania* parasites) in a Giemsa-stained impression smear of tissue from a patient with cutaneous leishmaniasis. Amastigotes are oval or egg shaped and ~2–4 μm in length. Their internal organelles include a nucleus (*larger arrow*) and rod-shaped kinetoplast (*smaller arrow*). In particular, the kinetoplast, a specialized mitochondrial structure that contains extranuclear DNA, should be visualized. The extracellular amastigotes probably were released from macrophages during manipulation of the specimen. Magnification: ×1000, obtained using a ×100 oil-immersion objective. *(Photograph courtesy of H. Bishop; with permission.)*

The predominant etiologic agents are *L. donovani* in southern Asia and eastern Africa and *L. infantum/L. chagasi* elsewhere in the Old and New Worlds. These organisms can also cause cutaneous leishmaniasis.

More than 90% of the world's cases of cutaneous leishmaniasis occur in Afghanistan (Fig. 205-2), Algeria, Iran, Iraq, Pakistan, Saudi Arabia, and Syria (Old World) and in Brazil and Peru (New World). The predominant etiologic agents are *L. tropica*, *L. major*, and *L. aethiopica* (Old World) and species of the *L. mexicana* complex and the *Viannia* subgenus (New World).

In general, prevention and control measures are difficult to sustain and must be tailored to the setting. Vaccine strategies are being explored. Vector characteristics contribute to the focality of transmission in time and place and have implications for preventive measures. Sandflies are nocturnal (i.e., most active from dusk to dawn), have a limited flight range (usually remaining within a few hundred meters of their breeding site), and are small (about one-third the size of mosquitoes). Personal protective measures include minimizing nocturnal outdoor activities, wearing protective clothing, and applying insect repellent to exposed skin. In settings with domiciliary transmission, spraying dwellings with residual-action insecticides and using bed nets treated with long-lasting insecticides may be protective.

Most transmission cycles traditionally have been classified as zoonotic, except for the anthroponotic cycles of *L. donovani* (in southern Asia and potentially in eastern Africa) and *L. tropica.* However, some zoonotic cycles may be partially anthroponotic (and vice versa), and transmission patterns can evolve (e.g., from predominantly sylvatic to include domiciliary transmission) in the context of environmental and epidemiologic changes.

If transmission is exclusively or partially anthroponotic, treatment of infected persons can serve as a control measure, and suboptimal treatment can lead to dissemination of drug resistance. In southern Asia, which arguably carries ~70% of the global burden of visceral leishmaniasis, transmission of *L. donovani* is anthroponotic and largely intra- or peridomiciliary. In 2005, India, Nepal, and Bangladesh resolved to collaborate to reduce the annual incidence of visceral leishmaniasis to <1 case per 10,000 persons by the year 2015. For areas where canids are reservoir hosts (*L. infantum/L. chagasi*–endemic regions), various control strategies are being explored (e.g., insecticide-impregnated dog collars and vaccine candidates).

VISCERAL LEISHMANIASIS

The general term *visceral leishmaniasis* encompasses a broad spectrum of severity and manifestations, with a chronic, subacute, or acute onset and an incubation period of weeks, months, or sometimes years. In contrast, the term *kala-azar* typically is reserved for advanced, life-threatening disease. Although *kala-azar* means black [*kala*] fever [*azar*] in Hindi, darkening of the skin is uncommon. The classic manifestations of advanced disease include prolonged fever; cachexia (malnutrition being both a risk factor for and a sequela of visceral leishmaniasis); hepatosplenomegaly (with splenomegaly usually predominant and the spleen sometimes massive); anemia; leukopenia (neutropenia, marked eosinopenia, and relative lymphocytosis and monocytosis); thrombocytopenia, sometimes associated with bleeding; hypergammaglobulinemia (chiefly IgG, from polyclonal B cell activation); and hypoalbuminemia. The differential diagnosis includes tropical and infectious diseases that cause fever or organomegaly (e.g., typhoid fever, subacute bacterial endocarditis, miliary tuberculosis, brucellosis, histoplasmosis, tropical splenomegaly syndrome, and schistosomiasis) and myeloproliferative diseases (e.g., leukemia and lymphoma).

Post–kala-azar dermal leishmaniasis (PKDL) is a syndrome characterized by skin lesions (including macules, papules, nodules, and patches) that are typically most prominent on the face and that develop during or after therapy for visceral leishmaniasis. In Sudan, PKDL is noted in ~50% of patients from 0 to 6 months after therapy and usually heals spontaneously. In contrast, in India, PKDL is noted in ~5–10% of patients, occurring several years after treatment and usually requiring further therapy. PKDL can be confused with miliaria rubra, syphilis, yaws, and leprosy.

The diagnosis of visceral leishmaniasis should be considered for HIV-infected patients who have ever been in leishmaniasis-endemic areas and have manifestations consistent with visceral infection. The leishmanial infection may have been acquired recently (e.g., from a contaminated syringe) or may represent activation of latent infection acquired in

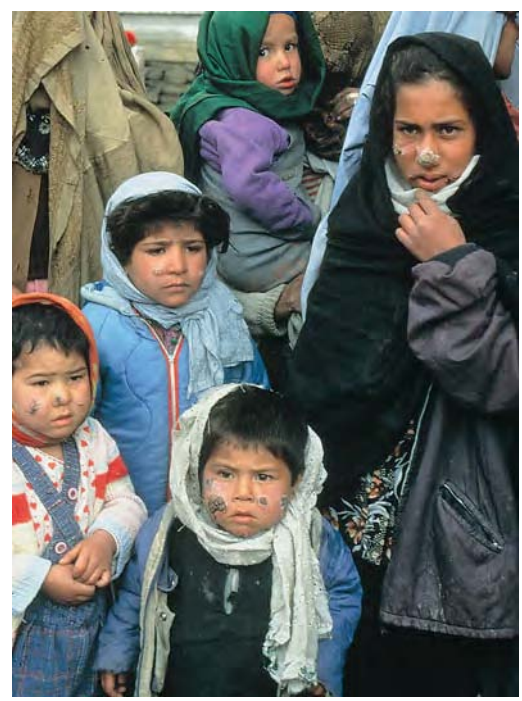

FIGURE 205-2 People in Kabul, Afghanistan, standing in line for hours on a bitterly cold day in February 1997 at a treatment center for cutaneous leishmaniasis. Kabul is experiencing a prolonged epidemic of anthroponotic cutaneous leishmaniasis caused by *Leishmania tropica. [Photograph courtesy of Dr. R. Ashford and reprinted with permission from Elsevier Science (Lancet 354:1193, 1999).]*

the distant past; most co-infected patients with clinically evident visceral infection have CD4+ T lymphocyte counts of <200/μL.

Most cases of *Leishmania*-HIV co-infection have been reported from southern Europe (particularly Spain, France, Italy, and Portugal). Whereas antiretroviral therapy has decreased the incidence of clinically manifest leishmanial infection in Europe, increasing numbers of co-infected cases are being reported in resource-poor countries.

CUTANEOUS LEISHMANIASIS

Typically, the incubation period of cutaneous leishmaniasis ranges from weeks to months. Lesions progress from papules to plaques (which can be smooth or scaly and develop central ulceration; Fig. 205-3) to atrophic scars. The spectrum includes papulonodular, nodular, and noduloulcerative lesions. Multiple primary lesions, satellite lesions, regional adenopathy, nodular lymphangitis, secondary bacterial infection, and thick hemorrhagic crusts or verrucous (wart-like) scale are variably present. Both active and healed lesions can cause considerable morbidity. Spontaneous resolution does not preclude reactivation of infection, dissemination to mucous membranes (see below), or reinfection.

Cutaneous leishmaniasis can be confused with tropical, traumatic, and venous-stasis ulcers; foreign-body reactions; myiasis; infected insect bites; impetigo, ecthyma, and pyoderma gangrenosum; superficial and deep fungal, mycobacterial, and spirochetal infections; and cutaneous sarcoidosis and neoplasms.

The polyparasitic and oligoparasitic ends of the disease spectrum are represented by diffuse cutaneous leishmaniasis (DCL) and leishmaniasis recidivans, respectively. DCL, which typically is caused by *L. aethiopica* (Old World) and *L. mexicana* species (New World), develops in the context of *Leishmania*-specific anergy and is manifested by chronic, disseminated, nonulcerative lesions, with abundant parasites but few lymphocytes. DCL should be differentiated from benign disseminated cutaneous leishmaniasis, lepromatous leprosy, and PKDL. Leishmaniasis recidivans, which most characteristically is caused by *L. tropica*, is a hyperergic variant with scarce parasites. It resembles lupus vulgaris and is characterized by a chronic, solitary plaque (typically on the cheek) that heals centrally but slowly expands at the periphery.

MUCOSAL LEISHMANIASIS

Traditionally, the term *mucosal leishmaniasis* (or *espundia*) refers to a potentially disfiguring sequela of New World cutaneous leishmaniasis that results from dissemination of parasites from the skin to the naso-oropharyngeal mucosa. Mucosal leishmaniasis is caused by species in the *Viannia* subgenus [especially *L. (V.) braziliensis* and *L. (V.) panamensis* but also *L. (V.) guyanensis*] and by *L. amazonensis* (Table 205-1).

The magnitudes and the determinants (both parasite- and host-related) of the risks for mucosal dissemination and mucosal disease are poorly defined. Overall risk estimates for mucosal disease typically are ≤5% (~1–10%). The risk appears to be higher in South America and southern Central America than in *L. Viannia*–endemic regions further north (e.g., in Guatemala and Mexico). Mucosal and cutaneous lesions can be noted concomitantly or appear decades apart. Mucosal disease typically is noted within several years after the resolution of the original cutaneous lesions, which usually were not treated or were treated suboptimally.

The initial manifestations of mucosal disease typically are persistent, unusual nasal symptoms (e.g., epistaxis and stuffiness), with erythema and edema of the nasal mucosa, which can be followed by progressive, ulcerative destruction of the naso-oropharyngeal mucosa and surrounding tissues in the context of a hyperactive immune response. The differential diagnosis includes other infectious diseases (e.g., rhinoscleroma, paracoccidioidomycosis, histoplasmosis, leprosy, syphilis, and tertiary yaws), sarcoidosis, neoplasms, and mucosal ulceration from cocaine use.

DIAGNOSIS

PRINCIPLES AND PERSPECTIVE

Leishmaniasis often is diagnosed presumptively by clinical and epidemiologic criteria. Definitive diagnosis requires demonstration of the parasite in specimens from infected sites, which typically relies on classic microbiologic methods—i.e., detection of amastigotes by light microscopic examination of stained slides or detection of promastigotes by in vitro culture. In general, amastigotes, including their characteristic internal organelles (Fig. 205-1), are more easily recognizable on Giemsa-stained smears (e.g., thin smears of dermal scrapings or bone marrow aspirates and impression smears of biopsy specimens) than in tissue sections, particularly if organisms are rare.

Leishmania species can be distinguished by isoenzyme analysis of cultured promastigotes or determination of monoclonal antibody specificity. Molecular techniques of assorted types, with diverse genetic markers, are at various stages of development and validation for diagnosis of leishmaniasis and identification of species. Analyses of the genomes and the proteome profiles of *Leishmania* species may lead to novel diagnostic approaches.

Immunologic diagnostic methods include serologic assays and tests for *Leishmania*-specific cell-mediated immunity (e.g., skin testing for delayed-type hypersensitivity reactions). The utility of such methods depends in part on the syndrome. Most serologic assays do not reliably distinguish active from quiescent infection. No leishmanin skin-test preparation has been approved for use in the United States.

VISCERAL LEISHMANIASIS

Patients with advanced visceral leishmaniasis commonly have relatively heavy parasite burdens and high-level antibody responses that are not protective but are useful diagnostically; skin-test reactivity develops after recovery. Aspirates and biopsy specimens (e.g., of spleen, bone marrow, liver, or lymph node) are useful for parasitologic confirmation by traditional and molecular methods. Although the diagnostic yield is highest for splenic aspirates (>95%), bone marrow aspiration is safer.

In the appropriate setting, seropositivity is often the diagnostic standard. Although test performance can vary by region, approaches that offer the potential for improved field applicability include direct agglutination testing with freeze-dried antigen and immunochromatographic dipstick testing of fingerstick blood for antibody to recombinant antigens or synthetic peptides (e.g., rK39). In addition, assays for detection of leishmanial antigen in urine are being evaluated.

The sensitivity of serologic methods is lower in HIV-infected patients than in persons not infected with HIV (~50% vs. >90%). In contrast, the parasites may be abundant in typical sites (e.g., bone marrow), in atypical sites (e.g., gastrointestinal tissue), and in circulating monocytes—a circumstance that facilitates parasitologic diagnosis. The sensitivities of peripheral-blood smear and buffy-coat culture are ~50% and ~70%, respectively. PCR may be even more sensitive.

CUTANEOUS AND MUCOSAL LEISHMANIASIS

Aspirates and biopsy specimens of skin lesions and lymph nodes are useful for parasitologic confirmation of cutaneous and mucosal leishmania-

sis by traditional and molecular methods. Parasitologic confirmation of mucosal leishmaniasis—a pauciparasitic syndrome—by traditional methods can be difficult. Serologic testing usually is not helpful for patients with cutaneous leishmaniasis; except in patients with DCL and some patients with mucosal leishmaniasis, antibody is either undetectable or present at low levels. In contrast, skin-test reactivity usually develops during active infection except in patients with DCL.

Rx LEISHMANIASIS

PRINCIPLES AND PERSPECTIVE **(Table 205-2)** Decisions about whether and how to treat leishmaniasis should be individualized. For cases in which systemic treatment is indicated, the parenterally administered pentavalent antimonial (Sb^V) compounds sodium stibogluconate and meglumine antimonate have been the mainstays of therapy for more than half a century. Manifestations of toxicity (e.g., body aches, malaise, elevated aminotransferase levels, chemical pancreatitis, and electrocardiographic abnormalities) are commonly noted but usually do not limit therapy and are reversible.

Conventional amphotericin B deoxycholate and pentamidine isethionate, the traditional parenteral alternatives to Sb^V, were previously relegated to second-line status, largely because of less experience with their use for the treatment of leishmaniasis and greater concern about their induction of potentially serious or irreversible toxicities (e.g., renal impairment). Amphotericin B, which has high-level, broad-spectrum antileishmanial activity, has been upgraded to first-line status in settings in which its benefits outweigh its risks (e.g., for Sb^V-resistant visceral leishmaniasis).

Lipid formulations of amphotericin B passively target the agent to macrophage-rich organs, resulting in less renal and other toxicity and permitting the use of higher daily doses and shorter courses of therapy. Targeting of drug to the reticuloendothelial system is ideal for visceral leishmaniasis but may not be advantageous for other syndromes. For amphotericin B and other antileishmanial agents, various delivery/targeting mechanisms and formulations are being explored.

Although some alternative therapies may have utility in particular settings, even data from well-conducted clinical trials cannot necessarily be generalized to other contexts. Of particular note, data from the many clinical trials of therapy for visceral leishmaniasis in foci in northeastern India are not necessarily directly applicable to visceral leishmaniasis caused by *L. donovani* in other foci in southern Asia or elsewhere (e.g., eastern Africa) or to visceral infection caused by *L. infantum/chagasi*—let alone to other leishmanial syndromes.

Except for the development of resistance to Sb^V and pentamidine, Indian kala-azar typically is easier to treat than visceral leishmaniasis elsewhere: i.e., it is more responsive to therapy, even with lower total doses. Counterintuitively, visceral leishmaniasis often is easier to treat than cutaneous or mucosal leishmaniasis. Achieving adequate drug levels in the phagolysosomes of dermal and mucosal macrophages can be challenging, and the difficulty can be compounded by the fact that some dermotropic species are intrinsically less sensitive than *L. donovani* to particular drugs.

Some of these issues are exemplified by miltefosine, the first highly active oral agent for visceral leishmaniasis. Both experimental (in vitro) and clinical data indicate that *L. donovani* (the agent of Indian visceral leishmaniasis) is highly sensitive to miltefosine, whereas other species are variably responsive. In addition, the long half-life of the drug and suboptimal treatment predispose to the development of resistance. The most common side effects of therapy include gastrointestinal symptoms and reversible elevations in creatinine and aminotransferase levels. Miltefosine's teratogenicity in animals has implications for its use in women of child-bearing age (Table 205-2).

TABLE 205-2 PARENTERAL AND ORAL DRUG REGIMENS FOR TREATMENT OF LEISHMANIASIS[a]

Clinical Syndrome, Drug	Route of Administration	Regimen
Visceral Leishmaniasis		
Parenteral therapy		
Pentavalent antimony[b]	IV, IM	20 mg Sb^V/kg qd for 28 days
Amphotericin B, lipid formulation[c]	IV	2–5 mg/kg qd (total: usually ~15–21 mg/kg)
Amphotericin B (deoxycholate)	IV	0.5–1 mg/kg qod or qd (total: usually ~15–20 mg/kg)
Paromomycin sulfate[d]	IV, IM	15–20 mg/kg qd for ~21 days
Pentamidine isethionate	IV, IM	4 mg/kg qod or thrice weekly for ~15–30 doses
Oral therapy		
Miltefosine[d,e]	PO	2.5 mg/kg qd for 28 days
Cutaneous Leishmaniasis		
Parenteral therapy		
Pentavalent antimony[b]	IV, IM	20 mg Sb^V/kg qd for 10–20 days (standard recommendation: 20 days)
Pentamidine isethionate	IV, IM	2 mg/kg qod for 7 doses
Amphotericin B (deoxycholate)	IV	0.5–1 mg/kg qod or qd (total: up to ~20 mg/kg)
Oral therapy		
Fluconazole	PO	200 mg qd for 6 weeks[f]
Ketoconazole	PO	600 mg qd for 28 days[f]
Itraconazole	PO	200 mg bid for 28 days[f]
Miltefosine[d,e]	PO	2.5 mg/kg qd for 28 days
Mucosal Leishmaniasis		
Pentavalent antimony[b]	IV, IM	20 mg Sb^V/kg qd for 28 days
Amphotericin B (deoxycholate)	IV	1 mg/kg qod or qd (total: usually ~20–40 mg/kg)
Pentamidine isethionate	IV, IM	2–4 mg/kg qod or thrice weekly for ≥15 doses

[a]See text for additional details and perspective about the drugs and regimens in this table and about treatment of leishmaniasis in general. Some of the listed drugs are effective only against certain *Leishmania* species/strains and only in certain areas of the world. Classification of drugs/regimens in such categories as first-line, alternative, (in)effective, investigational, (un)available, and cost-prohibitive is highly dependent on the setting. Ranges shown for doses and durations of therapy reflect variability both in dosage regimens among clinical trials and in responsiveness in different settings. To maximize effectiveness and minimize toxicity, the listed regimens should be individualized according to the particularities of the case and in consultation with an expert. Children may need different dosage regimens. Except for liposomal amphotericin B (see footnote *c*), as of this writing, none of the drugs listed is licensed by the U.S. Food and Drug Administration (FDA) for the treatment of leishmaniasis per se.

[b]The Centers for Disease Control and Prevention (CDC) provides the pentavalent antimonial (Sb^V) compound sodium stibogluconate (Pentostam; Glaxo Operations UK Limited, Barnard Castle, United Kingdom; 100 mg Sb^V/mL) to U.S.-licensed physicians through the CDC Drug Service (404-639-3670) under an IND mechanism with the FDA. The other widely used Sb^V compound, meglumine antimonate (Glucantime; typically, ~85 mg Sb^V/mL), is available primarily in Spanish- and French-speaking areas of the world. Locally made (generic) Sb^V preparations may have different Sb^V concentrations and may vary in quality and safety.

[c]The lipid formulations of amphotericin B include liposomal amphotericin B and amphotericin B lipid complex. In 1997, the FDA approved the following regimen of liposomal amphotericin B for immunocompetent patients with visceral leishmaniasis: 3 mg/kg qd on days 1–5, 14, and 21, for a total of 21 mg/kg. For immunosuppressed patients, the approved regimen is 4 mg/kg qd on days 1–5, 10, 17, 24, 31, and 38, for a total of 40 mg/kg. Many alternative regimens have been proposed for immunocompetent patients in various regions of the world; the regimens vary with respect to total and daily doses, number of doses, and intervals between doses. See text for perspective on the use of lipid formulations of amphotericin B for treatment of cutaneous and mucosal leishmaniasis.

[d]Not commercially available in the United States as of this writing.

[e]Miltefosine, which is teratogenic in animals, should not be used to treat pregnant women. Women of child-bearing age should use effective birth control during treatment and for 2 months thereafter. See text regarding the treatment of mucosal leishmaniasis.

[f]Adult dosage.

VISCERAL LEISHMANIASIS The primary goal of treatment for visceral leishmaniasis is to prevent death. Highly effective antileishmanial therapy is essential, as is supportive care (e.g., therapy for malnutrition, anemia, bleeding, and intercurrent infections). In most regions, Sb^V therapy remains highly effective. However, use of an alternative agent should be considered if high-level Sb^V resistance is prevalent or if non-Sb^V therapy is advantageous for other reasons (e.g., duration, cost, or tolerability). In general, most patients feel better and become afebrile during the first week of therapy; resolution of splenomegaly and hematologic abnormalities may require weeks or months.

In northeastern India, districts of Bihar State north of the Ganges River constitute the epicenter of the epidemic of Sb^V resistance, which is spreading—to varying degrees—to contiguous areas of India and southern Nepal. Conventional amphotericin B has become first-line therapy where Sb^V and pentamidine are no longer effective. Lipid formulations of amphotericin B, which are cost-prohibitive where they are most needed, are increasingly being used in southern Europe.

The anthroponotic transmission of *L. donovani* in southern Asia is both a blessing and a curse: a blessing because treatment can serve as a control measure, and a curse because suboptimal treatment can and does lead to the development and dissemination of drug resistance and thereby to the elimination of drugs from the limited armamentarium and to the demise of patients who cannot afford or access the few alternatives. In this context, the oral agent miltefosine, which is registered for commercial use in India and some other countries, has great potential but also is highly vulnerable. The advent of oral therapy translates into unsupervised outpatient treatment, in which patients buy the quantity of drug they can afford and prematurely stop therapy when their supply is depleted or their symptoms are alleviated. Unless protective measures are implemented (e.g., with directly observed or multidrug therapy), drug resistance almost assuredly will develop and spread. The oral agent sitamaquine, an 8-amino-quinoline, is being field-tested in various regions but appears to have a narrow therapeutic window and can cause nephrotoxicity.

The aminoglycoside paromomycin (the chemical equivalent of aminosidine) is a candidate parenteral agent for use alone or in drug combinations. To date, the rates of response in field tests have been variable; response rates may be higher in India than in eastern Africa.

Patients who are co-infected with HIV may initially respond well to standard therapy but typically experience more toxicity. Antiretroviral therapy delays but does not prevent relapses. Consensus approaches to treatment and secondary prophylaxis have not been established.

CUTANEOUS LEISHMANIASIS Decisions about clinical management of cutaneous leishmaniasis should be based on consideration of goals (e.g., accelerating the healing of skin lesions, decreasing morbidity, decreasing risks for local and mucosal dissemination and relapse), parasite factors (e.g., tissue tropisms and drug sensitivities), and the extent to which the lesions are of concern or are bothersome because of their location (e.g., on the face or near joints), number, size, persistence, or other features (e.g., nodular lymphangitis). When optimal effectiveness is important, parenteral Sb^V therapy is generally recommended. The first sign of a clinical response typically is decreasing induration, and relapses usually are noted first at the margins of healed lesions.

Although clinical trials of conventional amphotericin B for cutaneous leishmaniasis have not been conducted and standard dosage regimens have not been established, this agent almost assuredly is highly and broadly effective, albeit potentially toxic. Conflicting, limited data are available for lipid formulations. Pentamidine was effective in Colombia [predominantly against *L. (V.) panamensis*] but not in Peru [against *L. (V.) braziliensis*].

The effectiveness of the oral agent miltefosine is species and strain dependent. For example, this drug has been effective against *L. (V.) panamensis* in Colombia but ineffective against *L. (V.) braziliensis* in Guatemala. At best, azoles have shown modest activity against particular species in isolated studies—e.g., ketoconazole and itraconazole against *L. mexicana* in Guatemala, ketoconazole against *L. (V.) panamensis* in Panama, and fluconazole against *L. major* in Saudi Arabia. Itraconazole has been ineffective against *L. (V.) panamensis* in Colombia.

Local therapy can be considered for some cases without demonstrable local dissemination or risk of mucosal dissemination (e.g., for relatively benign lesions caused by *L. mexicana* or *L. major*). Examples of approaches being used or evaluated in some settings include intralesional Sb^V, various formulations of paromomycin ointments, topical immunomodulators, thermotherapy, and cryotherapy.

MUCOSAL LEISHMANIASIS The traditional treatment options for mucosal leishmaniasis include Sb^V and conventional amphotericin B; conflicting, limited data are available for lipid formulations of the latter drug. The response rates approach those for cutaneous leishmaniasis if mucosal disease is detected and treated at early stages, whereas advanced disease may be unresponsive or relapse repeatedly. Oral miltefosine therapy shows promise, on the basis of a clinical trial in Bolivia. Adjunctive immunotherapy is being evaluated. Concomitant glucocorticoid therapy is indicated if respiratory compromise develops after initiation of therapy.

206 Trypanosomiasis

Louis V. Kirchhoff

The genus *Trypanosoma* contains many species of protozoans. *Trypanosoma cruzi*, the cause of Chagas' disease in the Americas, and the two trypanosome subspecies that cause human African trypanosomiasis, *Trypanosoma brucei gambiense* and *T. brucei rhodesiense*, are the only members of the genus that cause disease in humans.

CHAGAS' DISEASE

DEFINITION

Chagas' disease, or American trypanosomiasis, is a zoonosis caused by the protozoan parasite *T. cruzi*. Acute Chagas' disease is usually a mild febrile illness that results from initial infection with the organism. After spontaneous resolution of the acute illness, most infected persons remain for life in the indeterminate phase of chronic Chagas' disease, which is characterized by subpatent parasitemia, easily detectable antibodies to *T. cruzi*, and an absence of symptoms. In a minority of chronically infected patients, cardiac and gastrointestinal lesions develop that can result in serious morbidity and even death.

LIFE CYCLE AND TRANSMISSION

T. cruzi is transmitted among its mammalian hosts by hematophagous triatomine insects, often called *reduviid bugs*. The insects become infected by sucking blood from animals or humans who have circulating parasites. Ingested organisms multiply in the gut of the triatomines, and infective forms are discharged with the feces at the time of subsequent blood meals. Transmission to a second vertebrate host occurs when breaks in the skin, mucous membranes, or conjunctivae become contaminated with bug feces that contain infective parasites. *T. cruzi* can also be transmitted by the transfusion of blood donated by infected persons, by organ transplantation, from mother to fetus, and in laboratory accidents.

PATHOLOGY

An indurated inflammatory lesion called a *chagoma* often appears at the parasites' portal of entry. Local histologic changes include the presence of parasites within leukocytes and cells of subcutaneous tissues and the development of interstitial edema, lymphocytic infiltration, and reactive hyperplasia of adjacent lymph nodes. After dissemination of the organisms through the lymphatics and the bloodstream, muscles (including the myocardium) may become heavily parasitized (Fig. 206-1). The characteristic pseudocysts present in sections of infected tissues are intracellular aggregates of multiplying parasites.

In the minority of persons with chronic *T. cruzi* infections who develop related clinical manifestations, the heart is the organ most commonly affected. Changes include thinning of the ventricular walls, biventricular enlargement, apical aneurysms, and mural thrombi. Widespread lymphocytic infiltration, diffuse interstitial fibrosis, and atrophy of myocardial cells are often apparent, but parasites are difficult to find in myocardial tissue. Conduction-system involvement often affects the right branch and the left anterior branch of the bundle of His. In chronic Chagas' disease of the gastrointestinal tract (megadisease), the esophagus and colon may exhibit varying degrees of dilatation. On microscopic examination, focal inflammatory lesions with lymphocytic infiltration are seen, and the number of neurons in the myenteric plexus may be markedly reduced. Accumulating experimental evidence implicates the persistence of parasites and the accompanying chronic inflammation—rather than autoimmune mechanisms—as the basis for the pathology in patients with chronic *T. cruzi* infection.

EPIDEMIOLOGY

T. cruzi is found only in the Americas. Wild and domestic mammals harboring *T. cruzi* and infected triatomines are found in spotty distributions from the southern United States to southern Argentina. Humans become involved in the cycle of transmission when infected vectors take up residence in the primitive wood, adobe, and stone houses common in much of Latin America. Thus human *T. cruzi* infection is a health problem primarily among the poor in rural areas of Mexico and Central and South America. Most new *T. cruzi* infections in rural settings occur in children, but the incidence is unknown because most cases go undiagnosed. Historically, transfusion-associated transmission of *T. cruzi* has been a serious public health problem in many endemic countries. However, with some notable exceptions, transmission by this route has been markedly reduced as effective programs for the screening of donated blood have been implemented. Several dozen patients with HIV and chronic *T. cruzi* infections who underwent acute recrudescence of the latter have been described. These patients generally presented with *T. cruzi* brain abscesses, a manifestation of the illness that does not occur in immunocompetent persons. Currently, it is estimated that 12 million people are chronically infected with *T. cruzi* and that 25,000 deaths due to the illness occur each year. Of chronically infected persons, 10–30% eventually develop symptomatic cardiac lesions or gastrointestinal disease. The resulting morbidity and mortality make Chagas' disease the most important parasitic disease burden in Latin America.

In recent years, the rate of *T. cruzi* transmission has decreased markedly in several endemic countries as a result of successful programs involving vector control, blood-bank screening, and education of at-risk populations. A major program begun in 1991 in the "southern cone" nations of South America (Uruguay, Paraguay, Bolivia, Brazil, Chile, and Argentina) has provided the framework for much of this progress. Uruguay and Chile were certified transmission-free in the late 1990s, and Brazil was declared free of transmission in 2006. Transmission has been reduced markedly in Argentina as well. Similar control programs have been initiated in the countries of northern South America and in the Central American nations.

Acute Chagas' disease is rare in the United States. Five cases of autochthonous transmission and five instances of transmission by blood transfusion have been reported. Moreover, *T. cruzi* was transmitted to five recipients of organs from three *T. cruzi*–infected donors. Two of these recipients became infected through cardiac transplants. Acute Chagas' disease has not been reported in tourists returning to the United States from Latin America, although two such instances have been reported in Europe. In contrast, the prevalence of chronic *T. cruzi* infections in the United States has increased considerably in recent years. Data from the 2000 census indicate that >12 million immigrants from Chagas'-endemic countries currently live in the United States, ~8 million of whom are Mexicans. The prevalence of *T. cruzi* infection in Mexico is 0.5–1.0%, and most of the 4 million immigrants from Chagas'-endemic nations who are not Mexicans come from countries in which the prevalence of *T. cruzi* infection is greater than it is in Mexico. The total number of *T. cruzi*–infected persons living in the United States can be estimated reasonably to be 80,000–120,000. The number of instances of transfusion-associated transmission in this country is likely to be considerably greater than the number reported. Screening of the U.S. blood supply for evidence of *T. cruzi* infection has recently begun (see "Diagnosis," below).

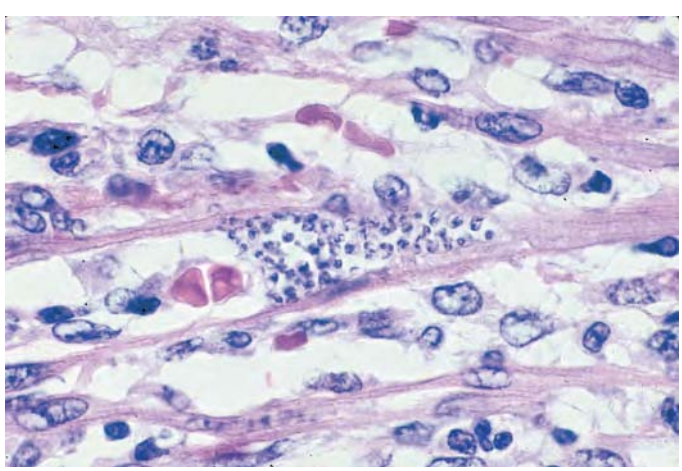

FIGURE 206-1 *Trypanosoma cruzi* in the heart muscle of a child who died of acute Chagas' myocarditis. An infected myocyte containing several dozen *T. cruzi* amastigotes is in the center of the field (hematoxylin and eosin, ×900).

CLINICAL COURSE

The first signs of acute Chagas' disease develop at least 1 week after invasion by the parasites. When the organisms enter through a break in the skin, an indurated area of erythema and swelling (the chagoma), accompanied by local lymphadenopathy, may appear. *Romaña's sign*—the classic finding in acute Chagas' disease, which consists of unilateral painless edema of the palpebrae and periocular tissues—can result when the conjunctiva is the portal of entry (Fig. 206-2). These initial local signs may be followed by malaise, fever, anorexia, and edema of the face and lower extremities. A morbilliform rash may also appear. Generalized lymphadenopathy and hepatosplenomegaly may develop. Severe myocarditis develops rarely; most deaths in acute Chagas' disease are due to heart failure. Neurologic signs are not common, but meningoencephalitis occurs occasionally. The acute symptoms resolve spontaneously in virtually all patients, who then enter the asymptomatic or indeterminate phase of chronic *T. cruzi* infection.

Symptomatic chronic Chagas' disease becomes apparent years or even decades after the initial infection. The heart is commonly involved, and symptoms are caused by rhythm disturbances, dilated cardiomyopathy, and thromboembolism. Right bundle-branch block is a common electrocardiographic abnormality, but other types of atrioventricular block, premature ventricular contractions, and tachy- and bradyarrhythmias occur frequently. Cardiomyopathy often results in right-sided or biventricular heart failure. Embolization of mural thrombi to the brain or other areas may take place. Patients with megaesophagus suffer from dysphagia, odynophagia, chest pain, and regurgitation. Aspiration can occur (especially during sleep) in patients with severe esophageal dysfunction, and repeated episodes of aspiration pneumonitis are common. Weight loss, cachexia, and pulmonary infection can result in death. Patients with megacolon are

FIGURE 206-2 Romaña's sign in an Argentinean patient with acute *T. cruzi* infection. *(Courtesy of Dr. Humberto Lugones, Centro de Chagas, Santiago del Estero, Argentina; with permission.)*

plagued by abdominal pain and chronic constipation, and advanced megacolon can cause obstruction, volvulus, septicemia, and death.

DIAGNOSIS

The diagnosis of acute Chagas' disease requires the detection of parasites. Microscopic examination of fresh anticoagulated blood or of the buffy coat is the simplest way to see the motile organisms. Parasites also can be seen in Giemsa-stained thin and thick blood smears. Microhematocrit tubes containing acridine orange as a stain can be used for the same purpose. When repeated attempts to visualize the organisms are unsuccessful, polymerase chain reaction (PCR) or hemoculture in special media can be performed. When used by experienced personnel, all of these methods yield positive results in a high proportion of cases of acute Chagas' disease. Hemoculture has the disadvantage of taking several weeks to give positive results. Serologic testing plays no role in diagnosing acute Chagas' disease.

Chronic Chagas' disease is diagnosed by the detection of specific antibodies that bind to *T. cruzi* antigens. Demonstration of the parasite is not of primary importance. In Latin America, ~20 assays are commercially available, including several based on recombinant antigens. Unfortunately, these tests have varying levels of sensitivity and specificity, and false-positive reactions are a particular problem—typically with samples from patients who have other infectious and parasitic diseases or autoimmune disorders. In addition, confirmatory testing has presented a persistent challenge. For these reasons, it is generally recommended that specimens be tested in at least two assays and that well-characterized positive and negative comparison samples be included in each run. The radioimmune precipitation assay (Chagas' RIPA) is a highly sensitive and specific confirmatory method for detecting antibodies to *T. cruzi* [approved under the Clinical Laboratory Improvement Amendment (CLIA) and available in the author's laboratory]. In December 2006, the U.S. Food and Drug Administration (FDA) approved a test to screen blood and organ donors for *T. cruzi* infection (Ortho *T. cruzi* ELISA Test System, Ortho-Clinical Diagnostics, Raritan, NJ). In late January 2007, the American Red Cross and Blood Systems, Inc.—blood-collection agencies that together account for ~65% of the U.S. blood supply—initiated screening of all the donations they process for *T. cruzi*. The Chagas' RIPA is being used as the confirmatory assay. Data generated during the first 2 months of screening suggest that if 65% of the blood supply continues to be tested, ~1500 Ortho-reactive donors will be identified annually, ~350 of whom will be RIPA-positive; these figures reflect an overall prevalence of ~1 in 30,000 donors. The use of PCR assays to detect *T. cruzi* DNA in chronically infected persons has been studied extensively. The sensitivity of this approach has not been shown to be reliably greater than that of serology, and no PCR assays are commercially available.

Rx CHAGAS' DISEASE

Therapy for Chagas' disease is unsatisfactory. For many years, only two drugs—nifurtimox and benznidazole—have been available for this purpose. Unfortunately, both drugs lack efficacy and often cause severe side effects.

In acute Chagas' disease, nifurtimox markedly reduces the duration of symptoms and parasitemia and decreases the mortality rate. Nevertheless, limited studies have shown that only ~70% of acute infections are cured parasitologically by a full course of treatment. Despite its limitations, treatment with nifurtimox should be initiated as early as possible in acute Chagas' disease. Common adverse effects of nifurtimox include abdominal pain, anorexia, nausea, vomiting, and weight loss. Neurologic reactions to the drug may include restlessness, disorientation, insomnia, twitching, paresthesia, polyneuritis, and seizures. These symptoms usually disappear when the dosage is reduced or treatment is discontinued. The recommended daily dosage is 8–10 mg/kg for adults, 12.5–15 mg/kg for adolescents, and 15–20 mg/kg for children 1–10 years of age. The drug should be given orally in four divided doses each day, and therapy should be continued for 90–120 days. Nifurtimox is available from the Drug Service of the Centers for Disease Control and Prevention (CDC) in Atlanta (telephone number, 770-639-3670).

The efficacy of benznidazole is similar to that of nifurtimox; a cure rate of 90% among congenitally infected infants treated before their first birthday has been reported. Adverse effects include peripheral neuropathy, rash, and granulocytopenia. The recommended oral dosage is 5 mg/kg per day for 60 days. Benznidazole is generally considered the drug of choice in Latin America.

The question of whether patients in the indeterminate or chronic symptomatic phase of Chagas' disease should be treated with nifurtimox or benznidazole has been debated for years. The fact that parasitologic cure rates in chronically infected persons may be <10% is central to this controversy. There is no convincing evidence from properly controlled trials that treatment of adults with long-standing *T. cruzi* infections with either of the drugs is beneficial. The current consensus of Latin American authorities is that all *T. cruzi*–infected persons up to 18 years old should be given benznidazole or nifurtimox.

The usefulness of allopurinol, fluconazole, and itraconazole for the treatment of acute Chagas' disease has been studied in laboratory animals and to a lesser extent in humans. None of these drugs has exhibited a level of anti–*T. cruzi* activity that warrants its use in patients. Several newer antifungal azoles have shown promise in animal studies but have not yet been tested in humans.

Patients who develop cardiac and/or gastrointestinal disease in association with *T. cruzi* infection should be referred to appropriate subspecialists for further evaluation and treatment. Cardiac transplantation is an option for patients with end-stage chagasic cardiopathies, and >100 such transplantations have been done in Brazil and the United States. The survival rate among Chagas' disease cardiac transplant recipients is higher than that among persons receiving cardiac transplants for other reasons. This better outcome may be due to the fact that lesions are limited to the heart in most patients with symptomatic chronic Chagas' disease.

PREVENTION

Since drug therapy is unsatisfactory and vaccines are not available, the control of *T. cruzi* transmission in endemic countries must depend on reduction of domiciliary vector populations by spraying of insecticides, improvements in housing, and education of at-risk persons. As noted above, these measures, coupled with serologic screening of blood donors, have markedly reduced transmission of the parasite in many endemic countries. Tourists would be wise to avoid sleeping in dilapidated houses in rural areas of endemic countries. Mosquito nets and insect repellent provide additional protection.

In view of the possibly serious consequences of chronic *T. cruzi* infection, it would be prudent for all immigrants from endemic regions living in the United States to be tested for evidence of infection. Identi-

fication of persons harboring the parasite would permit periodic electrocardiographic monitoring, which can be important because pacemakers benefit some patients who develop ominous rhythm disturbances. The possibility of congenital transmission is yet another justification for screening. Guidance for the evaluation and long-term monitoring of *T. cruzi*–infected persons is being developed by staff at the CDC.

Laboratory personnel should wear gloves and eye protection when working with *T. cruzi* and infected vectors.

SLEEPING SICKNESS

DEFINITION

Sleeping sickness, or human African trypanosomiasis (HAT), is caused by flagellated protozoan parasites that belong to the *T. brucei* complex and are transmitted to humans by tsetse flies. In untreated patients, the trypanosomes first cause a febrile illness that is followed months or years later by progressive neurologic impairment and death.

THE PARASITES AND THEIR TRANSMISSION

The East African (*rhodesiense*) and the West African (*gambiense*) forms of sleeping sickness are caused, respectively, by two trypanosome subspecies: *T. brucei rhodesiense* and *T. brucei gambiense*. These subspecies are morphologically indistinguishable but cause illnesses that are epidemiologically and clinically distinct (Table 206-1). The parasites are transmitted by blood-sucking tsetse flies of the genus *Glossina*. The insects acquire the infection when they ingest blood from infected mammalian hosts. After many cycles of multiplication in the midgut of the vector, the parasites migrate to the salivary glands. Their transmission takes place when they are inoculated into a mammalian host during a subsequent blood meal. The injected trypanosomes multiply in the blood (Fig. 206-3) and other extracellular spaces and evade immune destruction for long periods by undergoing antigenic variation, a process driven by gene switching in which the antigenic structure of the organisms' surface coat of glycoproteins changes periodically.

PATHOGENESIS AND PATHOLOGY

A self-limited inflammatory lesion (trypanosomal chancre) may appear a week or so after the bite of an infected tsetse fly. A systemic febrile illness then evolves as the parasites are disseminated through the lymphatics and bloodstream. Systemic HAT without central nervous system (CNS) involvement is generally referred to as *stage I disease*. In this stage, widespread lymphadenopathy and splenomegaly reflect marked lymphocytic and histiocytic proliferation and invasion of morular cells, which are plasmacytes that may be involved in the production of IgM. Endarteritis, with perivascular infiltration of both parasites and lymphocytes, may develop in lymph nodes and the spleen. Myocarditis develops frequently in patients with stage I disease and is especially common in *T. b. rhodesiense* infections.

Hematologic manifestations that accompany stage I HAT include moderate leukocytosis, thrombocytopenia, and anemia. High levels of immunoglobulins, consisting primarily of polyclonal IgM, are a constant feature, and heterophile antibodies, antibodies to DNA, and rheumatoid factor are often detected. High levels of antigen-antibody complexes may play a role in the tissue damage and increased vascular permeability that facilitate dissemination of the parasites.

Stage II disease involves invasion of the CNS. The presence of trypanosomes in perivascular areas is accompanied by intense infiltration of mononuclear cells. Abnormalities in cerebrospinal fluid (CSF) include increased pressure, elevated total protein concentration, and pleocytosis. In addition, trypanosomes are frequently found in CSF.

TABLE 206-1 COMPARISON OF WEST AFRICAN AND EAST AFRICAN TRYPANOSOMIASES

Point of Comparison	West African (*Gambiense*)	East African (*Rhodesiense*)
Organism	*T. b. gambiense*	*T. b. rhodesiense*
Vectors	Tsetse flies (palpalis group)	Tsetse flies (morsitans group)
Primary reservoir	Humans	Antelope and cattle
Human illness	Chronic (late CNS disease)	Acute (early CNS disease)
Duration of illness	Months to years	<9 months
Lymphadenopathy	Prominent	Minimal
Parasitemia	Low	High
Diagnosis by rodent inoculation	No	Yes
Epidemiology	Rural populations	Workers in wild areas, rural populations, tourists in game parks

Abbreviation: CNS, central nervous system.

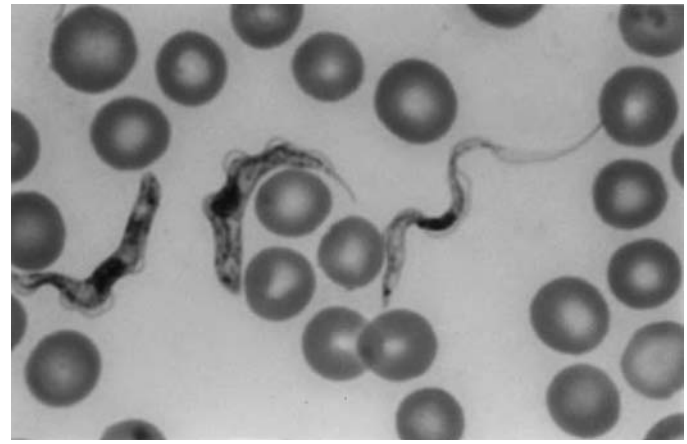

FIGURE 206-3 *Trypanosoma brucei rhodesiense* forms in rat blood. The slender parasite is thought to be the form that multiplies in mammalian hosts, while the stumpy forms are nondividing and are capable of infecting insect vectors (Giemsa, ×1200). *(Courtesy of Dr. G. A. Cook, Madison, WI; with permission.)*

EPIDEMIOLOGY

The trypanosomes that cause sleeping sickness are found only in Africa. Approximately 50 million persons are at risk of acquiring HAT, and tens of thousands of new cases occur every year. Precise data are not available because health statistics are often incomplete in the developing countries where HAT is endemic. Sleeping sickness has undergone a resurgence in recent years, with major epidemics in the Sudan, Ivory Coast, Chad, the Central African Republic, and several other endemic countries.

Humans are the only reservoir of *T. b. gambiense*, which occurs in widely distributed foci in tropical rain forests of Central and West Africa. *Gambiense* trypanosomiasis is primarily a problem in rural populations; tourists rarely become infected. Trypanotolerant antelope species in savanna and woodland areas of Central and East Africa are the principal reservoir of *T. b. rhodesiense*. Cattle can also be infected with this and other trypanosome species but generally succumb to the infection. Since risk results for the most part from contact with tsetse flies that feed on wild animals, humans acquire *T. b. rhodesiense* infection only incidentally, usually while visiting or working in areas where infected game and vectors are present. Roughly one or two patients with HAT acquired in East African game parks (and typically caused by *T. b. rhodesiense*) are reported to the CDC each year.

CLINICAL COURSE

A painful trypanosomal chancre appears in some patients at the site of inoculation of the parasite. Hematogenous and lymphatic dissemination (stage I disease) is marked by the onset of fever. Typically, bouts of

high temperatures lasting several days are separated by afebrile periods. Lymphadenopathy is prominent in *T. b. gambiense* trypanosomiasis. The nodes are discrete, movable, rubbery, and nontender. Cervical nodes are often visible, and enlargement of the nodes of the posterior cervical triangle, or *Winterbottom's sign*, is a classic finding. Pruritus and maculopapular rashes are common. Inconstant findings include malaise, headache, arthralgias, weight loss, edema, hepatosplenomegaly, and tachycardia. The differential diagnosis of stage I HAT includes many diseases that are common in the tropics and are associated with fevers. HIV infection, malaria, and typhoid fever are common in populations at risk for HAT and need to be considered.

CNS invasion (stage II disease) is characterized by the insidious development of protean neurologic manifestations that are accompanied by progressive abnormalities in the CSF. A picture of progressive indifference and daytime somnolence develops (hence the designation "sleeping sickness"), sometimes alternating with restlessness and insomnia at night. A listless gaze accompanies a loss of spontaneity, and speech may become halting and indistinct. Extrapyramidal signs may include choreiform movements, tremors, and fasciculations. Ataxia is frequent, and the patient may appear to have Parkinson's disease, with a shuffling gait, hypertonia, and tremors. In the final phase, progressive neurologic impairment ends in coma and death.

The most striking difference between the West African and East African trypanosomiases is that the latter illness tends to follow a more acute course. Typically, in tourists with *T. b. rhodesiense* disease, systemic signs of infection, such as fever, malaise, and headache, appear before the end of the trip or shortly after the return home. Persistent tachycardia unrelated to fever is common early in the course of *T. b. rhodesiense* trypanosomiasis, and death may result from arrhythmias and congestive heart failure before CNS disease develops. In general, untreated *T. b. rhodesiense* trypanosomiasis leads to death in a matter of weeks to months, often without a clear distinction between the hemolymphatic and CNS stages. In contrast, *T. b. gambiense* disease can smolder for many months or even for years.

DIAGNOSIS

A definitive diagnosis of HAT requires detection of the parasite. If a chancre is present, fluid should be expressed and examined directly by light microscopy for the highly motile trypanosomes. The fluid also should be fixed and stained with Giemsa. Material obtained by needle aspiration of lymph nodes early in the illness should be examined similarly. Examination of wet preparations and Giemsa-stained thin and thick films of serial blood samples is also useful. If parasites are not seen initially in blood, efforts should be made to concentrate the organisms; the simplest method involves the use of microhematocrit tubes containing acridine orange. In these tubes the parasites are separated from blood cells by centrifugation and are easily seen under light microscopy because of the stain. Alternatively, the buffy coat from 10–15 mL of anticoagulated blood can be examined directly under a microscope. The likelihood of finding parasites in blood is higher in stage I than in stage II disease and in patients infected with *T. b. rhodesiense* rather than *T. b. gambiense*. Trypanosomes may also be seen in material aspirated from the bone marrow; the aspirate can be inoculated into liquid culture medium, as can blood, buffy coat, lymph node aspirates, and CSF. Finally, *T. b. rhodesiense* infection can be detected by inoculation of these specimens into mice or rats, which—when positive—results in patent parasitemias in a week or two. Although this method is highly sensitive for the detection of *T. b. rhodesiense*, it does not detect *T. b. gambiense* because of host specificity.

It is essential to examine CSF from all patients in whom HAT is suspected. Abnormalities in the CSF that may be associated with stage II disease include an increase in the CSF mononuclear cell count as well as increases in opening pressure and in levels of total protein and IgM. Trypanosomes may be seen in the sediment of centrifuged CSF. Any CSF abnormality in a patient in whom trypanosomes have been found at other sites must be viewed as pathognomonic for CNS involvement and thus must prompt specific treatment for CNS disease. In patients with CSF pleocytosis in whom parasites are not found, tuberculous meningitis and HIV-associated CNS infections such as cryptococcosis should be considered in the differential diagnosis.

A number of serologic assays are available to aid in the diagnosis of HAT, but their variable sensitivity and specificity mandate that decisions about treatment be based on demonstration of the parasite. These tests are of value for epidemiologic surveys. PCR assays for detecting African trypanosomes in humans have been developed, but none is commercially available.

TABLE 206-2 TREATMENT OF HUMAN AFRICAN TRYPANOSOMIASES[a]

Causative Organism	Clinical Stage	
	I (Normal CSF)	II (Abnormal CSF)
T. brucei gambiense (West African)	Pentamidine Alternative: Suramin	Eflornithine Alternative: Melarsoprol
T. brucei rhodesiense (East African)	Suramin	Melarsoprol

[a]For doses and duration, see text.
Note: CSF, cerebrospinal fluid.

℞ SLEEPING SICKNESS

The drugs used for treatment of HAT are suramin, pentamidine, eflornithine, and the organic arsenical melarsoprol. In the United States these drugs can be obtained from the CDC. Therapy for HAT must be individualized on the basis of the infecting subspecies, the presence or absence of CNS disease, adverse reactions, and occasionally drug resistance. The choices of drugs for the treatment of HAT are summarized in **Table 206-2**.

Suramin is highly effective against stage I East African disease. However, it can cause serious adverse effects and must be administered under the close supervision of a physician. A 100- to 200-mg IV test dose should be given to detect hypersensitivity. The dosage for adults is 20 mg/kg on days 1, 5, 12, 18, and 26. The drug is given by slow IV infusion of a freshly prepared 10% aqueous solution. Approximately 1 patient in 20,000 has an immediate, severe, and potentially fatal reaction to the drug, developing nausea, vomiting, shock, and seizures. Less severe reactions include fever, photophobia, pruritus, arthralgias, and skin eruptions. Renal damage is the most common important adverse effect of suramin. Transient proteinuria often appears during treatment. A urinalysis should be done before each dose, and treatment should be discontinued if proteinuria increases or if casts and red cells appear in the sediment. Suramin should not be given to patients with renal insufficiency.

Eflornithine is highly effective for treatment of both stages of West African trypanosomiasis. In the trials on which the FDA based its approval, this agent cured >90% of 600 patients with stage II disease. The recommended treatment schedule is 400 mg/kg per day, given intravenously in four divided doses, for 2 weeks. Adverse reactions include diarrhea, anemia, thrombocytopenia, seizures, and hearing loss. The high dosage and duration of therapy required are disadvantages that make widespread use of eflornithine difficult.

Pentamidine is the first-line drug for patients with stage I West African HAT. The dose for both adults and children is 4 mg/kg per day, given intramuscularly or intravenously, for 10 days. Frequent, immediate adverse reactions include nausea, vomiting, tachycardia, and hypotension. These reactions are usually transient and do not warrant cessation of therapy. Other adverse reactions include nephrotoxicity, abnormal liver function tests, neutropenia, rashes, hypoglycemia, and sterile abscesses.

The arsenical melarsoprol is the drug of choice for the treatment of East African trypanosomiasis with CNS involvement and is an alternative agent for stage II West African disease. Melarsoprol cures both stages of the disease and therefore is also indicated for the treatment of stage I disease in patients who fail to respond to or cannot tolerate suramin or pentamidine. However, because of its relatively high toxicity, melarsoprol is never the first choice for the treatment of stage I disease. For East African disease, the drug should be given to adults in three courses of 3 days each. The dosage is 2–3.6 mg/kg per day, given intravenously in three divided doses for 3 days, followed 1 week later by 3.6 mg/kg per day, also in three divided doses and for 3 days. The latter course is repeated 7 days later. In debilitated patients, suramin is administered for 2–4 days before therapy with melar-

soprol is initiated; an 18-mg initial dose of the latter drug, followed by progressive increases to the standard dose, has been recommended. For children, a total of 18–25 mg/kg should be given over 1 month. An IV starting dose of 0.36 mg/kg should be increased gradually to a maximum of 3.6 mg/kg at 1- to 5-day intervals, for a total of 9 or 10 doses. The regimen for West African disease is 2.2 mg/kg per day, given intravenously for 10 days.

Melarsoprol is highly toxic and should be administered with great care. To reduce the likelihood of drug-induced encephalopathy, all patients receiving melarsoprol should be given prednisolone at a dose of 1 mg/kg (up to 40 mg) per day, beginning 1–2 days before the first dose of melarsoprol and continuing through the last dose. Without prednisolone prophylaxis, the incidence of reactive encephalopathy has been reported to be as high as 18% in some series. Clinical manifestations of reactive encephalopathy include high fever, headache, tremor, impaired speech, seizures, and even coma and death. Treatment with melarsoprol should be discontinued at the first sign of encephalopathy but may be restarted cautiously at lower doses a few days after signs have resolved. Extravasation of the drug results in intense local reactions. Vomiting, abdominal pain, nephrotoxicity, and myocardial damage can occur.

PREVENTION

HAT poses complex public-health and epizootic problems in Africa. Considerable progress has been made in some areas through control programs that focus on eradication of vectors and drug treatment of infected humans; however, there is no consensus on the best approach to solving the overall problem, and major epidemics continue to occur. Individuals can reduce their risk of acquiring trypanosomiasis by avoiding areas known to harbor infected insects, by wearing protective clothing, and by using insect repellent. Chemoprophylaxis is not recommended, and no vaccine is available to prevent transmission of the parasites.

207 *Toxoplasma* Infections

Lloyd H. Kasper

DEFINITION

Toxoplasmosis is caused by infection with the obligate intracellular parasite *Toxoplasma gondii*. Acute infection acquired after birth may be asymptomatic but frequently results in the chronic persistence of cysts in the host's tissues. In both acute and chronic toxoplasmosis, the parasite is responsible for clinically evident disease, including lymphadenopathy, encephalitis, myocarditis, and pneumonitis. Congenital toxoplasmosis is an infection of newborns that results from the transplacental passage of parasites from an infected mother to the fetus. These infants usually are asymptomatic at birth but later manifest a wide range of signs and symptoms, including chorioretinitis, strabismus, epilepsy, and psychomotor retardation.

ETIOLOGY

T. gondii is an intracellular coccidian that infects both birds and mammals. There are two distinct stages in the life cycle of *T. gondii* (Fig. 207-1). In the *nonfeline* stage, tissue cysts that contain bradyzoites or sporulated oocysts are ingested by an intermediate host (e.g., a human, mouse, sheep, pig, or bird). The cyst is rapidly digested by the acidic-pH gastric secretions. Bradyzoites or sporozoites are released, enter the small-intestinal epithelium, and transform into rapidly dividing tachyzoites. The tachyzoites can infect and replicate in all mammalian cells except red blood cells. Once attached to the host cell, the parasite penetrates the cell and forms a parasitophorous vacuole within which it divides. Parasite replication continues until the number of parasites within the cell approaches a critical mass and the cell ruptures, releasing parasites that infect adjoining cells.

As a result of this process, an infected organ soon shows evidence of cytopathology. Most tachyzoites are eliminated by the host's humoral and cell-mediated immune responses. Tissue cysts containing many bradyzoites develop 7–10 days after systemic tachyzoite infection. These tissue cysts occur in various host organs but persist principally within the central nervous system (CNS) and muscle. The development of this chronic stage completes the nonfeline portion of the life cycle. Active infection in the immunocompromised host is most likely to be due to the spontaneous release of encysted parasites that undergo rapid transformation into tachyzoites within the CNS.

The principal (*feline*) stage in the life cycle takes place in the cat (the definitive host) and its prey. The parasite's sexual phase is defined by the formation of oocysts within the feline host. This enteroepithelial cycle begins with the ingestion of the bradyzoite tissue cysts and culminates (after several intermediate stages) in the production of gametes. Gamete fusion produces a zygote, which envelops itself in a rigid wall and is secreted in the feces as an unsporulated oocyst. After 2–3 days of exposure to air at ambient temperature, the noninfectious oocyst sporulates to produce eight sporozoite progeny. The sporulated oocyst can be ingested by an intermediate host, such as a person emptying a cat's litter box or a pig rummaging in a barnyard. It is in the intermediate host that *T. gondii* completes its life cycle.

EPIDEMIOLOGY

T. gondii infects a wide range of mammals and birds. Its seroprevalence depends on the locale and the age of the population. Generally, hot arid climatic conditions are associated with a low prevalence of infection. In the United States and most European countries, the seroprevalence increases with age and exposure. For example, in the United States, 5–30% of individuals 10–19 years old and 10–67% of those >50 years old have serologic evidence of exposure; seroprevalence increases by ~1% per year. In Central America, France, Turkey, and Brazil, the seroprevalence is higher. There may be as many as 2100 cases of toxoplasmic encephalitis (TE) each year in the United States.

TRANSMISSION

Oral Transmission The principal source of human *Toxoplasma* infection remains uncertain. Transmission usually takes place by the oral route and can be attributable to ingestion of either sporulated oocysts from contaminated soil or bradyzoites from undercooked meat. During

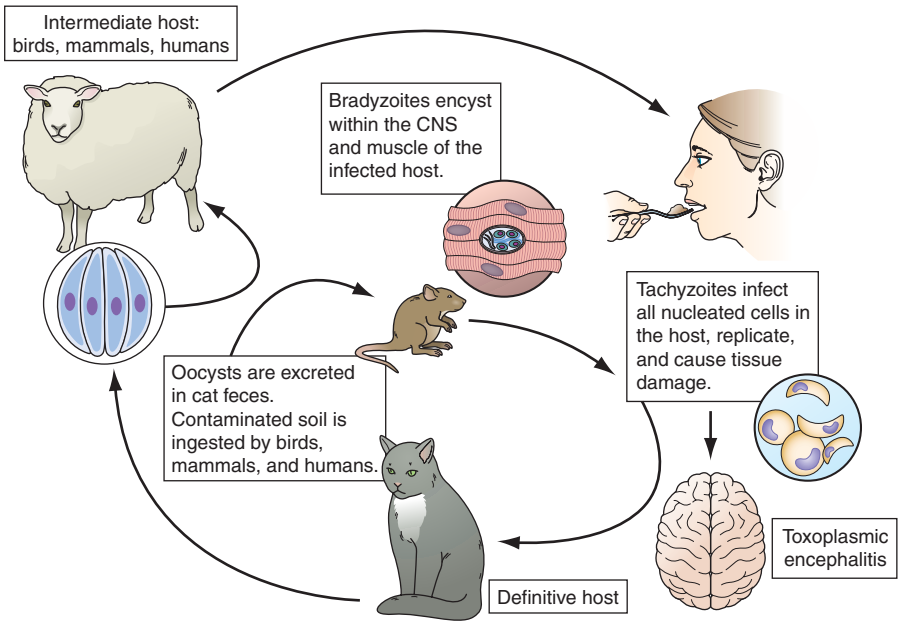

FIGURE 207-1 Life cycle of *Toxoplasma gondii*. The cat is the definitive host in which the sexual phase of the cycle is completed. Oocysts shed in cat feces can infect a wide range of animals, including birds, rodents, grazing domestic animals, and humans. The bradyzoites found in the muscle of food animals may infect humans who eat insufficiently cooked meat products, particularly lamb and pork. Although human disease can take many forms, congenital infection and encephalitis from reactivation of latent infection in the brains of immunosuppressed persons are the most important manifestations. CNS, central nervous system. *(Courtesy of Dominique Buzoni-Gatel, Institut Pasteur, Paris; with permission.)*

acute feline infection, a cat may excrete as many as 100 million parasites per day. These very stable sporozoite-containing oocysts are highly infectious and may remain viable for many years in the soil. Humans infected during a well-documented outbreak of oocyst-transmitted infection develop stage-specific antibodies to the oocyst/sporozoite.

Children and adults also can acquire infection from tissue cysts containing bradyzoites. The ingestion of a single cyst is all that is required for human infection. Undercooking or insufficient freezing of meat is an important source of infection in the developed world. In the United States, 10–20% of lamb products and 25–35% of pork products show evidence of cysts that contain bradyzoites. The incidence in beef is much lower—perhaps as low as 1%. Direct ingestion of bradyzoite cysts in these various meat products leads to acute infection.

Transmission via Blood or Organs In addition to oral transmission, direct transmission of the parasite by blood or organ products during transplantation takes place at a low rate. Viable parasites can be cultured from refrigerated anticoagulated blood, which may be a source of infection in individuals receiving blood transfusions. *T. gondii* infection also has been reported in kidney and heart transplant recipients who were uninfected before transplantation.

Transplacental Transmission About one-third of all women who acquire infection with *T. gondii* during pregnancy transmit the parasite to the fetus; the remainder give birth to normal, uninfected babies. Of the various factors that influence fetal outcome, gestational age at the time of infection is the most critical (see below). Few data support a role for recrudescent maternal infection as the source of congenital disease. Thus, women who are seropositive before pregnancy usually are protected against acute infection and do not give birth to congenitally infected neonates.

The following general guidelines can be used to evaluate congenital infection. There is essentially no risk if the mother becomes infected ≥6 months before conception. If infection is acquired <6 months before conception, the likelihood of transplacental infection increases as the interval between infection and conception decreases. In pregnancy, if the mother becomes infected during the first trimester, the incidence of transplacental infection is lowest (~15%), but the disease in the neonate is most severe. If maternal infection occurs during the third trimester, the incidence of transplacental infection is greatest (65%), but the infant is usually asymptomatic at birth. Infected infants who are normal at birth may have a higher incidence of learning disabilities and chronic neurologic sequelae than uninfected children. Only a small proportion (20%) of women infected with *T. gondii* develop clinical signs of infection. Often the diagnosis is first appreciated when routine postconception serologic tests show evidence of specific antibody.

PATHOGENESIS

Upon the host's ingestion of either tissue cysts containing bradyzoites or oocysts containing sporozoites, the parasites are released from the cysts by a digestive process. Bradyzoites are resistant to the effect of pepsin and invade the host's gastrointestinal tract. Within enterocytes (or other gut-associated cells), the parasites undergo morphologic transformation, giving rise to invasive tachyzoites. These tachyzoites induce a parasite-specific secretory IgA response. From the gastrointestinal tract, parasites are disseminated to a variety of organs, particularly lymphatic tissue, skeletal muscle, myocardium, retina, placenta, and the CNS. At these sites, the parasite infects host cells, replicates, and invades the adjoining cells. In this fashion, the hallmarks of the infection develop: cell death and focal necrosis surrounded by an acute inflammatory response.

In the immunocompetent host, both the humoral and the cellular immune responses control infection; parasite virulence and tissue tropism may be strain specific. Tachyzoites are sequestered by a variety of immune mechanisms, including induction of parasiticidal antibody, activation of macrophages with radical intermediates, production of interferon γ (IFN-γ), and stimulation of cytotoxic T lymphocytes of the CD8+ phenotype. These antigen-specific lymphocytes are capable of killing both extracellular parasites and target cells infected with parasites. As tachyzoites are cleared from the acutely infected host, tissue cysts containing bradyzoites begin to appear, usually within the CNS and the retina. In the immunocompromised or fetal host, the immune factors necessary to control the spread of tachyzoite infection are lacking. This altered immune state allows the persistence of tachyzoites and gives rise to progressive focal destruction that results in organ failure (i.e., necrotizing encephalitis, pneumonia, and myocarditis).

Persistence of infection with cysts containing bradyzoites is common in the immunocompetent host. This lifelong infection usually remains subclinical. Although bradyzoites are in a slow metabolic phase, cysts do degenerate and rupture within the CNS. This degenerative process, with the development of new bradyzoite-containing cysts, is the most probable source of recrudescent infection in immunocompromised individuals and the most likely stimulus for the persistence of antibody titers in the immunocompetent host.

PATHOLOGY

Cell death and focal necrosis due to replicating tachyzoites induce an intense mononuclear inflammatory response in any tissue or cell type infected. Tachyzoites rarely can be visualized by routine histopathologic staining of these inflammatory lesions. However, immunofluorescent staining with parasitic antigen–specific antibodies can reveal either the organism itself or evidence of antigen. In contrast to this inflammatory process caused by tachyzoites, bradyzoite-containing cysts cause inflammation only at the early stages of development, and even this inflammation may be a response to the presence of tachyzoite an-

tigens. Once the cysts reach maturity, the inflammatory process can no longer be detected, and the cysts remain immunologically quiescent within the brain matrix until they rupture.

Lymph Nodes During acute infection, lymph node biopsy demonstrates characteristic findings, including follicular hyperplasia and irregular clusters of tissue macrophages with eosinophilic cytoplasm. Granulomas rarely are evident in these specimens. Although tachyzoites are not usually visible, they can be sought either by subinoculation of infected tissue into mice, with resultant disease, or by polymerase chain reaction (PCR). PCR amplification of DNA fragments representing either p30 (SAG-1) or p22 (SAG-2) surface antigen or B1 antigen is an effective and sensitive assay for establishing lymph node infection by tachyzoites.

Eyes In the eye, infiltrates of monocytes, lymphocytes, and plasma cells may produce uni- or multifocal lesions. Granulomatous lesions and chorioretinitis can be observed in the posterior chamber after acute necrotizing retinitis. Other ocular complications include iridocyclitis, cataracts, and glaucoma.

Central Nervous System During CNS involvement, both focal and diffuse meningoencephalitis can be documented, with evidence of necrosis and microglial nodules. Necrotizing encephalitis in patients without AIDS is characterized by small diffuse lesions with perivascular cuffing in contiguous areas. In the AIDS population, polymorphonuclear leukocytes may be present in addition to monocytes, lymphocytes, and plasma cells. Cysts containing bradyzoites frequently are found contiguous with the necrotic tissue border. As stated previously, it is estimated that there are as many as 2100 cases of TE in the United States each year.

Lungs and Heart Among patients with AIDS who die of toxoplasmosis, 40–70% have involvement of the lungs and heart. Interstitial pneumonitis can develop in neonates and immunocompromised patients. Thickened and edematous alveolar septa infiltrated with mononuclear and plasma cells are apparent. This inflammation may extend to the endothelial walls. Tachyzoites and bradyzoite-containing cysts have been observed within the alveolar membrane. Superimposed bronchopneumonia can be caused by other microbial agents. Cysts and aggregates of parasites in cardiac muscle tissue are evident in patients with AIDS who die of toxoplasmosis. Focal necrosis surrounded by inflammatory cells is associated with hyaline necrosis and disrupted myocardial cells. Pericarditis is associated with toxoplasmosis in some patients.

Gastrointestinal Tract Acute infection in certain strains of inbred mice (B6) results in lethal ileitis within 7–9 days. This inflammatory bowel disease has been recognized in several mammalian species, including pigs and nonhuman primates. The association between human inflammatory bowel disease and either acute or recurrent *Toxoplasma* infection has not been established.

Other Sites Pathologic changes during disseminated infection are similar to those described for the lymph nodes, eyes, and CNS. In patients with AIDS, the skeletal muscle, pancreas, stomach, and kidneys can be involved, with necrosis, invasion by inflammatory cells, and (rarely) tachyzoites detectable by routine staining. Large necrotic lesions may cause direct tissue destruction. In addition, secondary effects from acute infection of these various organs, including pancreatitis, myositis, and glomerulonephritis, have been reported.

HOST IMMUNE RESPONSE

Acute *Toxoplasma* infection evokes a cascade of protective immune responses in the immunocompetent host. *Toxoplasma* enters the host at the gut mucosal level and evokes a mucosal immune response that includes the production of antigen-specific secretory IgA. Titers of serum IgA antibody directed at p30 (SAG-1) are a useful marker for congenital and acute toxoplasmosis. Milk-whey IgA from acutely infected mothers contains a high titer of antibody to *T. gondii* and can block infection of enterocytes in vitro. In mice, IgA intestinal secretions directed at the parasite are abundant and are associated with the induction of mucosal T cells.

Within the host, *T. gondii* rapidly induces detectable levels of both IgM and IgG serum antibodies. Monoclonal gammopathy of the IgG class can occur in congenitally infected infants. IgM levels may be increased in newborns with congenital infection. The polyclonal IgG antibodies evoked by infection are parasiticidal in vitro in the presence of serum complement and are the basis for the Sabin-Feldman dye test. However, cell-mediated immunity is the major protective response evoked by the parasite during host infection. Macrophages are activated after phagocytosis of antibody-opsonized parasites. This activation can lead to death of the parasite by either an oxygen-dependent or an oxygen-independent process. If the parasite is not phagocytosed and enters the macrophage by active penetration, it continues to replicate, and this replication may represent the mechanism for transport and dissemination to distant organs. *Toxoplasma* stimulates a robust interleukin (IL) 12 response by human dendritic cells. The requirement for costimulation via CD40/154 has been established. The CD4+ and CD8+ T cell responses are antigen-specific and further stimulate the production of a variety of important lymphokines that expand the T cell and natural killer cell repertoire. *T. gondii* is a potent inducer of a T_H1 phenotype, with IL-12 and IFN-γ playing an essential role in the control of the parasites' growth in the host. Regulation of the inflammatory response is at least partially under the control of a T_H2 response that includes the production of IL-4 and IL-10 in seropositive individuals. Both asymptomatic patients and those with active infection may have a depressed CD4+ to CD8+ ratio. This shift may be correlated with a disease syndrome but is not necessarily correlated with disease outcome. Human T cell clones of both the CD4+ and the CD8+ phenotypes are cytolytic against parasite-infected macrophages. These T cell clones produce cytokines that are "microbistatic." IL-18, IL-7, and IL-15 upregulate the production of IFN-γ and may be important during acute and chronic infection. The effect of IFN-γ may be paradoxical, with stimulation of a host downregulatory response as well.

Although in patients with AIDS *T. gondii* infection is believed to be recrudescent, determination of antibody titers is not helpful in establishing reactivation. Because of the severe depletion in CD4+ T cells, quite frequently there is no observed increase in antibody titer during exacerbation of infection. T cells from AIDS patients with reactivation of toxoplasmosis fail to secrete both IFN-γ and IL-2. This alteration in the production of these critical immune cytokines contributes to the persistence of infection. *Toxoplasma* infection frequently develops late in the course of AIDS, when the loss of T cell–dependent protective mechanisms, particularly CD8+ T cells, becomes most pronounced.

CLINICAL MANIFESTATIONS

In persons whose immune systems are intact, acute toxoplasmosis is usually asymptomatic and self-limited. This condition can go unrecognized in 80–90% of adults and children with acquired infection. The asymptomatic nature of this infection makes diagnosis difficult in mothers infected during pregnancy. In contrast, the wide range of clinical manifestations in congenitally infected children includes severe neurologic complications such as hydrocephalus, microcephaly, mental retardation, and chorioretinitis. If prenatal infection is severe, multiorgan failure and subsequent intrauterine fetal death can occur. In children and adults, chronic infection can persist throughout life, with little consequence to the immunocompetent host.

Toxoplasmosis in Immunocompetent Patients The most common manifestation of acute toxoplasmosis is cervical lymphadenopathy. The nodes may be single or multiple, are usually nontender, are discrete, and vary in firmness. Lymphadenopathy also may be found in suboccipital, supraclavicular, inguinal, and mediastinal areas. Generalized lymphadenopathy occurs in 20–30% of symptomatic patients. Between 20 and 40% of patients with lymphadenopathy also have headache, malaise, fatigue, and fever [usually with a temperature of <40°C (<104°F)]. A

smaller proportion of symptomatic individuals have myalgia, sore throat, abdominal pain, maculopapular rash, meningoencephalitis, and confusion. Rare complications associated with infection in the normal immune host include pneumonia, myocarditis, encephalopathy, pericarditis, and polymyositis. Symptoms associated with acute infection usually resolve within several weeks, although the lymphadenopathy may persist for some months. In one epidemic, toxoplasmosis was diagnosed correctly in only 3 of the 25 patients who consulted physicians. If toxoplasmosis is considered in the differential diagnosis, routine laboratory and serologic screening should precede node biopsy.

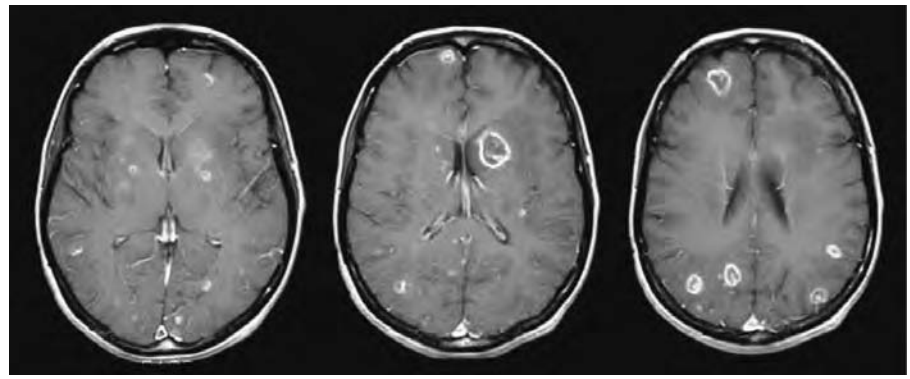

FIGURE 207-2 Toxoplasmic encephalitis in a 36-year-old patient with AIDS. The multiple lesions are demonstrated by magnetic resonance scanning (T1 weighted with gadolinium enhancement). *(Courtesy of Clifford Eskey, Dartmouth Hitchcock Medical Center, Hanover, NH; with permission.)*

The results of routine laboratory studies are usually unremarkable except for minimal lymphocytosis, an elevated erythrocyte sedimentation rate, and a nominal increase in liver aminotransferases. Evaluation of cerebrospinal fluid (CSF) in cases with evidence of encephalopathy or meningoencephalitis shows an elevation of intracranial pressure, mononuclear pleocytosis (10–50 cells/mL), a slight increase in protein concentration, and (occasionally) an increase in the gamma globulin level. PCR amplification of the *Toxoplasma* DNA target sequence in CSF may be beneficial. The CSF of chronically infected individuals is normal.

Infection of Immunocompromised Patients Patients with AIDS and those receiving immunosuppressive therapy for lymphoproliferative disorders are at greatest risk for developing acute toxoplasmosis. This predilection may be due either to reactivation of latent infection or to acquisition of parasites from exogenous sources such as blood or transplanted organs. In individuals with AIDS, >95% of cases of TE are believed to be due to recrudescent infection. In most of these cases, encephalitis develops when the CD4+ T cell count falls below 100/μL. In immunocompromised hosts, the disease may be rapidly fatal if untreated. Thus accurate diagnosis and initiation of appropriate therapy are necessary to prevent fulminant infection.

Toxoplasmosis is a principal opportunistic infection of the CNS in persons with AIDS. Although geographic origin may be related to frequency of infection, it has no correlation with the severity of disease in immunocompromised hosts. Individuals with AIDS who are seropositive for *T. gondii* are at very high risk for encephalitis. In the United States, about one-third of the 15–40% of adult AIDS patients who are latently infected with *T. gondii* develop TE.

The signs and symptoms of acute toxoplasmosis in immunocompromised patients principally involve the CNS (Fig. 207-2). More than 50% of patients with clinical manifestations have intracerebral involvement. Clinical findings at presentation range from nonfocal to focal dysfunction. CNS findings include encephalopathy, meningoencephalitis, and mass lesions. Patients may present with altered mental status (75%), fever (10–72%), seizures (33%), headaches (56%), and focal neurologic findings (60%), including motor deficits, cranial nerve palsies, movement disorders, dysmetria, visual-field loss, and aphasia. Patients who present with evidence of diffuse cortical dysfunction develop evidence of focal neurologic disease as infection progresses. This altered condition is due not only to the necrotizing encephalitis caused by direct invasion by the parasite but also to secondary effects, including vasculitis, edema, and hemorrhage. The onset of infection can range from an insidious process over several weeks to an acute confusional state with fulminant focal deficits, including hemiparesis, hemiplegia, visual-field defects, localized headache, and focal seizures.

Although lesions can occur anywhere in the CNS, the areas most often involved appear to be the brainstem, basal ganglia, pituitary gland, and corticomedullary junction. Brainstem involvement gives rise to a variety of neurologic dysfunctions, including cranial nerve palsy, dysmetria, and ataxia. With basal ganglionic infection, patients may develop hydrocephalus, choreiform movements, and choreoathetosis. Because *Toxoplasma* usually causes encephalitis, meningeal involvement is uncommon, and thus CSF findings may be unremarkable or may include a modest increase in cell count and in protein—but not glucose—concentration.

Cerebral toxoplasmosis must be differentiated from other opportunistic infections or tumors in the CNS of AIDS patients. The differential diagnosis includes herpes simplex encephalitis, cryptococcal meningitis, progressive multifocal leukoencephalopathy, and primary CNS lymphoma. Involvement of the pituitary gland can give rise to panhypopituitarism and hyponatremia from inappropriate secretion of vasopressin (antidiuretic hormone). AIDS-dementia complex may present as cognitive impairment, attention loss, and altered memory. Brain biopsy in patients who have been treated for TE but who continue to exhibit neurologic dysfunction often fails to identify organisms.

Autopsies of *Toxoplasma*-infected patients have demonstrated the involvement of multiple organs, including the lungs, gastrointestinal tract, pancreas, skin, eyes, heart, and liver. *Toxoplasma* pneumonia can be confused with *Pneumocystis* pneumonia (PcP). Respiratory involvement usually presents as dyspnea, fever, and a nonproductive cough and may rapidly progress to acute respiratory failure with hemoptysis, metabolic acidosis, hypotension, and (occasionally) disseminated intravascular coagulation. Histopathologic studies demonstrate necrosis and a mixed cellular infiltrate. The presence of organisms is a helpful diagnostic indicator, but organisms can also be found in healthy tissue. Infection of the heart is usually asymptomatic but can be associated with cardiac tamponade or biventricular failure. Infections of the gastrointestinal tract and the liver have been documented.

Congenital Toxoplasmosis Between 400 and 4000 infants born each year in the United States are affected by congenital toxoplasmosis. Infection of the placenta leads to hematogenous infection of the fetus. As stated earlier, the proportion of fetuses that become infected increases but the clinical severity of the infection declines as gestation proceeds. Persistence of *T. gondii* can ultimately result in reactivation and further damage decades later. Factors associated with relatively severe disabilities include delays in diagnosis and in initiation of therapy, neonatal hypoxia and hypoglycemia, profound visual impairment (see "Ocular Infection," below), uncorrected hydrocephalus, and increased intracranial pressure. If treated appropriately, upwards of 70% of children have normal developmental, neurologic, and ophthalmologic findings at follow-up evaluations. Treatment for 1 year with pyrimethamine and a sulfonamide is tolerated with minimal toxicity (see "Treatment," below).

Ocular Infection Infection with *T. gondii* is estimated to cause 35% of all cases of chorioretinitis in the United States and Europe. Most ocular involvement is believed to be due to congenital infection, with a very low incidence following acquired infection. Between 1 and 3% of all patients with AIDS develop debilitating chorioretinitis due to *T. gondii*. A variety of ocular manifestations are documented, including blurred vision, scotoma, photophobia, and eye pain. Macular involve-

ment occurs with loss of central vision, and nystagmus is secondary to poor fixation. Involvement of the extraocular muscles may lead to disorders of convergence and to strabismus. Ophthalmologic examination should be undertaken in newborns with suspected congenital infection. As the inflammation resolves, vision improves, but episodic flare-ups of chorioretinitis, which progressively destroy retinal tissue and lead to glaucoma, are common.

The ophthalmologic examination reveals yellow-white, cotton-like patches with indistinct margins of hyperemia. As the lesions age, white plaques with distinct borders and black spots within the retinal pigment become more apparent. Lesions usually are located near the posterior pole of the retina; they may be single but are more commonly multiple. Congenital lesions may be unilateral or bilateral and show evidence of massive chorioretinal degeneration with extensive fibrosis. Surrounding these areas of involvement are a normal retina and vasculature. In patients with AIDS, retinal lesions are often large, with diffuse retinal necrosis, and include both free tachyzoites and cysts containing bradyzoites. Toxoplasmic chorioretinitis may be a prodrome to the development of encephalitis.

DIAGNOSIS

Tissue and Body Fluids

The differential diagnosis of acute toxoplasmosis can be made by appropriate culture, serologic testing, and PCR (Table 207-1). Although difficult, the isolation of *T. gondii* from blood or other body fluids can be accomplished after subinoculation of the sample into the peritoneal cavity of mice. Mice should be tested for organisms in the peritoneal fluid 6–10 days after inoculation. If no parasites are found in the mouse's peritoneal fluid, its anti-*Toxoplasma* serum titer can be evaluated 4–6 weeks after inoculation. Isolation of *T. gondii* from the patient's body fluids reflects acute infection, whereas isolation from biopsied tissue is an indication only of the presence of tissue cysts and should not be misinterpreted as evidence of acute toxoplasmosis. Persistent parasitemia in patients with latent, asymptomatic infection is rare. Histologic examination of lymph nodes may suggest the characteristic changes described above. Demonstration of tachyzoites in lymph nodes establishes the diagnosis of acute toxoplasmosis. Like subinoculation into mice, histologic demonstration of cysts containing bradyzoites confirms prior infection with *T. gondii* but is nondiagnostic for acute infection.

TABLE 207-1 DIFFERENTIAL LABORATORY DIAGNOSIS OF TOXOPLASMOSIS

Clinical Setting	Alternative Diagnosis	Distinguishing Characteristics
Mononucleosis syndrome	Epstein-Barr virus	Serologic test
	Cytomegalovirus	Serologic test
	HIV	Serologic test
Congenital infection	Cytomegalovirus	Viral culture
	Herpes simplex virus	Viral culture
	Rubella virus	Viral culture/serologic test
	Syphilis	Serologic test
	Listeriosis	Bacterial culture
Retinochoroiditis in immunocompetent individual	Tuberculosis	Bacterial culture
	Syphilis	Serologic test
	Histoplasmosis	Serologic test/culture
Retinochoroiditis in AIDS	Cytomegalovirus	Viral culture/PCR
	Syphilis	Serologic test
	Herpes simplex virus	Viral culture/PCR
	Varicella-zoster virus	Viral culture/PCR
	Fungal infection	Culture
CNS lesions in AIDS	Lymphoma or metastatic tumor	Tissue biopsy
	Brain abscess	Bacterial culture
	Progressive multifocal leukoencephalopathy	PCR
	Fungal/mycobacterial infection	Biopsy and culture

Serology

The procedures just described have great diagnostic value but are limited by difficulties encountered either in the growth of parasites in vivo or in the identification of tachyzoites by histochemical methods. Serologic testing has become the routine method of diagnosis. A wide range of serologic tests that can be used to measure antibody to *T. gondii* are available commercially.

Diagnosis of acute infection with *T. gondii* can be established by detection of the simultaneous presence of IgG and IgM antibodies to *Toxoplasma* in serum. The presence of circulating IgA favors the diagnosis of an acute infection. The Sabin-Feldman dye test, the indirect fluorescent antibody test, and the enzyme-linked immunosorbent assay (ELISA) all satisfactorily measure circulating IgG antibody to *Toxoplasma*. Positive IgG titers (>1:10) can be detected as early as 2–3 weeks after infection. These titers usually peak at 6–8 weeks and decline slowly to a new baseline level that persists for life. It is necessary to measure the serum IgM titer in concert with the IgG titer to better establish the time of infection. The methods currently available for this determination are the double-sandwich IgM-ELISA and the IgM-immunosorbent assay (IgM-ISAGA). Both of these assays are specific and sensitive, and their use precludes the false-positive results associated with tests for rheumatoid factor and antinuclear antibody. The double-sandwich IgA-ELISA is more sensitive than the IgM-ELISA for detecting congenital infection in the fetus and newborn.

Recently, the results obtained with PCR have suggested high sensitivity, specificity, and clinical utility in the diagnosis of TE in resource-poor settings.

Molecular Diagnostics

Molecular approaches can directly detect *T. gondii* in biologic samples independent of the serologic response. Specific molecular analysis for either the B1 gene or the 529-bp sequence is useful. Real-time PCR is a promising technique that can provide quantitative results. Isolates can be genotyped and polymorphic sequences can be obtained, with the consequent identification of the precise strain. Knowledge of the correct sequence is important in studies on the correlation of clinical signs and symptoms of disease with the *T. gondii* genotype.

The Immunocompetent Adult or Child

For the patient who presents with lymphadenopathy only, a positive IgM titer is an indication of acute infection—and an indication for therapy, if that is clinically warranted (see "Treatment," below). The serum IgM titer should be determined again in 3 weeks. An elevation in the IgG titer without an increase in the IgM titer suggests that infection is present but is not acute. If there is a borderline increase in either IgG or IgM, the titers should be reassessed in 3–4 weeks.

The Immunocompromised Host

A presumptive clinical diagnosis of TE in patients with AIDS is based on clinical presentation, history of exposure (as evidenced by positive serology), and radiologic evaluation. To detect latent infection with *T. gondii*, HIV-infected persons should be tested for IgG antibody to *Toxoplasma* soon after HIV infection is diagnosed. When these criteria are used, the predictive value is as high as 80%. More than 97% of patients with AIDS and toxoplasmosis have IgG antibody to *T. gondii* in serum. IgM serum antibody usually is not detectable. Attempts to evaluate rising IgG titers or to determine whether IgM is present are not productive. Serologic evidence of infection virtually always precedes the development of TE. It is therefore important to determine the *Toxoplasma* antibody status of all patients infected with HIV. Antibody titers may range from negative to 1:1024 in patients with AIDS and TE. Fewer than 3% of patients have no demonstrable antibody to *Toxoplasma* at diagnosis. Intrathecal antibody to *T. gondii* may be present; determination of the titer may help identify prior infection.

Patients with TE have focal or multifocal abnormalities demonstrable by CT or MRI. Neuroradiologic evaluation should include double-dose contrast CT of the head. By this test, single and frequently multiple contrast-enhancing lesions (<2 cm) may be identified. MRI usually demonstrates multiple lesions located in both hemispheres, with the basal ganglia and corticomedullary junction most commonly involved; MRI

provides a more sensitive evaluation of the efficacy of therapy than does CT (Fig. 207-2). These findings are not pathognomonic of *Toxoplasma* infection, since 40% of CNS lymphomas are multifocal and 50% are ring-enhancing. For both MRI and CT scans, the rate of false-negative results is ~10%. The finding of a single lesion on an MRI scan increases the likelihood of primary CNS lymphoma (in which solitary lesions are four times more likely than in TE) and strengthens the argument for the performance of a brain biopsy. A therapeutic trial of anti-*Toxoplasma* medications is frequently used to assess the diagnosis. Treatment of presumptive TE with pyrimethamine plus clindamycin results in quantifiable clinical improvement in >50% of patients by day 3. By day 7, >90% of treated patients show evidence of improvement. In contrast, if patients fail to respond or have lymphoma, clinical signs and symptoms worsen by day 7. Patients in this category require brain biopsy with or without a change in therapy. This procedure can now be performed by a stereotactic CT-guided method that reduces the potential for complications. Brain biopsy for *T. gondii* identifies organisms in 50–75% of cases. PCR amplification of genetic material of the parasite found in the CSF may prove diagnostically beneficial in the future.

Now used in some centers, single-photon emission CT (SPECT) has been touted as a definitive means of detecting or ruling out *Toxoplasma* infection when a CNS lesion is suspected. In the future, SPECT may well be widely used for this purpose.

As in other conditions, the radiologic response may lag behind the clinical response. Resolution of lesions may take from 3 weeks to 6 months. Some patients show clinical improvement despite worsening radiographic findings.

Congenital Infection The issue of concern when a pregnant woman has evidence of recent *T. gondii* infection is obviously whether the fetus is infected. PCR analysis of the amniotic fluid for the B1 gene of *T. gondii* has replaced fetal blood sampling. Serologic diagnosis is based on the persistence of IgG antibody or a positive IgM titer after the first week of life (a time frame that excludes placental leak). The IgG determination should be repeated every 2 months. An increase in IgM beyond the first week of life is indicative of acute infection. However, up to 25% of infected newborns may be seronegative and have normal routine physical examinations. Thus assessment of the eye and the brain, with ophthalmologic testing, CSF evaluation, and radiologic studies, is important in establishing the diagnosis.

Ocular Toxoplasmosis Because of the congenital nature of ocular toxoplasmosis, the serum antibody titer may not correlate with the presence of active lesions in the fundus. In general, a positive IgG titer (measured in undiluted serum if necessary) in conjunction with typical lesions establishes the diagnosis. Antibody production is expressed in terms of the Goldmann-Witmer coefficient (C), in which C = [anti-*Toxoplasma* IgG (aqueous humor/serum)]/[total IgG (serum/aqueous humor)]. The positive cutoff of 3 is the generally accepted discrimination level. The sensitivity of this index as a diagnostic tool lies between 60 and 85%, with a specificity close to 90% in persons of European or North American origin. Confirmation of local specific antibody production in the eye indicates that the site of inflammatory activity is localized to this organ. However, two-thirds of patients without evidence of specific antibody production at initial clinical presentation later develop a detectable titer. If lesions are atypical and the titer is in the low-positive range, the diagnosis is presumptive. The parasitic antigen–specific polyclonal IgG assay as well as parasitic antigen–specific PCR may facilitate the diagnosis. Accordingly, the clinical diagnosis of ocular toxoplasmosis can be supported in 60–90% of cases by laboratory tests, depending on the time of anterior chamber puncture and the panel of antibody analyses used. In the remaining cases, the possibility of a falsely negative laboratory diagnosis or of an incorrect clinical diagnosis cannot be clarified further.

Rx TOXOPLASMOSIS

CONGENITAL INFECTION Congenitally infected neonates are treated with daily oral pyrimethamine (0.5–1 mg/kg) and sulfadiazine (100 mg/kg) for 1 year. In addition, therapy with spiramycin (100 mg/kg per day) plus prednisone (1 mg/kg per day) is efficacious for congenital infection.

INFECTION IN IMMUNOCOMPETENT PATIENTS Immunologically competent adults and older children who have only lymphadenopathy do not require specific therapy unless they have persistent, severe symptoms. Patients with ocular toxoplasmosis should be treated for 1 month with pyrimethamine plus either sulfadiazine or clindamycin. Prenatal antibiotic therapy can reduce the number of infants severely affected by *Toxoplasma* infection.

INFECTION IN IMMUNOCOMPROMISED PATIENTS Primary Prophylaxis Patients with AIDS should be treated for acute toxoplasmosis; in immunocompromised patients, toxoplasmosis is rapidly fatal if untreated. Before the introduction of antiretroviral therapy (ART), the median survival time was >1 year for patients who could tolerate treatment for TE. Despite their toxicity, the drugs used to treat TE were required for survival prior to ART. The incidence of TE has declined as survival of patients with HIV infection has increased as a result of ART.

In Africa, many patients are diagnosed with HIV infection only after developing opportunistic infections such as TE. Hence, the optimal management of these opportunistic infections is important if the benefits of subsequent ART are to be realized. AIDS patients who are seropositive for *T. gondii* and who have a CD4+ T lymphocyte count of <100/μL should receive prophylaxis against TE. A recent Cochrane analysis of clinical trials of TE treatment failed to document the superiority of any one regimen. Of the currently available agents, trimethoprim-sulfamethoxazole (TMP-SMX) appears to be an effective alternative for TE in resource-poor settings where the preferred combination of pyrimethamine plus sulfadiazine is not available. The daily dose of TMP-SMX recommended as the preferred regimen for PcP prophylaxis (one double-strength tablet) is effective against TE. If patients cannot tolerate TMP-SMX, the recommended alternative is dapsone-pyrimethamine, which is also effective against PcP. Atovaquone with or without pyrimethamine also can be considered. Prophylactic monotherapy with dapsone, pyrimethamine, azithromycin, clarithromycin, or aerosolized pentamidine is probably insufficient. AIDS patients who are seronegative for *Toxoplasma* and are not receiving prophylaxis for PcP should be retested for IgG antibody to *Toxoplasma* if their CD4+ T cell count drops to <100/μL. If seroconversion has taken place, then the patient should be given prophylaxis as described above.

Discontinuing Primary Prophylaxis Some current studies indicate that prophylaxis against TE can be discontinued in patients who have responded to ART and whose CD4+ T lymphocyte count has been >200/μL for 3 months. Although patients with CD4+ T lymphocyte counts of <100/μL are at greatest risk for developing TE, the risk that this condition will develop when the count has increased to 100–200/μL has not been established. Thus, prophylaxis should indeed be discontinued only when the count has increased to >200/μL. Continued prophylaxis at a CD4+ count of >200/μL has only a limited preventive effect against TE. Discontinuation of therapy reduces the pill burden; the potential for drug toxicity, drug interaction, or selection of drug-resistant pathogens; and cost. Prophylaxis should be recommenced if the CD4+ T lymphocyte count again decreases to <100–200/μL.

Individuals who have completed initial therapy for TE should receive treatment indefinitely unless immune reconstitution, with a CD4+ T cell count of >200/μL, occurs as a consequence of ART. Combination therapy with pyrimethamine plus sulfadiazine plus leucovorin is effective for this purpose. An alternative to sulfadiazine in this regimen is clindamycin. Unfortunately, only the combination of pyrimethamine plus sulfadiazine provides protection against PcP as well.

Discontinuing Secondary Prophylaxis (Chronic Maintenance Therapy) Patients receiving secondary prophylaxis for TE are at low risk for recurrence when they have completed initial therapy for TE, remain asymptomatic, and have a CD4+ T lymphocyte count of >200/μL for at least 6 months after ART. This recommendation is based on recent observations in a large cohort (381 patients) and is consistent with more extensive data indicating the safety of discontinuing secondary prophylaxis for other opportunistic infections during advanced HIV disease. Discontinuation of chronic maintenance therapy among these patients appears reasonable. A repeat MRI brain scan is recommended. Secondary prophylaxis should be reintroduced if the CD4+ T lymphocyte count decreases to <200/μL.

PREVENTION

All HIV-infected persons, including those who lack IgG antibody to *Toxoplasma*, should be counseled regarding sources of *Toxoplasma* infection. The chances of primary infection with *Toxoplasma* can be reduced by not eating undercooked meat and by avoiding oocyst-contaminated material (i.e., a cat's litter box). Specifically, lamb, beef, and pork should be cooked to an internal temperature of 165°–170°F; from a more practical perspective, meat cooked until it is no longer pink inside usually satisfies this requirement. Hands should be washed thoroughly after work in the garden, and all fruits and vegetables should be washed. If the patient owns a cat, the litter box should be cleaned or changed daily, preferably by an HIV-negative, nonpregnant person; alternatively, patients should wash their hands thoroughly after changing the litter box. Patients should be encouraged to keep their cats inside and not to adopt or handle stray cats. Cats should be fed only canned or dried commercial food or well-cooked table food, not raw or undercooked meats. Patients need not be advised to part with their cats or to have their cats tested for toxoplasmosis. Blood intended for transfusion into *Toxoplasma*-seronegative immunocompromised individuals should be screened for antibody to *T. gondii*. Although such serologic screening is not routinely performed, seronegative women should be screened for evidence of infection several times during pregnancy if they are exposed to environmental conditions that put them at risk for infection with *T. gondii*. HIV-positive individuals should adhere closely to these preventive measures.

208 Protozoal Intestinal Infections and Trichomoniasis

Peter F. Weller

PROTOZOAL INFECTIONS

GIARDIASIS

Giardia lamblia (also known as *G. intestinalis*) is a cosmopolitan protozoal parasite that inhabits the small intestines of humans and other mammals.

Giardiasis is one of the most common parasitic diseases in both developed and developing countries worldwide, causing both endemic and epidemic intestinal disease and diarrhea.

Life Cycle and Epidemiology (Fig. 208-1) Infection follows the ingestion of environmentally hardy cysts, which excyst in the small intestine, releasing flagellated trophozoites (Fig. 208-2) that multiply by binary fission. *Giardia* remains a pathogen of the proximal small bowel and does not disseminate hematogenously. Trophozoites remain free in the lumen or attach to the mucosal epithelium by means of a ventral sucking disk. As a trophozoite encounters altered conditions, it forms a morphologically distinct cyst, which is the stage of the parasite usually found in the feces. Trophozoites may be present and even predominate in loose or watery stools, but it is the resistant cyst that survives outside the body and is responsible for transmission. Cysts do not tolerate heating, desiccation, or continued exposure to feces but do remain viable for months in cold fresh water. The number of cysts excreted varies widely but can approach 10^7 per gram of stool.

Ingestion of as few as 10 cysts is sufficient to cause infection in humans. Because cysts are infectious when excreted, person-to-person transmission occurs where fecal hygiene is poor. Giardiasis, as symptomatic or asymptomatic infections, is especially prevalent in day-care centers; person-to-person spread also takes place in other institutional settings with poor fecal hygiene and during anal-oral contact. If food is contaminated with *Giardia* cysts after cooking or preparation, foodborne transmission can occur. Waterborne transmission accounts for episodic infections (e.g., in campers and travelers) and for major epidemics in metropolitan areas. Surface water, ranging from mountain streams to large municipal reservoirs, can become contaminated with fecally derived *Giardia* cysts; outmoded water systems are subject to cross-contamination from leaking sewer lines. The efficacy of water as a means of transmission is enhanced by the small infectious inoculum of *Giardia*, the prolonged survival of cysts in cold water, and the resistance of cysts to killing by routine chlorination methods that are adequate for controlling bacteria. Viable cysts can be eradicated from water by either boiling or filtration. In the United States, *Giardia* (like *Cryptosporidium*; see below) is a common cause of waterborne epidemics of gastroenteritis. *Giardia* is common in developing countries, and infections may be acquired by travelers.

The importance of animal reservoirs as sources of infection for humans is unclear. *Giardia* parasites morphologically similar to those in humans are found in many mammals, including beavers from reservoirs implicated in epidemics, dogs, and cats.

Giardiasis, like cryptosporidiosis, creates a significant economic burden because of the costs incurred in the installation of water filtration systems required to prevent waterborne epidemics, in the management of epidemics that involve large communities, and in the evaluation and treatment of endemic infections.

Pathophysiology The reasons that some, but not all, infected patients develop clinical manifestations and the mechanisms by which *Giardia* causes alterations in small-bowel function are largely unknown. Although trophozoites adhere to the epithelium, they do not cause invasive or locally destructive alterations. The lactose intolerance and, in a minority of infected adults and children, significant malabsorption that develop are clinical signs of the loss of brush-border enzyme activities. In most infections, the morphology of the bowel is unaltered; however, in a few cases (usually in chronically infected, symptomatic patients), the histopathologic findings (including flattened villi) and the clinical manifestations resemble those of tropical sprue and gluten-sensitive enteropathy. The pathogenesis of diarrhea in giardiasis is not known.

The natural history of *Giardia* infection varies markedly. Infections may be aborted, transient, recurrent, or chronic. Parasite as well as host factors may be important in determining the course of infection and disease. Both cellular and humoral responses develop in human infections, but their precise roles in the control of infection and/or dis-

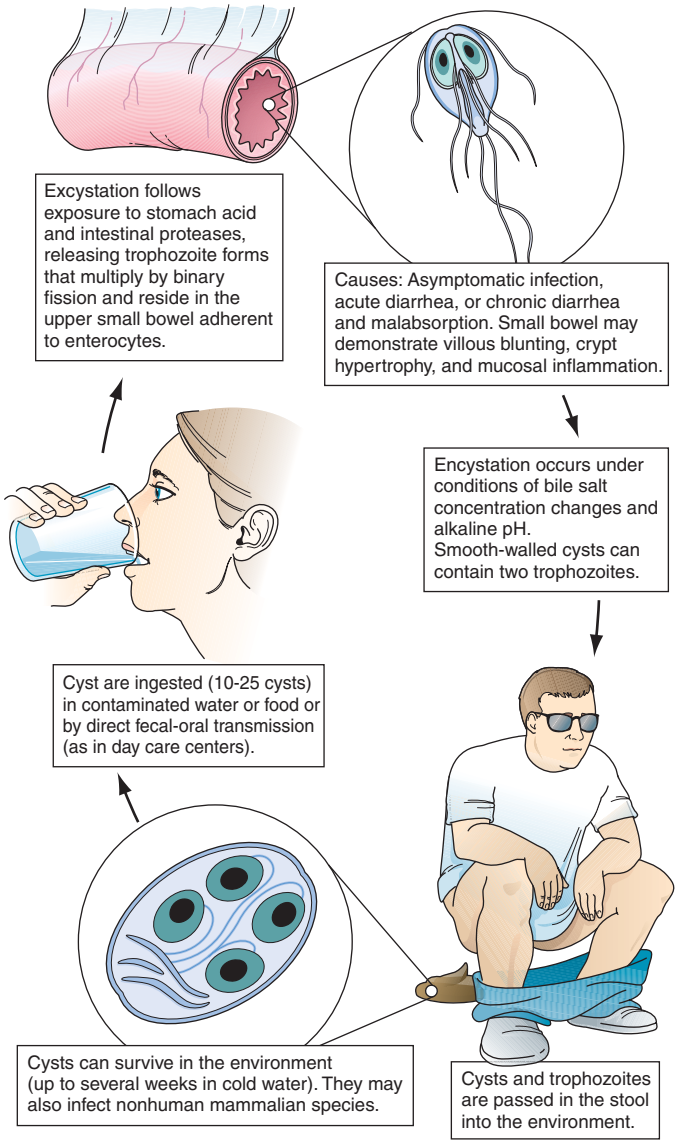

FIGURE 208-1 **Life cycle of *Giardia*.** (*Reprinted from RL Guerrant et al: Tropical Infectious Disease: Principles, Pathogens and Practice, 2d ed, 2006, p 987, with permission from Elsevier Science.*)

ease are unknown. Because patients with hypogammaglobulinemia suffer from prolonged, severe infections that are poorly responsive to treatment, humoral immune responses appear to be important. The greater susceptibility of the young than of the old and of newly exposed persons than of chronically exposed populations suggests that at least partial protective immunity may develop. *Giardia* isolates vary genotypically, biochemically, and biologically, and variations among isolates may contribute to different courses of infection.

Clinical Manifestations Disease manifestations of giardiasis range from asymptomatic carriage to fulminant diarrhea and malabsorption. Most infected persons are asymptomatic, but in epidemics the proportion of symptomatic cases may be higher. Symptoms may develop suddenly or gradually. In persons with acute giardiasis, symptoms develop after an incubation period that lasts at least 5–6 days and usually 1–3 weeks. Prominent early symptoms include diarrhea, abdominal pain, bloating, belching, flatus, nausea, and vomiting. Although diarrhea is common, upper intestinal manifestations such as nausea, vomiting, bloating, and abdominal pain may predominate. The duration of acute giardiasis is usually >1 week, although diarrhea often subsides. Individuals with chronic giardiasis may present with or without having experienced an antecedent acute symptomatic episode. Diarrhea is not necessarily prominent, but increased flatus, loose stools, sulfurous belching, and (in some instances) weight loss occur. Symptoms may be continual or episodic and can persist for years. Some persons who have relatively mild symptoms for long periods recognize the extent of their discomfort only in retrospect. Fever, the presence of blood and/or mucus in the stools, and other signs and symptoms of colitis are uncommon and suggest a different diagnosis or a concomitant illness. Symptoms tend to be intermittent yet recurring and gradually debilitating, in contrast with the acute disabling symptoms associated with many enteric bacterial infections. Because of the less severe illness and the propensity for chronic infections, patients may seek medical advice late in the course of the illness; however, disease can be severe, resulting in malabsorption, weight loss, growth retardation, and dehydration. A number of extraintestinal manifestations have been described, such as urticaria, anterior uveitis, and arthritis; whether these are caused by giardiasis or concomitant processes is unclear.

FIGURE 208-2 Flagellated, binucleate ***Giardia* trophozoite.**

Giardiasis can be severe in patients with hypogammaglobulinemia and can complicate other preexisting intestinal diseases, such as that occurring in cystic fibrosis. In patients with AIDS, *Giardia* can cause enteric illness that is refractory to treatment.

Diagnosis (Table 208-1) Giardiasis is diagnosed by detection of parasite antigens in the feces or by identification of cysts in the feces or of trophozoites in the feces or small intestines. Cysts are oval, measure 8–12 μm × 7–10 μm, and characteristically contain four nuclei. Trophozoites are pear-shaped, dorsally convex, flattened parasites with two nuclei and four pairs of flagella (Fig. 208-2). The diagnosis is sometimes difficult to establish. Direct examination of fresh or properly preserved stools as well as concentration methods should be used. Because cyst excretion is variable and may be undetectable at times, repeated examination of stool, sampling of duodenal fluid, and biopsy of the small intestine may be required to detect the parasite. Tests for parasitic antigens in stool are at least as sensitive and specific as good microscopic examinations and are easier to perform. All of these methods occasionally yield false-negative results.

TABLE 208-1 DIAGNOSIS OF INTESTINAL PROTOZOAL INFECTIONS

Parasite	Stool O+P[a]	Fecal Acid-Fast Stain	Stool Antigen Immunoassays	Other

[a]O+P, ova and parasites.

Rx GIARDIASIS

Cure rates with metronidazole (250 mg thrice daily for 5 days) are usually >90%. Tinidazole (2 g once by mouth) is reportedly more effective than metronidazole. Nitazoxanide (500 mg twice daily for 3 days) is an alternative agent for treatment of giardiasis. Paromomycin, an oral aminoglycoside that is not well absorbed, can be given to symptomatic pregnant patients, although information is limited on how effectively this agent eradicates infection.

Almost all patients respond to therapy and are cured, although some with chronic giardiasis experience delayed resolution of symptoms after eradication of *Giardia*. For many of the latter patients, residual symptoms probably reflect delayed regeneration of intestinal brush-border enzymes. Continued infection should be documented by stool examinations before treatment is repeated. Patients who remain infected after repeated treatments should be evaluated for reinfection through family members, close personal contacts, and environmental sources as well as for hypogammaglobulinemia. In cases refractory to multiple treatment courses, prolonged therapy with metronidazole (750 mg thrice daily for 21 days) has been successful.

Prevention Although *Giardia* is extremely infectious, disease can be prevented by consumption of noncontaminated food and water and by personal hygiene when caring for infected children. Boiling or filtering potentially contaminated water prevents infection.

CRYPTOSPORIDIOSIS

The coccidian parasite *Cryptosporidium* causes diarrheal disease that is self-limited in immunocompetent human hosts but can be severe in persons with AIDS or other forms of immunodeficiency. Two species of *Cryptosporidium, C. hominis* and *C. parvum,* cause most human infections.

Life Cycle and Epidemiology *Cryptosporidium* species are widely distributed in the world. Cryptosporidiosis is acquired by the consumption of oocysts (50% infectious dose: ~132 oocysts in nonimmune individuals), which excyst to liberate sporozoites that in turn enter and infect intestinal epithelial cells. The parasite's further development involves both asexual and sexual cycles, which produce forms capable of infecting other epithelial cells and of generating oocysts that are passed in the feces. *Cryptosporidium* species infect a number of animals, and *C. parvum* can spread from infected animals to humans. Since oocysts are immediately infectious when passed in feces, person-to-person transmission takes place in day-care centers and among household contacts and medical providers. Waterborne transmission (especially that of *C. hominis*) accounts for infections in travelers and for common-source epidemics. Oocysts are quite hardy and resist killing by routine chlorination. Both drinking water and recreational water (e.g., pools, waterslides) have been increasingly recognized as sources of infection.

Pathophysiology Although intestinal epithelial cells harbor cryptosporidia in an intracellular vacuole, the means by which secretory diarrhea is elicited remain uncertain. No characteristic pathologic changes are found by biopsy. The distribution of infection can be spotty within the principal site of infection, the small bowel. Cryptosporidia are found in the pharynx, stomach, and large bowel of some patients and at times in the respiratory tract. Especially in patients with AIDS, involvement of the biliary tract can cause papillary stenosis, sclerosing cholangitis, or cholecystitis.

Clinical Manifestations Asymptomatic infections can occur in both immunocompetent and immunocompromised hosts. In immunocompetent persons, symptoms develop after an incubation period of ~1 week and consist principally of watery nonbloody diarrhea, sometimes in conjunction with abdominal pain, nausea, anorexia, fever, and/or weight loss. In these hosts, the illness usually subsides after 1–2 weeks. In contrast, in immunocompromised hosts (especially those with AIDS and CD4+ T cell counts <100/μL), diarrhea can be chronic, persistent, and remarkably profuse, causing clinically significant fluid and electrolyte depletion. Stool volumes may range from 1 to 25 L/d. Weight loss, wasting, and abdominal pain may be severe. Biliary tract involvement can manifest as midepigastric or right upper quadrant pain.

Diagnosis (Table 208-1) Evaluation starts with fecal examination for small oocysts, which are smaller (4–5 μm in diameter) than the fecal stages of most other parasites. Because conventional stool examination for ova and parasites does not detect *Cryptosporidium*, specific testing must be requested. Detection is enhanced by evaluation of stools (obtained on multiple days) by several techniques, including modified acid-fast and direct immunofluorescent stains and enzyme immunoassays. Cryptosporidia can also be identified by light and electron microscopy at the apical surfaces of intestinal epithelium from biopsy specimens of the small bowel and, less frequently, the large bowel.

Rx CRYPTOSPORIDIOSIS

Nitazoxanide is approved by the U.S. Food and Drug Administration for the treatment of cryptosporidiosis and is available in tablet form for adults (500 mg twice daily for 3 days) and as an elixir for children. To date, however, this agent has not been effective for the treatment of HIV-infected patients, in whom improved immune status due to antiretroviral therapy can lead to amelioration of cryptosporidiosis. Otherwise, treatment includes supportive care with replacement of fluids and electrolytes and administration of antidiarrheal agents. Biliary tract obstruction may require papillotomy or T-tube placement. Prevention requires minimizing exposure to infectious oocysts in human or animal feces. Use of submicron water filters may minimize acquisition of infection from drinking water.

ISOSPORIASIS

The coccidian parasite *Isospora belli* causes human intestinal disease. Infection is acquired by the consumption of oocysts, after which the parasite invades intestinal epithelial cells and undergoes both sexual and asexual cycles of development. Oocysts excreted in stool are not immediately infectious but must undergo further maturation.

Although *I. belli* infects many animals, little is known about the epidemiology or prevalence of this parasite in humans. It appears to be most common in tropical and subtropical countries. Acute infections can begin abruptly with fever, abdominal pain, and watery nonbloody diarrhea and can last for weeks or months. In patients who have AIDS or are immunocompromised for other reasons, infections often are not self-limited but rather resemble cryptosporidiosis, with chronic, profuse watery diarrhea. Eosinophilia, which is not found in other enteric protozoan infections, may be detectable. The diagnosis (Table 208-1) is usually made by detection of the large (~25-μm) oocysts in stool by modified acid-fast staining. Oocyst excretion may be low-level and intermittent; if repeated stool examinations are unrevealing, sampling of duodenal contents by aspiration or small-bowel biopsy (often with electron-microscopic examination) may be necessary.

Rx ISOSPORIASIS

Trimethoprim-sulfamethoxazole (TMP-SMX; 160/800 mg four times daily for 10 days, and for HIV-infected patients, then three times daily for 3 weeks) is effective. For patients intolerant of sulfonamides, pyrimethamine (50–75 mg/d) can be used. Relapses can occur in persons with AIDS and necessitate maintenance therapy with TMP-SMX (160/800 mg three times per week).

CYCLOSPORIASIS

Cyclospora cayetanensis, a cause of diarrheal illness, is globally distributed: illness due to *C. cayetanensis* has been reported in the United States, Asia, Africa, Latin America, and Europe. The epidemiology of this parasite has not yet been fully defined, but waterborne transmission and food-borne transmission by basil and imported raspberries have been recognized. The full spectrum of ill-

ness attributable to *Cyclospora* has not been delineated. Some patients may harbor the infection without symptoms, but many have diarrhea, flulike symptoms, and flatulence and belching. The illness can be self-limited, can wax and wane, or in many cases can involve prolonged diarrhea, anorexia, and upper gastrointestinal symptoms, with sustained fatigue and weight loss in some instances. Diarrheal illness may persist for >1 month. *Cyclospora* can cause enteric illness in patients infected with HIV.

The parasite is detectable in epithelial cells of small-bowel biopsy samples and elicits secretory diarrhea by unknown means. The absence of fecal blood and leukocytes indicates that disease due to *Cyclospora* is not caused by destruction of the small-bowel mucosa. The diagnosis (Table 208-1) can be made by detection of spherical 8- to 10-μm oocysts in the stool, although routine stool O and P examinations are not sufficient. Specific fecal examinations must be requested to detect the oocysts, which are variably acid-fast and are fluorescent when viewed with ultraviolet light microscopy. Cyclosporiasis should be considered in the differential diagnosis of prolonged diarrhea, with or without a history of travel by the patient to other countries.

℞ CYCLOSPORIASIS

Cyclosporiasis is treated with TMP-SMX (160/800 mg twice daily for 7 days). HIV-infected patients may experience relapses after such treatment and thus may require longer-term suppressive maintenance therapy.

MICROSPORIDIOSIS

Microsporidia are obligate intracellular spore-forming protozoa that infect many animals and cause disease in humans, especially as opportunistic pathogens in AIDS. Microsporidia are members of a distinct phylum, Microspora, which contains dozens of genera and hundreds of species. The various microsporidia are differentiated by their developmental life cycles, ultrastructural features, and molecular taxonomy based on ribosomal RNA. The complex life cycles of the organisms result in the production of infectious spores **(Fig. 208-3)**. Currently, eight genera of microsporidia—*Encephalitozoon*, *Pleistophora*, *Nosema*, *Vittaforma*, *Trachipleistophora*, *Brachiola*, *Microsporidium*, and *Enterocytozoon*—are recognized as causes of human disease. Although some microsporidia are probably prevalent causes of self-limited or asymptomatic infections in immunocompetent patients, little is known about how microsporidiosis is acquired.

Microsporidiosis is most common among patients with AIDS, less common among patients with other types of immunocompromise, and rare among immunocompetent hosts. In patients with AIDS, intestinal infections with *Enterocytozoon bieneusi* and *Encephalitozoon* (formerly *Septata*) *intestinalis* are recognized to contribute to chronic diarrhea and wasting; these infections are found in 10–40% of patients with chronic diarrhea. Both organisms have been found in the biliary tracts of patients with cholecystitis. *E. intestinalis* may also disseminate to cause fever, diarrhea, sinusitis, cholangitis, and bronchiolitis. In patients with AIDS, *Encephalitozoon hellem* has caused superficial keratoconjunctivitis as well as sinusitis, respiratory tract disease, and disseminated infection. Myositis due to *Pleistophora* has been documented. *Nosema*, *Vittaforma*, and *Microsporidium* have caused stromal keratitis associated with trauma in immunocompetent patients.

Microsporidia are small gram-positive organisms with mature spores measuring 0.5–2 μm × 1–4 μm. Diagnosis of microsporidial infections in tissue often requires electron microscopy, although intracellular spores can be visualized by light microscopy with hematoxylin and eosin, Giemsa, or tissue Gram's stain. For the diagnosis of intestinal microsporidiosis, modified trichrome or chromotrope 2R-based staining and Uvitex 2B or calcofluor fluorescent staining reveal spores in smears of feces or duodenal aspirates. Definitive therapies for microsporidial infections remain to be established. For superficial keratoconjunctivitis due to *E. hellem*, topical therapy with fumagillin suspension has shown promise (Chap. 201). For enteric infections with *E. bieneusi* and *E. intestinalis* in HIV-infected patients, therapy with albendazole may be efficacious (Chap. 201).

OTHER INTESTINAL PROTOZOA

Balantidiasis

Balantidium coli is a large ciliated protozoal parasite that can produce a spectrum of large-intestinal disease analogous to amebiasis.

The parasite is widely distributed in the world. Since it infects pigs, cases in humans are more common where pigs are raised. Infective cysts can be transmitted from person to person and

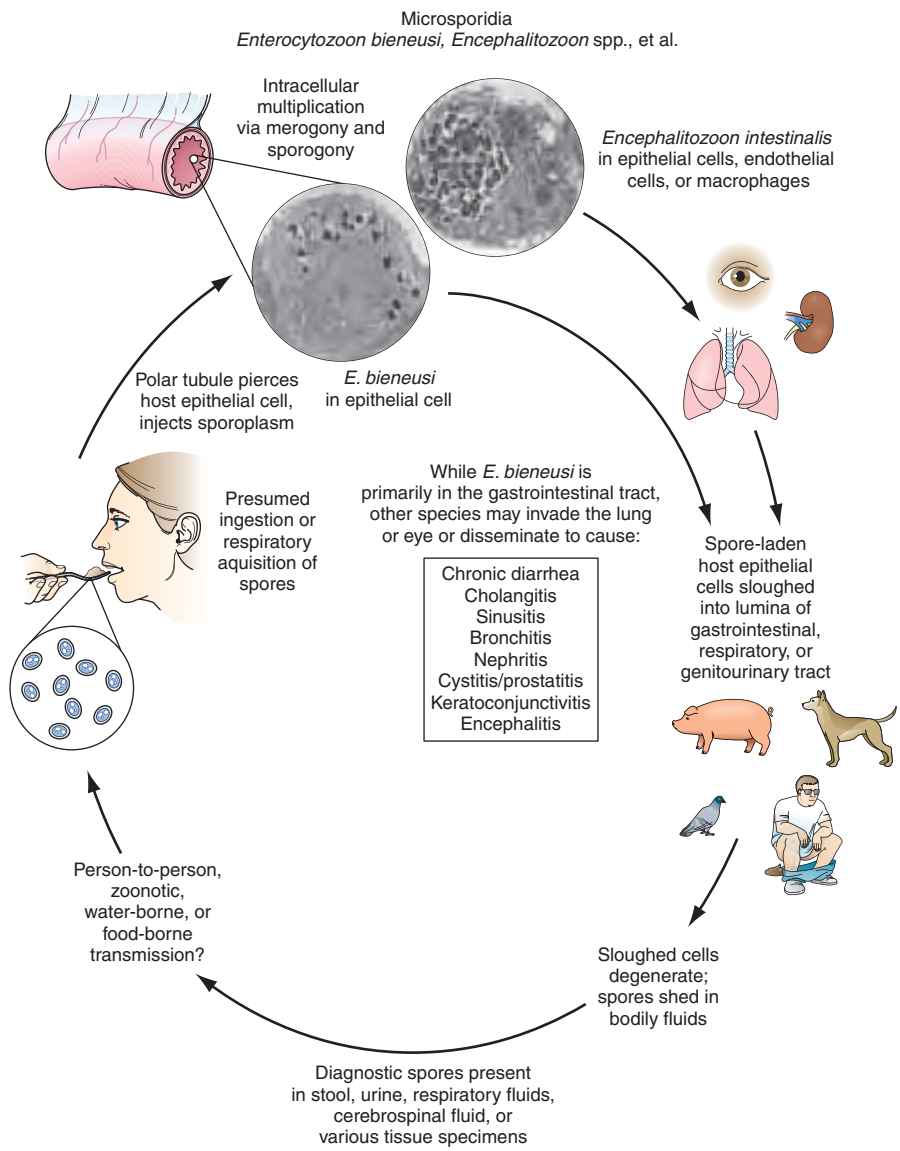

FIGURE 208-3 Life cycle of microsporidia. (*Reprinted from RL Guerrant et al: Tropical Infectious Disease: Principles, Pathogens and Practice, 2d ed, 2006, p 1128, with permission from Elsevier Science.*)

through water, but many cases are due to the ingestion of cysts derived from porcine feces in association with slaughtering, with use of pig feces for fertilizer, or with contamination of water supplies by pig feces.

Ingested cysts liberate trophozoites, which reside and replicate in the large bowel. Many patients remain asymptomatic, but some have persisting intermittent diarrhea, and a few develop more fulminant dysentery. In symptomatic individuals, the pathology in the bowel—both gross and microscopic—is similar to that seen in amebiasis, with varying degrees of mucosal invasion, focal necrosis, and ulceration. Balantidiasis, unlike amebiasis, does not spread hematogenously to other organs. The diagnosis is made by detection of the trophozoite stage in stool or sampled colonic tissue. Tetracycline (500 mg four times daily for 10 days) is an effective therapeutic agent.

***Blastocystis hominis* Infection** *B. hominis*, while believed by some to be a protozoan capable of causing intestinal disease, remains an organism of uncertain pathogenicity. Some patients who pass *B. hominis* in their stools are asymptomatic, whereas others have diarrhea and associated intestinal symptoms. Diligent evaluation reveals other potential bacterial, viral, or protozoal causes of diarrhea in some but not all patients with symptoms. Because the pathogenicity of *B. hominis* is uncertain and because therapy for *Blastocystis* infection is neither specific nor uniformly effective, patients with prominent intestinal symptoms should be fully evaluated for other infectious causes of diarrhea. If diarrheal symptoms associated with *Blastocystis* are prominent, either metronidazole (750 mg thrice daily for 10 days) or TMP-SMX (160 mg/800 mg twice daily for 7 days) can be used.

***Dientamoeba fragilis* Infection** *D. fragilis* is unique among intestinal protozoa in that it has a trophozoite stage but not a cyst stage. How trophozoites survive to transmit infection is not known. When symptoms develop in patients with *D. fragilis* infection, they are generally mild and include intermittent diarrhea, abdominal pain, and anorexia. The diagnosis is made by the detection of trophozoites in stool; the lability of these forms accounts for the greater yield when fecal samples are preserved immediately after collection. Since fecal excretion rates vary, examination of several samples obtained on alternate days increases the rate of detection. Iodoquinol (650 mg three times daily for 20 days), paromomycin (25–35 mg/kg per day in three doses for 7 days), metronidazole (500–750 mg three times daily for 10 days), or tetracycline (500 mg four times daily for 10 days) is appropriate for treatment.

TRICHOMONIASIS

Various species of trichomonads can be found in the mouth (in association with periodontitis) and occasionally in the gastrointestinal tract. *Trichomonas vaginalis*—one of the most prevalent protozoal parasites in the United States—is a pathogen of the genitourinary tract and a major cause of symptomatic vaginitis.

LIFE CYCLE AND EPIDEMIOLOGY

T. vaginalis is a pear-shaped, actively motile organism that measures about 10 × 7 μm, replicates by binary fission, and inhabits the lower genital tract of females and the urethra and prostate of males. In the United States, it accounts for ~3 million infections per year in women. While the organism can survive for a few hours in moist environments and could be acquired by direct contact, person-to-person venereal transmission accounts for virtually all cases of trichomoniasis. Its prevalence is greatest among persons with multiple sexual partners and among those with other sexually transmitted diseases (Chap. 124).

CLINICAL MANIFESTATIONS

Many men infected with *T. vaginalis* are asymptomatic, although some develop urethritis and a few have epididymitis or prostatitis. In contrast, infection in women, which has an incubation period of 5–28 days, is usually symptomatic and manifests with malodorous vaginal discharge (often yellow), vulvar erythema and itching, dysuria or urinary frequency (in 30–50% of patients), and dyspareunia. These manifestations, however, do not clearly distinguish trichomoniasis from other types of infectious vaginitis.

DIAGNOSIS

Detection of motile trichomonads by microscopic examination of wet mounts of vaginal or prostatic secretions has been the conventional means of diagnosis. Although this approach provides an immediate diagnosis, its sensitivity for the detection of *T. vaginalis* is only ~50–60% in routine evaluations of vaginal secretions. Direct immunofluorescent antibody staining is more sensitive (70–90%) than wet-mount examinations. *T. vaginalis* can be recovered from the urethra of both males and females and is detectable in males after prostatic massage. Culture of the parasite is the most sensitive means of detection; however, the facilities for culture are not generally available, and detection of the organism takes 3–7 days.

℞ TRICHOMONIASIS

Metronidazole, given either as a single 2-g dose or in 500-mg doses twice daily for 7 days, is usually effective. Tinidazole (a single 2-g dose) is also effective. All sexual partners must be treated concurrently to prevent reinfection, especially from asymptomatic males. In males with persistent symptomatic urethritis after therapy for nongonococcal urethritis, metronidazole therapy should be considered for possible trichomoniasis. Alternatives to metronidazole for treatment during pregnancy are not readily available, although use of 100-mg clotrimazole vaginal suppositories nightly for 2 weeks may cure some infections in pregnant women. Reinfection often accounts for apparent treatment failures, but strains of *T. vaginalis* exhibiting high-level resistance to metronidazole have been encountered. Treatment of these resistant infections with higher oral doses, parenteral doses, or concurrent oral and vaginal doses of metronidazole or with tinidazole has been successful.

209 *Trichinella* and Other Tissue Nematodes

Peter F. Weller

Nematodes are elongated, symmetric roundworms. Parasitic nematodes of medical significance may be broadly classified as either predominantly intestinal or tissue nematodes. This chapter covers trichinellosis, visceral and ocular larva migrans, cutaneous larva migrans, cerebral angiostrongyliasis, and gnathostomiasis. All are zoonotic infections caused by incidental exposure to infectious nematodes. The clinical symptoms of these infections are due largely to invasive larval stages that (except in the case of *Trichinella*) do not reach maturity in humans.

TRICHINELLOSIS

Trichinellosis develops after the ingestion of meat containing cysts of *Trichinella*—for example, pork or other meat from a carnivore. Although most infections are mild and asymptomatic, heavy infections can cause severe enteritis, periorbital edema, myositis, and (infrequently) death.

Life Cycle and Epidemiology Eight species of *Trichinella* are recognized as causes of infection in humans. Two species are distributed worldwide: *T. spiralis*, which is found in a great variety of carnivorous and omnivorous animals, and *T. pseudospiralis*, which is found in mammals and birds.

T. nativa is present in Arctic regions and infects bears; *T. nelsoni* is found in equatorial eastern Africa, where it is common among felid predators and scavengers such as hyenas and bush pigs; and *T. britovi* is found in Europe, western Africa, and western Asia among carnivores but not among domestic swine. *T. murrelli* is present in North American game animals.

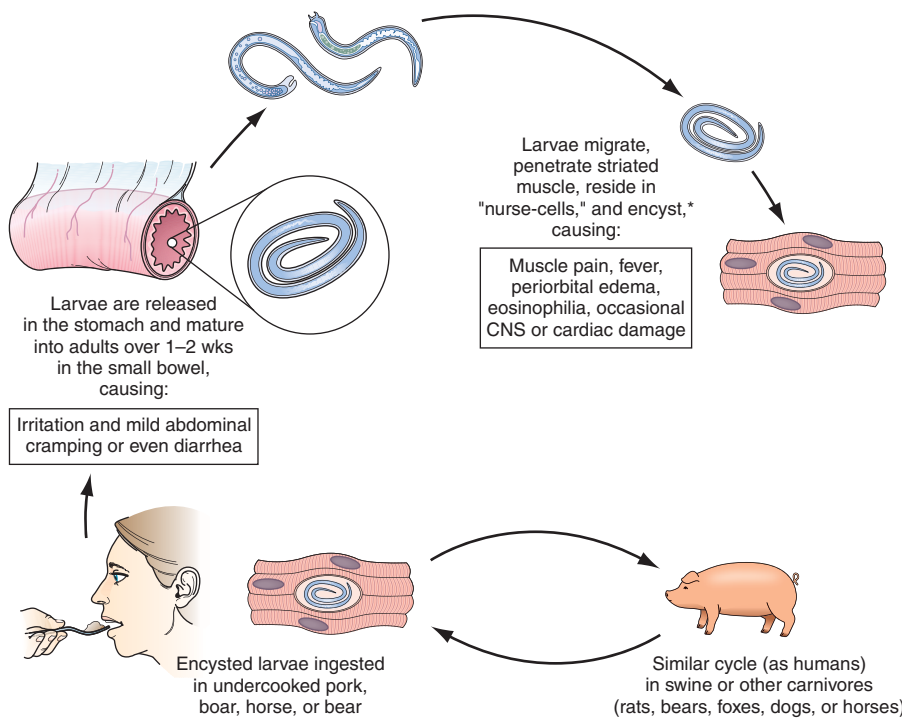
After human consumption of trichinous meat, encysted larvae are liberated by digestive acid and pepsin (Fig. 209-1). The larvae invade the small-bowel mucosa and mature into adult worms. After ~1 week, female worms release newborn larvae that migrate via the circulation to striated muscle. The larvae of all species except *T. pseudospiralis*, *T. papuae*, and *T. zimbabwensis* then encyst by inducing a radical transformation in the muscle cell architecture. Although host immune responses may help to expel intestinal adult worms, they have little effect on muscle-dwelling larvae.

Human trichinellosis is often caused by the ingestion of infected pork products and thus can occur in almost any location where the meat of domestic or wild swine is eaten. Human trichinellosis also may be acquired from the meat of other animals, including dogs (in parts of Asia and Africa), horses (in Italy and France), and bears and walruses (in northern regions). Although cattle (being herbivores) are not natural hosts of *Trichinella*, beef has been implicated in outbreaks when contaminated or adulterated with trichinous pork. Laws that prohibit the feeding of uncooked garbage to pigs have greatly reduced the transmission of trichinellosis in the United States. About 12 cases of trichinellosis are reported annually in this country, but most mild cases probably remain undiagnosed. Recent U.S. and Canadian outbreaks have been attributable to consumption of wild game (especially bear meat) and, less frequently, of pork.

Pathogenesis and Clinical Features Clinical symptoms of trichinellosis arise from the successive phases of parasite enteric invasion, larval migration, and muscle encystment (Fig. 209-1). Most light infections (those with <10 larvae per gram of muscle) are asymptomatic, whereas heavy infections (which can involve >50 larvae per gram of muscle) can be life-threatening. Invasion of the gut by large numbers of parasites occasionally provokes diarrhea during the first week after infection. Abdominal pain, constipation, nausea, or vomiting also may be prominent.

Symptoms due to larval migration and muscle invasion begin to appear in the second week after infection. The migrating *Trichinella* larvae provoke a marked local and systemic hypersensitivity reaction, with fever and hypereosinophilia. Periorbital and facial edema is common, as are hemorrhages in the subconjunctivae, retina, and nail beds ("splinter" hemorrhages). A maculopapular rash, headache, cough, dyspnea, or dysphagia sometimes develops. Myocarditis with tachyarrhythmias or heart failure—and, less commonly, encephalitis or pneumonitis—may develop and accounts for most deaths of patients with trichinellosis.

Upon onset of larval encystment in muscle 2–3 weeks after infection, symptoms of myositis with myalgias, muscle edema, and weakness develop, usually overlapping with the inflammatory reactions to



**T. papuae, T. zimbabwensis,* and *T. pseudospiralis* do not encyst.

FIGURE 209-1 Life cycle of *Trichinella spiralis* (cosmopolitan); *nelsoni* (equatorial Africa); *britovi* (Europe, western Africa, western Asia); *nativa* (Arctic); *murrelli* (North America); *papuae* (Papua New Guinea); *zimbabwensis* (Tanzania); and *pseudospiralis* (cosmopolitan). *[Reprinted from Guerrant RL et al (eds): Tropical Infectious Diseases: Principles, Pathogens and Practice, 2d ed, p 1218. © 2006, with permission from Elsevier Science.]*

migrating larvae. The most commonly involved muscle groups include the extraocular muscles; the biceps; and the muscles of the jaw, neck, lower back, and diaphragm. Peaking ~3 weeks after infection, symptoms subside only gradually during a prolonged convalescence. Uncommon infections with *T. pseudospiralis*, whose larvae do not encapsulate in muscles, elicit prolonged polymyositis-like illness.

Laboratory Findings and Diagnosis Blood eosinophilia develops in >90% of patients with symptomatic trichinellosis and may peak at a level of >50% between 2 and 4 weeks after infection. Serum levels of muscle enzymes, including creatine phosphokinase, are elevated in most symptomatic patients. Patients should be questioned thoroughly about their consumption of pork or wild-animal meat and about illness in other individuals who ate the same meat. A presumptive clinical diagnosis can be based on fevers, eosinophilia, periorbital edema, and myalgias after a suspect meal. A rise in the titer of parasite-specific antibody, which usually does not occur until after the third week of infection, confirms the diagnosis. Alternatively, a definitive diagnosis requires surgical biopsy of at least 1 g of involved muscle; the yields are highest near tendon insertions. The fresh muscle tissue should be compressed between glass slides and examined microscopically (Fig. 209-2), because larvae may be overlooked by examination of routine histopathologic sections alone.

℞ TRICHINELLOSIS

Most lightly infected patients recover uneventfully with bed rest, antipyretics, and analgesics. Glucocorticoids like prednisone (Table 209-1) are beneficial for severe myositis and myocarditis. Mebendazole and albendazole are active against enteric stages of the parasite, but their efficacy against encysted larvae has not been conclusively demonstrated.

Prevention Larvae may be killed by cooking pork until it is no longer pink or by freezing it at –15°C for 3 weeks. However, Arctic *T. nativa* larvae in walrus or bear meat are relatively resistant and may remain viable despite freezing.

VISCERAL AND OCULAR LARVA MIGRANS

Visceral larva migrans is a syndrome caused by nematodes that are normally parasitic for nonhuman host species. In humans, the nematode larvae do not develop into adult worms but instead migrate through host tissues and elicit eosinophilic inflammation. The more common form of visceral larva migrans is toxocariasis due to larvae of the canine ascarid *Toxocara canis*, less commonly to the feline ascarid *T. cati*, and even less commonly to the pig ascarid *Ascaris suum*. Rare cases with eosinophilic meningoencephalitis have been caused by the raccoon ascarid *Baylisascaris procyonis*.

Life Cycle and Epidemiology The canine roundworm *T. canis* is distributed among dogs worldwide. Ingestion of infective eggs by dogs is followed by liberation of *Toxocara* larvae, which penetrate the gut wall and migrate intravascularly into canine tissues, where most remain in a developmentally arrested state. During pregnancy, some larvae resume migration in bitches and infect puppies prenatally (through transplacental transmission) or after birth (through suckling). Thus, in lactating bitches and puppies, larvae return to the intestinal tract and develop into adult worms, which produce eggs that are released in the feces. Humans acquire toxocariasis mainly by eating soil contaminated by puppy feces that contains infective *T. canis* eggs. Visceral larva migrans is most common among children who habitually eat dirt.

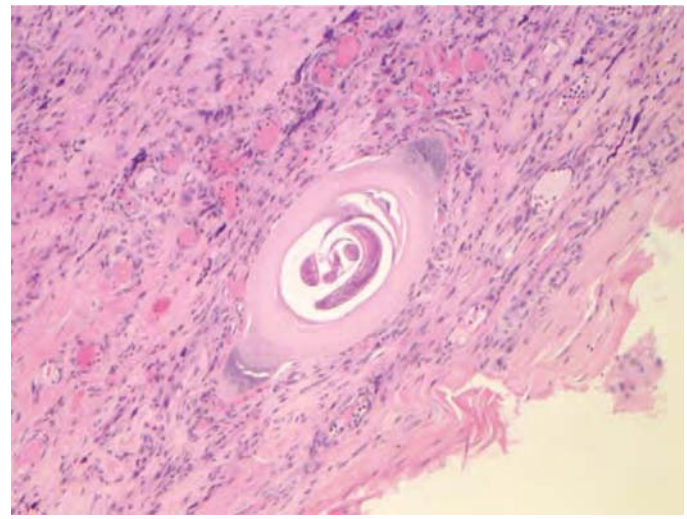


FIGURE 209-2 ***Trichinella*** **larva** encysted in a characteristic hyalinized capsule in striated muscle tissue. *(Photo/Wadsworth Center, New York State Department of Health. Reprinted from CDC MMWR 53:606, 2004; public domain.)*

Pathogenesis and Clinical Features Clinical disease most commonly afflicts preschool children. After humans ingest *Toxocara* eggs, the larvae hatch and penetrate the intestinal mucosa, from which they are carried by the circulation to a wide variety of organs and tissues. The larvae invade the liver, lungs, central nervous system (CNS), and other sites, provoking intense local eosinophilic granulomatous responses. The degree of clinical illness depends on larval number and tissue distribution, reinfection, and host immune responses. Most light infections are asymptomatic and may be manifest only by blood eosinophilia. Characteristic symptoms of visceral larva migrans include fever, malaise, anorexia and weight loss, cough, wheezing, and rashes. Hepatosplenomegaly is common. These features are often accompanied by extraordinary peripheral eosinophilia, which may approach 90%. Uncommonly, seizures or behavioral disorders develop. Rare deaths are due to severe neurologic, pneumonic, or myocardial involvement.

The ocular form of the larva migrans syndrome occurs when *Toxocara* larvae invade the eye. An eosinophilic granulomatous mass, most commonly in the posterior pole of the retina, develops around the entrapped larva. The retinal lesion can mimic retinoblastoma in appearance, and mistaken diagnosis of the latter condition can lead to unnecessary enucleation. The spectrum of eye involvement also in-

TABLE 209-1 THERAPY FOR TISSUE NEMATODE INFECTIONS

Infection	Severity	Treatment
Trichinellosis	Mild Moderate	Supportive Albendazole (400 mg bid × 8–14 days) *or* Mebendazole (200–400 mg tid × 3 days, then 400 mg tid × 8–14 days)
	Severe	Add glucocorticoids (e.g., prednisone, 1 mg/kg qd × 5 days)
Visceral larva migrans	Mild to moderate Severe Ocular	Supportive Glucocorticoids (as above) Not fully defined; albendazole (800 mg bid for adults, 400 mg bid for children) with glucocorticoids × 5–20 days has been effective
Cutaneous larva migrans		Ivermectin (single dose, 200 μg/kg) *or* Albendazole (200 mg bid × 3 days)
Angiostrongyliasis	Mild to moderate Severe	Supportive Glucocorticoids (as above)
Gnathostomiasis		Ivermectin (200 μg/kg per day × 2 days) *or* Albendazole (400 mg bid × 21 days)

cludes endophthalmitis, uveitis, and chorioretinitis. Unilateral visual disturbances, strabismus, and eye pain are the most common presenting symptoms. In contrast to visceral larva migrans, ocular toxocariasis usually develops in older children or young adults with no history of pica; these patients seldom have eosinophilia or visceral manifestations.

Diagnosis In addition to eosinophilia, leukocytosis and hypergammaglobulinemia may be evident. Transient pulmonary infiltrates are apparent on chest x-rays of about half of patients with symptoms of pneumonitis. The clinical diagnosis can be confirmed by an enzyme-linked immunosorbent assay for toxocaral antibodies. Stool examination for parasite eggs, while important in the evaluation of unexplained eosinophilia, is worthless for toxocariasis, since the larvae do not develop into egg-producing adults in humans.

Rx VISCERAL AND OCULAR LARVA MIGRANS

The vast majority of *Toxocara* infections are self-limited and resolve without specific therapy. In patients with severe myocardial, CNS, or pulmonary involvement, glucocorticoids may be employed to reduce inflammatory complications. Available anthelmintic drugs, including mebendazole and albendazole, have not been shown conclusively to alter the course of larva migrans. Control measures include prohibiting dog excreta in public parks and playgrounds, deworming dogs, and preventing pica in children. Treatment of ocular disease is not fully defined, but the administration of albendazole in conjunction with glucocorticoids has been effective (Table 209-1).

CUTANEOUS LARVA MIGRANS

Cutaneous larva migrans ("creeping eruption") is a serpiginous skin eruption caused by burrowing larvae of animal hookworms, usually the dog and cat hookworm *Ancylostoma braziliense*. The larvae hatch from eggs passed in dog and cat feces and mature in the soil. Humans become infected after skin contact with soil in areas frequented by dogs and cats, such as areas underneath house porches. Cutaneous larva migrans is prevalent among children and travelers in regions with warm humid climates, including the southeastern United States.

After larvae penetrate the skin, erythematous lesions form along the tortuous tracks of their migration through the dermal-epidermal junction; the larvae advance several centimeters in a day. The intensely pruritic lesions may occur anywhere on the body and can be numerous if the patient has lain on the ground. Vesicles and bullae may form later. The animal hookworm larvae do not mature in humans and, without treatment, will die after an interval ranging from weeks to a couple of months, with resolution of skin lesions. The diagnosis is made on clinical grounds. Skin biopsies only rarely detect diagnostic larvae. Symptoms can be alleviated by ivermectin or albendazole (Table 209-1).

ANGIOSTRONGYLIASIS

Angiostrongylus cantonensis, the rat lungworm, is the most common cause of human eosinophilic meningitis (Fig. 209-3).

Life Cycle and Epidemiology This infection occurs principally in Southeast Asia and the Pacific Basin but has spread to other areas of the world. *A. cantonensis* larvae produced by adult worms in the rat lung migrate to the gastrointestinal tract and are expelled with the feces. They develop into infective larvae in land snails and slugs. Humans acquire the infection by ingesting raw infected mollusks; vegetables contaminated by mollusk slime; or crabs, freshwater shrimp, and certain marine fish that have themselves eaten infected mollusks. The larvae then migrate to the brain.

Pathogenesis and Clinical Features The parasites eventually die in the CNS, but not before initiating pathologic consequences that, in heavy infections, can result in permanent neurologic sequelae or death. Migrating larvae cause marked local eosinophilic inflammation and hemorrhage, with subsequent necrosis and granuloma formation around dying worms. Clinical symptoms develop 2–35 days after the ingestion of larvae. Patients usually present with an insidious or abrupt excruciating frontal, occipital, or bitemporal headache. Neck stiffness, nausea and vomiting, and paresthesias are also common. Fever, cranial and extraocular nerve palsies, seizures, paralysis, and lethargy are uncommon.

Laboratory Findings Examination of cerebrospinal fluid (CSF) is mandatory in suspected cases and usually reveals an elevated opening pressure, a white blood cell count of 150–2000/μL, and an eosinophilic pleocytosis of >20%. The protein concentration is usually elevated and the glucose level normal. The larvae of *A. cantonensis* are only rarely seen in CSF. Peripheral-blood eosinophilia may be mild. The diagnosis is generally based on the clinical presentation of eosinophilic meningitis together with a compatible epidemiologic history.

Rx ANGIOSTRONGYLIASIS

Specific chemotherapy is not of benefit in angiostrongyliasis; larvicidal agents may exacerbate inflammatory brain lesions. Management consists of supportive measures, including the administration of analgesics, sedatives, and—in severe cases—glucocorticoids (Table 209-1). Repeated lumbar punctures with removal of CSF can relieve symptoms. In most patients, cerebral angiostrongyliasis has a self-limited course, and recovery is complete. The infection may be prevented by adequately cooking snails, crabs, and prawns and inspecting vegetables for mollusk infestation. Other parasitic or fungal causes of eosinophilic meningitis in endemic areas may include gnathostomiasis (see below), paragonimiasis (Chap. 212), schistosomiasis (Chap. 212), neurocysticercosis (Chap. 213), and coccidioidomycosis (Chap. 193).

GNATHOSTOMIASIS

Infection of human tissues with larvae of *Gnathostoma spinigerum* can cause eosinophilic meningoencephalitis, migratory cutaneous swellings, or invasive masses of the eye and visceral organs.

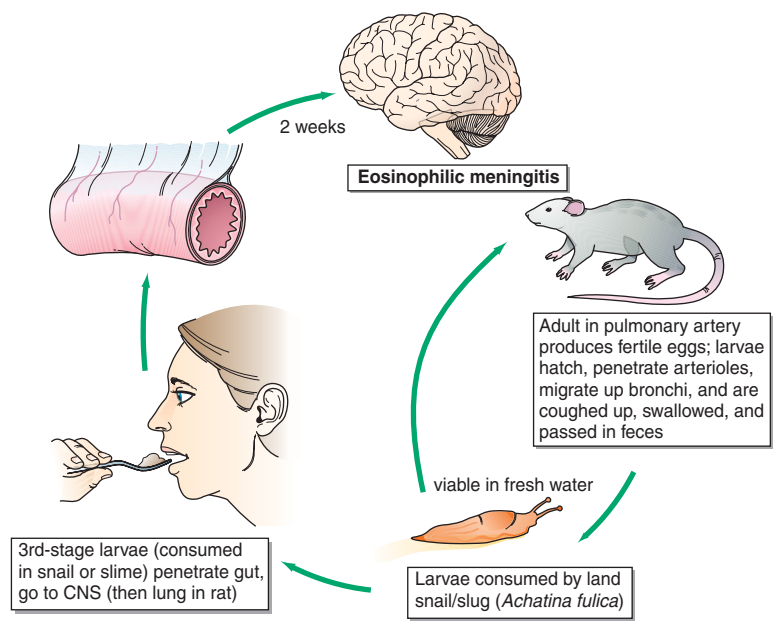

FIGURE 209-3 Life cycle of *Angiostrongylus cantonensis* (rat lung worm). Also found in Southeast Asia, Pacific Islands, Cuba, Australia, Japan, China, Mauritius, and U.S. ports. *[Reprinted from Guerrant RL et al (eds): Tropical Infectious Diseases: Principles, Pathogens and Practice, 2d ed, p 1225. © 2006, with permission from Elsevier Science.]*

Life Cycle and Epidemiology Human gnathostomiasis occurs in many countries and is notably endemic in Southeast Asia and parts of China and Japan. In nature, the mature adult worms parasitize the gastrointestinal tract of dogs and cats. First-stage larvae hatch from eggs passed into water and are ingested by *Cyclops* species (water fleas). Infective third-stage larvae develop in the flesh of many animal species (including fish, frogs, eels, snakes, chickens, and ducks) that have eaten either infected *Cyclops* or another infected second intermediate host. Humans typically acquire the infection by eating raw or undercooked fish or poultry. Raw fish dishes, such as *som fak* in Thailand and *sashimi* in Japan, account for many cases of human gnathostomiasis. Some cases in Thailand result from the local practice of applying frog or snake flesh as a poultice.

Pathogenesis and Clinical Features Clinical symptoms are due to the aberrant migration of a single larva into cutaneous, visceral, neural, or ocular tissues. After invasion, larval migration may cause local inflammation, with pain, cough, or hematuria accompanied by fever and eosinophilia. Painful, itchy, migratory swellings may develop in the skin, particularly in the distal extremities or periorbital area. Cutaneous swellings usually last ~1 week but often recur intermittently over many years. Larval invasion of the eye can provoke a sight-threatening inflammatory response. Invasion of the CNS results in eosinophilic meningitis with myeloencephalitis, a serious complication due to ascending larval migration along a large nerve track. Patients characteristically present with agonizing radicular pain and paresthesias in the trunk or a limb, which are followed shortly by paraplegia. Cerebral involvement, with focal hemorrhages and tissue destruction, is often fatal.

Diagnosis and Treatment Cutaneous migratory swellings with marked peripheral eosinophilia, supported by an appropriate geographic and dietary history, generally constitute an adequate basis for a clinical diagnosis of gnathostomiasis. However, patients may present with ocular or cerebrospinal involvement without antecedent cutaneous swellings. In the latter case, eosinophilic pleocytosis is demonstrable (usually along with hemorrhagic or xanthochromic CSF), but worms are almost never recovered from CSF. Surgical removal of the parasite from subcutaneous or ocular tissue, though rarely feasible, is both diagnostic and therapeutic. Albendazole or ivermectin may be helpful (Table 209-1). At present, cerebrospinal involvement is managed with supportive measures and generally with a course of glucocorticoids. Gnathostomiasis can be prevented by adequate cooking of fish and poultry in endemic areas.

210 Intestinal Nematodes

Peter F. Weller, Thomas B. Nutman

More than a billion persons worldwide are infected with one or more species of intestinal nematodes. Table 210-1 summarizes biologic and clinical features of infections due to the major intestinal parasitic nematodes. These parasites are most common in regions with poor fecal sanitation, particularly in resource-poor countries in the tropics and subtropics, but they have also been seen with increasing frequency among immigrants and refugees to resource-rich countries. Although nematode infections are not usually fatal, they contribute to malnutrition and diminished work capacity. It is interesting that these helminth infections may protect some individuals from allergic disease. Humans may on occasion be infected with nematode parasites that ordinarily infect animals; these zoonotic infections produce diseases such as trichostrongyliasis, anisakiasis, capillariasis, and abdominal angiostrongyliasis.

Intestinal nematodes are roundworms; they range in length from 1 mm to many centimeters when mature (Table 210-1). Their life cycles are complex and highly varied; some species, including *Strongyloides stercoralis* and *Enterobius vermicularis*, can be transmitted directly from person to person, while others, such as *Ascaris lumbricoides*, *Necator americanus*, and *Ancylostoma duodenale*, require a soil phase for development. Because most helminth parasites do not self-replicate, the acquisition of a heavy burden of adult worms requires repeated exposure to the parasite in its infectious stage, whether larva or egg. Hence, clinical disease, as opposed to asymptomatic infection, generally develops only with prolonged residence in an endemic area. In persons with marginal nutrition, intestinal helminth infections may impair growth and development. Eosinophilia and elevated serum IgE levels are features of many helminthic infections and, when unexplained, should always prompt a search for occult helminthiasis. Significant protective immunity to intestinal nematodes appears not to develop in humans, although mechanisms of parasite immune evasion and host immune responses to these infections have not been elucidated in detail.

ASCARIASIS

A. lumbricoides is the largest intestinal nematode parasite of humans, reaching up to 40 cm in length. Most infected individuals have low worm burdens and are asymptomatic. Clinical disease arises from larval migration in the lungs or effects of the adult worms in the intestines.

Life Cycle Adult worms live in the lumen of the small intestine. Mature female *Ascaris* worms are extraordinarily fecund, each producing up to 240,000 eggs a day, which pass with the feces. Ascarid eggs, which are remarkably resistant to environmental stresses, become infective after several weeks of maturation in the soil and can remain infective for years. After infective eggs are swallowed, larvae hatched in the intestine invade the mucosa, migrate through the circulation to the lungs, break into the alveoli, ascend the bronchial tree, and return via

[a]Time from infection to egg production by mature female worm.

swallowing to the small intestine, where they develop into adult worms. Between 2 and 3 months elapse between initial infection and egg production. Adult worms live for 1–2 years.

Epidemiology *Ascaris* is widely distributed in tropical and subtropical regions as well as in other humid areas, including the rural southeastern United States. Transmission typically occurs through fecally contaminated soil and is due either to a lack of sanitary facilities or to the use of human feces as fertilizer. With their propensity for hand-to-mouth fecal carriage, younger children are most affected. Infection outside endemic areas, though uncommon, can occur when eggs on transported vegetables are ingested.

Clinical Features During the lung phase of larval migration, ~9–12 days after egg ingestion, patients may develop an irritating nonproductive cough and burning substernal discomfort that is aggravated by coughing or deep inspiration. Dyspnea and blood-tinged sputum are less common. Fever is usually reported. Eosinophilia develops during this symptomatic phase and subsides slowly over weeks. Chest x-rays may reveal evidence of eosinophilic pneumonitis (Löffler's syndrome), with rounded infiltrates a few millimeters to several centimeters in size. These infiltrates may be transient and intermittent, clearing after several weeks. Where there is seasonal transmission of the parasite, seasonal pneumonitis with eosinophilia may develop in previously infected and sensitized hosts.

In established infections, adult worms in the small intestine usually cause no symptoms. In heavy infections, particularly in children, a large bolus of entangled worms can cause pain and small-bowel obstruction, sometimes complicated by perforation, intussusception, or volvulus. Single worms may cause disease when they migrate into aberrant sites. A large worm can enter and occlude the biliary tree, causing biliary colic, cholecystitis, cholangitis, pancreatitis, or (rarely) intrahepatic abscesses. Migration of an adult worm up the esophagus can provoke coughing and oral expulsion of the worm. In highly endemic areas, intestinal and biliary ascariasis can rival acute appendicitis and gallstones as causes of surgical acute abdomen.

Laboratory Findings Most cases of ascariasis can be diagnosed by microscopic detection of characteristic *Ascaris* eggs (65 by 45 μm) in fecal samples. Occasionally, patients present after passing an adult worm—identifiable by its large size and smooth cream-colored surface—in the stool or through the mouth or nose. During the early transpulmonary migratory phase, when eosinophilic pneumonitis occurs, larvae can be found in sputum or gastric aspirates before diagnostic eggs appear in the stool. The eosinophilia that is prominent during this early stage usually decreases to minimal levels in established infection. Adult worms may be visualized, occasionally serendipitously, on contrast studies of the gastrointestinal tract. A plain abdominal film may reveal masses of worms in gas-filled loops of bowel in patients with intestinal obstruction. Pancreaticobiliary worms can be detected by ultrasound and endoscopic retrograde cholangiopancreatography; the latter method also has been used to extract biliary *Ascaris* worms.

℞ ASCARIASIS

Ascariasis should always be treated to prevent potentially serious complications. Albendazole (400 mg once), mebendazole (500 mg once), or ivermectin (150–200 μg/kg once) is effective. These medications are contraindicated in pregnancy, however. Pyrantel pamoate (11 mg/kg once; maximum, 1 g) is safe in pregnancy. Mild diarrhea and abdominal pain are uncommon side effects of these agents. Partial intestinal obstruction should be managed with nasogastric suction, IV fluid administration, and instillation of piperazine through the nasogastric tube, but complete obstruction and its severe complications require immediate surgical intervention.

HOOKWORM

Two hookworm species (*A. duodenale* and *N. americanus*) are responsible for human infections. Most infected individuals are asymptomatic. Hookworm disease develops from a combination of factors—a heavy worm burden, a prolonged duration of infection, and an inade-

quate iron intake—and results in iron-deficiency anemia and, on occasion, hypoproteinemia.

Life Cycle Adult hookworms, which are ~1 cm long, use buccal teeth (*Ancylostoma*) or cutting plates (*Necator*) to attach to the small-bowel mucosa and suck blood (0.2 mL/d per *Ancylostoma* adult) and interstitial fluid. The adult hookworms produce thousands of eggs daily. The eggs are deposited with feces in soil, where rhabditiform larvae hatch and develop over a 1-week period into infectious filariform larvae. Infective larvae penetrate the skin and reach the lungs by way of the bloodstream. There they invade alveoli and ascend the airways before being swallowed and reaching the small intestine. The prepatent period from skin invasion to appearance of eggs in the feces is ~6–8 weeks, but it may be longer with *A. duodenale*. Larvae of *A. duodenale*, if swallowed, can survive and develop directly in the intestinal mucosa. Adult hookworms may survive over a decade but usually live ~6–8 years for *A. duodenale* and 2–5 years for *N. americanus*.

Epidemiology *A. duodenale* is prevalent in southern Europe, North Africa, and northern Asia, and *N. americanus* is the predominant species in the western hemisphere and equatorial Africa. The two species overlap in many tropical regions, particularly Southeast Asia. In most areas, older children have the highest incidence and greatest intensity of hookworm infection. In rural areas where fields are fertilized with human feces, older working adults also may be heavily affected.

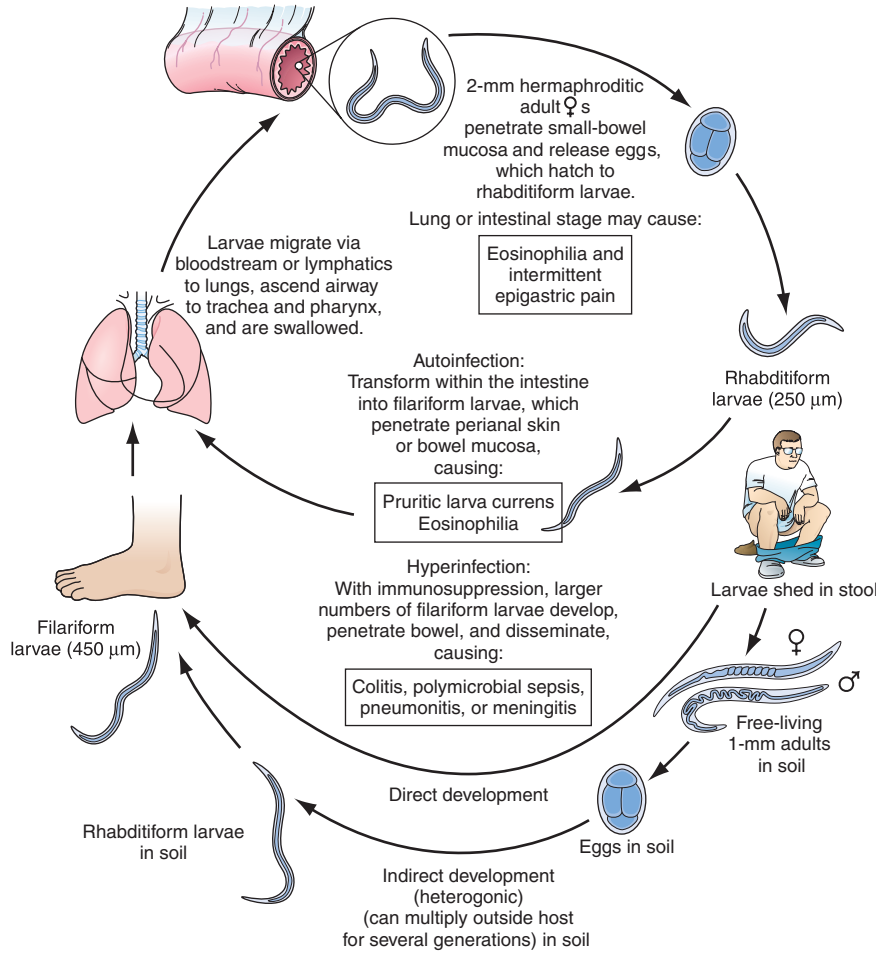

FIGURE 210-1 Life cycle of *Strongyloides stercoralis*. *[Adapted from Guerrant RL et al (eds): Tropical Infectious Diseases: Principles, Pathogens and Practice, 2d ed, p 1276. © 2006, with permission from Elsevier Science.]*

Clinical Features Most hookworm infections are asymptomatic. Infective larvae may provoke pruritic maculopapular dermatitis ("ground itch") at the site of skin penetration as well as serpiginous tracks of subcutaneous migration (similar to those of cutaneous larva migrans; Chap. 209) in previously sensitized hosts. Larvae migrating through the lungs occasionally cause mild transient pneumonitis, but this condition develops less frequently in hookworm infection than in ascariasis. In the early intestinal phase, infected persons may develop epigastric pain (often with postprandial accentuation), inflammatory diarrhea, or other abdominal symptoms accompanied by eosinophilia. The major consequence of chronic hookworm infection is iron deficiency. Symptoms are minimal if iron intake is adequate, but marginally nourished individuals develop symptoms of progressive iron-deficiency anemia and hypoproteinemia, including weakness and shortness of breath.

Laboratory Findings The diagnosis is established by the finding of characteristic 40- by 60-μm oval hookworm eggs in the feces. Stool-concentration procedures may be required to detect light infections. Eggs of the two species are indistinguishable by light microscopy. In a stool sample that is not fresh, the eggs may have hatched to release rhabditiform larvae, which need to be differentiated from those of *S. stercoralis*. Hypochromic microcytic anemia, occasionally with eosinophilia or hypoalbuminemia, is characteristic of hookworm disease.

℞ HOOKWORM INFECTION

Hookworm infection can be eradicated with several safe and highly effective anthelmintic drugs, including albendazole (400 mg once), mebendazole (500 mg once), and pyrantel pamoate (11 mg/kg for 3 days). Mild iron-deficiency anemia can often be treated with oral iron alone. Severe hookworm disease with protein loss and malabsorption necessitates nutritional support and oral iron replacement along with deworming.

Ancylostoma caninum* and *Ancylostoma braziliense *A. caninum*, the canine hookworm, has been identified as a cause of human eosinophilic enteritis, especially in northeastern Australia. In this zoonotic infection, adult hookworms attach to the small intestine (where they may be visualized by endoscopy) and elicit abdominal pain and intense local eosinophilia. Treatment with mebendazole (100 mg twice daily for 3 days) or albendazole (400 mg once) or endoscopic removal is effective. Both of these animal hookworm species can cause cutaneous larva migrans ("creeping eruption"; Chap. 209).

STRONGYLOIDIASIS

S. stercoralis is distinguished by its ability—unusual among helminths—to replicate in the human host. This capacity permits ongoing cycles of autoinfection as infective larvae are internally produced. Strongyloidiasis can thus persist for decades without further exposure of the host to exogenous infective larvae. In immunocompromised hosts, large numbers of invasive *Strongyloides* larvae can disseminate widely and can be fatal.

Life Cycle In addition to a parasitic cycle of development, *Strongyloides* can undergo a free-living cycle of development in the soil (Fig. 210-1). This adaptability facilitates the parasite's survival in the absence of mammalian hosts. Rhabditiform larvae passed in feces can transform into infectious filariform larvae either directly or after a free-living phase of development. Humans acquire strongyloidiasis when filariform lar-

vae in fecally contaminated soil penetrate the skin or mucous membranes. The larvae then travel through the bloodstream to the lungs, where they break into the alveolar spaces, ascend the bronchial tree, are swallowed, and thereby reach the small intestine. There the larvae mature into adult worms that penetrate the mucosa of the proximal small bowel. The minute (2-mm-long) parasitic adult female worms reproduce by parthenogenesis; adult males do not exist. Eggs hatch in the intestinal mucosa, releasing rhabditiform larvae that migrate to the lumen and pass with the feces into soil. Alternatively, rhabditiform larvae in the bowel can develop directly into filariform larvae that penetrate the colonic wall or perianal skin and enter the circulation to repeat the migration that establishes ongoing internal reinfection. This autoinfection cycle allows strongyloidiasis to persist for decades.

Epidemiology *S. stercoralis* is spottily distributed in tropical areas and other hot, humid regions and is particularly common in Southeast Asia, sub-Saharan Africa, and Brazil. In the United States, the parasite is endemic in parts of the South and is found in immigrants and military veterans who have lived in endemic areas abroad.

Clinical Features In uncomplicated strongyloidiasis, many patients are asymptomatic or have mild cutaneous and/or abdominal symptoms. Recurrent urticaria, often involving the buttocks and wrists, is the most common cutaneous manifestation. Migrating larvae can elicit a pathognomonic serpiginous eruption, *larva currens* ("running larva"). This pruritic, raised, erythematous lesion advances as rapidly as 10 cm/h along the course of larval migration. Adult parasites burrow into the duodenojejunal mucosa and can cause abdominal (usually midepigastric) pain, which resembles peptic ulcer pain except that it is aggravated by food ingestion. Nausea, diarrhea, gastrointestinal bleeding, mild chronic colitis, and weight loss can occur. Small-bowel obstruction may develop with early, heavy infection. Pulmonary symptoms are rare in uncomplicated strongyloidiasis. Eosinophilia is common, with levels fluctuating over time.

The ongoing autoinfection cycle of strongyloidiasis is normally contained by unknown factors of the host's immune system. Abrogation of host immunity, especially with glucocorticoid therapy and much less commonly with other immunosuppressive medications, leads to hyperinfection, with the generation of large numbers of filariform larvae. Colitis, enteritis, or malabsorption may develop. In disseminated strongyloidiasis, larvae may invade not only gastrointestinal tissues and the lungs but also the central nervous system, peritoneum, liver, and kidneys. Moreover, bacteremia may develop because of the passage of enteric flora through disrupted mucosal barriers. Gram-negative sepsis, pneumonia, or meningitis may complicate or dominate the clinical course. Eosinophilia is often absent in severely infected patients. Disseminated strongyloidiasis, particularly in patients with unsuspected infection who are given glucocorticoids, can be fatal. Strongyloidiasis is a frequent complication of infection with human T cell lymphotropic virus type I, but disseminated strongyloidiasis is not common among patients infected with HIV.

Diagnosis In uncomplicated strongyloidiasis, the finding of rhabditiform larvae in feces is diagnostic. Rhabditiform larvae are ~250 μm long, with a short buccal cavity that distinguishes them from hookworm larvae. In uncomplicated infections, few larvae are passed and single stool examinations detect only about one-third of cases. Serial examinations and the use of the agar plate detection method improve the sensitivity of stool diagnosis. In uncomplicated strongyloidiasis (but not in hyperinfection), stool examinations may be repeatedly negative. *Strongyloides* larvae may also be found by sampling of the duodenojejunal contents by aspiration or biopsy. An enzyme-linked immunosorbent assay for serum antibodies to antigens of *Strongyloides* is a sensitive method of diagnosing uncomplicated infections. Such serologic testing should be performed for patients whose geographic histories indicate potential exposure, especially those who exhibit eosinophilia and/or are candidates for glucocorticoid treatment of other conditions. In disseminated strongyloidiasis, filariform larvae should be sought in stool as well as in samples obtained from sites of potential larval migration, including sputum, bronchoalveolar lavage fluid, or surgical drainage fluid.

Rx STRONGYLOIDIASIS

Even in the asymptomatic state, strongyloidiasis must be treated because of the potential for subsequent fatal hyperinfection. Ivermectin (200 μg/kg daily for 2 days) is more effective than albendazole (400 mg daily for 3 days). For disseminated strongyloidiasis, treatment with ivermectin should be extended for at least 5–7 days or until the parasites are eradicated.

TRICHURIASIS

Most infections with the *Trichuris trichiura* are asymptomatic, but heavy infections may cause gastrointestinal symptoms. Like the other soil-transmitted helminths, whipworm is distributed globally in the tropics and subtropics and is most common among poor children from resource-poor regions of the world.

Life Cycle Adult *Trichuris* worms reside in the colon and cecum, the anterior portions threaded into the superficial mucosa. Thousands of eggs laid daily by adult female worms pass with the feces and mature in the soil. After ingestion, infective eggs hatch in the duodenum, releasing larvae that mature before migrating to the large bowel. The entire cycle takes ~3 months, and adult worms may live for several years.

Clinical Features Tissue reactions to *Trichuris* are mild. Most infected individuals have no symptoms or eosinophilia. Heavy infections may result in abdominal pain, anorexia, and bloody or mucoid diarrhea resembling inflammatory bowel disease. Rectal prolapse can result from massive infections in children, who often suffer from malnourishment and other diarrheal illnesses. Moderately heavy *Trichuris* burdens also contribute to growth retardation.

Diagnosis and Treatment The characteristic 50- by 20-μm lemon-shaped *Trichuris* eggs are readily detected on stool examination. Adult worms, which are 3–5 cm long, are occasionally seen on proctoscopy. Mebendazole (500 mg once) or albendazole (400 mg daily for 3 doses) is safe and effective for treatment. Ivermectin (200 μg/kg daily for 3 doses) is also safe but is not quite as efficacious as the benzimidazoles.

ENTEROBIASIS (PINWORM)

E. vermicularis is more common in temperate countries than in the tropics. In the United States, ~40 million persons are infected with pinworms, with a disproportionate number of cases among children.

Life Cycle and Epidemiology *Enterobius* adult worms are ~1 cm long and dwell in the cecum. Gravid female worms migrate nocturnally into the perianal region and release up to 10,000 immature eggs each. The eggs become infective within hours and are transmitted by hand-to-mouth passage. From ingested eggs, larvae hatch and mature into adults. This life cycle takes ~1 month, and adult worms survive for ~2 months. Self-infection results from perianal scratching and transport of infective eggs on the hands or under the nails to the mouth. Because of the ease of person-to-person spread, pinworm infections are common among family members.

Clinical Features Most pinworm infections are asymptomatic. Perianal pruritus is the cardinal symptom. The itching, which is often worse at night as a result of the nocturnal migration of the female worms, may lead to excoriation and bacterial superinfection. Heavy infections have been claimed to cause abdominal pain and weight loss. On rare occasions, pinworms invade the female genital tract, causing

vulvovaginitis and pelvic or peritoneal granulomas. Eosinophilia is uncommon.

Diagnosis Since pinworm eggs are not released in feces, the diagnosis cannot be made by conventional fecal ova and parasites tests. Instead, eggs are detected by the application of clear cellulose acetate tape to the perianal region in the morning. After the tape is transferred to a slide, microscopic examination will detect pinworm eggs, which are oval, measure 55 by 25 μm, and are flattened along one side.

℞ ENTEROBIASIS

Infected children and adults should be treated with mebendazole (100 mg once), albendazole (400 mg once), or pyrantel pamoate (11 mg/kg once; maximum, 1 g), with the same treatment repeated after 2 weeks. Treatment of household members is advocated to eliminate asymptomatic reservoirs of potential reinfection.

TRICHOSTRONGYLIASIS

Trichostrongylus species, which are normally parasites of herbivorous animals, occasionally infect humans, particularly in Asia and Africa. Humans acquire the infection by accidentally ingesting *Trichostrongylus* larvae on contaminated leafy vegetables. The larvae do not migrate in humans but mature directly into adult worms in the small bowel. These worms ingest far less blood than hookworms; most infected persons are asymptomatic, but heavy infections may give rise to mild anemia and eosinophilia. *Trichostrongylus* eggs in stool examinations resemble those of hookworms but are larger (85 by 115 μm). Treatment consists of mebendazole or albendazole (Chap. 201).

ANISAKIASIS

Anisakiasis is a gastrointestinal infection caused by the accidental ingestion in uncooked saltwater fish of nematode larvae belonging to the family Anisakidae. The incidence of anisakiasis in the United States has increased as a result of the growing popularity of raw fish dishes. Most cases occur in Japan, the Netherlands, and Chile, where raw fish—sashimi, pickled green herring, and ceviche, respectively—are national culinary staples. Anisakid nematodes parasitize large sea mammals such as whales, dolphins, and seals. As part of a complex parasitic life cycle involving marine food chains, infectious larvae migrate to the musculature of a variety of fish. Both *Anisakis simplex* and *Pseudoterranova decipiens* have been implicated in human anisakiasis, but an identical gastric syndrome may be caused by the red larvae of eustrongylid parasites of fish-eating birds.

When humans consume infected raw fish, live larvae may be coughed up within 48 h. Alternatively, larvae may immediately penetrate the mucosa of the stomach. Within hours, violent upper abdominal pain accompanied by nausea and occasionally vomiting ensues, mimicking an acute abdomen. The diagnosis can be established by direct visualization on upper endoscopy, outlining of the worm by contrast radiographic studies, or histopathologic examination of extracted tissue. Extraction of the burrowing larvae during endoscopy is curative. In addition, larvae may pass to the small bowel, where they penetrate the mucosa and provoke a vigorous eosinophilic granulomatous response. Symptoms may appear 1–2 weeks after the infective meal, with intermittent abdominal pain, diarrhea, nausea, and fever resembling the manifestations of Crohn's disease. The diagnosis may be suggested by barium studies and confirmed by curative surgical resection of a granuloma in which the worm is embedded. Anisakid eggs are not found in the stool, since the larvae do not mature in humans. Anisakid larvae in saltwater fish are killed by cooking to 60°C, freezing at –20°C for 3 days, or commercial blast freezing, but not usually by salting, marinating, or cold smoking. No medical treatment is available; surgical or endoscopic removal should be undertaken.

CAPILLARIASIS

Intestinal capillariasis is caused by ingestion of raw fish infected with *Capillaria philippinensis*. Subsequent autoinfection can lead to a severe wasting syndrome. The disease occurs in the Philippines and Thailand and, on occasion, elsewhere in Asia. The natural cycle of *C. philippinensis* involves fish from fresh and brackish water. When humans eat infected raw fish, the larvae mature in the intestine into adult worms, which produce invasive larvae that cause intestinal inflammation and villus loss. Capillariasis has an insidious onset with nonspecific abdominal pain and watery diarrhea. If untreated, progressive autoinfection can lead to protein-losing enteropathy and severe malabsorption and ultimately to death from cachexia, cardiac failure, or superinfection. The diagnosis is established by identification of the characteristic peanut-shaped (20- by 40-μm) eggs on stool examination. Severely ill patients require hospitalization and supportive therapy in addition to prolonged anthelmintic treatment with mebendazole or albendazole (Chap. 201).

ABDOMINAL ANGIOSTRONGYLIASIS

Abdominal angiostrongyliasis is found in Latin America and Africa. The zoonotic parasite *Angiostrongylus costaricensis* causes eosinophilic ileocolitis after the ingestion of contaminated vegetation. *A. costaricensis* normally parasitizes the cotton rat and other rodents, with slugs and snails serving as intermediate hosts. Humans become infected by accidentally ingesting infective larvae in mollusk slime deposited on fruits and vegetables; children are at highest risk. The larvae penetrate the gut wall and migrate to the mesenteric artery, where they develop into adult worms. Eggs deposited in the gut wall provoke an intense eosinophilic granulomatous reaction, and adult worms may cause mesenteric arteritis, thrombosis, or frank bowel infarction. Symptoms may mimic those of appendicitis, including abdominal pain and tenderness, fever, vomiting, and a palpable mass in the right iliac fossa. Leukocytosis and eosinophilia are prominent. A barium enema may reveal ileocecal-filling defects, but a definitive diagnosis is usually made surgically with partial bowel resection. Pathologic study reveals a thickened bowel wall with eosinophilic granulomas surrounding the *Angiostrongylus* eggs. In nonsurgical cases, the diagnosis rests solely on clinical grounds because larvae and eggs cannot be detected in the stool. Medical therapy for abdominal angiostrongyliasis (mebendazole, thiabendazole; Chap. 201) is of uncertain efficacy. Careful observation and surgical resection for severe symptoms are the mainstays of treatment.

211 Filarial and Related Infections

Thomas B. Nutman, Peter F. Weller

Filarial worms are nematodes that dwell in the subcutaneous tissues and the lymphatics. Eight filarial species infect humans (Table 211-1); of these, four—*Wuchereria bancrofti*, *Brugia malayi*, *Onchocerca volvulus*, and *Loa loa*—are responsible for most serious filarial infections. Filarial parasites, which infect an estimated 170 million persons worldwide, are transmitted by specific species of mosquitoes or other arthropods and have a complex life cycle including infective larval stages carried by insects and adult worms that reside in either lymphatic or subcutaneous tissues of humans. The offspring of adults are microfilariae, which, depending on their species, are 200–250 μm long and 5–7 μm wide, may or may not be enveloped in a loose sheath, and either circulate in the blood or migrate through the skin (Table 211-1). To complete the life cycle, microfilariae are ingested by the arthropod vector and develop over 1–2 weeks into new infective larvae. Adult worms live for many years, whereas microfilariae survive for 3–36 months. The *Rickettsia*-like endosymbiont *Wolbachia* has been found intracellularly in all stages of *Brugia*, *Wuchereria*, *Mansonella*, and *Onchocerca* and is viewed as a possible target for antifilarial chemotherapy.

Usually, infection is established only with repeated, prolonged exposures to infective larvae. Since the clinical manifestations of filarial diseases develop relatively slowly, these infections should be considered to induce chronic diseases with possible long-term debilitating effects. In terms of the nature, severity, and timing of clinical manifestations, patients with filarial infections who are native to endemic areas and undergo lifelong exposure may differ significantly from those who are travelers or who have recently moved to these areas. Characteristically, filarial disease is more acute and intense in newly exposed individuals than in natives of endemic areas.

LYMPHATIC FILARIASIS

Lymphatic filariasis is caused by *W. bancrofti*, *B. malayi*, or *B. timori*. The threadlike adult parasites reside in lymphatic channels or lymph nodes, where they may remain viable for more than two decades.

EPIDEMIOLOGY

W. bancrofti, the most widely distributed human filarial parasite, affects an estimated 115 million people and is found throughout the tropics and subtropics, including Asia and the Pacific Islands, Africa, areas of South America, and the Caribbean basin. Humans are the only definitive host for the parasite. Generally, the subperiodic form is found only in the Pacific Islands; elsewhere, *W. bancrofti* is nocturnally periodic. (Nocturnally periodic forms of microfilariae are scarce in peripheral blood by day and increase at night, whereas subperiodic forms are present in peripheral blood at all times and reach maximal levels in the afternoon.) Natural vectors for *W. bancrofti* are *Culex fatigans* mosquitoes in urban settings and anopheline or aedean mosquitoes in rural areas.

Brugian filariasis due to *B. malayi* occurs primarily in China, India, Indonesia, Korea, Japan, Malaysia, and the Philippines. *B. malayi* also has two forms distinguished by the periodicity of microfilaremia. The more common nocturnal form is transmitted in areas of coastal rice fields, while the subperiodic form is found in forests. *B. malayi* naturally infects cats as well as humans. *B. timori* exists only on islands of the Indonesian archipelago.

PATHOLOGY

The principal pathologic changes result from inflammatory damage to the lymphatics, which is typically caused by adult worms and not by microfilariae. Adult worms live in afferent lymphatics or sinuses of lymph nodes and cause lymphatic dilatation and thickening of the vessel walls. The infiltration of plasma cells, eosinophils, and macrophages in and around the infected vessels, along with endothelial and connective tissue proliferation, leads to tortuosity of the lymphatics and damaged or incompetent lymph valves. Lymphedema and chronic-stasis changes with hard or brawny edema develop in the overlying skin. These consequences of filariasis are due both to direct effects of the worms and to the inflammatory response of the host to the parasite. Inflammatory responses are believed to cause the granulomatous and proliferative processes that precede total lymphatic obstruction. It is thought that the lymphatic vessel remains patent as long as the worm remains viable and that the death of the worm leads to enhanced granulomatous reaction and fibrosis. Lymphatic obstruction results, and, despite collateralization of the lymphatics, lymphatic function is compromised.

CLINICAL FEATURES

The most common presentations of the lymphatic filariases are asymptomatic (or subclinical) microfilaremia, hydrocele (Fig. 211-1), acute adenolymphangitis (ADL), and chronic lymphatic disease. In areas where *W. bancrofti* or *B. malayi* is endemic, the overwhelming majority of infected individuals have few overt clinical manifestations of filarial infection despite large numbers of circulating microfilariae in the peripheral blood. Although they may be clinically asymptomatic, virtually all persons with *W. bancrofti* or *B. malayi* microfilaremia have some degree of subclinical disease that includes microscopic hematuria and/or proteinuria, dilated (and tortuous) lymphatics (visualized

TABLE 211-1 CHARACTERISTICS OF THE FILARIAE

Organism	Periodicity	Distribution	Vector	Location of Adult	Microfilarial Location	Sheath

FIGURE 211-1 Hydrocele associated with *Wuchereria bancrofti* infection.

by imaging), and—in men—scrotal lymphangiectasia (detectable by ultrasound). In spite of these findings, the majority of individuals appear to remain clinically asymptomatic for years; relatively few progress to either acute or chronic disease.

ADL is characterized by high fever, lymphatic inflammation (lymphangitis and lymphadenitis), and transient local edema. The lymphangitis is retrograde, extending peripherally from the lymph node draining the area where the adult parasites reside. Regional lymph nodes are often enlarged, and the entire lymphatic channel can become indurated and inflamed. Concomitant local thrombophlebitis can occur as well. In brugian filariasis, a single local abscess may form along the involved lymphatic tract and subsequently rupture to the surface. The lymphadenitis and lymphangitis can involve both the upper and lower extremities in both bancroftian and brugian filariasis, but involvement of the genital lymphatics occurs almost exclusively with *W. bancrofti* infection. This genital involvement can be manifested by funiculitis, epididymitis, and scrotal pain and tenderness. In endemic areas, another type of acute disease—dermatolymphangioadenitis (DLA)—is recognized as a syndrome that includes high fever, chills, myalgias, and headache. Edematous inflammatory plaques clearly demarcated from normal skin are seen. Vesicles, ulcers, and hyperpigmentation may also be noted. There is often a history of trauma, burns, radiation, insect bites, punctiform lesions, or chemical injury. Entry lesions, especially in the interdigital area, are common. DLA is often diagnosed as cellulitis.

If lymphatic damage progresses, transient lymphedema can develop into lymphatic obstruction and the permanent changes associated with elephantiasis (Fig. 211-2). Brawny edema follows early pitting edema, and thickening of the subcutaneous tissues and hyperkeratosis occur. Fissuring of the skin develops, as do hyperplastic changes. Superinfection of these poorly vascularized tissues becomes a problem. In bancroftian filariasis, in which genital involvement is common, hydroceles may develop (Fig. 211-1); in advanced stages, this condition may evolve into scrotal lymphedema and scrotal elephantiasis. Furthermore, if there is obstruction of the retroperitoneal lymphatics, the increased renal lymphatic pressure leads to rupture of the renal lymphatics and the development of chyluria, which is usually intermittent and most prominent in the morning.

The clinical manifestations of filarial infections in travelers or transmigrants who have recently entered an endemic region are distinctive. Given a sufficient number of bites by infected vectors, usually over a 3- to 6-month period, recently exposed patients can develop acute lymphatic or scrotal inflammation with or without urticaria and localized angioedema. Lymphadenitis of epitrochlear, axillary, femoral, or inguinal lymph nodes is often followed by retrogradely evolving lymphangitis. Acute attacks are short-lived and are not usually accompanied by fever. With prolonged exposure to infected mosquitoes, these attacks, if untreated, become more severe and lead to permanent lymphatic inflammation and obstruction.

DIAGNOSIS

A definitive diagnosis can be made only by detection of the parasites and hence can be difficult. Adult worms localized in lymphatic vessels or nodes are largely inaccessible. Microfilariae can be found in blood, in hydrocele fluid, or (occasionally) in other body fluids. Such fluids can be examined microscopically, either directly or—for greater sensitivity—after concentration of the parasites by the passage of fluid through a polycarbonate cylindrical pore filter (pore size, 3 μm) or by the centrifugation of fluid fixed in 2% formalin (Knott's concentration technique). The timing of blood collection is critical and should be based on the periodicity of the microfilariae in the endemic region involved. Many infected individuals do not have microfilaremia, and definitive diagnosis in such cases can be difficult. Assays for circulating antigens of *W. bancrofti* permit the diagnosis of microfilaremic and cryptic (amicrofilaremic) infection. Two tests are commercially available: an enzyme-linked immunosorbent assay (ELISA) and a rapid-format immunochromatographic card test. Both assays have sensitivities of 96–100% and specificities approaching 100%. There are currently no tests for circulating antigens in brugian filariasis.

Polymerase chain reaction (PCR)–based assays for DNA of *W. bancrofti* and *B. malayi* in blood have been developed. A number of studies indicate that this diagnostic method is of equivalent or greater sensitivity compared with parasitologic methods, detecting patent infection in almost all infected individuals.

In cases of suspected lymphatic filariasis, examination of the scrotum or the female breast by means of high-frequency ultrasound in conjunction with Doppler techniques may result in the identification of motile adult worms within dilated lymphatics. Worms may be visualized in the lymphatics of the spermatic cord in up to 80% of infected men. Live adult worms have a distinctive pattern of movement within the lymphatic vessels (termed the *filaria dance sign*). Radionuclide lymphoscintigraphic imaging of the limbs reliably demonstrates widespread lymphatic abnormalities in both asymptomatic microfilaremic persons and those with clinical manifestations of lymphatic pathology. While of potential utility in the delineation of anatomic changes associated with

FIGURE 211-2 Elephantiasis of the lower extremity associated with *Wuchereria bancrofti* infection.

infection, lymphoscintigraphy is unlikely to assume primacy in the diagnostic evaluation of individuals with suspected infection; it is principally a research tool, although it has been used more widely for assessment of lymphedema of any cause. Eosinophilia and elevated serum concentrations of IgE and antifilarial antibody support the diagnosis of lymphatic filariasis. There is, however, extensive cross-reactivity between filarial antigens and antigens of other helminths, including the common intestinal roundworms; thus, interpretations of serologic findings can be difficult. In addition, residents of endemic areas can become sensitized to filarial antigens (and thus be serologically positive) through exposure to infected mosquitoes without having patent filarial infections.

The ADL associated with lymphatic filariasis must be distinguished from thrombophlebitis, infection, and trauma. Retrogradely evolving lymphangitis is a characteristic feature that helps distinguish filarial lymphangitis from ascending bacterial lymphangitis. Chronic filarial lymphedema must also be distinguished from the lymphedema of malignancy, postoperative scarring, trauma, chronic edematous states, and congenital lymphatic system abnormalities.

Rx LYMPHATIC FILARIASIS

With newer definitions of clinical syndromes in lymphatic filariasis and new tools to assess clinical status (e.g., ultrasound, lymphoscintigraphy, circulating filarial antigen assays, PCR), approaches to treatment based on infection status can be considered. Diethylcarbamazine (DEC, 6 mg/kg daily for 12 days), which has both macro- and microfilaricidal properties, remains the treatment of choice for the individual with active lymphatic filariasis (microfilaremia, antigen positivity, or adult worms on ultrasound). An alternative treatment is albendazole (400 mg bid for 21 days), although this drug's macrofilaricidal efficacy may be less than that of DEC. An 8-week course of daily doxycycline (targeting the intracellular *Wolbachia* endosymbiont) has significant macrofilaricidal activity, as does a 7-day course of daily DEC/albendazole.

As has already been mentioned, a growing body of evidence indicates that, although they may be asymptomatic, virtually all persons with *W. bancrofti* or *B. malayi* microfilaremia have some degree of subclinical disease (hematuria, proteinuria, abnormalities on lymphoscintigraphy). Thus, early treatment of asymptomatic persons is recommended to prevent further lymphatic damage. For ADL, supportive treatment (including the administration of antipyretics and analgesics) is recommended, as is antibiotic therapy if secondary bacterial infection is likely. Similarly, because lymphatic disease is associated with the presence of adult worms, treatment with DEC is recommended for microfilaria-negative adult-worm carriers.

In persons with chronic manifestations of lymphatic filariasis, treatment regimens that emphasize hygiene, prevention of secondary bacterial infections, and physiotherapy have gained wide acceptance for morbidity control. These regimens are similar to those recommended for lymphedema of most nonfilarial causes and known by a variety of names, including *complex decongestive physiotherapy* and *complex lymphedema therapy*. Hydroceles (Fig. 211-1) can be drained repeatedly or managed surgically. With chronic manifestations of lymphatic filariasis, drug treatment should be reserved for individuals with evidence of active infection; therapy has been associated with clinical improvement and, in some cases, reversal of lymphedema.

The recommended course of DEC treatment (12 days; total dose, 72 mg/kg) has remained standard for many years. However, data indicate that single-dose DEC treatment with 6 mg/kg may be equally efficacious. The 12-day course provides more rapid short-term microfilarial suppression. Regimens that use combinations of single doses of albendazole and either DEC or ivermectin all have a sustained microfilaricidal effect. As mentioned above, an 8-week course of daily doxycycline (200 mg/d) or a 7-day course of daily DEC/albendazole has both significant macrofilaricidal activity and sustained microfilaricidal activity.

Side effects of DEC treatment include fever, chills, arthralgias, headaches, nausea, and vomiting. Both the development and the severity of these reactions are directly related to the number of microfilariae circulating in the bloodstream. The adverse reactions may represent either an acute hypersensitivity reaction to the antigens being released by dead and dying parasites or an inflammatory reaction induced by lipopolysaccharides from the intracellular *Wolbachia* endosymbionts freed from their intracellular niche. Ivermectin has a side effect profile similar to that of DEC when used in lymphatic filariasis. In patients infected with *L. loa*, who have high levels of *Loa* microfilaremia, DEC—like ivermectin (see "Loiasis," below)—can elicit severe encephalopathic complications. When used in single-dose regimens for the treatment of lymphatic filariasis, albendazole is associated with relatively few side effects.

PREVENTION AND CONTROL

Avoidance of mosquito bites usually is not feasible for residents of endemic areas, but visitors should make use of insect repellent and mosquito nets. Impregnated bednets have a salutary effect. DEC can kill developing forms of filarial parasites and is useful as a prophylactic agent in humans.

Community-based intervention is the current approach to elimination of lymphatic filariasis as a public health problem. The underlying tenet of this approach is that mass annual distribution of antimicrofilarial chemotherapy—albendazole with either DEC (for all areas except those where onchocerciasis is coendemic) or ivermectin—will profoundly suppress microfilaremia. If the suppression is sustained, then transmission can be interrupted. As an added benefit, these combinations have secondary effects on gastrointestinal helminths. An alternative approach to the control of lymphatic filariasis is the use of salt fortified with DEC. Community use of DEC-fortified salt dramatically reduces microfilarial density with no apparent adverse reactions. Community education and clinical care for persons already suffering from the chronic sequelae of lymphatic filariasis are important components of filariasis control and elimination programs.

TROPICAL PULMONARY EOSINOPHILIA

Tropical pulmonary eosinophilia (TPE) is a distinct syndrome that develops in some individuals infected with lymphatic filarial species. This syndrome affects males and females in a ratio of 4:1, often during the third decade of life. The majority of cases have been reported from India, Pakistan, Sri Lanka, Brazil, Guyana, and Southeast Asia.

CLINICAL FEATURES

The main features include a history of residence in filarial-endemic regions, paroxysmal cough and wheezing (usually nocturnal and probably related to the nocturnal periodicity of microfilariae), weight loss, low-grade fever, adenopathy, and pronounced blood eosinophilia (>3000 eosinophils/μL). Chest x-rays or CT scans may be normal but generally show increased bronchovascular markings. Diffuse miliary lesions or mottled opacities may be present in the middle and lower lung fields. Tests of pulmonary function show restrictive abnormalities in most cases and obstructive defects in half. Characteristically, total serum IgE levels (10,000–100,000 ng/mL) and antifilarial antibody titers are markedly elevated.

PATHOLOGY

In TPE, microfilariae and parasite antigens are rapidly cleared from the bloodstream by the lungs. The clinical symptoms result from allergic and inflammatory reactions elicited by the cleared parasites. In some patients, trapping of microfilariae in other reticuloendothelial organs can cause hepatomegaly, splenomegaly, or lymphadenopathy. A prominent, eosinophil-enriched, intraalveolar infiltrate is often reported, and with it comes the release of cytotoxic proinflammatory granular proteins that may mediate some of the pathology seen in TPE. In the absence of successful treatment, interstitial fibrosis can lead to progressive pulmonary damage.

DIFFERENTIAL DIAGNOSIS

TPE must be distinguished from asthma, Löffler's syndrome, allergic bronchopulmonary aspergillosis, allergic granulomatosis with angiitis (Churg-Strauss syndrome), the systemic vasculitides (most notably periarteritis nodosa and Wegener's granulomatosis), chronic eosinophilic pneumonia, and the idiopathic hypereosinophilic syndrome. In addition to a geographic history of filarial exposure, useful features for distinguishing TPE include wheezing that is solely nocturnal, very

high levels of antifilarial antibodies, and a rapid initial response to treatment with DEC.

TROPICAL PULMONARY EOSINOPHILIA

DEC is used at a daily dosage of 4–6 mg/kg for 14 days. Symptoms usually resolve within 3–7 days after the initiation of therapy. Relapse, which occurs in ~12–25% of cases (sometimes after an interval of years), requires re-treatment.

ONCHOCERCIASIS

Onchocerciasis ("river blindness") is caused by the filarial nematode *O. volvulus*, which infects an estimated 13 million individuals. The majority of individuals infected with *O. volvulus* live in the equatorial region of Africa extending from the Atlantic coast to the Red Sea. About 70,000 persons are infected in Guatemala and Mexico, with smaller foci in Venezuela, Colombia, Brazil, Ecuador, Yemen, and Saudi Arabia. Onchocerciasis is the second leading cause of infectious blindness worldwide.

ETIOLOGY AND EPIDEMIOLOGY

Infection in humans begins with the deposition of infective larvae on the skin by the bite of an infected blackfly. The larvae develop into adults, which are typically found in subcutaneous nodules. About 7 months to 3 years after infection, the gravid female releases microfilariae that migrate out of the nodule and throughout the tissues, concentrating in the dermis. Infection is transmitted to other persons when a female fly ingests microfilariae from the host's skin and these microfilariae then develop into infective larvae. Adult *O. volvulus* females and males are ~40–60 cm and ~3–6 cm in length, respectively. The life span of adults can be as long as 18 years, with an average of ~9 years. Because the blackfly vector breeds along free-flowing rivers and streams (particularly in rapids) and generally restricts its flight to an area within several kilometers of these breeding sites, both biting and disease transmission are most intense in these locations.

PATHOLOGY

Onchocerciasis primarily affects the skin, eyes, and lymph nodes. In contrast to the pathology in lymphatic filariasis, the damage in onchocerciasis is elicited by microfilariae and not by adult parasites. In the skin, there are mild but chronic inflammatory changes that can result in loss of elastic fibers, atrophy, and fibrosis. The subcutaneous nodules, or onchocercomata, consist primarily of fibrous tissues surrounding the adult worm, often with a peripheral ring of inflammatory cells. In the eye, neovascularization and corneal scarring lead to corneal opacities and blindness. Inflammation in the anterior and posterior chambers frequently results in anterior uveitis, chorioretinitis, and optic atrophy. Although punctate opacities are due to an inflammatory reaction surrounding dead or dying microfilariae, the pathogenesis of most manifestations of onchocerciasis is still unclear.

CLINICAL FEATURES

Skin Pruritus and rash are the most frequent manifestations of onchocerciasis. The pruritus can be incapacitating; the rash is typically a papular eruption (Fig. 211-3) that is generalized rather than localized to a particular region of the body. Long-term infection results in exaggerated and premature wrinkling of the skin, loss of elastic fibers, and epidermal atrophy that can lead to loose, redundant skin and hypo- or hyperpigmentation. Localized eczematoid dermatitis can cause hyperkeratosis, scaling, and pigmentary changes. In an immunologically hyperreactive form of onchodermatitis (commonly termed *sowdah*, from the Yemeni word meaning "black"), the affected skin darkens as a consequence of the profound inflammation that occurs as microfilariae in the skin are cleared.

Onchocercomata These subcutaneous nodules, which can be palpable and/or visible, contain the adult worm. In African patients, they are common over the coccyx and sacrum, the trochanter of the femur, the lateral anterior crest, and other bony prominences; in patients from South and Central America, nodules tend to develop preferentially in the upper part of the body, particularly on the head, neck, and shoulders.

FIGURE 211-3 Papular eruption as a consequence of onchocerciasis.

Nodules vary in size and characteristically are firm and not tender. It has been estimated that, for every palpable nodule, there are four deeper nonpalpable ones.

Ocular Tissue Visual impairment is the most serious complication of onchocerciasis and usually affects only those persons with moderate or heavy infections. Lesions may develop in all parts of the eye. The most common early finding is conjunctivitis with photophobia. Punctate keratitis—acute inflammatory reactions surrounding dying microfilariae and manifested as "snowflake" opacities—is common among younger patients and resolves without apparent complications.

Sclerosing keratitis occurs in 1–5% of infected persons and is the leading cause of onchocercal blindness in Africa. Anterior uveitis and iridocyclitis develop in ~5% of infected persons in Africa. In Latin America, complications of the anterior uveal tract (pupillary deformity) may cause secondary glaucoma. Characteristic chorioretinal lesions develop as a result of atrophy and hyperpigmentation of the retinal pigment epithelium. Constriction of the visual fields and frank optic atrophy may occur.

Lymph Nodes Mild to moderate lymphadenopathy is common, particularly in the inguinal and femoral areas, where the enlarged nodes may hang down in response to gravity ("hanging groin"), sometimes predisposing to inguinal and femoral hernias.

Systemic Manifestations Some heavily infected individuals develop cachexia with loss of adipose tissue and muscle mass. Among adults who become blind, there is a three- to fourfold increase in the mortality rate.

DIAGNOSIS

Definitive diagnosis depends on the detection of an adult worm in an excised nodule or, more commonly, of microfilariae in a skin snip. Skin snips are obtained with a corneal-scleral punch, which collects a blood-free skin biopsy sample extending to just below the epidermis, or by lifting of the skin with the tip of a needle and excision of a small (1- to 3-mm) piece with a sterile scalpel blade. The biopsy tissue is incubated in tissue culture medium or in saline on a glass slide or flat-bottomed microtiter plate. After incubation for 2–4 h (or occasionally overnight in light infections), microfilariae emergent from the skin can be seen by low-power microscopy.

Eosinophilia and elevated serum IgE levels are common but, because they occur in many parasitic infections, are not diagnostic in

themselves. Assays to detect specific antibodies to *Onchocerca* and PCR to detect onchocercal DNA in skin snips are used in specialized laboratories and are highly sensitive and specific.

The *Mazzotti test* is a provocative technique that can be used in cases where the diagnosis of onchocerciasis is still in doubt (i.e., when skin snips and ocular examination reveal no microfilariae). A small dose of DEC (0.5–1.0 mg/kg) is given orally; the ensuing death of any dermal microfilariae elicits the development or exacerbation of pruritus or dermatitis within hours—an event that strongly suggests onchocerciasis.

℞ ONCHOCERCIASIS

The main goals of therapy are to prevent the development of irreversible lesions and to alleviate symptoms. Surgical excision is recommended when nodules are located on the head (because of the proximity of microfilaria-producing adult worms to the eye), but chemotherapy is the mainstay of management. Ivermectin, a semisynthetic macrocyclic lactone active against microfilariae, is the first-line agent for the treatment of onchocerciasis. It is given orally in a single dose of 150 μg/kg, either yearly or semiannually. Recently, more frequent ivermectin administration (every 3 months) has been suggested to ameliorate pruritus and skin disease. Moreover, quadrennial administration of ivermectin has some macrofilaricidal activity.

After treatment, most individuals have few or no reactions. Pruritus, cutaneous edema, and/or maculopapular rash occurs in ~1–10% of treated individuals.

In areas of Africa co-endemic for *O. volvulus* and *L. loa*, however, ivermectin is contraindicated (as it is for pregnant or breast-feeding women) because of severe posttreatment encephalopathy seen in patients, especially children, who are heavily microfilaremic for *L. loa* (2000–5000 microfilariae/mL). Although ivermectin treatment results in a marked drop in microfilarial density, its effect can be short-lived (<3 months in some cases). Thus, it is occasionally necessary to give ivermectin more frequently for persistent symptoms. A 6-week course of doxycycline is macrofilaristatic, rendering female adult worms sterile for long periods. Because this agent targets the *Wolbachia* endosymbiont of the filarial parasite, new approaches for definitive treatment (i.e., cure) may become available.

PREVENTION

Vector control has been beneficial in highly endemic areas in which breeding sites are vulnerable to insecticide spraying, but most areas endemic for onchocerciasis are not suited to this type of control. Community-based administration of ivermectin every 6–12 months is being used to interrupt transmission in endemic areas. This measure, in conjunction with vector control, has already helped reduce the prevalence of disease in endemic foci in Africa and Latin America. No drug has proved useful for prophylaxis of *O. volvulus* infection.

LOIASIS

ETIOLOGY AND EPIDEMIOLOGY

Loiasis is caused by *L. loa* (the African eye worm), which is present in the rain forests of West and Central Africa. Adult parasites (females, 50–70 mm long and 0.5 mm wide; males, 25–35 mm long and 0.25 mm wide) live in subcutaneous tissues. Microfilariae circulate in the blood with a diurnal periodicity that peaks between 12:00 noon and 2:00 P.M.

CLINICAL FEATURES

Manifestations of loiasis in natives of endemic areas may differ from those in temporary residents or visitors. Among the indigenous population, loiasis is often an asymptomatic infection with microfilaremia. Infection may be recognized only after subconjunctival migration of an adult worm (Fig. 211-4) or may be manifested by episodic Calabar swellings—evanescent localized areas of angioedema and erythema developing on the extremities and less frequently at other sites. Nephropathy, encephalopathy, and cardiomyopathy are rare. In patients who are not residents of endemic areas, allergic symptoms predominate, episodes of Calabar swelling tend to be more frequent and debilitating, microfilaremia is rare, and eosinophilia and increased levels of antifilarial antibodies are characteristic.

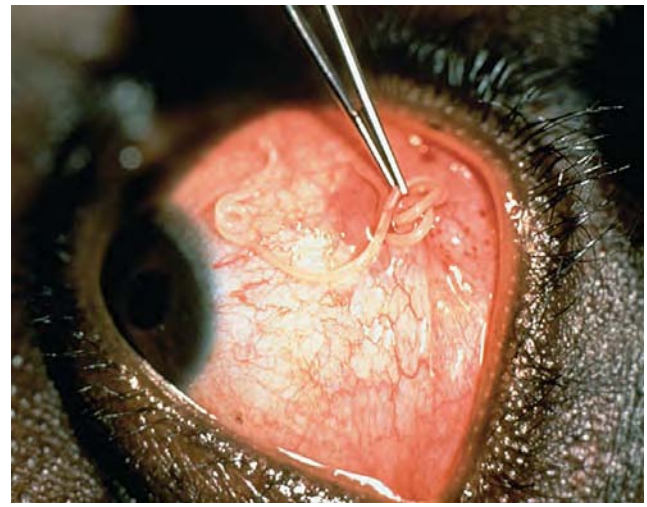

FIGURE 211-4 Adult *Loa loa* being surgically removed after its subconjunctival migration.

PATHOLOGY

The pathogenesis of the manifestations of loiasis is poorly understood. Calabar swellings are thought to result from a hypersensitivity reaction to adult worm antigens.

DIAGNOSIS

Definitive diagnosis of loiasis requires the detection of microfilariae in the peripheral blood or the isolation of the adult worm from the eye (Fig. 211-4) or from a subcutaneous biopsy specimen from a site of swelling developing after treatment. PCR-based assays for the detection of *L. loa* DNA in blood are available in specialized laboratories and are highly sensitive and specific. In practice, the diagnosis must often be based on a characteristic history and clinical presentation, blood eosinophilia, and elevated levels of antifilarial antibodies, particularly in travelers to an endemic region, who are usually amicrofilaremic. Other clinical findings in the latter individuals include hypergammaglobulinemia, elevated levels of serum IgE, and elevated leukocyte and eosinophil counts.

℞ LOIASIS

DEC (8–10 mg/kg per day for 21 days) is effective against both the adult and the microfilarial forms of *L. loa*, but multiple courses are frequently necessary before loiasis resolves completely. In cases of heavy microfilaremia, allergic or other inflammatory reactions can take place during treatment, including central nervous system involvement with coma and encephalitis. Heavy infections can be treated initially with apheresis to remove the microfilariae and with glucocorticoids (40–60 mg of prednisone per day) followed by doses of DEC (0.5 mg/kg per day). If antifilarial treatment has no adverse effects, the prednisone dose can be rapidly tapered and the dose of DEC gradually increased to 8–10 mg/kg per day.

Albendazole or ivermectin is effective in reducing microfilarial loads, although neither is approved for this purpose by the U.S. Food and Drug Administration. DEC (300 mg weekly) is an effective prophylactic regimen for loiasis.

STREPTOCERCIASIS

Mansonella streptocerca, found mainly in the tropical forest belt of Africa from Ghana to the Democratic Republic of the Congo, is transmitted by biting midges. The major clinical manifestations involve the skin and include pruritus, papular rashes, and pigmentation changes. Many infected individuals have inguinal

adenopathy, although most are asymptomatic. The diagnosis is made by detection of the characteristic microfilariae in skin snips. DEC (6 mg/kg per day in divided doses for 14–21 days) effectively kills both microfilariae and adult worms. As in onchocerciasis, treatment is sometimes accompanied by urticaria, arthralgias, myalgias, headaches, and abdominal discomfort. Ivermectin at a single dose of 150 μg/kg leads to sustained suppression of microfilariae in the skin and is likely to assume primacy in the treatment of streptocerciasis.

MANSONELLA PERSTANS INFECTION

Mansonella perstans, distributed across the center of Africa and in northeastern South America, is transmitted by midges. Adult worms reside in serous cavities—pericardial, pleural, and peritoneal—as well as in the mesentery and the perirenal and retroperitoneal tissues. Microfilariae circulate in the blood without periodicity. The clinical and pathologic features of the infection are poorly defined. Most patients appear to be asymptomatic, but manifestations may include transient angioedema and pruritus of the arms, face, or other parts of the body (analogous to the Calabar swellings of loiasis); fever; headache; arthralgias; and right-upper-quadrant pain. Occasionally, pericarditis and hepatitis occur. The diagnosis is based on the demonstration of microfilariae in blood or serosal effusions. Perstans filariasis is often associated with peripheral-blood eosinophilia and antifilarial antibody elevations. Although DEC (8–10 mg/kg per day for 21 days) is the standard therapeutic agent, there is little evidence that it is effective. Cure is indicated by the disappearance of symptoms and eosinophilia; multiple courses of therapy are usually required. Ivermectin, used in frequent repeated doses, can reduce blood microfilarial levels. Both mebendazole (100 mg bid for 30 days) and albendazole (400 mg bid for 10 days) have occasionally been reported to be effective.

MANSONELLA OZZARDI INFECTION

The distribution of *Mansonella ozzardi* is restricted to Central and South America and certain Caribbean islands. Adult worms are rarely recovered from humans. Microfilariae circulate in the blood without periodicity. Although this organism has often been considered nonpathogenic, headache, articular pain, fever, pulmonary symptoms, adenopathy, hepatomegaly, pruritus, and eosinophilia have been ascribed to *M. ozzardi* infection. The diagnosis is made by detection of microfilariae in peripheral blood. Ivermectin (a single dose of 6 mg) is effective in treating this infection.

DRACUNCULIASIS (GUINEA WORM INFECTION)

ETIOLOGY AND EPIDEMIOLOGY

The incidence of dracunculiasis, caused by *Dracunculus medinensis*, has declined dramatically because of global eradication efforts. Current estimates suggest that there are slightly more than 10,000 cases worldwide, the majority in Sudan, Ghana, and Mali. Asia has now been deemed dracunculiasis-free.

Humans acquire *D. medinensis* when they ingest water containing infective larvae derived from *Cyclops*, a crustacean that is the intermediate host. Larvae penetrate the stomach or intestinal wall, mate, and mature. The adult male probably dies; the female worm develops over a year and migrates to subcutaneous tissues, usually in the lower extremity. As the thin female worm, ranging in length from 30 cm to 1 m, approaches the skin, a blister forms that, over days, breaks down and forms an ulcer. When the blister opens, large numbers of motile, rhabditiform larvae can be released into stagnant water; ingestion by *Cyclops* completes the life cycle.

CLINICAL FEATURES

Few or no clinical manifestations of dracunculiasis are evident until just before the blister forms, when there is an onset of fever and generalized allergic symptoms, including periorbital edema, wheezing, and urticaria. The emergence of the worm is associated with local pain and swelling. When the blister ruptures (usually as a result of immersion in water) and the adult worm releases larva-rich fluid, symptoms are relieved. The shallow ulcer surrounding the emerging adult worm heals over weeks to months. Such ulcers, however, can become secondarily infected, the result being cellulitis, local inflammation, abscess formation, or (uncommonly) tetanus. Occasionally, the adult worm does not emerge but becomes encapsulated and calcified.

DIAGNOSIS

The diagnosis is based on the findings developing with the emergence of the adult worm, as described above.

℞ DRACUNCULIASIS

Gradual extraction of the worm by winding of a few centimeters on a stick each day remains the common and effective practice. Worms may be excised surgically. The administration of metronidazole (250 mg tid for 10 days) may relieve symptoms but has no proven activity against the worm.

PREVENTION

Prevention, which remains the only real control measure, depends on the provision of safe drinking water.

ZOONOTIC FILARIAL INFECTIONS

Dirofilariae that affect primarily dogs, cats, and raccoons occasionally infect humans incidentally, as do *Brugia* and *Onchocerca* parasites that affect small mammals. Because humans are an abnormal host, the parasites never develop fully. Pulmonary dirofilarial infection caused by the canine heartworm *Dirofilaria immitis* generally presents in humans as a solitary pulmonary nodule. Chest pain, hemoptysis, and cough are uncommon. Infections with *D. repens* (from dogs) or *D. tenuis* (from raccoons) can cause local subcutaneous nodules in humans. Zoonotic *Brugia* infection can produce isolated lymph node enlargement, whereas zoonotic *Onchocerca* can cause subconjunctival masses. Eosinophilia levels and antifilarial antibody titers are not commonly elevated. Excisional biopsy is both diagnostic and curative. These infections usually do not respond to chemotherapy.

212 Schistosomiasis and Other Trematode Infections

Adel A.F. Mahmoud

Trematodes, or flatworms, are a group of morphologically and biologically heterogeneous organisms that belong to the phylum Platyhelminthes. Human infection with trematodes occurs in many geographic areas and can cause considerable morbidity and mortality. For clinical purposes, significant trematode infections of humans may be divided according to tissues invaded by adult flukes: blood, biliary tree, intestines, and lungs (Table 212-1).

Trematodes share some common morphologic features, including macroscopic size (from 1 cm to several cm); dorsoventral, flattened, bilaterally symmetric bodies (adult worms); and the prominence of two suckers. Except for schistosomes, all human parasitic trematodes are hermaphroditic. Their life cycle involves a definitive host (mammalian/human), in which adult worms initiate sexual reproduction, and an intermediate host (snails), in which asexual multiplication of larvae occurs. More than one intermediate host may be necessary for some species of trematodes. Human infection is initiated either by direct penetration of intact skin or by ingestion. Upon maturation within humans, adult flukes initiate sexual reproduction and egg production. Helminth ova leave the definitive host in excreta or sputum and, upon reaching suitable environmental conditions, they hatch, releasing free-living miracidia that seek specific snail intermediate hosts. After asexual reproduction, cercariae are released from infected snails. In certain species, these organisms infect humans; in others, they find a second intermediate host to allow encystment into metacercariae—the infective stage.

The host-parasite relationship in trematode infections is a product of certain biologic features of these organisms: they are multicellular, undergo several developmental changes within the host, and usually result in chronic infections. In general, the distribution of worm infections in human populations is *overdispersed*; i.e., it follows a negative binomial mathematical relationship in which most infected individuals harbor low worm burdens while a small percentage are heavily infected. It is the heavily infected minority who are particularly prone to disease sequelae and who constitute an epidemiologically significant reservoir of infection in endemic areas. Equally important is an appreciation that worms do not multiply within the definitive host and that they have a relatively long life span, ranging from a few months to a few years. Morbidity and death due to trematode infections reflect a multifactorial process that results from the tipping of a delicate balance between intensity of infection and host reactions, which initiate and modulate immunologic and pathologic outcome. Furthermore, the genetics of the parasite and of the human host contribute to the outcome of infection and disease. Infections with trematodes that migrate through or reside in host tissues are associated with a moderate to high degree of peripheral blood eosinophilia; this association is of significance in protective and immunopathologic sequelae and is a useful clinical indicator of infection.

APPROACH TO THE PATIENT: Trematode Infection

The approach to individuals with suspected trematode infection begins with a question: Where have you been? Details of geographic history, exposure to freshwater bodies, and indulgence in local eating habits without ensuring safety of food and drink are all essential elements in the history. The workup plan must include a detailed physical examination and tests appropriate for the suspected infection. Diagnosis is based either on detection of the relevant stage of the parasite in excreta, sputum, or (rarely) tissue samples or on sensitive and specific serologic tests. Consultation with physicians familiar with these infections or with the U.S. Centers for Disease Control and Prevention (CDC) is helpful in guiding diagnosis and selecting therapy.

BLOOD FLUKES: SCHISTOSOMIASIS

Human schistosomiasis is caused by five species of the parasitic trematode genus *Schistosoma*: the intestinal species *S. mansoni*, *S. japonicum*, *S. mekongi*, and *S. intercalatum* and the urinary species *S. haematobium*. Infection may cause considerable morbidity in the intestines, liver, and urinary tract, and a proportion of affected individuals die. Other schistosomes (e.g., avian species) may invade human skin but then die in subcutaneous tissue, producing only self-limiting cutaneous manifestations.

ETIOLOGY

Human infection is initiated by penetration of intact skin with infective cercariae. These organisms, which are released from infected snails in freshwater bodies, measure ~2 mm in length and possess an anterior and a ventral sucker that attach to the skin and facilitate penetration. Once in subcutaneous tissue, cercariae transform into schistosomula, with morphologic, membrane, and immunologic changes. The cercarial outer membrane changes from a trilaminar to a heptalaminar structure that is then maintained throughout the organism's life span in humans. This transformation is thought to be the schistosome's main adaptive mechanism for survival in humans. Schistosomula begin their migration within 2–4 days via venous or lymphatic vessels, reaching the lungs and finally the liver parenchyma. Sexually mature worms descend into the

TABLE 212-1 MAJOR HUMAN TREMATODE INFECTIONS

Trematode	Transmission	Endemic Area(s)
Blood Flukes		
Schistosoma mansoni	Skin penetration by cercariae released from snails	Africa, South America, Middle East
S. japonicum	Skin penetration by cercariae released from snails	China, Philippines, Indonesia
S. intercalatum	Skin penetration by cercariae released from snails	West Africa
S. mekongi	Skin penetration by cercariae released from snails	Southeast Asia
S. haematobium	Skin penetration by cercariae released from snails	Africa, Middle East
Biliary (Hepatic) Flukes		
Clonorchis sinensis	Ingestion of metacercariae in freshwater fish	Far East
Opisthorchis viverrini	Ingestion of metacercariae in freshwater fish	Far East, Thailand
O. felineus	Ingestion of metacercariae in freshwater fish	Far East, Europe
Fasciola hepatica	Ingestion of metacercariae on aquatic plants or in water	Worldwide
F. gigantica	Ingestion of metacercariae on aquatic plants or in water	Sporadic, Africa
Intestinal Flukes		
Fasciolopsis buski	Ingestion of metacercariae on aquatic plants	Southeast Asia
Heterophyes heterophyes	Ingestion of metacercariae in freshwater or brackish-water fish	Far East, North Africa
Lung Flukes		
Paragonimus westermani	Ingestion of metacercariae in crayfish or crabs	Global except North America and Europe

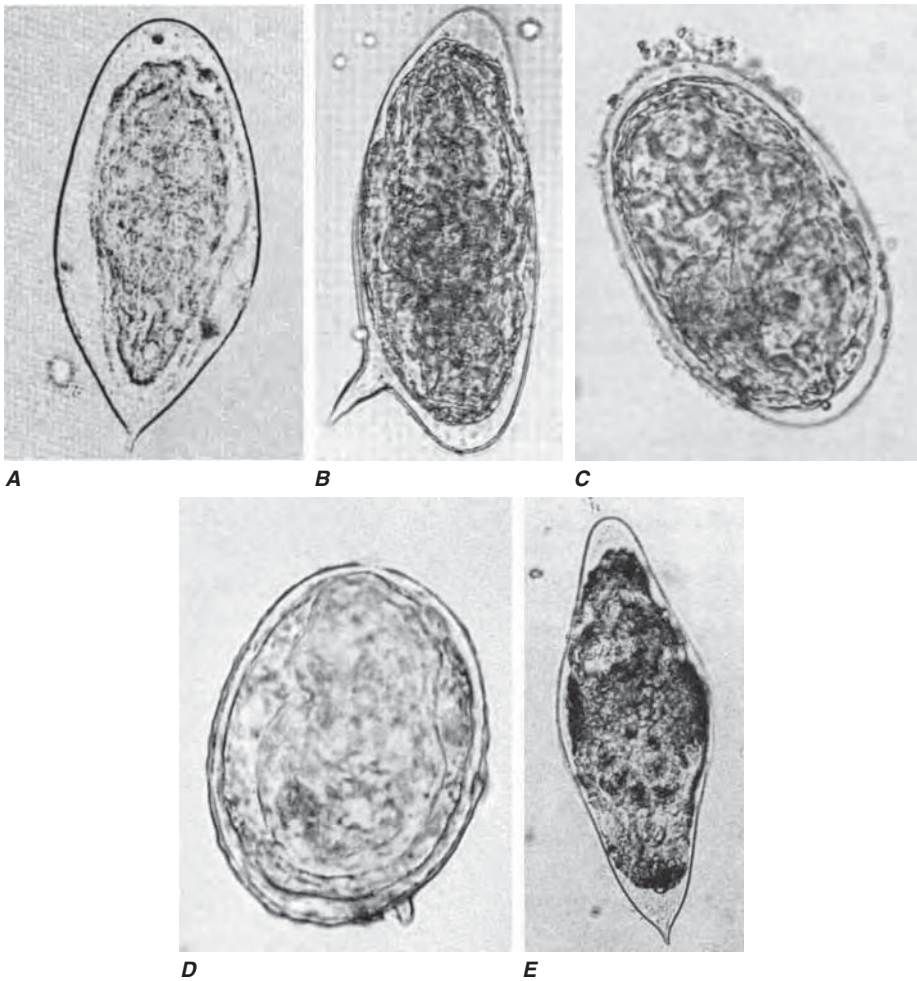

FIGURE 212-1 Morphology of schistosome eggs, the diagnostic stage of the parasite's life cycle. ***A.*** *S. haematobium* egg found in urine sample. Egg is large (~140 μm long), with a terminal spine. ***B.*** *S. mansoni* egg found in feces. Egg is large (~150 μm long), with a thin shell and lateral spine. ***C.*** *S. japonicum* egg found in feces. Egg is smaller than that of *S. mansoni* (~90 μm long), with a small spine or hooklike structure. ***D.*** *S. mekongi* egg found in feces. Egg is similar to that of *S. japonicum* but smaller (~65 μm long). ***E.*** *S. intercalatum* egg found in feces. Egg is larger than that of *S. haematobium* (~190 μm long), with a longer, sharply pointed spine. (*From LR Ash, TC Orihel: Atlas of Human Parasitology, 3d ed. Chicago, ASCP Press, 1990; with permission.*)

venous system at specific anatomic locations: intestinal veins (*S. mansoni*, *S. japonicum*, *S. mekongi*, and *S. intercalatum*) and vesical veins (*S. haematobium*). After mating, adult gravid females travel against venous blood flow to small tributaries, where they deposit their ova intravascularly. Schistosome ova (Fig. 212-1) have specific morphologic features that vary with the species. Aided by enzymatic secretions through minipores in eggshells, ova move through the venous wall, traversing host tissues to reach the lumen of the intestinal or urinary tract, and are voided with stools or urine. Approximately 50% of ova are retained in host tissues locally (intestines or urinary tract) or are carried by venous blood flow to the liver and other organs. Schistosome ova that reach freshwater bodies hatch, releasing free-living miracidia that seek the snail intermediate host and undergo several asexual multiplication cycles. Finally, infective cercariae are shed from snails.

Adult schistosomes are ~1–2 cm long. Males are slightly shorter than females, with flattened bodies and anteriorly curved edges forming the gynecophoral canal, in which mature adult females are usually held. Females are longer, slender, and rounded in cross-section. The precise nature of biochemical and reproductive exchanges between the two sexes is unknown, as are the regulatory mechanisms for pairing. Adult schistosomes parasitize specific sites in the host venous system. What guides adult intestinal schistosomes to branches of the superior or inferior mesenteric veins or adult *S. haematobium* worms to the vesical plexus is unknown. In addition, adult worms inhibit the coagulation cascade and evade the effector arms of the host immune responses by still-undetermined mechanisms. The genome of schistosomes is relatively large (~270 Mb) and is arrayed on seven pairs of autosomes and one pair of sex chromosomes. For *S. mansoni*, a total of ~14,000 genes have been estimated; some are species-conserved. The complete sequence of the schistosome genome should be available soon.

EPIDEMIOLOGY

The global distribution of schistosome infection in human populations (Fig. 212-2) is dependent on both parasite and host factors. Information on prevalence and global distribution is inexact. The five *Schistosoma* species are estimated to infect 200–300 million individuals in South America, the Caribbean, Africa, the Middle East, and Southeast Asia. The total population living under conditions favoring transmission approximates double or triple that number—a fact reflecting the public health significance of schistosomiasis.

In endemic areas, the rate of yearly onset of new infection, or incidence, is generally low. Prevalence, on the other hand, starts to be appreciable by the age of 3–4 years and builds to a maximum that varies by endemic region (up to 100%) in the 15- to 20-year age group. Prevalence then stabilizes or decreases slightly in older age groups (>40 years). Intensity of infection (as measured by fecal or urinary egg counts, which correlate with adult worm burdens in most circumstances) follows the increase in prevalence up to the age of 15–20 years and then declines markedly in older age groups. This decline may reflect acquisition of resistance or may be due to changes in water contact patterns, since older people have less exposure. Furthermore, the overdispersed distribution of schistosomes in human populations may be due to the heterogeneity of worm populations, with some more invasive than others; alternatively, it may be due to the demonstrated differences in genetic susceptibility of host populations.

Disease due to schistosome infection is the outcome of parasitologic, host, and additional infectious, nutritional, and environmental factors. Most disease syndromes relate to the presence of one or more of the parasite stages in humans. Disease manifestations in the populations of endemic areas correlate, in general, with the intensity and duration of infection as well as with the age and genetic susceptibility of the host. Overall, disease manifestations are clinically relevant in only a small proportion of persons infected with any of the intestinal schistosomes. In contrast, urinary schistosomiasis manifests clinically in most infected individuals. Recent estimates of total morbidity due to chronic schistosomiasis indicate a significantly greater burden than was previously appreciated.

Patients with both HIV infection and schistosomiasis excrete far fewer eggs in their stools than those infected with *S. mansoni* alone; the mechanism underlying this difference is unknown. Treatment with praziquantel may result in reduced HIV replication and increased CD4+ T lymphocyte counts.

PATHOGENESIS AND IMMUNITY

Cercarial invasion is associated with dermatitis arising from dermal and subdermal inflammatory responses, both humoral and cell-me-

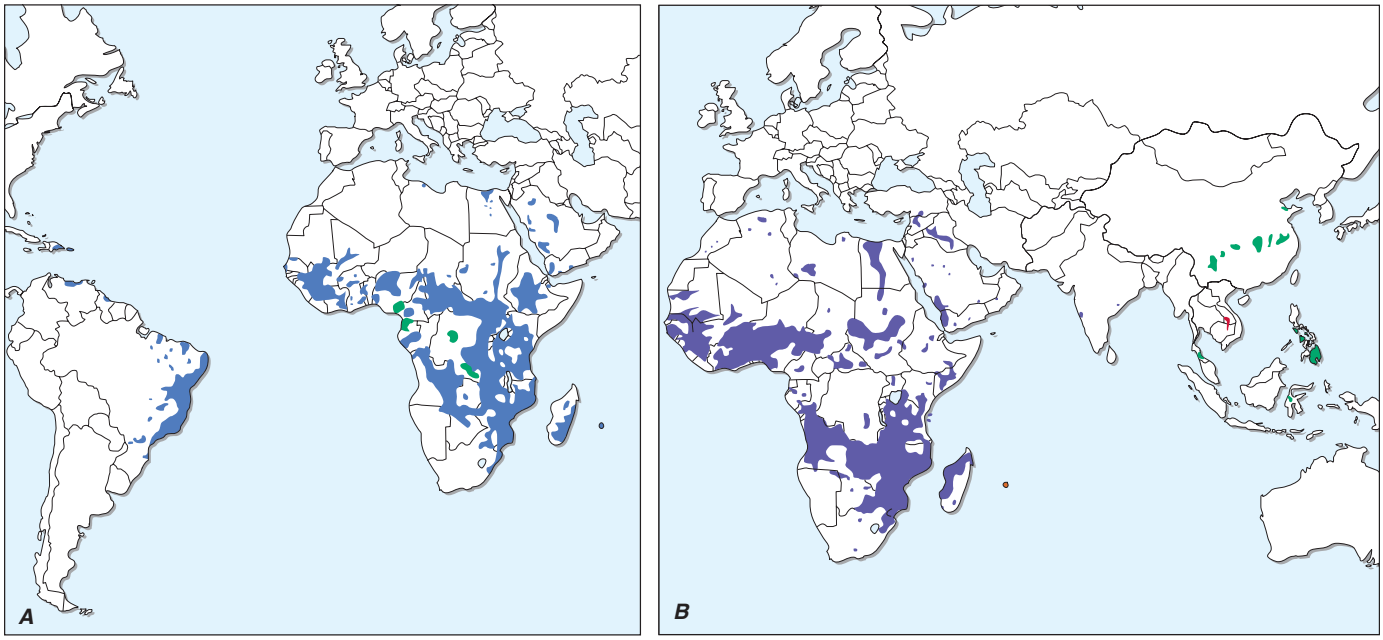

FIGURE 212-2 Global distribution of schistosomiasis. *A.* *S. mansoni* infection (*dark blue*) is endemic in Africa, the Middle East, South America, and a few Caribbean countries. *S. intercalatum* infection (*green*) is endemic in sporadic foci in West and Central Africa. ***B.*** *S. haematobium* infection (*purple*) is endemic in Africa and the Middle East. The major endemic countries for *S. japonicum* infection (*green*) are China, the Philippines, and Indonesia. *S. mekongi* infection (*red*) is endemic in sporadic foci in Southeast Asia.

diated. As the parasites approach sexual maturity and with the commencement of oviposition, acute schistosomiasis or Katayama fever (a serum sickness–like illness; see "Clinical Features," below) may occur. The associated antigen excess results in formation of soluble immune complexes, which may be deposited in several tissues, initiating multiple pathologic events. In chronic schistosomiasis, most disease manifestations are due to eggs retained in host tissues. The granulomatous response around these ova is cell-mediated and is regulated both positively and negatively by a cascade of cytokine, cellular, and humoral responses. Granuloma formation begins with recruitment of a host of inflammatory cells in response to antigens secreted by the living organism within the ova. Cells recruited initially include phagocytes, antigen-specific T cells, and eosinophils. Fibroblasts, giant cells, and B lymphocytes predominate later. These lesions reach a size many times that of parasite eggs, thus inducing organomegaly and obstruction. Immunomodulation or downregulation of host responses to schistosome eggs plays a significant role in limiting the extent of the granulomatous lesions—and consequently disease—in chronically infected experimental animals or humans. The underlying mechanisms involve another cascade of regulatory cytokines and idiotypic antibodies. Subsequent to the granulomatous response, fibrosis sets in, resulting in more permanent disease sequelae. Because schistosomiasis is also a chronic infection, the accumulation of antigen-antibody complexes results in deposits in renal glomeruli and may cause significant kidney disease.

The better-studied pathologic sequelae in schistosomiasis are those observed in liver disease. Ova that are carried by portal blood embolize to the liver. Because of their size (~150 × 60 μm in the case of *S. mansoni*), they lodge at presinusoidal sites, where granulomas are formed. These granulomas contribute to the hepatomegaly observed in infected individuals. Schistosomal liver enlargement is also associated with certain class I and class II human leukocyte antigen (HLA) haplotypes and markers; its genetic basis appears to be multigenic. Presinusoidal portal blockage causes several hemodynamic changes, including portal hypertension and associated development of portosystemic collaterals at the esophagogastric junction and other sites. Esophageal varices are most likely to break and cause repeated episodes of hematemesis. Because changes in hepatic portal blood flow occur slowly, compensatory arterialization of the blood flow through the liver is established. While this compensatory mechanism may be associated with certain metabolic side effects, retention of hepatocyte perfusion permits maintenance of normal liver function for several years.

The second most significant pathologic change in the liver relates to fibrosis. It is characteristically periportal (Symmers' clay pipe–stem fibrosis) but may be diffuse. Fibrosis, when diffuse, may be seen in areas of egg deposition and granuloma formation but is also seen in distant locations such as portal tracts. Schistosomiasis results in pure fibrotic lesions in the liver; cirrhosis occurs when other nutritional factors or infectious agents (e.g., hepatitis B or C virus) are involved. In recent years, it has been recognized that deposition of fibrotic tissue in the extracellular matrix results from the interaction of T lymphocytes with cells of the fibroblast series; several cytokines, such as interleukin (IL) 2, IL-4, IL-1, and transforming growth factor β (TGF-β), are known to stimulate fibrogenesis. The process may be dependent on the genetic constitution of the host. Furthermore, regulatory cytokines that can suppress fibrogenesis, such as interferon γ (IFN-γ) or IL-12, may play a role in modulating the response.

While the above description focuses on granuloma formation and fibrosis of the liver, similar processes occur in urinary schistosomiasis. Granuloma formation at the lower end of the ureters obstructs urinary flow, with subsequent development of hydroureter and hydronephrosis. Similar lesions in the urinary bladder cause the protrusion of papillomatous structures into its cavity; these may ulcerate and/or bleed. The chronic stage of infection is associated with scarring and deposition of calcium in bladder wall.

Studies on immunity to schistosomiasis, whether innate or adaptive, have expanded our knowledge of the components of these responses and target antigens. The critical question, however, is whether humans acquire immunity to schistosomes. Epidemiologic data suggest the onset of acquired immunity during the course of infection in young adults. Curative treatment of infection divides populations in endemic areas into those who acquire reinfection rapidly (susceptible) and those who follow a protracted course (resistant). This difference may be explained by differences in transmission, immunologic response, or genetic susceptibility. The mechanism of acquired immunity involves antibodies, complement, and several effector cells, particularly eosinophils. Furthermore, the intensity of schistosome infection has been correlated with a region in chromosome 5. In several

studies, a few protective schistosome antigens have been identified as vaccine candidates, but none has been evaluated in human populations to date.

CLINICAL FEATURES

In general, disease manifestations of schistosomiasis occur in three stages, which vary not only by species but also by intensity of infection and other host factors, such as age and genetics. During the phase of cercarial invasion, a form of dermatitis may be observed. This so-called swimmers' itch occurs most often with *S. mansoni* and *S. japonicum* infections, manifesting 2 or 3 days after invasion as an itchy maculopapular rash on the affected areas of the skin. The condition is particularly severe when humans are exposed to avian schistosomes. This form of cercarial dermatitis is also seen around freshwater lakes in the northern United States, particularly in the spring. Cercarial dermatitis is a self-limiting clinical entity. During worm maturation and at the beginning of oviposition (i.e., 4–8 weeks after skin invasion), acute schistosomiasis or Katayama fever—a serum sickness–like syndrome with fever, generalized lymphadenopathy, and hepatosplenomegaly—may develop. Individuals with acute schistosomiasis show a high degree of peripheral blood eosinophilia. Parasite-specific antibodies may be detected before schistosome eggs are identified in excreta. Acute schistosomiasis has become an important clinical entity worldwide because of increased travel to endemic areas. Travelers are exposed to parasites while swimming or wading in freshwater bodies and upon their return present with the acute manifestations. The course of acute schistosomiasis is generally benign, but deaths are occasionally reported in association with heavy exposure to schistosomes.

The main clinical manifestations of chronic schistosomiasis are species-dependent. Intestinal species (*S. mansoni*, *S. japonicum*, *S. mekongi*, and *S. intercalatum*) cause intestinal and hepatosplenic disease as well as several manifestations associated with portal hypertension. During the intestinal phase, which may begin a few months after infection and may last for years, symptomatic patients characteristically have colicky abdominal pain, bloody diarrhea, and anemia. Patients may also report fatigue and an inability to perform daily routine functions and may show evidence of growth retardation. It has been demonstrated that schistosomiasis morbidity is generally underappreciated. The severity of intestinal schistosomiasis is often related to the intensity of the worm burden. The disease runs a chronic course and may result in colonic polyposis, which has been reported from some endemic areas, such as Egypt.

The hepatosplenic phase of disease manifests early (during the first year of infection, particularly in children) with liver enlargement due to parasite-induced granulomatous lesions. Hepatomegaly is seen in ~15–20% of infected individuals; it correlates roughly with intensity of infection, occurs more often in children, and may be related to specific HLA haplotypes. In subsequent phases of infection, presinusoidal blockage of blood flow leads to portal hypertension and splenomegaly. Moreover, portal hypertension may lead to varices at the lower end of the esophagus and at other sites. Patients with schistosomal liver disease may have right-upper-quadrant "dragging" pain during the hepatomegaly phase, and this pain may move to the left upper quadrant as splenomegaly progresses. Bleeding from esophageal varices may, however, be the first clinical manifestation of this phase. Patients may experience repeated bleeding but seem to tolerate its impact, since an adequate total hepatic blood flow permits normal liver function for a considerable duration. In late-stage disease, typical fibrotic changes occur along with liver function deterioration and the onset of ascites, hypoalbuminemia, and defects in coagulation. Intercurrent viral infections of the liver (especially hepatitis B and C) or nutritional deficiencies may well accelerate or exacerbate the deterioration of hepatic function.

The extent and severity of intestinal and hepatic disease in schistosomiasis mansoni and japonica have been well described. While it was originally thought that *S. japonicum* might induce more severe disease manifestations because the adult worms can produce 10 times more eggs than *S. mansoni*, subsequent field studies have not supported this claim. Clinical observations of individuals infected with *S. mekongi* or *S. intercalatum* have been less detailed, partly because of the limited geographic distribution of these organisms.

The clinical manifestations of *S. haematobium* infection occur relatively early and involve a high percentage of infected individuals. Up to 80% of children infected with *S. haematobium* have dysuria, frequency, and hematuria, which may be terminal. Urine examination reveals blood and albumin as well as an unusually high frequency of bacterial urinary tract infection and urinary sediment cellular metaplasia. These manifestations correlate with intensity of infection, the presence of urinary bladder granulomas, and subsequent ulceration. Along with local effects of granuloma formation in the urinary bladder, obstruction of the lower end of the ureters results in hydroureter and hydronephrosis, which may be seen in 25–50% of infected children. As infection progresses, bladder granulomas undergo fibrosis, which results in typical sandy patches visible on cystoscopy. In many endemic areas, an association between squamous cell carcinoma of the bladder and *S. haematobium* infection has been observed. Such malignancy is detected in a younger age group than is transitional cell carcinoma. In fact, *S. haematobium* has now been classified as a human carcinogen.

Significant disease may occur in other organs during chronic schistosomiasis. Most important are the lungs and central nervous system (CNS); other locations, such as the skin and the genital organs, are far less frequently affected. In pulmonary schistosomiasis, embolized eggs lodge in small arterioles, producing acute necrotizing arteriolitis and granuloma formation. During *S. mansoni* and *S. japonicum* infection, schistosome eggs reach the lungs after the development of portosystemic collateral circulation; in *S. haematobium* infection, ova may reach the lungs directly via connections between the vesical and systemic circulation. Subsequent fibrous tissue deposition leads to endarteritis obliterans, pulmonary hypertension, and cor pulmonale. The most common symptoms are cough, fever, and dyspnea. Cor pulmonale may be diagnosed radiologically on the basis of prominent right side of the heart and dilation of the pulmonary artery. Frank evidence of right-sided heart failure may be seen in late cases.

CNS schistosomiasis is important but less common than pulmonary schistosomiasis. It characteristically occurs as cerebral disease due to *S. japonicum* infection. Migratory worms deposit eggs in the brain and induce a granulomatous response. The frequency of this manifestation among infected individuals in some endemic areas (e.g., the Philippines) is calculated at 2–4%. Jacksonian epilepsy due to *S. japonicum* infection is the second most common cause of epilepsy in these areas. *S. mansoni* and *S. haematobium* infections have been associated with transverse myelitis. This syndrome is thought to be due to eggs traveling to the venous plexus around the spinal cord. In schistosomiasis mansoni, transverse myelitis is usually seen in the chronic stage after the development of portal hypertension and portosystemic shunts, which allow ova to travel to the spinal cord veins. This proposed sequence of events has been challenged because of a few reports of transverse myelitis occurring early in the course of *S. mansoni* infection. More information is needed to confirm these observations. During schistosomiasis haematobia, ova may travel through communication between vesical and systemic veins, resulting in spinal cord disease that may be detected at any stage of infection. Pathologic study of lesions in schistosomal transverse myelitis may reveal eggs along with necrotic or granulomatous lesions. Patients usually present with acute or rapidly progressing lower-leg weakness accompanied by sphincter dysfunction.

DIAGNOSIS

Physicians in areas not endemic for schistosomiasis face considerable diagnostic challenges. In the most common clinical presentation, a traveler returns with symptoms and signs of acute syndromes of schistosomiasis—namely, cercarial dermatitis or Katayama fever. Central to correct diagnosis is a thorough inquiry into travel history and exposure to freshwater bodies, whether slow or fast running. Differential diagnosis of fever in returned travelers includes a spectrum of infections whose etiologies are viral (e.g., Dengue fever), bacterial (e.g., enteric fever, leptospirosis), rickettsial, or protozoal (e.g., malaria). In cases of

Katayama fever, prompt diagnosis is essential and is based on clinical presentation, high-level peripheral blood eosinophilia, and a positive serologic assay for schistosomal antibodies. Two tests are available at the CDC: the Falcon assay screening test/enzyme-linked immunosorbent assay (FAST-ELISA) and the confirmatory enzyme-linked immunoelectrotransfer blot (EITB). Both tests are highly sensitive and ~96% specific. In some instances, examination of stool or urine for ova may yield positive results.

Individuals with established infection are diagnosed by a combination of geographic history, characteristic clinical presentation, and presence of schistosome ova in excreta. The diagnosis may also be established with the serologic assays mentioned above or with those that detect circulating schistosome antigens. These assays can be applied either to blood or to other body fluids (e.g., cerebrospinal fluid). For suspected schistosome infection, stool examination by the Kato thick smear or any other concentration method generally identifies all but the most lightly infected individuals. For *S. haematobium,* urine may be examined by microscopy of sediment or by filtration of a known volume through Nuclepore filters. Kato thick smear and Nuclepore filtration provide quantitative data on the intensity of infection, which is of value in assessing the degree of tissue damage and in monitoring the effect of chemotherapy. Schistosome infection may also be diagnosed by examination of tissue samples, typically rectal biopsies; other biopsy procedures (e.g., liver biopsy) are not needed, except in rare circumstances.

Differential diagnosis of schistosomal hepatomegaly must include viral hepatitis of all etiologies, miliary tuberculosis, malaria, visceral leishmaniasis, ethanol abuse, and causes of hepatic and portal vein obstruction. Differential diagnosis of hematuria in *S. haematobium* infection includes bacterial cystitis, tuberculosis, urinary stones, and malignancy.

Rx SCHISTOSOMIASIS

Treatment of schistosomiasis depends on stage of infection and clinical presentation. Other than topical dermatologic applications for relief of itching, no specific treatment is indicated for cercarial dermatitis caused by avian schistosomes. Therapy for acute schistosomiasis or Katayama fever needs to be adjusted appropriately for each case. While antischistosomal chemotherapy may be used, it does not have a significant impact on maturing worms. In severe acute schistosomiasis, management in an acute-care setting is necessary, with supportive measures and consideration of glucocorticoid treatment. Once the acute critical phase is over, specific chemotherapy is indicated for parasite elimination. For all individuals with established infection, treatment to eradicate the parasite should be administered. The drug of choice is praziquantel, which—depending on the infecting species **(Table 212-2)**—is administered PO as a total of 40 or 60 mg/kg in two or three doses over a single day. Praziquantel treatment results in parasitologic cure in ~85% of cases and reduces egg counts by >90%. Few side effects have been encountered, and those that do develop usually do not interfere with completion of treatment. Dependence on a single chemotherapeutic agent has raised the possibility of development of resistance in schistosomes; to date, such resistance does not seem to be clinically significant. The effect of antischistosomal treatment on disease manifestations varies by stage. Early hepatomegaly and bladder lesions are known to resolve after chemotherapy, but the late established manifestations, such as fibrosis, do not recede. Additional management modalities are needed for individuals with other manifestations, such as hepatocellular failure or recurrent hematemesis. The use of these interventions is guided by general medical and surgical principles.

PREVENTION AND CONTROL

Transmission of schistosomiasis is dependent on human behavior. Since the geographic distribution of infections in endemic regions of the world is not clearly demarcated, it is prudent for travelers to avoid contact with all freshwater bodies, irrespective of the speed of water flow or unsubstantiated claims of safety. Some topical agents, when applied to skin, may inhibit cercarial penetration, but none is currently available. If exposure occurs, a follow-up visit with a health care provider is strongly recommended. Prevention of infection in inhabitants of endemic areas is a significant challenge. Residents of these regions use freshwater bodies for sanitary, domestic, recreational, and agricultural purposes. Several control measures have been used, including application of molluscicides, provision of sanitary water and sewage disposal, chemotherapy, and health education. Current recommendations to countries endemic for schistosomiasis emphasize the use of multiple approaches. With the advent of an oral, safe, and effective antischistosomal agent, chemotherapy has been most successful in reducing intensity of infection and reversing disease. The duration of this positive impact depends on transmission dynamics of the parasite in any specific endemic region. The ultimate goal of research on prevention and control is development of a vaccine. Although there are a few promising leads, this goal is probably not within reach during the next decade or so.

TABLE 212-2 DRUG THERAPY FOR HUMAN TREMATODE INFECTIONS

Infection	Drug of Choice	Adult Dose and Duration
Blood Flukes		
S. mansoni, S. intercalatum, S. haematobium	Praziquantel	20 mg/kg, 2 doses in 1 day
S. japonicum, S. mekongi	Praziquantel	20 mg/kg, 3 doses in 1 day
Biliary (Hepatic) Flukes		
C. sinensis, O. viverrini, O. felineus	Praziquantel	25 mg/kg, 3 doses in 1 day
F. hepatica, F. gigantica	Triclabendazole	10 mg/kg once
Intestinal Flukes		
F. buski, H. heterophyes	Praziquantel	25 mg/kg, 3 doses in 1 day
Lung Flukes		
P. westermani	Praziquantel	25 mg/kg, 3 doses per day for 2 days

LIVER (BILIARY) FLUKES

Several species of biliary fluke infecting humans are particularly common in Southeast Asia and Russia. Other species are transmitted in Europe, Africa, and the Americas. On the basis of their migratory pathway in humans, these infections may be divided into the *Clonorchis* and *Fasciola* groups (Table 212-1).

CLONORCHIASIS AND OPISTHORCHIASIS

Infection with *Clonorchis sinensis*, the Chinese or oriental fluke, is endemic among fish-eating mammals in Southeast Asia. Humans are an incidental host; the prevalence of human infection is highest in China, Vietnam, and Korea. Infection with *Opisthorchis viverrini* and *O. felineus* is zoonotic in cats and dogs. Transmission to humans occurs occasionally, particularly in Thailand (*O. viverrini*) and in Southeast Asia and eastern Europe (*O. felineus*). Data on the exact geographic distribution of these infectious agents in human populations are rudimentary.

Infection with any of these three species is established by ingestion of raw or inadequately cooked freshwater fish harboring metacercariae. These organisms excyst in the duodenum, releasing larvae that travel through the ampulla of Vater and mature into adult worms in bile canaliculi. Mature flukes are flat and elongated, measuring 1–2 cm in length. The hermaphroditic worms reproduce by releasing small operculated eggs, which pass with bile into the intestines and are voided with stools. The life cycle is completed in the environment in specific freshwater snails (the first intermediate host) and encystment of metacercariae in freshwater fish.

Except for late sequelae, the exact clinical syndromes caused by clonorchiasis and opisthorchiasis are not well defined. Since most in-

fected individuals harbor a low worm burden, many are asymptomatic. Moderate to heavy infection may be associated with vague right-upper-quadrant pain. In contrast, chronic or repeated infection is associated with manifestations such as cholangitis, cholangiohepatitis, and biliary obstruction. Cholangiocarcinoma is epidemiologically related to *C. sinensis* infection in China and to *O. viverrini* infection in northeastern Thailand. This association has resulted in classification of these infectious agents as human carcinogens.

FASCIOLIASIS

Infections with *Fasciola hepatica* and *F. gigantica* are worldwide zoonoses that are particularly endemic in sheep-raising countries. Human cases have been reported in South America, Europe, Africa, Australia, and the Far East. Recent estimates indicate a worldwide prevalence of 17 million cases. High endemicity has been reported in certain areas of Peru and Bolivia. In most endemic areas the predominant species is *F. hepatica*, but in Asia and Africa a varying degree of overlap with *F. gigantica* has been observed.

Humans acquire fascioliasis by ingestion of metacercariae attached to certain aquatic plants, such as watercress. Infection may also be acquired by consumption of contaminated water or ingestion of food items washed with such water. Acquisition of human infection through consumption of freshly prepared raw liver containing immature flukes has been reported. Infection is initiated when metacercariae excyst, penetrate the gut wall, and travel through the peritoneal cavity to invade the liver capsule. Adult worms finally reach bile ducts, where they produce large operculated eggs, which are voided in bile through the gastrointestinal tract to the outside environment. The flukes' life cycle is completed in specific snails (the first intermediate host) and encystment on aquatic plants.

Clinical features of fascioliasis relate to the stage and intensity of infection. Acute disease develops during parasite migration (1–2 weeks after infection) and includes fever, right-upper-quadrant pain, hepatomegaly, and eosinophilia. CT of the liver may show migratory tracks. Symptoms and signs usually subside as the parasites reach their final habitat. In individuals with chronic infection, bile duct obstruction and biliary cirrhosis are infrequently demonstrated. No relation to hepatic malignancy has been ascribed to fascioliasis.

DIAGNOSIS

Diagnosis of infection with any of the biliary flukes depends on a high degree of suspicion, elicitation of an appropriate geographic history, and stool examination for characteristically shaped parasite ova. Additional evidence may be obtained by documenting peripheral blood eosinophilia or imaging the liver. Serologic testing is helpful, particularly in lightly infected individuals.

BILIARY FLUKES

Drug therapy (praziquantel or triclabendazole) is summarized in Table 212-2. Patients with anatomic lesions in the biliary tract or malignancy are managed according to general medical guidelines.

INTESTINAL FLUKES

Two species of intestinal flukes cause human infection in defined geographic areas worldwide (Table 212-1). The large *Fasciolopsis buski* (adults measure 2 × 7 cm) is endemic in Southeast Asia, while the smaller *Heterophyes heterophyes* is found in the Nile Delta of Egypt and in the Far East. Infection is initiated by ingestion of metacercariae attached to aquatic plants (*F. buski*) or encysted in freshwater or brackish-water fish (*H. heterophyes*). Flukes mature in human intestines, and eggs are passed with stools. Most individuals infected with intestinal flukes are asymptomatic. In heavy *F. buski* infection, diarrhea, abdominal pain, and malabsorption may be encountered. Heavy infection with *H. heterophyes* may be associated with abdominal pain and mucous diarrhea. Diagnosis is established by detection of characteristically shaped ova in stool samples. The drug of choice for treatment is praziquantel (Table 212-2).

LUNG FLUKES

Infection with the lung fluke *Paragonimus westermani* (Table 212-1) and related species (e.g., *P. africanus*) is endemic in many parts of the world, excluding North America and Europe. Endemicity is particularly noticeable in West Africa, Central and South America, and Asia. In nature, the reservoir hosts of *P. westermani* are wild and domestic felines. In Africa, *P. africanus* has been found in other species, such as dogs. Adult lung flukes, which are 7–12 mm in length, are found encapsulated in the lungs of infected persons. In rare circumstances, flukes are found encysted in the CNS (cerebral paragonimiasis) or abdominal cavity. Humans acquire lung fluke infection by ingesting infective metacercariae encysted in the muscles and viscera of crayfish and freshwater crabs. In endemic areas, these crustaceans are consumed either raw or pickled. Once the organisms reach the duodenum, they excyst, penetrate the gut wall, and travel through the peritoneal cavity, diaphragm, and pleural space to reach the lungs. Mature flukes are found in the bronchioles surrounded by cystic lesions. Parasite eggs are either expectorated with sputum or swallowed and passed to the outside environment with feces. The life cycle is completed in snails and freshwater crustacea.

When maturing flukes lodge in lung tissues, they cause hemorrhage and necrosis, resulting in cyst formation. The adjacent lung parenchyma shows evidence of inflammatory infiltration, predominantly by eosinophils. Cysts usually measure 1–2 cm in diameter and may contain one or two worms each. With the onset of oviposition, cysts usually rupture in adjacent bronchioles—an event allowing ova to exit the human host. Older cysts develop thickened walls, which may undergo calcification. During the active phase of paragonimiasis, lung tissues surrounding parasite cysts may contain evidence of pneumonia, bronchitis, bronchiectasis, and fibrosis.

Pulmonary paragonimiasis is particularly symptomatic in persons with moderate to heavy infection. Productive cough with brownish sputum or frank hemoptysis associated with peripheral blood eosinophilia is usually the presenting feature. Chest examination may reveal signs of pleurisy. In chronic cases, bronchitis or bronchiectasis may predominate, but these conditions rarely proceed to lung abscess. Imaging of the lungs demonstrates characteristic features, including patchy densities, cavities, pleural effusion, and ring shadows. Cerebral paragonimiasis presents as either space-occupying lesions or epilepsy.

DIAGNOSIS

Pulmonary paragonimiasis is diagnosed by detection of parasite ova in sputum and/or stools. Serology is of considerable help in egg-negative cases and in cerebral paragonimiasis.

LUNG FLUKES

The drug of choice for treatment is praziquantel (Table 212-2). Other medical or surgical management may be needed for pulmonary or cerebral lesions.

CONTROL AND PREVENTION OF TISSUE FLUKES

For residents of nonendemic areas who are visiting an endemic region, the only effective preventive measure is to avoid ingestion of local plants, fish, or crustaceans; if their ingestion is necessary, these items should be washed or cooked thoroughly. Instruction on water and food preparation and consumption should be included in physicians' advice to travelers (Chap. 117). Interruption of transmission among residents of endemic areas depends on avoiding ingestion of infective stages and disposing of feces and sputum appropriately to prevent hatching of eggs in the environment. These two approaches rely greatly on socioeconomic development and health education. In countries where economic progress has resulted in financial and social improvements, transmission has decreased. The third approach to control in endemic communities entails selective use of chemotherapy for individuals posing the highest risk of transmission—i.e., those with heavy infections. The availability of praziquantel—a broad-spectrum, safe, and effective anthel-

mintic agent—provides a means for reducing the reservoirs of infection in human populations. However, the existence of most of these helminths as zoonoses in several animal species complicates control efforts.

213 Cestodes

A. Clinton White, Jr., Peter F. Weller

Cestodes, or tapeworms, are segmented worms. The adults reside in the gastrointestinal tract, but the larvae can be found in almost any organ. Human tapeworm infections can be divided into two major clinical groups. In one group, humans are the definitive hosts, with the adult tapeworms living in the gastrointestinal tract (*Taenia saginata*, *Diphyllobothrium*, *Hymenolepis*, and *Dipylidium caninum*). In the other, humans are intermediate hosts, with larval-stage parasites present in the tissues; diseases in this category include echinococcosis, sparganosis, and coenurosis. For *Taenia solium*, the human may be either the definitive or the intermediate host.

The ribbon-shaped tapeworm attaches to the intestinal mucosa by means of sucking cups or hooks located on the scolex. Behind the scolex is a short, narrow neck from which proglottids (segments) form. As each proglottid matures, it is displaced further back from the neck by the formation of new, less mature segments. The progressively elongating chain of attached proglottids, called the *strobila*, constitutes the bulk of the tapeworm. The length varies among species. In some, the tapeworm may consist of more than 1000 proglottids and may be several meters long. The mature proglottids are hermaphroditic and produce eggs, which are subsequently released. Since eggs of the different *Taenia* species are morphologically identical, differences in the morphology of the scolex or proglottids provide the basis for diagnostic identification to the species level.

Most human tapeworms require at least one intermediate host for complete larval development. After ingestion of the eggs or proglottids by an intermediate host, the larval oncospheres are activated, escape the egg, and penetrate the intestinal mucosa. The oncosphere migrates to tissues and develops into an encysted form known as a *cysticercus* (single scolex), a *coenurus* (multiple scolices), or a *hydatid* (cyst with daughter cysts, each containing several protoscolices). Ingestion by the definitive host of tissues containing a cyst enables a scolex to develop into a tapeworm.

TAENIASIS SAGINATA

The beef tapeworm *T. saginata* occurs in all countries where raw or undercooked beef is eaten. It is most prevalent in sub-Saharan African and Middle Eastern countries. *T. saginata asiatica* is a variant of *T. saginata* that is found in Asia and for which pigs are the intermediate host.

Etiology and Pathogenesis Humans are the only definitive host for the adult stage of *T. saginata*. This tapeworm, which can reach 8 m in length, inhabits the upper jejunum and has a scolex with four prominent suckers and 1000–2000 proglottids. Each gravid segment has 15–30 uterine branches (in contrast to 8–12 for *T. solium*). The eggs are indistinguishable from those of *T. solium*; they measure 30–40 μm, contain the oncosphere, and have a thick brown striated shell. Eggs deposited on vegetation can live for months or years until they are ingested by cattle or other herbivores. The embryo released after ingestion invades the intestinal wall and is carried to striated muscle, where it transforms into a cysticercus. When ingested in raw or undercooked beef, this form can infect humans. After the cysticercus is ingested, it takes ~2 months for the mature adult worm to develop.

Clinical Manifestations Patients become aware of the infection most commonly by noting passage of proglottids in their feces. The proglottids are often motile, and patients may experience perianal discomfort when proglottids are discharged. Mild abdominal pain or discomfort, nausea, change in appetite, weakness, and weight loss can occur with *T. saginata* infection.

Diagnosis The diagnosis is made by the detection of eggs or proglottids in the stool. Eggs may also be present in the perianal area; thus, if proglottids or eggs are not found in the stool, the perianal region should be examined with use of a cellophane-tape swab (as in pinworm infection; Chap. 210). Distinguishing *T. saginata* from *T. solium* requires examination of mature proglottids or the scolex. Serologic tests are not helpful diagnostically. Eosinophilia and elevated levels of serum IgE may be detected.

℞ TAENIASIS SAGINATA

A single dose of praziquantel (10 mg/kg) is highly effective.

Prevention The major method of preventing infection is the adequate cooking of beef; exposure to temperatures as low as 56°C for 5 min will destroy cysticerci. Refrigeration or salting for long periods or freezing at –10°C for 9 days also kills cysticerci in beef. General preventive measures include inspection of beef and proper disposal of human feces.

TAENIASIS SOLIUM AND CYSTICERCOSIS

The pork tapeworm *T. solium* can cause two distinct forms of infection in humans: adult tapeworms in the intestine or larval forms in the tissues (cysticercosis). Humans are the only definitive hosts for *T. solium*; pigs are the usual intermediate hosts, although other animals may harbor the larval forms.

T. solium exists worldwide but is most prevalent in Latin America, sub-Saharan Africa, China, southern and Southeast Asia, and eastern Europe. Cysticercosis occurs in industrialized nations largely as a result of the immigration of infected persons from endemic areas.

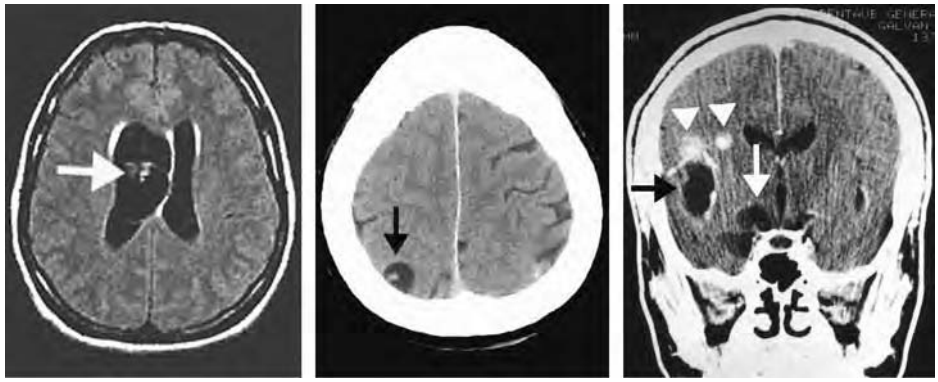

FIGURE 213-1 Neurocysticercosis is caused by *Taenia solium*. Neurologic infection can be classified on the basis of the location and viability of the parasites. When the parasites are in the ventricles, they often cause obstructive hydrocephalus. ***Left:*** MRI showing a cysticercus in the lateral ventricle, with resultant hydrocephalus. The arrow points to the scolex within the cystic parasite. ***Center:*** CT showing a parenchymal cysticercus, with enhancement of the cyst wall and an internal scolex (*arrow*). ***Right:*** Multiple cysticerci, including calcified lesions from prior infection (*arrowheads*), viable cysticerci in the basilar cisterns (*white arrow*), and a large degenerating cysticercus in the Sylvian fissure (*black arrow*). (*Modified with permission from JC Bandres et al: Clin Infect Dis 15:799, 1992. © The University of Chicago Press.*)

Etiology and Pathogenesis The adult tapeworm generally resides in the upper jejunum. The scolex attaches by both sucking disks and two rows of hooklets. Often only one adult worm is present, but that worm may live for years. The tapeworm, usually ~3 m in length, may have as many as 1000 proglottids, each of which produces up to 50,000 eggs. Groups of 3–5 proglottids are generally released and excreted into the feces, and the eggs in these proglottids are infective for both humans and animals. The eggs may survive in the environment for several months. After ingestion of eggs by the pig intermediate host, the larvae are activated, escape the egg, penetrate the intestinal wall, and are carried to many tissues, with a predilection for striated muscle of the neck, tongue, and trunk. Within 60–90 days, the encysted larval stage develops. These cysticerci can survive for months to years. By ingesting undercooked pork containing cysticerci, humans acquire infections that lead to intestinal tapeworms. Infections that cause human cysticercosis follow the ingestion of *T. solium* eggs, usually from close contact with a tapeworm carrier. Autoinfection may occur if an individual with an egg-producing tapeworm ingests eggs derived from his or her own feces.

Clinical Manifestations Intestinal infections with *T. solium* may be asymptomatic. Fecal passage of proglottids may be noted by patients. Other symptoms are infrequent.

In cysticercosis, the clinical manifestations are variable. Cysticerci can be found anywhere in the body but are most commonly detected in the brain, cerebrospinal fluid (CSF), skeletal muscle, subcutaneous tissue, or eye. The clinical presentation of cysticercosis depends on the number and location of cysticerci as well as the extent of associated inflammatory responses or scarring. Neurologic manifestations are the most common (Fig. 213-1). Seizures are associated with inflammation surrounding cysticerci in the brain parenchyma. These seizures may be generalized, focal, or Jacksonian. Hydrocephalus results from obstruction of CSF flow by cysticerci and accompanying inflammation or by CSF outflow obstruction from arachnoiditis. Signs of increased intracranial pressure, including headache, nausea, vomiting, changes in vision, dizziness, ataxia, or confusion, are often evident. Patients with hydrocephalus may develop papilledema or display altered mental status. When cysticerci develop at the base of the brain or in the subarachnoid space, they may cause chronic meningitis or arachnoiditis, communicating hydrocephalus, or strokes.

Diagnosis The diagnosis of intestinal *T. solium* infection is made by the detection of eggs or proglottids, as described for *T. saginata*. In cysticercosis, diagnosis can be difficult. A consensus conference has delineated absolute, major, minor, and epidemiologic criteria for diagnosis (Table 213-1). Diagnostic certainty is possible only with definite demonstration of the parasite (absolute criteria). This task can be accomplished by histologic observation of the parasite in excised tissue, by funduscopic visualization of the parasite in the eye (in the anterior chamber, vitreous, or subretinal spaces), or by neuroimaging studies demonstrating cystic lesions containing a characteristic scolex. In most cases, diagnostic certainty is not possible. Instead, a clinical diagnosis is made on the basis of a combination of clinical presentation, radiographic studies, serologic tests, and exposure history.

Neuroimaging findings suggestive of neurocysticercosis constitute the primary major diagnostic criterion. These findings include cystic lesions with or without enhancement (e.g., ring enhancement), one or more nodular calcifications (which may also have associated enhancement), or focal enhancing lesions. Cysticerci in the brain parenchyma are usually 5–20 mm in diameter and rounded. Cystic lesions in the subarachnoid space or fissures may enlarge up to 6 cm in diameter and may be lobulated. For cysticerci within the subarachnoid space or ventricles, the walls may be very thin and the cyst fluid is often isodense with CSF. Thus, obstructive hydrocephalus or enhancement of the basilar meninges may be the only finding on CT in extraparenchymal neurocysticercosis. Cysticerci in the ventricles or subarachnoid space are usually visible to an experienced neuroradiologist on MRI or on CT with intraventricular contrast injection. CT is more sensitive than MRI in identifying calcified lesions, whereas MRI is better for identifying cystic lesions and enhancement.

The second major diagnostic criterion is detection of specific antibodies to cysticerci. While most tests employing unfractionated antigen have high rates of false-positive and false-negative results, this problem

TABLE 213-1 DIAGNOSTIC CRITERIA FOR HUMAN CYSTICERCOSIS[a]

1. Absolute criteria
   a. Demonstration of cysticerci by histologic or microscopic examination of biopsy material
   b. Visualization of the parasite in the eye by funduscopy
   c. Neuroradiologic demonstration of cystic lesions containing a characteristic scolex
2. Major criteria
   a. Neuroradiologic lesions suggestive of neurocysticercosis
   b. Demonstration of antibodies to cysticerci in serum by enzyme-linked immunoelectrotransfer blot
   c. Resolution of intracranial cystic lesions spontaneously or after therapy with albendazole or praziquantel alone
3. Minor criteria
   a. Lesions compatible with neurocysticercosis detected by neuroimaging studies
   b. Clinical manifestations suggestive of neurocysticercosis
   c. Demonstration of antibodies to cysticerci or cysticercal antigen in cerebrospinal fluid by ELISA
   d. Evidence of cysticercosis outside the central nervous system (e.g., cigar-shaped soft tissue calcifications)
4. Epidemiologic criteria
   a. Residence in a cysticercosis-endemic area
   b. Frequent travel to a cysticercosis-endemic area
   c. Household contact with an individual infected with *Taenia solium*

[a]Diagnosis is confirmed by either one absolute criterion or a combination of two major criteria, one minor criterion, and one epidemiologic criterion. A probable diagnosis is supported by the fulfillment of (1) one major criterion plus two minor criteria; (2) one major criterion plus one minor criterion and one epidemiologic criterion; or (3) three minor criteria plus one epidemiologic criterion.

Note: ELISA, enzyme-linked immunosorbent assay.

Source: Modified from Del Brutto et al.

can be overcome by using the more specific immunoblot assay. An immunoblot assay using lentil-lectin purified glycoproteins has >99% specificity and is highly sensitive. However, patients with single intracranial lesions or with calcifications may be seronegative. With this assay, serum samples provide greater diagnostic sensitivity than CSF. All of the diagnostic antigens have been cloned, and enzyme-linked immunosorbent assays (ELISAs) using recombinant antigens are being developed. Antigen detection assays employing monoclonal antibodies to detect parasite antigen in the blood or spinal fluid may also facilitate diagnosis. However, these assays are not widely available.

Studies have demonstrated that clinical criteria can aid in the diagnosis in selected cases. In patients from endemic areas who had single enhancing lesions presenting with seizures, a normal physical examination, and no evidence of systemic disease (e.g., no fever, adenopathy, or abnormal chest radiograph), the constellation of rounded CT lesions 5–20 mm in diameter with no midline shift was almost always caused by neurocysticercosis. Finally, spontaneous resolution or resolution after therapy with albendazole alone is consistent with neurocysticercosis.

Minor diagnostic criteria include neuroimaging findings consistent with but less characteristic of cysticercosis, clinical manifestations suggestive of neurocysticercosis (e.g., seizures, hydrocephalus, or altered mental status), evidence of cysticercosis outside the central nervous system (CNS; e.g., cigar-shaped soft tissue calcifications), or detection of antibody in CSF by ELISA. Epidemiologic criteria include exposure to a tapeworm carrier or household member infected with *T. solium*, current or prior residence in an endemic area, and frequent travel to an endemic area.

Diagnosis is confirmed in patients with either one absolute criterion or a combination of two major criteria, one minor criterion, and one epidemiologic criterion (Table 213-1). A probable diagnosis is supported by the fulfillment of (1) one major criterion plus two minor criteria; (2) one major criterion plus one minor criterion and one epidemiologic criterion; or (3) three minor criteria plus one epidemiologic criterion. While the CSF is usually abnormal in neurocysticercosis, CSF abnormalities are not pathognomonic. Patients may have CSF pleocytosis with a predominance of lymphocytes, neutrophils, or eosinophils. The protein level in CSF may be elevated; the glucose concentration is usually normal but may be depressed.

Rx TAENIASIS SOLIUM AND CYSTICERCOSIS

Intestinal *T. solium* infection is treated with a single dose of praziquantel (10 mg/kg). However, praziquantel occasionally evokes an inflammatory response in the CNS if concomitant cryptic cysticercosis is present. Niclosamide (2 g) is also effective but is not widely available.

The initial management of neurocysticercosis should focus on symptom-based treatment of seizures or hydrocephalus. Seizures can usually be controlled with antiepileptic treatment. If parenchymal lesions resolve without development of calcifications and patients remain free of seizures, antiepileptic therapy can usually be discontinued after 1–2 years. Placebo-controlled trials are beginning to clarify the clinical advantage of antiparasitic drugs for parenchymal neurocysticercosis. Trends toward faster resolution of neuroradiologic abnormalities have been observed in most studies. The clinical benefits are less dramatic and consist mainly of shortening the period during which recurrent seizures occur and decreasing the number of patients who have many recurrent seizures. For the treatment of patients with brain parenchymal cysticerci, most authorities favor antiparasitic drugs, including praziquantel (50–60 mg/kg daily in three divided doses for 15–30 days) or albendazole (15 mg/kg per day for 8–28 days). Both agents may exacerbate the inflammatory response around the dying parasite, thereby exacerbating seizures or hydrocephalus as well. Thus, patients receiving these drugs should be carefully monitored, and high-dose glucocorticoids should be used during treatment. Since glucocorticoids induce first-pass metabolism of praziquantel and may decrease its antiparasitic effect, cimetidine should be coadministered to inhibit praziquantel metabolism.

For patients with hydrocephalus, the emergent reduction of intracranial pressure is the mainstay of therapy. In the case of obstructive hydrocephalus, the preferred approach is removal of the cysticercus via endoscopic surgery. However, this intervention is not always possible. An alternative approach is initially to perform a diverting procedure, such as ventriculoperitoneal shunting. Historically, shunts have usually failed, but low failure rates have been attained with administration of antiparasitic drugs and glucocorticoids. Open craniotomy to remove cysticerci is now required only infrequently. For patients with subarachnoid cysts or giant cysticerci, glucocorticoids are needed to reduce arachnoiditis and accompanying vasculitis. Most authorities recommend prolonged courses of antiparasitic drugs and shunting when hydrocephalus is present. In patients with diffuse cerebral edema and elevated intracranial pressure due to multiple inflamed lesions, glucocorticoids are the mainstay of therapy, and antiparasitic drugs should be avoided. For ocular and spinal medullary lesions, drug-induced inflammation may cause irreversible damage. Most patients should be managed surgically, although case reports have described cures with medical therapy.

Prevention Measures for the prevention of intestinal *T. solium* infection consist of the application to pork of precautions similar to those described above for beef with regard to *T. saginata* infection. The prevention of cysticercosis involves minimizing the opportunities for ingestion of fecally derived eggs by means of good personal hygiene, effective fecal disposal, and treatment and prevention of human intestinal infections. Mass chemotherapy has been administered to human and porcine populations in efforts at disease eradication.

ECHINOCOCCOSIS

Echinococcosis is an infection caused in humans by the larval stage of the *Echinococcus granulosus* complex, *E. multilocularis*, or *E. vogeli*. *E. granulosus* complex parasites, which produce unilocular cystic lesions, are prevalent in areas where livestock is raised in association with dogs.

These parasites are found on all continents, with areas of high prevalence in China, central Asia, the Middle East, the Mediterranean region, eastern Africa, and parts of South America. Molecular evidence suggests that *E. granulosus* strains may actually belong to more than one species; specifically, strains from sheep, cattle, pigs, horses, and camels probably represent separate species. *E. multilocularis*, which causes multilocular alveolar lesions that are locally invasive, is found in Alpine, sub-Arctic, or Arctic regions, including Canada, the United States, and central and northern Europe; China; and central Asia. *E. vogeli* causes polycystic hydatid disease and is found only in Central and South America.

Like other cestodes, echinococcal species have both intermediate and definitive hosts. The definitive hosts are canines that pass eggs in their feces. After the ingestion of eggs, cysts develop in the intermediate hosts—sheep, cattle, humans, goats, camels, and horses for the *E. granulosus* complex and mice and other rodents for *E. multilocularis*. When a dog (*E. granulosus*) or fox (*E. multilocularis*) ingests infected meat containing cysts, the life cycle is completed.

Etiology The small (5-mm-long) adult *E. granulosus* worm, which lives for 5–20 months in the jejunum of dogs, has only three proglottids: one immature, one mature, and one gravid. The gravid segment splits to release eggs that are morphologically similar to *Taenia* eggs and are extremely hardy. After humans ingest the eggs, embryos escape from the eggs, penetrate the intestinal mucosa, enter the portal circulation, and are carried to various organs, most commonly the liver and lungs. Larvae develop into fluid-filled unilocular hydatid cysts that consist of an external membrane and an inner germinal layer. Daughter cysts develop from the inner aspect of the germinal layer, as do germinating cystic structures called *brood capsules*. New larvae, called *protoscolices*, develop in large numbers within the brood capsule. The cysts expand slowly over a period of years.

The life cycle of *E. multilocularis* is similar except that wild canines, such as foxes, serve as the definitive hosts and small rodents serve as the intermediate hosts. The larval form of *E. multilocularis*, however, is quite different in that it remains in the proliferative phase, the parasite is always multilocular, and vesicles without brood capsule or protoscolices progressively invade the host tissue by peripheral extension of processes from the germinal layer.

Clinical Manifestations Slowly enlarging echinococcal cysts generally remain asymptomatic until their expanding size or their space-occupying effect in an involved organ elicits symptoms. The liver and the lungs are the most common sites of these cysts. The liver is involved in about two-thirds of *E. granulosus* infections and in nearly all *E. multilocularis* infections. Since a period of years elapses before cysts enlarge sufficiently to cause symptoms, they may be discovered incidentally on a routine x-ray or ultrasound study.

Patients with hepatic echinococcosis who are symptomatic most often present with abdominal pain or a palpable mass in the right upper quadrant. Compression of a bile duct or leakage of cyst fluid into the biliary tree may mimic recurrent cholelithiasis, and biliary obstruction can result in jaundice. Rupture of or episodic leakage from a hydatid cyst may produce fever, pruritus, urticaria, eosinophilia, or anaphylaxis. Pulmonary hydatid cysts may rupture into the bronchial tree or peritoneal cavity and produce cough, dyspnea, chest pain, or hemoptysis. Rupture of hydatid cysts, which can occur spontaneously or at surgery, may lead to multifocal dissemination of protoscolices, which can form additional cysts. Other presentations are due to the involvement of bone (invasion of the medullary cavity with slow bone erosion producing pathologic fractures), the CNS (space-occupying lesions), the heart (conduction defects, pericarditis), and the pelvis (pelvic mass).

The larval forms of *E. multilocularis* characteristically present as a slowly growing hepatic tumor, with progressive destruction of the liver and extension into vital structures. Patients commonly report upper quadrant and epigastric pain. Liver enlargement and obstructive jaundice may be apparent. The lesions may infiltrate adjoining organs (e.g., diaphragm, kidneys, or lungs) or may metastasize to the spleen, lungs, or brain.

Diagnosis Radiographic and related imaging studies are important in detecting and evaluating echinococcal cysts. Plain films will define pulmonary cysts of *E. granulosus*—usually as rounded masses of uniform density—but may miss cysts in other organs unless there is cyst wall calcification (as occurs in the liver). MRI, CT, and ultrasound reveal well-defined cysts with thick or thin walls. When older cysts contain a layer of hydatid sand that is rich in accumulated protoscolices, these imaging methods may detect this fluid layer of different density. However, the most pathognomonic finding, if demonstrable, is that of daughter cysts within the larger cyst. This finding, like eggshell or mural calcification on CT, is indicative of *E. granulosus* infection and helps to distinguish the cyst from carcinomas, bacterial or amebic liver abscesses, or hemangiomas. In contrast, ultrasound or CT of alveolar hydatid cysts reveals indistinct solid masses with central necrosis and plaquelike calcifications.

A specific diagnosis of *E. granulosus* infection can be made by the examination of aspirated fluids for protoscolices or hooklets, but diagnostic aspiration is not usually recommended because of the risk of fluid leakage resulting in either dissemination of infection or anaphylactic reactions. Serodiagnostic assays can be useful, although a negative test does not exclude the diagnosis of echinococcosis. Cysts in the liver elicit positive antibody responses in ~90% of cases, whereas up to 50% of individuals with cysts in the lungs are seronegative. Detection of antibody to specific echinococcal antigens by immunoblotting has the highest degree of specificity.

℞ ECHINOCOCCOSIS

Therapy for cystic echinococcosis is based on considerations of the size, location, and manifestations of cysts and the overall health of the patient. Surgery has traditionally been the principal definitive method of treatment. Currently, ultrasound staging is recommended for *E. granulosus* infections **(Fig. 213-2)**. For CE1 lesions, uncomplicated CE3 lesions, and some CE2 lesions, PAIR (*p*ercutaneous *a*spiration, *i*nfusion of scolicidal agents, and *r*easpiration) is now recommended instead of surgery. PAIR is contraindicated for superficially located cysts (because of the risk of rupture), for cysts with multiple thick internal septal divisions (honeycombing pattern), and for cysts communicating with the biliary tree. For prophylaxis of secondary peritoneal echinococcosis due to inadvertent spillage of fluid during PAIR, the administration of albendazole (15 mg/kg daily in two divided doses) should be initiated at least 4 days before the procedure and continued for at least 4 weeks afterward. Ultrasound- or CT-guided aspiration allows confirmation of the diagnosis by demonstration of protoscolices in the aspirate. After aspiration, contrast material should be injected to detect occult communications with the biliary tract. Alternatively, the fluid should be checked for bile staining by dipstick. If no bile is found and no communication visualized, the contrast material is reaspirated, with subsequent infusion of scolicidal agents (usually 95% ethanol; alternatively, hypertonic saline). Daughter cysts within the primary cyst may need to be

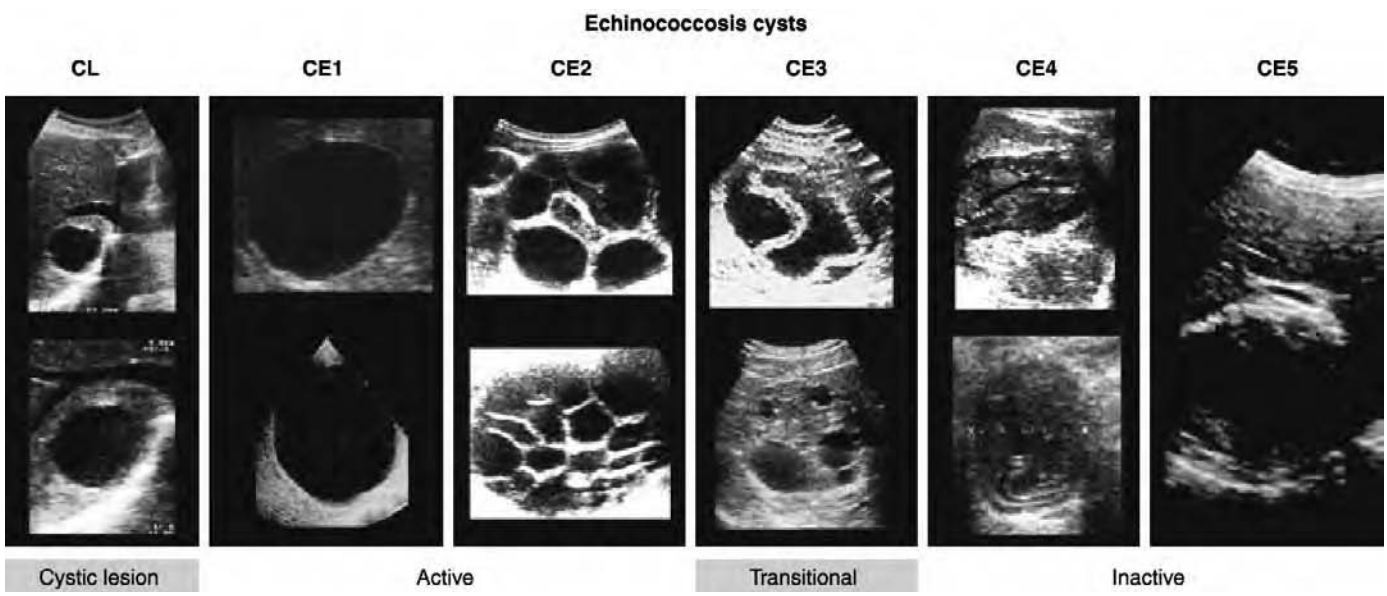

FIGURE 213-2 Management of cystic hydatid disease caused by *Echinococcus granulosus* should be based on viability of the parasite, which can be estimated from radiographic appearance. The ultrasound appearance includes lesions classified as active, transitional, and inactive. *Active* cysts include types CL (with a cystic lesion and no visible cyst wall), CE1 [with a visible cyst wall and internal echoes (snowflake sign)], and CE2 (with a visible cyst wall and internal septation). *Transitional cysts* (CE3) may have detached laminar membranes or may be partially collapsed. *Inactive cysts* include types CE4 (a nonhomogeneous mass) and CE5 (a cyst with a thick calcified wall). *[Adapted from RL Guerrant et al (eds): Tropical Infectious Diseases: Principles, Pathogens and Practice, 2d ed, p 1312. © 2005, with permission from Elsevier Science.]*

punctured separately. In experienced hands, this approach yields rates of cure and relapse equivalent to those following surgery, with less perioperative morbidity and shorter hospitalization.

Surgery remains the treatment of choice for complicated *E. granulosus* cysts (e.g., those communicating with the biliary tract) or for areas where PAIR is not possible. For *E. granulosus*, the preferred surgical approach is pericystectomy, in which the entire cyst and the surrounding fibrous tissue are removed. The risks posed by leakage of fluid during surgery or PAIR include anaphylaxis and dissemination of infectious protoscolices. The latter complication has been minimized by careful attention to the prevention of spillage of the cyst and by soaking of the drapes with hypertonic saline. Infusion of scolicidal agents is no longer recommended because of problems with hypernatremia, intoxication, or sclerosing cholangitis. Albendazole, which is active against *Echinococcus*, should be administered adjunctively, beginning several days before resection and continuing for several weeks for *E. granulosus*. Praziquantel (50 mg/kg daily for 2 weeks) may hasten the death of the protoscolices. Medical therapy with albendazole alone for 12 weeks to 6 months results in cure in ~30% of cases and in improvement in another 50%. In many instances of treatment failure, *E. granulosus* infections are subsequently treated successfully with PAIR or additional courses of medical therapy. Response to treatment is best assessed by serial imaging studies, with attention to cyst size and consistency. Some cysts may not demonstrate complete radiologic resolution even though no viable protoscolices are present. Some of these cysts with partial radiologic resolution (e.g., CE4) can be managed with observation only.

Surgical resection remains the treatment of choice for *E. multilocularis* infection. Complete removal of the parasite continues to offer the best chance for cure. Ongoing therapy with albendazole for at least 2 years after presumptively curative surgery is recommended. Most cases are diagnosed at a stage at which complete resection is not possible; in these cases, albendazole treatment should be continued indefinitely, with careful monitoring. In some cases, liver transplantation has been used because of the size of the necessary liver resection. However, continuous immunosuppression favors the proliferation of *E. multilocularis* larvae and reinfection of the transplant. Thus, indefinite treatment with albendazole is required.

Prevention In endemic areas, echinococcosis can be prevented by administering praziquantel to infected dogs, by denying dogs access to infected animals, or by vaccinating sheep. Limitation of the number of stray dogs is helpful in reducing the prevalence of infection among humans.

HYMENOLEPIASIS NANA

Infection with *Hymenolepis nana*, the dwarf tapeworm, is the most common of all the cestode infections. *H. nana* is endemic in both temperate and tropical regions of the world. Infection is spread by fecal/oral contamination and is common among institutionalized children.

Etiology and Pathogenesis *H. nana* is the only cestode of humans that does not require an intermediate host. Both the larval and adult phases of the life cycle take place in the human. The adult—the smallest tapeworm parasitizing humans—is ~2 cm long and dwells in the proximal ileum. Proglottids, which are quite small and are rarely seen in the stool, release spherical eggs 30–44 µm in diameter, each of which contains an oncosphere with six hooklets. The eggs are immediately infective and are unable to survive for >10 days in the external environment. *H. nana* can also be acquired by the ingestion of infected insects (especially larval meal-worms and larval fleas). When the egg is ingested by a new host, the oncosphere is freed and penetrates the intestinal villi, becoming a cysticercoid larva. Larvae migrate back into the intestinal lumen, attach to the mucosa, and mature into adult worms over 10–12 days. Eggs may also hatch before passing into the stool, causing internal autoinfection with increasing numbers of intestinal worms. Although the life span of adult *H. nana* worms is only ~4–10 weeks, the autoinfection cycle perpetuates the infection.

Clinical Manifestations *H. nana* infection, even with many intestinal worms, is usually asymptomatic. When infection is intense, anorexia, abdominal pain, and diarrhea develop.

Diagnosis Infection is diagnosed by the finding of eggs in the stool.

℞ HYMENOLEPIASIS NANA

Praziquantel (25 mg/kg once) is the treatment of choice, since it acts against both the adult worms and the cysticercoids in the intestinal villi. Nitazoxanide (500 mg bid for 3 days) may be used as an alternative.

Prevention Good personal hygiene and improved sanitation can eradicate the disease. Epidemics have been controlled by mass chemotherapy coupled with improved hygiene.

HYMENOLEPIASIS DIMINUTA

Hymenolepis diminuta, a cestode of rodents, occasionally infects small children, who ingest the larvae in uncooked cereal foods contaminated by fleas and other insects in which larvae develop. Infection is usually asymptomatic and is diagnosed by the detection of eggs in the stool. Treatment with praziquantel results in cure in most cases.

DIPHYLLOBOTHRIASIS

Diphyllobothrium latum and other *Diphyllobothrium* species are found in the lakes, rivers, and deltas of the northern hemisphere, Central Africa, and Chile.

Etiology and Pathogenesis The adult worm—the longest tapeworm (up to 25 m)—attaches to the ileal and occasionally to the jejunal mucosa by its suckers, which are located on its elongated scolex. The adult worm has 3000–4000 proglottids, which release ~1 million eggs daily into the feces. If an egg reaches water, it hatches and releases a free-swimming embryo that can be eaten by small freshwater crustaceans (*Cyclops* or *Diaptomus* species). After an infected crustacean containing a developed procercoid is swallowed by a fish, the larva migrates into the fish's flesh and grows into a plerocercoid, or sparganum larva. Humans acquire the infection by ingesting infected raw or smoked fish. Within 3–5 weeks, the tapeworm matures into an adult in the human intestine.

Clinical Manifestations Most *D. latum* infections are asymptomatic, although manifestations may include transient abdominal discomfort, diarrhea, vomiting, weakness, and weight loss. Occasionally, infection can cause acute abdominal pain and intestinal obstruction; in rare cases, cholangitis or cholecystitis may be produced by migrating proglottids. Because the tapeworm absorbs large quantities of vitamin B_{12} and interferes with ileal B_{12} absorption, vitamin B_{12} deficiency can develop. Up to 2% of infected patients, especially the elderly, have megaloblastic anemia resembling pernicious anemia and may exhibit neurologic sequelae of B_{12} deficiency.

Diagnosis The diagnosis is made readily by the detection of the characteristic eggs in the stool. The eggs possess a single shell with an operculum at one end and a knob at the other. Mild to moderate eosinophilia may be detected.

℞ DIPHYLLOBOTHRIASIS

Praziquantel (5–10 mg/kg once) is highly effective. Parenteral vitamin B_{12} should be given if B_{12} deficiency is manifest.

Prevention Infection can be prevented by heating fish to 54°C for 5 min or by freezing it at –18°C for 24 h. Placing fish in brine with a high salt concentration for long periods kills the eggs.

DIPYLIDIASIS

Dipylidium caninum, a common tapeworm of dogs and cats, may accidentally infect humans. Dogs, cats, and occasionally humans become infected by ingesting fleas harboring cysticercoids. Children are more likely to become infected than adults. Most infections are asymptomatic, but abdominal pain, diarrhea, anal pruritus, urticaria, eosinophilia, or passage of segments in the stool may occur. The diagnosis is made by the

detection of proglottids or ova in the stool. As in *D. latum* infection, therapy consists of praziquantel. Prevention requires anthelmintic treatment and flea control for pet dogs or cats.

SPARGANOSIS

Humans can be infected by the sparganum, or plerocercoid larva, of a diphyllobothrid tapeworm of the genus *Spirometra*. Infection can be acquired by the consumption of water containing infected *Cyclops*; by the ingestion of infected snakes, birds, or mammals; or by the application of infected flesh as poultices. The worm migrates slowly in tissues, and infection commonly presents as a subcutaneous swelling. Periorbital tissues can be involved, and ocular sparganosis may destroy the eye. Surgical excision is used to treat localized sparganosis.

COENUROSIS

This rare infection of humans by the larval stage (coenurus) of the dog tapeworm *Taenia multiceps* or *T. serialis* results in a space-occupying cystic lesion. As in cysticercosis, involvement of the CNS and subcutaneous tissue is most common. Both definitive diagnosis and treatment require surgical excision of the lesion. Chemotherapeutic agents generally are not effective.

214 Microbial Bioterrorism

H. Clifford Lane, Anthony S. Fauci

Descriptions of the use of microbial pathogens as potential weapons of war or terrorism date from ancient times. Among the most frequently cited of such episodes are the poisoning of water supplies in the sixth century B.C. with the fungus *Claviceps purpurea* (rye ergot) by the Assyrians, the hurling of the dead bodies of plague victims over the walls of the city of Kaffa by the Tartar army in 1346, and the efforts by the British to spread smallpox via contaminated blankets to the native American population loyal to the French in 1767. Although the use of chemical weapons in wartime took place in the not-too-distant past (Chap. 215), the tragic events of September 11, 2001, followed closely by the anthrax attacks through the U.S. Postal System, dramatically changed the mindset of the American public regarding both our vulnerability to microbial bioterrorist attacks and the seriousness and intent of the Federal government to protect its citizens against future attacks. Modern science has revealed methods of deliberately spreading or enhancing disease in ways not appreciated by our ancestors. The combination of basic research, good medical practice, and constant vigilance will be needed to defend against such attacks.

Although the potential impact of a bioterrorist attack could be enormous, leading to thousands of deaths and extensive morbidity, acts of bioterrorism would be expected to produce their greatest impact through the fear and terror they generate. In contrast to biowarfare, where the primary goal is destruction of the enemy through mass casualties, an important goal of bioterrorism is to destroy the morale of a society through fear and uncertainty. While the actual biologic impact of a single act may be small, the degree of disruption created by the realization that such an attack is possible may be enormous. This was readily apparent with the impact on the U.S. Postal System and the functional interruption of the activities of the legislative branch of government following the anthrax attacks noted above. Thus, the key to the defense against these attacks is a highly functioning system of public health surveillance and education so that attacks can be quickly recognized and effectively contained. This is complemented by the availability of appropriate countermeasures in the form of diagnostics, therapeutics, and vaccines, both in response to and in anticipation of bioterrorist attacks.

The Working Group for Civilian Biodefense has put together a list of key features that characterize the elements of biologic agents that make them particularly effective as weapons (Table 214-1). Included among these are the ease of spread and transmission of the agent as well as the presence of an adequate database to allow newcomers to the field to quickly apply the good science of others to bad intentions of their own. Agents of bioterrorism may be used in their naturally occurring forms or they can be deliberately modified to provide maximal impact. Among the approaches to maximizing the deleterious effects of biologic agents are the genetic modification of microbes for the purposes of antimicrobial resistance or evasion by the immune system, creation of fine-particle aerosols, chemical treatment to stabilize and prolong infectivity, and alteration of host range through changes in surface proteins. Certain of these approaches fall under the category of *weaponization*, which is a term generally used to describe the processing of microbes or toxins in a manner that would ensure a devastating effect of a release. For example, weaponization of anthrax by the Soviets comprised the production of vast amounts of spores in a form that maintained aerosolization for prolonged periods of time; the spores were of appropriate size to reach the lower respiratory tract easily and could be delivered in a massive release, such as via widely dispersed bomblets.

The U.S. Centers for Disease Control and Prevention (CDC) classifies potential biologic threats into three categories, A, B, and C (Table 214-2). Category A agents are the highest-priority pathogens. They pose the greatest risk to national security because they (1) can be easily disseminated or transmitted from person to person, (2) result in high mortality rates and have the potential for major public health impact, (3) might cause public panic and social disruption, and (4) require special action for public health preparedness. Category B agents are the second highest priority pathogens and include those that are moderately easy to disseminate, result in moderate morbidity rates and low mortality rates, and require specifically enhanced diagnostic capacity. Category C agents are the third highest priority. These include certain emerging pathogens, to which the general population lacks immunity, that could be engineered for mass dissemination in the future because of availability, ease of production, ease of dissemination, potential for high morbidity and mortality, and major public health impact. A potential pandemic strain of influenza, such as avian influenza, is one such example. It should be pointed out, however, that these designations are empirical, and, depending on evolving circumstances such as intelligence-based threat assessments, the priority rating of any given microbe or toxin could change. The CDC classification system also largely reflects the severity of illness produced by a given agent, rather than its accessibility to potential terrorists.

TABLE 214-1 KEY FEATURES OF BIOLOGIC AGENTS USED AS BIOWEAPONS

1. High morbidity and mortality
2. Potential for person-to-person spread
3. Low infective dose and highly infectious by aerosol
4. Lack of rapid diagnostic capability
5. Lack of universally available effective vaccine
6. Potential to cause anxiety

TABLE 214-2 CDC CATEGORY A, B, AND C AGENTS

Category A
- Anthrax (*Bacillus anthracis*)
- Botulism (*Clostridium botulinum* toxin)
- Plague (*Yersinia pestis*)
- Smallpox (*Variola major*)
- Tularemia (*Francisella tularensis*)
- Viral hemorrhagic fevers
  - Arenaviruses: Lassa, New World (Machupo, Junin, Guanarito, and Sabia)
  - Bunyaviridae: Crimean Congo, Rift Valley
  - Filoviridae: Ebola, Marburg

Category B
- Brucellosis (*Brucella* spp.)
- Epsilon toxin of *Clostridium perfringens*
- Food safety threats (e.g., *Salmonella* spp., *Escherichia coli* 0157:H7, *Shigella*)
- Glanders (*Burkholderia mallei*)
- Melioidosis (*B. pseudomallei*)
- Psittacosis (*Chlamydophila psittaci*)
- Q fever (*Coxiella burnetii*)
- Ricin toxin from *Ricinus communis* (castor beans)
- Staphylococcal enterotoxin B
- Typhus fever (*Rickettsia prowazekii*)
- Viral encephalitis [alphaviruses (e.g., Venezuelan, eastern, and western equine encephalitis)]
- Water safety threats (e.g., *Vibrio cholerae*, *Cryptosporidium parvum*)

Category C
- Emerging infectious diseases threats such as Nipah, hantavirus, SARS coronavirus, and pandemic influenza.

Centers for Disease Control and Prevention and the National Institute of Allergy and Infectious Diseases.

***Bacillus anthracis* as a Bioweapon** Anthrax may be the prototypic disease of bioterrorism. Although rarely, if ever, spread from person to person, the illness embodies the other major features of a disease introduced through terrorism, as outlined in Table 214-1. U.S. and British government scientists studied anthrax as a potential biologic weapon beginning approximately at the time of World War II (WWII). Offensive bioweapons activity including bioweapons research on microbes and toxins in the United States ceased in 1969 as a result of two executive orders by President Richard M. Nixon. The 1972 Biological and Toxin Weapons Convention Treaty outlawed research of this type worldwide. Clearly, the Soviet Union was in direct violation of this treaty until at least the Union dissolved in the late 1980s. It is well documented that during this post-treaty period, the Soviets produced and stored tons of anthrax spores for potential use as a bioweapon. At present there is suspicion that research on anthrax as an agent of bioterrorism is ongoing by several nations and extremist groups. One example of this is the release of anthrax spores by the Aum Shrinrikyo cult in Tokyo in 1993. Fortunately, there were no casualties associated with this episode because of the inadvertent use of a nonpathogenic strain of anthrax by the terrorists.

The potential impact of anthrax spores as a bioweapon was clearly demonstrated in 1979 following the accidental release of spores into the atmosphere from a Soviet Union bioweapons facility in Sverdlosk, Russia. While actual figures are not known, at least 77 cases of anthrax were diagnosed with certainty, of which 66 were fatal. These victims were exposed in an area within 4 km downwind of the facility, and deaths due to anthrax were also noted in livestock up to 50 km further downwind. Based on recorded wind patterns, the interval between the time of exposure and development of clinical illness ranged from 2–43 days. The majority of cases were within the first 2 weeks. Death typically occurred within 1–4 days following the onset of symptoms. It is likely that the widespread use of postexposure penicillin prophylaxis limited the total number of cases. The extended period of time between exposure and disease in some individuals supports the data from nonhuman primate studies suggesting the anthrax spores can lie dormant in the respiratory tract for at least 4–6 weeks without evoking an immune response. This extended period of microbiologic latency following exposure poses a significant challenge for management of victims in the postexposure period.

In September 2001, the American public was exposed to anthrax spores as a bioweapon delivered through the U.S. Postal System. The CDC identified 22 confirmed or suspected cases of anthrax as a consequence of this attack. These included 11 patients with inhalational anthrax, of whom 5 died, and 11 patients with cutaneous anthrax (7 confirmed), all of whom survived (Fig. 214-1). Cases occurred in individuals who opened contaminated letters as well as in postal workers involved in the processing of mail. A minimum of five letters mailed from Trenton, NJ, served as the vehicles for these attacks. One of these letters was reported to contain 2 g of material, equivalent to 100 billion to 1 trillion weapon-grade spores. Since studies performed in the 1950s using monkeys exposed to aerosolized anthrax suggested that ~10,000 spores were required to produce lethal disease in 50% of animals exposed to this dose (the LD_{50}), the contents of one letter had the theoretical potential, under optimal conditions, of causing illness or death in up to 50 million individuals when one considers an LD_{50} of 10,000 spores. The strain used in this attack was the Ames strain. Although it was noted to have an inducible beta-lactamase and to constitutively express a cephalosporinase, it was susceptible to all antibiotics standard for *B. anthracis*.

Microbiology and Clinical Features Anthrax is caused by *B. anthracis*, a gram-positive, nonmotile, spore-forming rod that is found in soil and predominantly causes disease in herbivores such as cattle, goats, and sheep. Anthrax spores can remain viable for decades. The remarkable stability of these spores makes them an ideal bioweapon, and their destruction in decontamination activities can be a challenge. Naturally occurring human infection is generally the result of contact with anthrax-infected animals or animal products such as goat hair. While an LD_{50} of 10,000 spores is a generally accepted number it has also been suggested that as few as one to three spores may be adequate to cause disease in some settings. Advanced technology is likely to be necessary to generate spores of the optimal size (1–5 μm) to travel to the alveolar spaces as a bioweapon.

The three major clinical forms of anthrax are gastrointestinal, cutaneous, and inhalational. *Gastrointestinal anthrax* typically results from the ingestion of contaminated meat; the condition is rarely seen and is unlikely to be the result of a bioterrorism event. The lesion of *cutaneous an-*

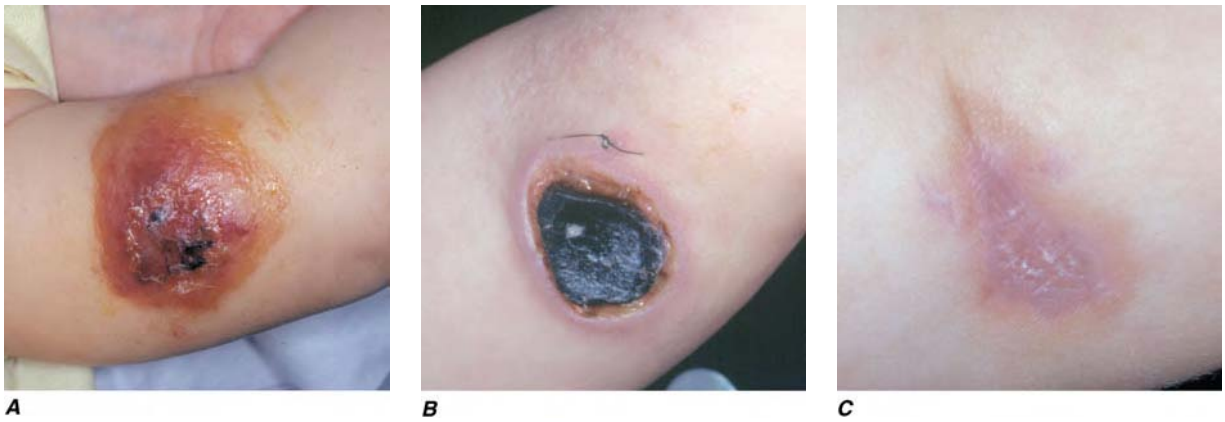

FIGURE 214-2 Clinical manifestations of a pediatric case of cutaneous anthrax associated with the bioterrorism attack of 2001. The lesion progresses from vesicular on day 5 ***(A)*** to necrotic with the classic black escar on day 12 ***(B)*** to a healed scar 2 months later ***(C)***. *(Photographs provided by Dr. Mary Wu Chang and (A) reprinted with permission of the New England Journal of Medicine.)*

thrax typically begins as a papule following the introduction of spores through an opening in the skin. This papule then evolves to a painless vesicle followed by the development of a coal-black, necrotic eschar (Fig. 214-2). It is the Greek word for coal (*anthrax*) that gives the organism and the disease its name. Cutaneous anthrax was ~20% fatal prior to the availability of antibiotics. *Inhalational anthrax* is the form most likely to be responsible for death in the setting of a bioterrorist attack. It occurs following the inhalation of spores that become deposited in the alveolar spaces. These spores are phagocytosed by macrophages and transported to the mediastinal and peribronchial lymph nodes where they germinate, leading to active bacterial growth and elaboration of the bacterial products edema toxin and lethal toxin. Subsequent hematogenous spread of bacteria is accompanied by cardiovascular collapse and death. The earliest symptoms are typically a viral-like prodrome with fever, malaise, and abdominal and/or chest symptoms that progress over the course of a few days to a moribund state. A characteristic finding is mediastinal widening and pleural effusions on chest x-ray (Fig. 214-3). While initially thought to be 100% fatal, the experiences at Sverdlosk in 1979 and in the United States in 2001 (see below) indicate that with prompt initiation of antibiotic therapy survival is possible. The characteristics of the 11 cases of inhalational anthrax diagnosed in the United States in 2001 following exposure to contaminated letters postmarked September 18 or October 9, 2001, followed the classic pattern established for this illness, with patients presenting with a rapidly progressive course characterized by fever, fatigue or malaise, nausea or vomiting, cough, and shortness of breath. At presentation, the total white blood cell counts were ~10,000 cells/μL; transaminases tended to be elevated, and all 11 had abnormal findings on chest x-ray and CT. Radiologic findings included infiltrates, mediastinal widening, and hemorrhagic pleural effusions. For cases in which the dates of exposure were known, symptoms appeared within 4–6 days. Death occurred within 7 days of diagnosis in the five fatal cases (overall mortality rate 55%). Rapid diagnosis and prompt initiation of antibiotic therapy were key to survival.

℞ ANTHRAX

Anthrax can be successfully treated if the disease is promptly recognized and appropriate therapy is initiated early. While penicillin, ciprofloxacin, and doxycycline are the currently licensed antibiotics for this indication, clindamycin and rifampin also have in vitro activity against the organism and have been used as part of treatment regimens. Until sensitivity results are known, suspected cases are best managed with a combination of broadly active agents **(Table 214-3)**. Patients with inhalational anthrax are not contagious and do not require special isolation procedures.

Vaccination and Prevention The first successful vaccine for anthrax was developed for animals by Louis Pasteur in 1881. At present, the single vaccine licensed for human use is a product produced from the cell-free culture supernatant of an attenuated, nonencapsulated strain of *B. anthracis* (Stern strain), referred to as *anthrax vaccine adsorbed* (AVA). Clinical trials for safety in humans and efficacy in animals are currently under way to evaluate the role of recombinant protective antigen (one of the major components, along with lethal factor and edema factor, of *B. anthracis* toxins) as an alternative to AVA. In a postexposure setting in non-human primates a 2-week course of AVA + ciprofloxacin was found to be superior to ciprofloxacin alone in preventing the development of clinical disease and death. While the current recommendation for postexposure prophylaxis is 60 days of antibiotics, it would seem prudent to include immunization with anthrax vaccine if available. Given the potential for *B. anthracis* to be engineered to express penicillin resistance, the empirical regimen of choice in this setting is either ciprofloxacin or doxycycline.

PLAGUE

***Yersinia pestis* as a Bioweapon** Although it lacks the environmental stability of anthrax, the highly contagious nature and high mortality of plague make it a close to ideal agent of bioterrorism, particularly if delivered in a weaponized form. Occupying a unique place in history, plague has been alleged to have been used as a biologic weapon for centuries. The catapulting of plague-infected corpses into besieged fortresses is a practice that was first noted in 1346 during the assault of the city of Kaffa by the Tartars. Although unlikely to have resulted in disease transmission, some believe that this event may have played a role in the start of the Black Death pandemic of the fourteenth and fifteenth centuries in Europe. Given that plague was already moving across Asia toward Europe at this time, it is unclear whether such an allegation is accurate. During WWII, the infamous Unit 731 of the Japanese army was reported to have repeatedly dropped plague-infested fleas over parts of China, including Manchuria. These drops were associated with subsequent outbreaks of plague in the targeted areas. Following WWII, the United States and the Soviet Union conducted programs of research on how to create aerosolized *Y. pestis* that could be used as a bioweapon to cause primary pneumonic plague. As mentioned above, plague was thought to be an excellent bioweapon due to the fact that in addition to causing infection in those inhaling the aerosol, significant numbers of secondary cases of primary pneumonic plague would likely occur due to the contagious nature of the disease and person-to-person transmission via respiratory aerosol. Secondary reports of research conducted during that time suggest that organisms remain viable for up to 1 h and can be dispersed for distances up to 10 km. While the offensive bioweapons program in the United States was terminated prior to production of sufficient quantities of plague organisms for use as a weapon, it is believed that Soviet scientists did manufacture quantities sufficient for such a purpose. It has also been

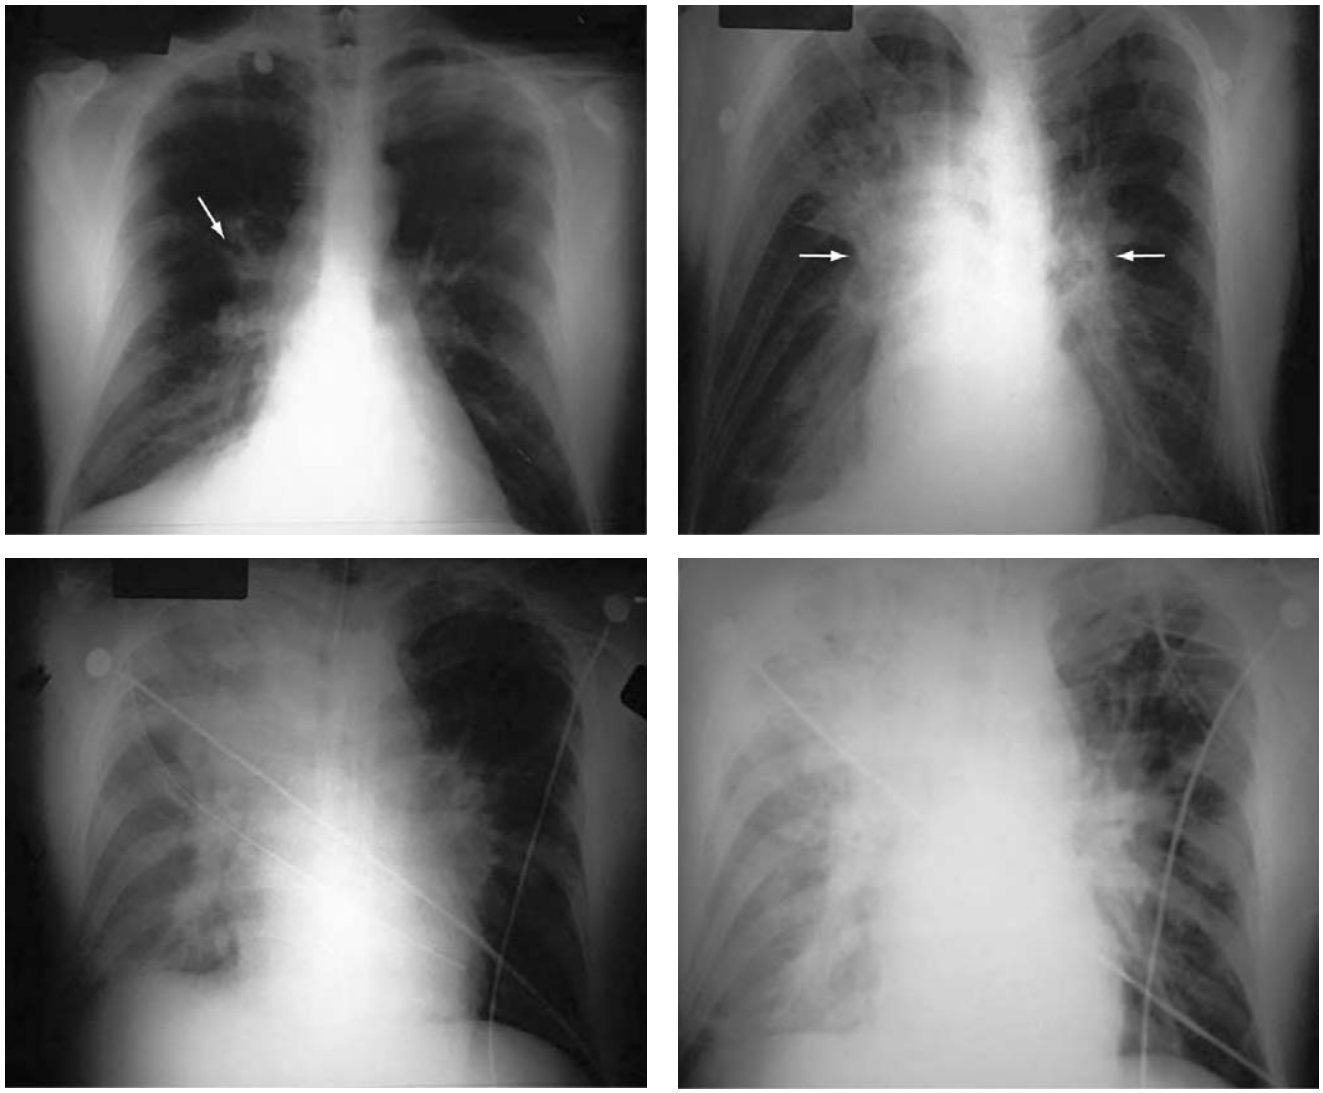

FIGURE 214-3 Progression of chest x-ray findings in a patient with inhalational anthrax. Findings evolved from subtle hilar prominence and right perihilar infiltrate to a progressively widened mediastinum, marked perihilar infiltrates, peribronchial cuffing, and air bronchograms. (*From L Borio et al: Death due to bioterrorism-related inhalational anthrax. JAMA 286:2554, 2001; with permission.*)

reported that more than 10 Soviet Institutes and >1000 scientists were working with plague as a biologic weapon. Of concern is the fact that in 1995 a microbiologist in Ohio was arrested for having obtained *Y. pestis* in the mail from the American Type Culture Collection, using a credit card and a false letterhead. In the wake of this incident, the U.S. Congress passed a law in 1997 requiring that anyone intending to send or receive any of 42 different agents that could potentially be used as bioweapons first register with the CDC.

Microbiology and Clinical Features Plague is caused by *Y. pestis*, a nonmotile, gram-negative bacillus that exhibits bipolar, or "safety pin," staining with Wright, Giemsa, or Wayson stains. It has had a major impact on the course of history, thus adding to the element of fear evoked by its mention. The earliest reported plague epidemic was in 224 B.C. in China. The most infamous pandemic began in Europe in the fourteenth century, during which time one-third to one-half of the entire population of Europe was killed. During a plague outbreak in India in 1994, even though the number of confirmed cases was relatively small, it is estimated that 500,000 individuals fled their homes in fear of this disease.

The clinical syndromes of plague generally reflect the mode of infection. *Bubonic plague* is the consequence of an insect bite; primary *pneumonic plague* arises through the inhalation of bacteria. Most of the plague seen in the world today is bubonic plague and is the result of a bite by a plague-infected flea. In part as a consequence of past pandemics, plague infection of rodents exists widely in nature, including in the southwestern United States, and each year thousands of cases of plague occur worldwide through contact with infected animals or fleas. Following inoculation of regurgitated bacteria into the skin by a flea bite, organisms travel through the lymphatics to regional lymph nodes, where they are phagocytized but not destroyed. Inside the cell, they multiply rapidly leading to inflammation, painful lymphadenopathy with necrosis, fever, bacteremia, septicemia, and death. The characteristic enlarged, inflamed lymph nodes, or *buboes*, give this form of plague its name. In some instances, patients may develop bacteremia without lymphadenopathy following infection, a condition referred to as *primary septicemic plague*. Extensive ecchymoses may develop due to disseminated intravascular coagulation, and gangrene of the digits and/or nose may develop in patients with advanced septicemic plague. It is thought that this appearance of some patients gave rise to the term *Black Death* in reference to the plague epidemic of the fourteenth and fifteenth centuries. Some patients may develop pneumonia (secondary pneumonic plague) as a complication of bubonic or septicemic plague. These patients may then transmit the agent to others via the respiratory route, causing cases of primary pneumonic plague. Primary pneumonic plague is the manifestation most likely to occur as the result of a bioterrorist attack, with an aerosol of bacteria spread over a wide area or a particular environment that is densely populated. In this setting patients would be expected to develop fever, cough with hemoptysis, dyspnea, and gastrointestinal

TABLE 214-3 CLINICAL SYNDROMES, PREVENTION, AND TREATMENT STRATEGIES FOR DISEASES CAUSES BY CATEGORY A AGENTS

Agent	Clinical Syndrome	Incubation Period	Diagnosis	Treatment	Prophylaxis
Bacillus anthracis (anthrax)	Cutaneous lesion: Papule to eschar Inhalational disease: Fever, malaise, chest and abdominal discomfort Pleural effusion, widened mediastinum on chest x-ray	1–12 days 1–60 days	Culture, Gram stain, PCR, Wright stain of peripheral smear	Postexposure: Ciprofloxacin, 500 mg, PO bid × 60 d *or* Doxycycline, 100 mg PO bid × 60 d also (Amoxicillin, 500 mg PO q8h, likely to be effective if strain penicillin sensitive) *Active disease:* Ciprofloxacin, 400 mg IV q12h *or* Doxycycline, 100 mg IV q12 *plus* Clindamycin, 900 mg IV q8h and/or rifampin, 300 mg IV q12h; switch to PO when stable ×60 d total *Antitoxin strategies:* Neutralizing monoclonal and polyclonal antibodies are under study	Anthrax vaccine adsorbed Recombinant protective antigen vaccines are under study
Yersinia pestis (pneumonic plague)	Fever, cough, dyspnea, hemoptysis Infiltrates and consolidation on chest x-ray	1–6 days	Culture, Gram stain, direct fluorescent antibody, PCR	Gentamicin, 2.0 mg/kg IV loading then 1.7 mg/kg q8h IV *or* Streptomycin, 1.0 g q12h IM or IV Alternatives include doxycycline, 100 mg bid PO or IV; chloramphenicol 500 mg qid PO or IV	Doxycycline, 100 mg PO bid (ciprofloxacin may also be active) Formalin-fixed vaccine (FDA licensed; not available)
Variola major (smallpox)	Fever, malaise, headache, backache, emesis Maculopapular to vesicular to pustular skin lesions	7–17 days	Culture, PCR, electron microscopy	Supportive measures; consideration for cidofovir, anti-vaccinia immunoglobulin	Vaccinia immunization
Francisella tularensis (tularemia)	Fever, chills, malaise, myalgia, chest discomfort, dyspnea, headache, skin rash, pharyngitis, conjunctivitis Hilar adenopathy on chest x-ray	1–14 days	Gram stain, culture, immunohistochemistry, PCR	Streptomycin, 1 g IM bid *or* Gentamicin, 5 mg/kg per day div q8h IV for 14 days *or* Doxycycline, 100 mg IV bid *or* Chloramphenicol, 15 mg/kg IV qid *or* Ciprofloxacin, 400 mg IV bid	Doxycycline, 100 mg PO bid × 14 days *or* Ciprofloxacin, 500 mg PO bid × 14 days
Viral hemorrhagic fevers	Fever, myalgia, rash, encephalitis, prostration	2–21 days	RT-PCR, serologic testing for antigen or antibody Viral isolation by CDC or U.S. Army Medical Institute of Infectious Diseases (USAMRIID)	Supportive measures Ribavirin 30 mg/kg up to 2 g × 1, followed by 16 mg/kg IV up to 1 g q6h for 4 days, followed by 8 mg/kg IV up to 0.5 g q8h × 6 days	No known chemoprophylaxis Consideration for ribavirin in high-risk situations Vaccine exists for yellow fever
Botulinum toxin (*Clostridium botulinum*)	Dry mouth, blurred vision, ptosis, weakness, dysarthria, dysphagia, dizziness, respiratory failure, progressive paralysis, dilated pupils	12–72 h	Mouse bioassay, toxin immunoassay	Supportive measures including ventilation 5000–9000 IU equine antitoxin	Administration of antitoxin

Note: CDC, U.S. Centers for Disease Control and Prevention; FDA, U.S. Food and Drug Administration; PCR, polymerase chain reaction; RT-PCR, reverse transcriptase PCR.

symptoms 1–6 days following exposure. Clinical features of pneumonia would be accompanied by pulmonary infiltrates and consolidation on chest x-ray. In the absence of antibiotics, the mortality of this disease is on the order of 85%, and death usually occurs within 2–6 days.

Rx PLAGUE

Streptomycin, tetracycline, and doxycycline are licensed by the U.S. Food and Drug Administration (FDA) for the treatment of plague. Multiple additional antibiotics licensed for other infections are commonly used and are likely effective. Among these are aminoglycosides such as gentamicin, cephalosporins, trimethoprim/sulfamethoxazole, chloramphenicol, and ciprofloxacin (Table 214-3). A multidrug-resistant strain of *Y. pestis* was identified in 1995 from a patient with bubonic plague in Madagascar. While this organism was resistant to streptomycin, ampicillin, chloramphenicol, sulfonamides, and tetracycline, it retained its susceptibility to other aminoglycosides and cephalosporins. Given the subsequent identification of a similar organism in 1997 coupled with the fact that this resistance is plasmid-mediated, it seems likely that genetically modifying *Y. pestis* to a multidrug resistant form is possible. Unlike patients with inhalational anthrax (see above), patients with pulmonary plague should be cared for under conditions of strict respiratory isolation comparable to that used for multidrug-resistant tuberculosis.

Vaccination and Prevention A formalin-fixed, whole-organism vaccine was licensed by the FDA for the prevention of plague. That vaccine is no longer being manufactured, but its potential value as a current countermeasure against bioterrorism would likely have been modest at best as it was ineffective against animal models of primary pneumonic plague. Efforts are under way to develop a second generation of vaccines that will protect against aerosol challenge. Among the candidates being tested are recombinant forms of the F1 and V antigens of *Y. pestis*. It is likely that doxycycline or ciprofloxacin would provide coverage in a chemoprophylaxis setting. Unlike the case with anthrax, in which one has to be concerned about the persistence of ungerminated spores in the respiratory tract, the duration of prophylaxis against plague need only extend to 7 days following exposure.

SMALLPOX

See also Chap. 176.

Variola Virus as a Bioweapon Given that most of the world's population was vaccinated against smallpox, variola virus would not have been considered a good candidate as a bioweapon 30 years ago. However, with the cessation of immunization programs in the United States in 1972 and throughout the world in 1980 due to the successful global eradication of smallpox, close to 50% of the U.S. population is fully susceptible to smallpox today. Given its infectious nature and the 10–30% mortality in unimmunized individuals, the deliberate spread of this virus could have a devastating effect on our society and unleash a previously conquered deadly disease. It is estimated that an initial infection of 50–100 persons in a first-generation of cases could expand by a factor of 10–20 with each succeeding generation in the absence of any effective containment measures. While the likely implementation of an effective public health response makes this scenario unlikely, it does illustrate the potential damage and disruption that can result from a smallpox outbreak.

In 1980, the World Health Organization (WHO) recommended that all immunization programs be terminated; that representative samples of variola virus be transferred to two locations: one at the CDC in Atlanta, GA, in the United States and the other at the Institute of Virus Preparations in the Soviet Union; and that all other stocks of smallpox be destroyed. Several years later, it was recommended that these two authorized collections be destroyed. However, these latter recommendations were placed on hold in the wake of increased concerns on the use of *variola virus* as a biologic weapon and thus the need to maintain an active program of defensive research. Many of these concerns were based upon allegations made by former Soviet officials that extensive programs had been in place in that country for the production and weaponization of large quantities of smallpox virus. The dismantling of these programs with the fall of the Soviet Union and the subsequent weakening of security measures led to fears that stocks of *V. major* may have made their way to other countries or terrorist organizations. In addition, accounts that efforts had been taken to produce recombinant strains of *Variola* that would be more virulent and more contagious than the wild-type virus have led to an increase in the need to be vigilant for the reemergence of this often fatal infectious disease.

Microbiology and Clinical Features Smallpox is caused by one of two variants of variola virus, *V. major* and *V. minor*. Variola is a double-strand DNA virus and member of the Orthopoxvirus genus of the Poxviridae family. Infections with *V. minor* are generally less severe than those of *V. major*, with milder constitutional symptoms and lower mortality rates; thus *V. major* is the only one considered to be a viable bioweapon. Infection with *V. major* typically occurs following contact with an infected person from the time that a maculopapular rash appears on the skin and oropharynx, through the resolution and scabbing of the pustular lesions. Infection occurs principally during close contact, through the inhalation of saliva droplets containing virus from the oropharyngeal exanthem. Aerosolized material from contaminated clothing or linen can also spread infection. Several days after exposure, a primary viremia is believed to occur that results in dissemination of virus to lymphoid tissues. A secondary viremia occurs ~4 days later that leads to localization of infection in the dermis. Approximately 12–14 days following the initial exposure the patient develops high fever, malaise, vomiting, headache, backache, and a maculopapular rash that begins on the face and extremities and spreads to the trunk (centripetal) with lesions in the same developmental stage in any given location. This is in contrast to the rash of varicella (chickenpox) that begins on the trunk and face and spreads to the extremities (centrifugal) with lesions at all stages of development. The lesions are initially maculopapular and evolve to vesicles that eventually become pustules and then scabs. The oral mucosa also develops maculopapular lesions that evolve to ulcers. The lesions appear over a period of 1–2 days and evolve at the same rate. Although virus can be isolated from the scabs on the skin, the conventional thinking is that once the scabs have formed the patient is no longer contagious. Smallpox is associated with a 10–30% mortality, with patients typically dying of severe systemic illness during the second week of symptoms. Historically, ~5–10% of naturally occurring smallpox cases take either of two highly virulent atypical forms, classified as *hemorrhagic* and *malignant*. These are difficult to recognize because of their atypical presentations. The hemorrhagic form is uniformly fatal and begins with the relatively abrupt onset of a severely prostrating illness characterized by high fevers and severe headache and back and abdominal pain. This form of the illness resembles a severe systemic inflammatory syndrome, in which patients have a high viremia, but die without developing the characteristic rash. Cutaneous erythema develops accompanied by petechiae and hemorrhages into the skin and mucous membranes. Death usually occurs within 5–6 days. The malignant, or "flat," form of smallpox is frequently fatal and has an onset similar to the hemorrhagic form, but with confluent skin lesions developing more slowly and never progressing to the pustular stage.

Rx SMALLPOX

Given the infectious nature of smallpox and the extreme vulnerability of contemporary society, patients who are suspected cases should be handled with strict isolation procedures. While laboratory confirmation of a suspected case by culture and electron microscopy is essential, it is equally important that appropriate precautions be employed when obtaining samples for culture and laboratory testing. All health care and laboratory workers caring for patients should have been recently immunized with vaccinia, and all samples should be transported in doubly sealed containers. Patients should be cared for in negative-pressure rooms with strict isolation precautions.

There is no licensed specific therapy for smallpox, and historic treatments have focused solely on supportive care. While several antiviral agents, including cidofovir, that are licensed for other diseases have in vitro activity against *V. major*, they have never been tested in the setting of human disease. For this reason it is difficult to predict whether or not they would be effective in cases of smallpox and, if effective, whether or not they would be of value in patients with advanced disease. Research programs studying the efficacy of new antiviral compounds against *V. major* are currently under way.

Vaccination and Prevention In 1796 Edward Jenner demonstrated that deliberate infection with cowpox virus could prevent illness on subsequent exposure to smallpox. Today, smallpox is a preventable disease following immunization with vaccinia. The current dilemma facing our society regarding assessment of the risk and/or benefit of smallpox vaccination is that the degree of risk that someone will deliberately and effectively release smallpox into our society is unknown. As a prudent first step in preparedness for a smallpox attack, virtually all members of the U.S. armed services have received primary or booster immunizations with vaccinia. In addition, tens of thousands of civilian health care workers who comprise smallpox-response teams at the state and local public health level have been vaccinated.

Initial fears regarding the immunization of a segment of the American population with vaccinia when there are more individuals receiving

TABLE 214-4 COMPLICATIONS FROM 438,134 ADMINISTRATIONS OF VACCINIA DURING THE UNITED STATES DEPARTMENT OF DEFENSE (DOD) SMALLPOX IMMUNIZATION CAMPAIGN INITIATED IN DECEMBER 2002

Complication	Number of Cases	DoD Rate per Million Vaccinees (95% Confidence Interval)	Historic Rate Per Million Vaccinees
Mild or temporary:			
Generalized vaccinia, mild	35	67 (52, 85)	45 to 212[a]
Inadvertent inoculation, self	62	119 (98, 142)	606[a]
Vaccinia transfer to contact	28	53 (40, 69)	8 to 27[a]
Moderate or serious:			
Encephalitis	1	2.2 (0.6, 7.2)	2.6 to 8.7[a]
Acute myopericarditis	69	131 (110, 155)	100[b]

immunosuppressive drugs and other immunocompromised patients than ever before have largely been dispelled as data are generated from the current military and civilian immunization campaigns. Adverse event rates for the first 450,000 immunizations are similar to and, in certain categories of adverse events, even lower than those from historic data, in which most severe sequelae of vaccination occurred in young infants (Table 214-4). In addition, 11 patients with early stage HIV infection have been inadvertently immunized without problem. One significant concern during the recent immunization campaign, however, has been the description of a syndrome of myopericarditis, which was not appreciated during prior immunization campaigns with vaccinia.

TULAREMIA

See also Chap. 151.

***Francisella tularensis* as a Bioweapon** Tularemia has been studied as an agent of bioterrorism since the mid-twentieth century. It has been speculated by some that the outbreak of tularemia among German and Soviet soldiers during fighting on the Eastern Front during WWII was the consequence of a deliberate release. Unit 731 of the Japanese Army studied the use of tularemia as a bioweapon during WWII. Large preparations were made for mass productive of *F. tularensis* by the United States, but no stockpiling of any agent took place. Stocks of *F. tularensis* were reportedly generated by the Soviet Union in the mid-1950s. It has also been suggested that the Soviet program extended into the era of molecular biology and that some strains were engineered to be resistant to common antibiotics. *F. tularensis* is an extremely infectious organism, and human infections have occurred from merely examining an uncovered petri dish streaked with colonies. Given these facts, it is reasonable to conclude that this organism might be utilized as a bioweapon through either an aerosol or contamination of food or drinking water.

Microbiology and Clinical Features While similar in many ways to anthrax and plague, tularemia, also referred to as rabbit fever or deer fly fever, is neither as lethal nor as fulminant as either of these other two category A bacterial infections. It is, however, extremely infectious, and as few as 10 organisms can lead to establishment of infection. Despite this fact, it is not spread from person to person. Tularemia is caused by *F. tularensis*, a small, nonmotile, gram-negative coccobacillus. Although it is not a spore-forming organism, it is a hardy bacterium that can survive for weeks in the environment. Infection typically comes from insect bites or contact with organisms in the environment. Large waterborne outbreaks have been recorded. It is most likely that the outbreak among German and Russian soldiers and Russian civilians noted above during WWII represented a large waterborne tularemia outbreak in a *Tularensis*-enzootic area devastated by warfare.

Humans can become infected through a variety of environmental sources. Infection is most common in rural areas where a variety of small mammals may serve as reservoirs. Human infections in the summer are often the result of insect bites from ticks, flies, or mosquitoes that have bitten infected animals. In colder months infections are most likely the result of direct contact with infected mammals and are most common in hunters. In these settings infection typically presents as a systemic illness with an area of inflammation and necrosis at the site of tissue entry. Drinking of contaminated water may lead to an oropharyngeal form of tularemia characterized by pharyngitis with cervical and/or retropharyngeal lymphadenopathy (Chap. 151). The most likely mode of dissemination of tularemia as a biologic weapon would be as an aerosol, as has occurred in a number of natural outbreaks in rural areas, including Martha's Vineyard in the United States. Approximately 1–14 days following exposure by this route one would expect to see inflammation of the airways with pharyngitis, pleuritis, and bronchopneumonia. Typical symptoms would include the abrupt onset of fever, fatigue, chills, headache, and malaise (Table 214-3). Some patients might experience conjunctivitis with ulceration, pharyngitis, and/or cutaneous exanthems. A pulse-temperature dissociation might be present. Approximately 50% of patients would show a pulmonary infiltrate on chest x-ray. Hilar adenopathy might also be present, and a small percent of patients could have adenopathy without infiltrates. The highly variable presentation makes acute recognition of aerosol-disseminated tularemia very difficult. The diagnosis would likely be made by immunohistochemistry or culture of infected tissues or blood. Untreated, mortality rates range from 5–15% for cutaneous routes of infection and 30–60% for infection by inhalation. Since the advent of antibiotic therapy, these rates have dropped to <2%.

Rx TULAREMIA

Both streptomycin and doxycycline are licensed for treatment of tularemia. Other agents likely to be effective include gentamicin, chloramphenicol, and ciprofloxacin (Table 214-3). Given the potential for genetic modification of this organism to yield antibiotic-resistant strains, broad-spectrum coverage should be the rule until sensitivities have been determined. As mentioned above, special isolation procedures are not required.

Vaccination and Prevention There are no vaccines currently licensed for the prevention of tularemia. While a live, attenuated strain of the organism has been used in the past with some reported success, there are inadequate data to support its widespread use at this time. Development of a vaccine for this agent is an important part of the current biodefense research agenda. In the absence of an effective vaccine, postexposure chemoprophylaxis with either doxycycline or ciprofloxacin appears to be a reasonable approach (Table 214-3).

VIRAL HEMORRHAGIC FEVERS

See also Chaps. 189 and 190.

Hemorrhagic Fever Viruses as Bioweapons Several of the hemorrhagic fever viruses have been reported to have been weaponized by the Soviet Union and the United States. Nonhuman primate studies indicate that infection can be established with very few virions and that infectious aerosol preparations can be produced. Under the guise of wanting to aid victims of an Ebola outbreak, members of the Aum Shrinrikyo cult in Japan were reported to have traveled to central Africa in 1992 in an attempt to obtain Ebola virus for use in a bioterrorist attack. Thus, while there has been no evidence that these agents have

ever been used in a biologic attack, there is clear interest in their potential for this purpose.

Microbiology and Clinical Features The viral hemorrhagic fevers are a group of illnesses caused by any one of a number of similar viruses (Table 214-2). These viruses are all enveloped, single-strand RNA viruses that are thought to depend upon a rodent or insect host reservoir for long-term survival. They tend to be geographically restricted according to the migration patterns of their hosts. Great apes are not a natural reservoir for Ebola virus, but large numbers of these animals in sub-Saharan Africa have died from Ebola infection over the past decade. Humans can become infected with hemorrhagic fever viruses if they come into contact with an infected host or other infected animals. Person-to-person transmission, largely through direct contact with virus-containing body fluids, has been documented for Ebola, Marburg and Lassa virus and rarely for the New World arenaviruses. While there is no clear evidence of respiratory spread among humans, these viruses have been shown in animal models to be highly infectious by the aerosol route. This, coupled with mortality rates as high as 90%, makes them excellent candidate agents of bioterrorism.

The clinical features of the viral hemorrhagic fevers vary depending upon the particular agent (Table 214-3). Initial signs and symptoms typically include fever, myalgia, prostration, and disseminated intravascular coagulation with thrombocytopenia and capillary hemorrhage. These findings are consistent with a cytokine-mediated systemic inflammatory syndrome. A variety of different maculopapular or erythematous rashes may be seen. Leukopenia, temperature-pulse dissociation, renal failure, and seizures may also be part of the clinical presentation. Outbreaks of most of these diseases are sporadic and unpredictable. As a consequence, most studies of pathogenesis have been performed using laboratory animals. The diagnosis should be suspected in anyone with temperature >38.3°C for <3 weeks who also exhibits at least two of the following: hemorrhagic or purpuric rash, epistaxis, hematemesis, hemoptysis, or hematochezia in the absence of any other identifiable cause. In this setting, samples of blood should be sent after consultation to the CDC or the U.S. Army Medical Research Institute of Infectious Diseases (USAMRIID) for serologic testing for antigen and antibody as well as reverse transcriptase polymerase chain reaction (RT-PCR) testing for hemorrhagic fever viruses. All samples should be handled with double-bagging. Given how little is known regarding the human-to-human transmission of these viruses, appropriate isolation measures would include full barrier precautions with negative-pressure rooms and use of N95 masks or powered air-purifying respirators (PAPRs). Unprotected skin contact with cadavers has been implicated in the transmission of certain hemorrhagic fever viruses such as Ebola, so it is recommended that autopsies be performed using the strictest measures for protection and that burial or cremation be performed promptly without embalming.

℞ VIRAL HEMORRHAGIC FEVERS

There are no approved and effective antiviral therapies for this class of viruses (Table 214-3). While there are anecdotal reports of the efficacy of ribavirin, interferon-α, or hyperimmune immunoglobulin, definitive data are lacking. The best data for ribavirin are in arenavirus (Lassa and New World) infections. In some in vitro systems specific immunoglobulin has been reported to enhance infectivity, and thus these potential treatments must be approached with caution.

Vaccination and Prevention A live attenuated virus vaccine is available in limited quantities for prevention of yellow fever. There are no other licensed and effective vaccines for these agents. Studies are currently underway examining the potential role of DNA, recombinant viruses, and attenuated viruses as vaccines for several of these infections. Among the most promising at present are vaccines for Argentine, Ebola, Rift Valley, and Kayasanur Forest viruses.

BOTULISM TOXIN (*CLOSTRIDIUM BOTULINUM*)

See also Chap. 135.

Botulinum Toxin as a Bioweapon In a bioterrorist attack, botulinum toxin would likely be dispersed as an aerosol or as contamination of a food supply. While contamination of a water supply is possible, it is likely that any toxin would be rapidly inactivated by the chlorine used to purify drinking water. Similarly, toxin can be inactivated by heating any food to >85°C for >5 min. Without external facilitation, the environmental decay rate is estimated at 1% per minute, and thus the time interval between weapon release and ingestion or inhalation needs to be rather short. The Japanese biologic warfare group, Unit 731, is reported to have conducted experiments on botulism poisoning in prisoners in the 1930s. The United States and the Soviet Union both acknowledged producing botulinum toxin, and there is some evidence that the Soviet Union attempted to create recombinant bacteria containing the gene for botulinum toxin. In records submitted to the United Nations, Iraq admitted to having produced 19,000 L of concentrated toxin—enough toxin to kill the entire population of the world three times over. By many accounts, botulinum toxin was the primary focus of the pre-1991 Iraqi bioweapons program. In addition to these examples of state-supported research into the use of botulinum toxin as a bioweapon, the Aum Shrinrikyo cult unsuccessfully attempted on a least three occasions to disperse botulism toxin into the civilian population of Tokyo.

Microbiology and Clinical Features Unique among the category A agents for not being a live microorganism, botulinum toxin is one of the most potent toxins ever described and is thought by some to be the most poisonous substance in existence. It is estimated that 1 g of botulinum toxin would be sufficient to kill 1 million individuals if adequately dispersed. Botulinum toxin is produced by the gram-positive, spore-forming anaerobe *C. botulinum* (Chap. 135). Its natural habitat is soil. There are seven antigenically distinct forms of botulinum toxin, designated A–G. The majority of naturally occurring human cases are of types A, B, and E. Antitoxin directed toward one of these will have little to no activity against the others. The toxin is a 150-kDa zinc-containing protease that prevents the intracellular fusion of acetylcholine vesicles with the motor neuron membrane, thus preventing the release of acetylcholine. In the absence of acetylcholine-dependent triggering of muscle fibers, a flaccid paralysis develops. Although botulism does not spread from person to person, the ease of production of the toxin coupled with its high morbidity and 60–100% mortality make it a close to ideal bioweapon.

Botulism can result from the presence of *C. botulinum* infection in a wound or the intestine, the ingestion of contaminated food, or the inhalation of aerosolized toxin. The latter two forms are the most likely modes of transmission for bioterrorism. Once toxin is absorbed into the bloodstream it binds to the neuronal cell membrane, enters the cell, and cleaves one of the proteins required for the intracellular binding of the synaptic vesicle to the cell membrane, thus preventing release of the neurotransmitter to the membrane of the adjacent muscle cell. Patients initially develop multiple cranial nerve palsies that are followed by a descending flaccid paralysis. The extent of the neuromuscular compromise is dependent upon the level of toxemia. The majority of patients experience diplopia, dysphagia, dysarthria, dry mouth, ptosis, dilated pupils, fatigue, and extremity weakness. There are minimal true central nervous system effects, and patients rarely show significant alterations in mental status. Severe cases can involve complete muscular collapse, loss of the gag reflex, and respiratory failure, requiring weeks or months of ventilator support. Recovery requires the regeneration of new motor neuron synapses with the muscle cell, a process that can take weeks to months. In the absence of secondary infections, which may be common during the protracted recovery phase of this illness, patients remain afebrile. The diagnosis is suspected on clinical grounds and confirmed by a mouse bioassay or toxin immunoassay.

℞ BOTULISM

Treatment for botulism is mainly supportive and may require intubation, mechanical ventilation, and parenteral nutrition (Table 214-3). If diagnosed early enough, administration of equine antitoxin may reduce the extent of nerve injury and decrease the severity of disease. At present antitoxins are available on a limited basis as a licensed bivalent product with activity

against toxin types A and B and as an experimental product with activity against toxin type E. In the event of attack with another toxin type, an investigational antitoxin with activity against all seven toxin types is also available through the U.S. Army. A single dose of antitoxin is usually adequate to neutralize any circulating toxin. Given that these preparations are all derived from horse serum, one needs to be vigilant for hypersensitivity reactions, including serum sickness and anaphylaxis following their administration. Once the damage to the nerve axon has been done, however, there is little possible in the way of specific therapy. At this point vigilance for secondary complications such as infections during the protracted recovery phase is of the utmost importance. Due to their ability to worsen neuromuscular blockade, aminoglycosides and clindamycin should be avoided in the treatment of these infections.

Vaccination and Prevention A botulinum toxoid preparation has been used as a vaccine for laboratory workers at high risk of exposure and in certain military situations; however, it is not currently available in quantities that could be used for the general population. At present, early recognition of the clinical syndrome and use of appropriate equine antitoxin is the mainstay of prevention of full-blown disease in exposed individuals. The development of human monoclonal antibodies as a replacement for equine antitoxin antibodies is an area of active research interest.

CATEGORY B AND C AGENTS

The category B agents include those that are easy or moderately easy to disseminate and result in moderate morbidity and low mortality rates. A listing of the current category B agents is provided in Table 214-2. As can be seen, it includes a wide array of microorganisms and products of microorganisms. Several of these agents have been used in bioterrorist attacks, although never with the impact of the agents described above. Among the more notorious of these was the contamination of salad bars in Oregon in 1984 with *Salmonella typhimurium* by the religious cult Rajneeshee. In this outbreak, which many consider to be the first bioterrorist attack against U.S. citizens, >750 individuals were poisoned and 40 were hospitalized in an effort to influence a local election. The intentional nature of this outbreak went unrecognized for more than a decade.

Category C agents are the third highest priority agents in the biodefense agenda. These agents include emerging pathogens to which little or no immunity exists in the general population, such as the severe acute respiratory syndrome (SARS) coronavirus or pandemic-potential strains of influenza that could be obtained from nature and deliberately disseminated. These agents are characterized as being relatively easy to produce and disseminate and as having high morbidity and mortality rates as well as a significant public health impact. There is no running list of category C agents at the present time.

PREVENTION AND PREPAREDNESS

As noted above, a large and diverse array of agents has the potential to be used in a bioterrorist attack. In contrast to the military situation with biowarfare, where the primary objective is to inflict mass casualties on a healthy and prepared militia, the objectives of bioterrorism are to harm civilians as well as to create fear and disruption among the civilian population. While the military needs only to prepare their troops to deal with the limited number of agents that pose a legitimate threat of biowarfare, the public health system needs to prepare the entire civilian population to deal with the multitude of agents and settings that could be utilized in a bioterrorism attack. This includes anticipating issues specific to the very young and the very old, the pregnant patient, and the immunocompromised individual. The challenges in this regard are enormous and immediate. While military preparedness emphasizes vaccines toward a limited number of agents, civilian preparedness needs to rely upon rapid diagnosis and treatment of a wide array of conditions.

The medical profession must maintain a high index of suspicion that unusual clinical presentations or the clustering of cases of a rare disease may not be a chance occurrence but rather the first sign of a bioterrorist event. This is particularly true when such diseases occur in traditionally healthy populations, when surprisingly large numbers of rare conditions occur, and when diseases commonly seen in rural settings appear in urban populations. Given the importance of rapid diagnosis and early treatment for many of these conditions, it is essential that the medical care team report any suspected cases of bioterrorism immediately to local and state health authorities and/or to the CDC (888-246-2675). Recent enhancements have been made to the public health surveillance network to facilitate the rapid sharing of information among public health agencies.

At present a series of efforts are taking place to ensure the biomedical security of the civilian population of the United States. The Public Health Service is moving toward a larger, more highly trained, fully deployable force. A Strategic National Stockpile (SNS) has been created by the CDC to provide rapid access to quantities of pharmaceuticals, antidotes, vaccines, and other medical supplies that may be of value in the event of biologic or chemical terrorism. The SNS has two basic components. The first of these consists of "push packages" that can be deployed anywhere in the United States within 12 h. These push packages are a preassembled set of supplies, pharmaceuticals, and medical equipment ready for immediate delivery to the field. They provide treatment for a variety of conditions given the fact that an actual threat may not have been precisely identified at the time of stockpile deployment. The contents of the push packs are constantly updated to ensure that they reflect current needs as determined by national security threat assessments; they include antibiotics for treatment of anthrax, plague, and tularemia as well as a cache of vaccine to deal with a smallpox threat. The second component of the SNS comprises inventories managed by specific vendors and consists of the provision of additional pharmaceuticals, supplies, and/or products tailored to the specific attack.

The number of FDA-approved and -licensed drugs and vaccines for category A and B agents is currently limited and not reflective of the pharmacy of today. In an effort to speed the licensure of additional drugs and vaccines for these diseases, the FDA has proposed a new rule for the licensure of such countermeasures against agents of bioterrorism when adequate and well-controlled clinical efficacy studies cannot be ethically conducted in humans. Thus, for indications in which field trials of prophylaxis or therapy for naturally occurring disease are not feasible, the FDA is proposing to rely on evidence solely from laboratory animal studies. For this rule to apply it must be shown that (1) there are reasonably well-understood pathophysiologic mechanisms for the condition and its treatment; (2) the effect of the intervention is independently substantiated in at least two animal species, including species expected to react with a response predictive for humans; (3) the animal study endpoint is clearly related to the desired benefit in humans; and (4) the data in animals allow selection of an effective dose in humans.

Finally, an initiative referred to as Project BioShield has been established to facilitate biodefense research within the federal government, create a stable source of funding for the purchase of countermeasures against agents of bioterrorism, and create a category of "emergency use authorization" to allow the FDA to approve the use of unlicensed treatments during times of extraordinary unmet needs, as might be present in the context of a bioterrorist attack.

While the prospect of a deliberate attack on civilians with disease-producing agents may seem to be an act of incomprehensible evil, history shows us that it is something that has been done in the past and will likely be done again in the future. It is the responsibility of health care providers to be aware of this possibility, to be able to recognize early signs of a potential bioterrorist attack and alert the public health system, and to respond quickly to provide care to the individual patient. Among the web sites with current information on microbial bioterrorism are *www.bt.cdc.gov*, *www.niaid.nih.gov*, *www.jhsph.edu/preparedness*, and *www.cns.miis.edu/research/cbw/index.htm*.

215 Chemical Bioterrorism

Charles G. Hurst, Jonathan Newmark, James A. Romano, Jr.

The use of chemical warfare agents (CWAs) in modern warfare dates back to World War I (WWI). Most recently, sulfur mustard and nerve agents were used by Iraq against the Iranian military and Kurdish civilians. Since the Japanese sarin attacks in 1994–1995 and the terrorist strikes of September 11, 2001, the all too real possibility of chemical or biological terrorism against civilian populations anywhere in the world has attracted increased attention.

Military planners consider the WWI blistering agent, sulfur mustard, and the organophosphorus nerve agents as the most likely agents to be used on the battlefield. In a civilian or terrorist scenario, the choice widens considerably. Cyanide, a common chemical, causes symptoms within seconds and death in 5–10 min if not treated rapidly. Chlorine and phosgene have no specific antidotes but can require intensive care for weeks to months. These agents or one of the industrial HAZMATs will be the likely choice of terrorists. Table 215-1 gives antidote recommendations following exposure to cyanide.

Many mistakenly believe that chemical attacks will always be so severe that little can be done except to bury the dead. History proves the opposite. Even in WWI, when IV fluids, endotracheal tubes, and antibiotics were unavailable, the mortality rate in U.S. forces on the battlefield from chemical warfare agents, chiefly sulfur mustard and the pulmonary intoxicants, was only 1.9%. This was far less than the 7% mortality rate from conventional wounds. In the 1995 Tokyo subway sarin incident, of the 5500 patients who sought medical attention at hospitals, 80% of whom were not actually symptomatic, only 12 died. Recent events should produce not a fatalistic attitude but a realistic wish to understand the pathophysiology of the syndromes these agents cause, with a view to treating expeditiously all patients who present for care and an expectation of saving the vast majority. As we prepare to defend our civilian population from the effects of chemical terrorism, we must also consider the fact that terrorism itself can produce sequelae such as physiologic or neurologic effects that may resemble the effects of nonlethal exposures to CWAs. These effects are due to a general fear of chemicals, fear of decontamination, fear of protective ensemble, or other phobic reactions.

Many writers have pointed out the increased difficulty in differentiating between stress reactions and nerve agent–induced organic brain syndromes. Knowledge of the behavioral effects of CWAs and their medical countermeasures is imperative to ensure that military and civilian medical and mental health organizations can deal with possible incidents involving weapons of mass destruction.

The chemical warfare agents, their NATO codes, and initial effects are listed in Table 215-2.

VESICANTS

Sulfur Mustard

Sulfur mustard has been a military threat since it first appeared on the battlefield in Belgium during WWI. In modern times it remains a threat on the battlefield as well as a potential terrorist threat for bioterrorism because of simplicity of manufacture and extreme effectiveness. Sulfur mustard accounted for 70% of the 1.3 million chemical casualties in WWI.

MECHANISM Sulfur mustard constitutes both a vapor and a liquid threat to all exposed epithelial surfaces. Mustard's effects are delayed, appearing hours after exposure. Organs most commonly affected are the skin (with erythema and vesicles), eyes (ranging from mild conjunctivitis to severe eye damage), and airways (ranging from mild upper airway irritation, to severe bronchiolar damage). Following exposure to large quantities of mustard, precursor cells of the bone marrow are damaged, leading to pancytopenia and secondary infection. The gastrointestinal mucosa may be damaged, and there are sometimes central nervous system (CNS) signs of unknown mechanism. No specific antidotes exist; management is entirely supportive. Immediate decontamination of the liquid is the only way to reduce damage. Complete decontamination in 2 min stops clinical injury; decontamination at 5 min will reduce skin injury by ~50%. Table 215-3

TABLE 215-1 ANTIDOTE RECOMMENDATIONS FOLLOWING EXPOSURE TO CYANIDE

Patient	Mild (Conscious)	Severe (Unconscious)	Other Treatment
Child	If patient is conscious and has no other signs or symptoms, antidotes may not be necessary.	Sodium nitrite[a]: 0.12–0.33 mL/kg, not to exceed 10 mL of 3% solution[b] slow IV over no less than 5 min, or slower if hypotension develops *and* Sodium thiosulfate: 1.65 mL/kg of 25% solution IV over 10–20 min	For sodium nitrite–induced orthostatic hypotension, normal saline infusion and supine position are recommended. If still apneic after antidote administration, consider sodium bicarbonate for severe acidosis.
Adult	If patient is conscious and has no other signs or symptoms, antidotes may not be necessary.	Sodium nitrite[a]: 10–20 mL of 3% solution[b] slow IV over no less than 5 min, or slower if hypotension develops *and* Sodium thiosulfate: 50 mL of 25% solution IV over 10–20 min	

[a]If sodium nitrite is unavailable, administer amyl nitrite by inhalation from crushable ampules.
[b]Available in Pasadena Cyanide Antidote Kit, formerly Lilly Cyanide Kit.
Note: Victims whose clothing or skin is contaminated with hydrogen cyanide liquid or solution can secondarily contaminate response personnel by direct contact or through off-gassing vapors. Avoid dermal contact with cyanide-contaminated victims or with gastric contents of victims who may have ingested cyanide-containing materials. Victims exposed only to hydrogen cyanide gas do not pose contamination risks to rescuers. *If the patient is a victim of recent smoke inhalation (may have high carboxyhemoglobin levels), administer only sodium thiosulfate.*

TABLE 215-2 RECOGNIZING AND DIAGNOSING HEALTH EFFECTS OF CHEMICAL TERRORISM

Agent	Agent Name	Unique Characteristics	Initial Effects
Nerve	Cyclohexyl sarin (GF) Sarin (GB) Soman (GD) Tabun (GA) VX	Miosis (pinpoint pupils) Copious secretions Muscle twitching/fasciculations	Miosis (pinpoint pupils) Blurred/dim vision Headache Nausea, vomiting, diarrhea Copious secretions/sweating Muscle twitching/fasciculations Breathing difficulty Seizures
Asphyxiant/blood	Arsine Cyanogen chloride Hydrogen cyanide	Possible cherry red skin Possible cyanosis Possible frostbite[a]	Confusion Nausea Patients may gasp for air, similar to asphyxiation but more abrupt onset Seizures prior to death
Choking/pulmonary-damaging	Chlorine Hydrogen chloride Nitrogen oxides Phosgene	Chlorine is a greenish-yellow gas with pungent odor Phosgene gas smells like newly mown hay or grass Possible frostbite[a]	Eye and skin irritation Airway irritation Dyspnea, cough Sore throat Chest tightness
Blistering/vesicant	Mustard/Sulfur mustard (HD, H) Mustard gas (H) Nitrogen mustard (HN-1, HN-2, HN-3) Lewisite (L) Phosgene oxime (CX)	Mustard (HD) has an odor like burning garlic or horseradish Lewisite (L) has an odor like penetrating geranium Phosgene oxime (CX) has a pepperish or pungent odor	Severe irritation Redness and blisters of the skin Tearing, conjunctivitis, corneal damage Mild respiratory distress to marked airway damage May cause death
Incapacitating/behavior-altering	Agent 15/BZ	May appear as mass drug intoxication with erratic behaviors, shared realistic and distinct hallucinations, disrobing and confusion Hyperthermia Mydriasis (dilated pupils)	Dry mouth and skin Initial tachycardia Altered consciousness, delusions, denial of illness, belligerence Hyperthermia Ataxia (lack of coordination) Hallucinations Mydriasis (dilated pupils)

[a]Frostbite may occur from skin contact with liquid arsine, cyanogen chloride, or phosgene. ***Source:*** State of New York, Department of Health.

TABLE 215-3 DECONTAMINATION AND TREATMENT OF CHEMICAL TERRORISM

Agent	Decontamination	First Aid	Other Patient Considerations
Nerve	Remove clothing immediately Gently wash skin with soap and water Do not abrade skin For eyes, flush with plenty of water or normal saline	Atropine before other measures Pralidoxime (2-PAM) chloride	Onset of symptoms from dermal contact with liquid forms may be delayed Repeated antidote administration may be necessary
Asphyxiant/blood	Remove clothing immediately if no frostbite[a] Gently wash skin with soap and water Do not abrade skin For eyes, flush with plenty of water or normal saline	Rapid treatment with oxygen For cyanide, use antidotes (sodium nitrite and then sodium thiosulfate)	Arsine and cyanogen chloride may cause delayed pulmonary edema
Choking/pulmonary-damaging	Remove clothing immediately if no frostbite[a] Gently wash skin with soap and water Do not abrade skin For eyes, flush with plenty of water or normal saline	Fresh air, forced rest Semi-upright position If signs of respiratory distress are present, oxygen with or without positive airway pressure may be needed Other supportive therapy, as needed	May cause delayed pulmonary edema, even following a symptom-free period that varies in duration with the amount inhaled
Blistering/vesicant	Immediate decontamination is essential to minimize damage Remove clothing immediately Gently wash skin with soap and water Do not abrade skin For eyes, flush with plenty of water or normal saline	Immediately decontaminate skin Flush eyes with water or normal saline for 10–15 min If breathing difficulty, give oxygen Supportive care	Mustard has an asymptomatic latent period There is no antidote or treatment for mustard Lewisite has immediate burning pain, blisters later Specific antidote British Anti-Lewisite (BAL) may decrease systemic effects of Lewisite Phosgene oxime causes immediate pain Possible pulmonary edema
Incapacitating/behavior-altering	Remove clothing immediately Gently wash skin with water or soap and water Do not abrade skin	Remove heavy clothing Evaluate mental status Use restraints as needed Monitor core temperature carefully Supportive care	Hyperthermia and self-injury are largest risks Hard to detect because it is an odorless and non-irritating substance Possible serious arrhythmias Specific antidote (physostigmine) may be available

[a]For frostbite areas, do NOT remove any adhering clothing. Wash area with plenty of warm water to release clothing. ***Source:*** State of New York, Department of Health.

lists approaches to decontamination of mustard and other CWAs.

Mustard dissolves slowly in aqueous media, such as sweat, but once dissolved, it rapidly forms extremely reactive cyclic ethylene sulfonium ions, which react with cell proteins, cell membranes, and especially DNA in rapidly dividing cells. The ability of mustard to react with and alkylate DNA gives rise to the effects by which it has been characterized as "radiomimetic," similar to radiation injury. Mustard has many biologic actions, but its actual mechanism of action is largely unknown. Much of the biologic damage from mustard results from DNA alkylation and crosslinking in rapidly dividing cells: corneal epithelium, basal keratinocytes, bronchial mucosal epithelium, gastrointestinal mucosal epithelium, and bone marrow precursor cells. This may lead to cellular death and inflammatory reactions. In the skin, proteolytic digestion of anchoring filaments at the epidermal-dermal junction may be the major mechanism of action resulting in blister formation. Mustard also possesses mild cholinergic activity, which may be responsible for effects such as early gastrointestinal and CNS symptoms.

Mustard reacts with tissue within minutes of entering the body. Its circulating half-life in unaltered form is extremely brief.

CLINICAL FEATURES Topical effects of mustard occur in the skin, airways, and eyes, with the eyes being most sensitive, followed by the airways. Absorbed mustard may produce effects in the bone marrow, gastrointestinal tract, and CNS. Direct injury to the gastrointestinal tract may also occur following ingestion of the compound through contamination of water or food.

Erythema is the mildest and earliest form of mustard skin injury. It resembles sunburn and is associated with pruritus, burning, or stinging pain. Erythema begins to appear within 2 h to 2 d after vapor exposure. Time of onset depends on severity of exposure, ambient temperature and humidity, and type of skin. The most sensitive sites are the warm moist locations and thin delicate skin, such as the perineum, external genitalia, axillae, antecubital fossae, and neck.

Within the erythematous areas, small vesicles can develop, which may later coalesce to form bullae (Fig. 215-1). The typical bulla is large, dome-shaped, flaccid, thin-walled, translucent, and surrounded by erythema. The blister fluid, a transudate, is clear to straw-colored, which becomes yellow tending to coagulate. The fluid does not contain mustard and is not itself a vesicant. Lesions from high-dose liquid exposure may develop a central zone of coagulation necrosis with blister formation at the periphery. These lesions take longer to heal and are more prone to secondary infection than the uncomplicated lesions seen at lower exposure levels. Severe lesions might require skin grafting.

The primary airway lesion is necrosis of the mucosa with possible damage to underlying smooth muscle. The damage begins in the upper airways and descends to the lower airways in a dose-dependent manner. Usually the terminal airways and alveoli are affected only as a terminal event. Pulmonary edema is not usually present unless the damage is very severe, and then it becomes hemorrhagic.

FIGURE 215-1 Large bulla formation from mustard burn in Iranian patient. Although the blisters on this patient's hand involve only 7% of the body surface area, this patient still required hospitalization in a burn intensive care unit.

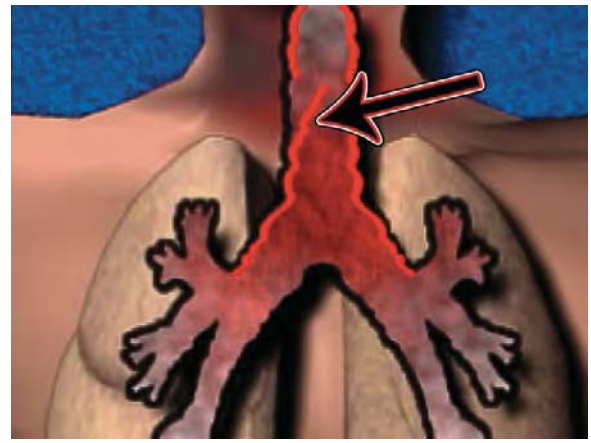

FIGURE 215-2 Schematic diagram of pseudomembrane formation as is seen in high-dose sulfur mustard vapor inhalation exposure. In World War I, severe inhalation exposure often caused death via large airways obstruction.

The earliest effects from mustard and perhaps the only effects from a low concentration involve the nose, sinuses, and pharynx. There may be irritation or burning of the nares, epistaxis, sinus pain, and pharyngeal pain. As the concentration increases, laryngitis, voice changes, and nonproductive cough develop. Damage to the trachea and upper bronchi leads to a productive cough. Lower airway involvement causes dyspnea, severe cough, and increasing quantities of sputum. Terminally, there may be necrosis of the smaller airways with hemorrhagic edema into surrounding alveoli. Hemorrhagic pulmonary edema is rare.

Necrosis of airway mucosa causes "pseudomembrane" formation. These membranes may cause obstruction of the bronchi. During WWI, high dose mustard exposure caused acute death via this mechanism in a small minority of cases (Fig. 215-2).

The eyes are the organs most sensitive to mustard vapor injury. The latent period is shorter for eye injury than for skin injury and is also exposure concentration–dependent. After low-dose vapor exposure, irritation evidenced by reddening of the eyes may be the only effect. As the dose increases, the injury includes progressively more severe conjunctivitis, photophobia, blepharospasm, pain, and corneal damage (Fig. 215-3).

FIGURE 215-3 World War I photograph of troops exposed to sulfur mustard vapor. The vast majority of these troops survived with no long-term damage to the eyes; however, they were effectively rendered blind for days to weeks.

About 90% of eye injuries related to mustard heal in 2 weeks to 2 months without sequelae. Scarring between the iris and lens may follow severe effects; this scarring may restrict pupillary movements and may predispose victims to glaucoma. The most severe damage is caused by liquid mustard. After extensive eye exposure, severe corneal damage with possible perforation of the cornea and loss of the eye can occur. In some individuals, a latent chronic keratitis sometimes associated with corneal ulcerations has been described as early as 8 months and as late as 20 years after initial exposure.

The mucosa of the gastrointestinal tract is susceptible to mustard damage, either from systemic absorption or ingestion of the agent. Mustard exposure in small amounts will cause nausea and vomiting lasting up to 24 h. The mechanism of the nausea and vomiting is not understood, but mustard does have a cholinergic-like effect. The CNS effects of mustard, likewise, remain poorly defined. Large exposures can cause seizures in animals. Reports from WWI, and again from the Iran-Iraq war, described people exposed to small amounts of mustard acting sluggish, apathetic, and lethargic. These reports suggest that minor psychological problems could linger for a year or longer.

The cause of death in the majority of mustard poisoning cases is sepsis and respiratory failure. Mechanical obstruction via pseudomembrane formation and agent-induced laryngospasm is important in the first 24 h, but only in cases of severe exposure. From the third through the fifth day after exposure, expect a secondary pneumonia due to bacterial invasion of denuded necrotic mucosa. The third wave of death is caused by agent-induced bone marrow suppression, which peaks 7–21 days after exposure and causes death via sepsis.

℞ SULFUR MUSTARD

A patient severely ill from mustard poisoning requires the general supportive care provided for any severely ill patient, as well as the specific care given to a burn patient. Liberal use of systemic analgesics, maintenance of fluid and electrolyte balance, nutrition, appropriate antibiotics, and other supportive measures are necessary (Table 215-3).

The management of a patient exposed to mustard may range from simple, as in the provision of symptomatic care for a sunburn-like erythema, to complex, as in providing total management for a severely ill patient with burns, immunosuppression, and multi-system involvement. Before raw denuded areas of skin develop, especially with less severe exposures, topical cortisone creams or lotions may be of benefit. Some very basic research data point to the early use of anti-inflammatory preparations. Small blisters (<1–2 cm) should be left intact. Because larger bullae will eventually break, they should be carefully unroofed. Denuded areas should be irrigated three to four times daily with saline, other sterile solutions, or soapy water and then liberally covered with the topical antibiotic of choice, such as silver sulfadiazine or mafenide acetate to a thickness of 1–2 mm. Some physicians advocate sterile needle drainage of large blisters, collapsing the blister roof to form a sterile dressing. Mustard blister fluid does not contain sulfur mustard, only sterile tissue fluid. Health care staff should not fear possible contamination. If an antibiotic cream is not available, sterile petrolatum will be useful. Modified Dakins solution (sodium hypochlorite 0.5%) was used both in WWI and in Iranian casualties (1984–1987) for field-expedient irrigation and antisepsis. Large areas of vesication require hospitalization, IV therapy, and whirlpool bath irrigation.

Systemic analgesics should be used liberally, particularly before manipulation of the patient. Monitoring of fluids and electrolytes is important in any sick patient, but it must be recognized that fluid loss is not of the magnitude seen with thermal burns. Overly rigorous hydration seems to have precipitated pulmonary edema in a few Iranian casualties sent to European hospitals.

Conjunctival irritation from a low vapor exposure will respond to any of a number of available ophthalmic solutions after the eyes are thoroughly irrigated. A topical antibiotic applied several times a day will reduce the incidence and severity of infection. Animal laboratory data have shown remarkable results with commercially available topical antibiotic/glucocorticoid ophthalmologic ointments applied early. An ophthalmologist should be consulted. Topical glucocorticoids are not of proven value, but their use during the first few hours or days might significantly reduce inflammation and subsequent damage. Further use should be relegated to an ophthalmologist.

Vaseline or a similar substance should be applied regularly to the edges of the lids to prevent them from sticking together. Topical analgesics may be useful initially if blepharospasm is too severe to permit an adequate examination; however, topical analgesics have limited value.

A productive cough and dyspnea accompanied by fever and leukocytosis occurring within 12–24 h is indicative of a chemical pneumonitis. The clinician must resist the urge to use prophylactic antibiotics for this process. Infection often occurs on the third to fifth day and is signaled by an increased fever, pulmonary infiltrate, and an increase in sputum production with a change in color. Appropriate antibiotic therapy should await confirmation by Gram stain, and later, positive culture and sensitivity.

Intubation may be necessary if laryngeal spasm or edema makes it difficult or becomes life-threatening. Intubation permits better ventilation and facilitates suction of the necrotic and inflammatory debris. Early use of positive end-expiratory pressure (PEEP) or continuous positive airway pressure (CPAP) may be beneficial. Pseudomembrane formation may require fiberoptic bronchoscopy for suctioning of the necrotic debris.

Bronchodilators are of benefit for bronchospasm. If additional relief of bronchospasm is needed, glucocorticoids should be used. There is little evidence that the routine use of glucocorticoids is beneficial, except for additional relief of bronchospasm.

Leukopenia begins around day 3 with major systemic absorption. Marrow suppression peaks at 7–14 days. In the Iran/Iraq war, a white blood count of ≤200/μL usually resulted in death of the patient. Sterilization of the gut by nonabsorbable antibiotics should be considered to reduce the possibility of sepsis from enteric organisms. Cellular replacement (bone marrow transplants or transfusions) may be successful. Granulocyte colony-stimulating factor (G-CSF) produced a 50% reduction in the time for the bone marrow to recover in non-human primates exposed to sulfur mustard. Medication for nausea and vomiting may be necessary for gastrointestinal side effects.

Excellent assessments of the contributions of DNA alkylation, inflammation, activation of proteolytic enzymes, or lipid peroxidation to the mustard injury have been developed in the past 15–20 years. Some examples include (1) the demonstration of up to 75% reduction of inflammation and tissue damage in the mouse ear swelling test by vanilloid compounds, and (2) the demonstration of 50–60% protection by *N*-acetylcysteine in the generation of free radicals within guinea pig lung exposed to mustard. In many cases, the demonstration of protection is dependent on the availability of sufficient amounts of drug with adequate half-lives. Strategies to enhance bioavailability include attachment of polyethylene glycol to the antioxidant drug/enzyme or delivery of the drug/enzyme in a liposome (or both).

NERVE AGENTS

The organophosphorus nerve agents are the deadliest of the CWAs. They work by inhibition of tissue synaptic acetylcholinesterase, creating an acute cholinergic crisis. Death ensues because of respiratory depression, and can occur within seconds to minutes.

The nerve agents tabun and sarin were first used on the battlefield by Iraq against Iran during the first Persian Gulf War (1984–1987). Estimates of casualties from these agents range from 20,000–100,000. In 1994 and 1995, the Japanese cult Aum Shinrikyo used sarin in two terrorist attacks in Matsumoto and Tokyo.

The "classic" nerve agents include tabun (GA), sarin (GB), soman (GD), cyclosarin (GF), and VX. VR, similar to VX, was manufactured in the former Soviet Union (Table 215-2). The two-letter codes were established by a North Atlantic Treaty Organization (NATO) international convention and convey no clinical implications. All of the nerve agents are organophosphorus compounds, which are liquid at standard temperature and pressure. The "G" agents evaporate at about the rate of water, except for GF, which is oily, and thus will probably have evaporated within 24 h after deposition on the ground. Their high volatility thus makes a spill of any amount a serious vapor hazard. In the Tokyo subway attack where sarin was used, 100% of the symptomatic patients inhaled sarin vapor that spilled out on the floor of the subway cars. VX, an oily liquid, is the exception. Its low vapor pressure makes

it much less of a vapor hazard but potentially a greater environmental hazard because it persists in the environment far longer.

MECHANISM Acetylcholinesterase inhibition accounts for the major life-threatening effects of nerve agent poisoning. Reversal of this inhibition by antidotal therapy is effective, proving that this is the primary toxic action of these poisons. At cholinergic synapses, acetylcholinesterase, bound to the postsynaptic membrane, functions as a turn-off switch to regulate cholinergic transmission. Inhibition of acetylcholinesterases causes the released neurotransmitter, acetylcholine, to accumulate abnormally. End-organ overstimulation, recognized by clinicians as cholinergic crisis, ensues **(Fig. 215-4)**.

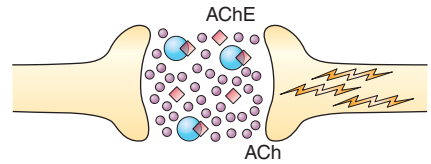

FIGURE 215-4 Schematic diagram of the pathophysiology of nerve agent exposure. Nerve agent (◆) binds to the active site of acetylcholinesterase (AChE), which is shown as floating free in space but is in reality a postsynaptic membrane-bound enzyme. As a result, acetylcholine (●), which is normally released from presynaptic membrane but normally degraded, accumulates, and this leads (↯) to organ overstimulation and cholinergic crisis.

CLINICAL FEATURES Clinical effects of nerve agent exposure are identical for vapor and liquid exposure routes if the dose is sufficiently large. The speed and order of symptom onset will differ (Table 215-2).

Exposure of a patient to nerve agent vapor, overwhelmingly the more likely route of exposure in both battlefield and terrorist scenarios, will cause cholinergic symptoms in the order that the toxin encounters cholinergic synapses. The most exposed synapses on the integument of the human are in the pupillary muscles. Nerve agent vapor easily crosses the cornea, interacts with these synapses, and produces miosis, described by Tokyo subway victims as "the world going black." Rarely this can also cause eye pain and nausea. Exocrine glands located in the nose, mouth, and pharynx next become exposed to the vapor, and cholinergic overload here causes increased secretions, rhinorrhea, excess salivation, and drooling. Next, toxin interacts with exocrine glands in the upper airway, causing bronchorrhea, and with bronchial smooth muscle, causing bronchospasm. This combination of events can cause hypoxia.

Once the victim has inhaled, vapor can passively cross the alveolar-capillary membrane, enter the bloodstream, and, incidentally and asymptomatically, inhibit circulating cholinesterases, particularly free butyrylcholinesterase and erythrocyte acetylcholinesterase, both of which can be assayed. Unfortunately, the assay may not be easily interpreted without a baseline, since cholinesterase levels vary enormously between subjects and over time in an individual healthy patient.

Usually the first organ system to become symptomatic from bloodborne nerve agent exposure is the gastrointestinal tract, where cholinergic overload causes abdominal cramping and pain, nausea, vomiting, and diarrhea. After the gastrointestinal tract is involved, nerve agents will affect the heart, distant exocrine glands, muscles, and brain. Because there are cholinergic synapses on both the vagal (parasympathetic) and sympathetic sides of the autonomic input to the heart, one cannot predict how heart rate and blood pressure will change once intoxicated. Remote exocrine activity will include oversecretion in the salivary, nasal, respiratory, and sweat glands—the patient will be "wet all over." Bloodborne nerve agents will overstimulate neuromuscular junctions in skeletal muscles, causing fasciculations followed by frank twitching. If the process goes on long enough, eventually ATP in muscle will be depleted and flaccid paralysis will ensue.

In the brain, since the cholinergic system is so widely distributed, bloodborne nerve agents will, in sufficient doses, cause rapid loss of consciousness, seizures, and central apnea leading to death within minutes. If respiration is supported, status epilepticus, which does not respond to usual anticonvulsants, may ensue (Chap. 363). If status epilepticus persists, neuronal death and permanent brain dysfunction may occur. Even in mild nerve agent intoxication, patients may recover but may experience weeks of irritability, sleep disturbance, and nonspecific neurobehavioral symptoms.

The time from exposure to development of the full-blown cholinergic crisis from nerve agent vapor inhalation can be minutes or even seconds, yet there is no depot effect. Since nerve agents have a short circulating half-life, if the patient is supported and, ideally, treated with antidotes, improvement should be rapid without subsequent deterioration.

Liquid exposure to nerve agents differs in speed and order of symptom onset. A nerve agent on intact skin will partially evaporate and partially begin to travel through the skin, causing localized sweating and then localized fasciculations when it encounters neuromuscular junctions. Once in muscle, it will cross into the circulation and cause gastrointestinal discomfort, respiratory distress, heart rate changes, generalized fasciculations and twitching, loss of consciousness, seizures, and central apnea. The time course will be much longer than with vapor inhalation; even a large, lethal droplet can take up to 30 min to have an effect, and a small, sublethal dose could continue to take effect over 18 h. Clinical worsening that occurs hours after treatment has started is far more likely with liquid than with vapor exposure. Additionally, miosis, practically unavoidable with vapor exposure, is not always present with liquid exposure and may be the last symptom to present in this situation. This is due to the relative insulation of the pupillary muscle from the systemic circulation.

Unless removed by specific therapy (oximes), binding of a nerve agent to cholinesterase is essentially irreversible. Erythrocyte acetylcholinesterase activity recovers at about 1% per day. Plasma butyrylcholinesterase recovers more quickly and is a better guide to recovery of tissue enzyme activity.

℞ NERVE AGENTS

Acute nerve agent poisoning is treated by decontamination, respiratory support, and three antidotes—an anticholinergic, an oxime, and an anticonvulsant (Tables 215-3 and **215-4**). In acute cases, all of these forms of therapy may be given simultaneously.

DECONTAMINATION Decontamination of a vapor is formally not necessary, but in the Tokyo subway attack, sarin vapor trapped in the patients' clothing caused miosis in 10% of emergency personnel. Removal of clothing would have obviated most of this problem. Decontamination of liquid is accomplished in the military using the M291 skin decontamination kit, containing an Ambergard resin capable of absorbing liquid off the skin. Civilian agencies now stockpile this product approved by the U.S. Food and Drug Administration (FDA). At hospitals, soap and copious amounts of water should suffice. Physical removal of the agent is superior to all known decontamination solutions and lotions. In any event, decontamination must be accomplished before the patient enters the hospital facility to avoid contaminating the facility and its staff. In patients with contaminated wounds, extract potentially contaminated clothing and other foreign material that may serve as a depot for the liquid agent.

RESPIRATORY SUPPORT Death from nerve agent poisoning is almost always from respiratory causes. Ventilation will be complicated by increased resistance and secretions. Atropine should be given before ventilation or as ventilation begins, since it will make ventilation far easier.

ANTIDOTAL THERAPY **Atropine** In theory, any anticholinergic could be used to treat nerve agent poisoning, but worldwide the choice is invariably atropine due to its wide temperature stability, rapid effectiveness either IM or IV, and because inadvertent administration of this drug usually causes little CNS dysfunction (Table 215-4). Atropine rapidly reverses cholinergic overload at muscarinic synapses but has little effect at nicotinic synapses. Practically, this implies that atropine can quickly treat the life-threatening respiratory effects of nerve agents but will probably not help neuromuscular and possibly sympathetic effects. In the field, military personnel are given MARK I kits **(Fig. 215-5*A*)** containing 2 mg atro-

TABLE 215-4 ANTIDOTE RECOMMENDATIONS FOLLOWING EXPOSURE TO NERVE AGENTS

Patient Age	Antidotes: Mild/Moderate Effects[a]	Antidotes: Severe Effects[b]	Other Treatment
Infants (0–2 yrs)	Atropine: 0.05 mg/kg IM, *or* 0.02 mg/kg IV; *and* 2-PAM chloride: 15 mg/kg IM *or* IV slowly	Atropine: 0.1 mg/kg IM, *or* 0.02 mg/kg IV; *and* 2-PAM chloride: 25 mg/kg IM, *or* 15 mg/kg IV slowly	Assisted ventilation after antidotes for severe exposure.
Child (2–10 yrs)	Atropine: 1 mg IM, *or* 0.02 mg/kg IV; *and* 2-PAM chloride[c]: 15 mg/kg IM *or* IV slowly	Atropine: 2 mg IM, *or* 0.02 mg/kg IV; *and* 2-PAM chloride[c]: 25 mg/kg IM, *or* 15 mg/kg IV slowly	Repeat atropine (2 mg IM, or 1 mg IM for infants) at 5- to 10-min intervals until secretions have diminished and breathing is comfortable or airway resistance has returned to near normal.
Adolescent (>10 yrs)	Atropine: 2 mg IM, *or* 0.02 mg/kg IV; *and* 2-PAM chloride[c]: 15 mg/kg IM *or* IV slowly	Atropine: 4 mg IM, *or* 0.02 mg/kg IV; *and* 2-PAM chloride[c]: 25 mg/kg IM, *or* 15 mg/kg IV slowly	
Adult	Atropine: 2 to 4 mg IM *or* IV; *and* 2-PAM chloride: 600 mg IM, *or* 15 mg/kg IV slowly	Atropine: 6 mg IM; *and* 2-PAM chloride: 1800 mg IM, *or* 15 mg/kg IV slowly	Phentolamine for 2-PAM-induced hypertension: (5 mg IV for adults; 1 mg IV for children). Diazepam for convulsions: (0.2 to 0.5 mg IV for infants <5 years: 1 mg IV for children >5 years; 5 mg IV for adults).
Elderly, frail	Atropine: 1 mg IM; *and* 2-PAM chloride: 10 mg/kg IM, *or* 5 to 10 mg/kg IV slowly	Atropine: 2 to 4 mg IM; *and* 2-PAM chloride: 25 mg/kg IM, *or* 5 to 10 mg/kg IV slowly	

[a]Mild/moderate effects include localized sweating, muscle fasciculations, nausea, vomiting, weakness, dyspnea.
[b]Severe effects include unconsciousness, convulsions, apnea, flaccid paralysis.
[c]If calculated dose exceeds the adult IM dose, adjust accordingly.
Note: 2-PAM chloride is pralidoxime chloride or protopam chloride.
Source: State of New York, Department of Health.

pine in autoinjector form for IM use. Civilian agencies are now stockpiling this FDA-approved product as well. One can only give full autoinjector doses and not divide them. The field-loading dose is 2, 4, or 6 mg, with retreatment every 5–10 min until the patient's breathing and secretions improve. The Iranians used larger doses initially during the Iran-Iraq war where oximes were in short supply. When the patient reaches a level of medical care where drugs can be given IV, this is the preferred route; in small children this may be the initial form of atropine therapy. However, pediatric autoinjectors of 0.5 mg and 1.0 mg are now manufactured. There is no upper limit to atropine therapy in a patient either IM or IV; however, a total average adult dose for a severely afflicted patient would usually be 20–30 mg.

In a mildly afflicted patient with miosis and no other systemic symptoms, atropine or homatropine eye drops may suffice for therapy. This will produce ~24 h of mydriasis. Frank miosis or imperfect accommodation may persist for weeks or even months after all other signs and symptoms have resolved.

Oxime Therapy Oximes are nucleophiles that reactivate the cholinesterase whose active site has been occupied and bound to nerve agent (Table 215-4). Therapy with oximes therefore restores normal enzyme function. Oxime therapy is limited by a second side reaction, called "aging," in which a side chain on nerve agents falls off the complex at a characteristic rate. "Aged" complexes are negatively charged, and oximes cannot reactivate negatively charged complexes. The practical effect of this differs from one nerve agent to another since each ages at a characteristic rate. VX, for practical purposes, never ages, sarin ages in 3–5 h, and tabun ages over a longer period. All of these are so much longer than the patient's expected lifespan after acute nerve agent toxicity that they may be ignored. Soman, on the other hand, ages in 2 min. Thus, after only a few minutes following exposure, oximes are useless in treating soman poisoning. The oxime used varies by country; the United States has approved and fielded 2-pralidoxime chloride (2-PAM Cl). MARK I kits (Fig. 215-5*A*) contain autoinjectors of 600 mg 2-PAM Cl. Initial field loading doses are 600, 1200, or 1800 mg. Since blood pressure elevation may occur after administration of 45 mg/kg in adults, field use of 2-PAM Cl is restricted to 1800 mg, IM, per hour. During the time when more oxime cannot be given, atropine alone is recommended. In the hospital setting, 2.5–25 mg/kg IV 2-PAM Cl has been found to reactivate 50% of inhibited cholinesterase. The usual recommendation is 1000 mg through slow IV drip over 20–30 min, with ≤2500 mg over a period of 1–1.5 h.

Anticonvulsants Nerve agent–induced seizures do not respond to the usual anticonvulsants used for status epilepticus, including phenytoin, phenobarbital, carbamazepine, valproic acid, and lamotrigine (Chap. 363). The only class of anticonvulsants that has been shown to stop this form of status are the benzodiazepines. Diazepam is the only benzodiazepine approved for seizures in humans, although other FDA-approved benzodiazepines work well against nerve agent–induced seizures in animal models. Diazepam, therefore, is manufactured in 10-mg injectors for IM use and given to U.S. forces for this purpose **(Fig. 215-5*B*)**. Civilian agencies are stockpiling this field product (convulsive antidote for nerve agent, "CANA"), which is not generally used in hospital practice. Extrapolation from animal studies indicates that adults will probably require 30–40 mg diazepam, IM, to stop nerve agent–induced status epilepticus. In the hospital, or in a small child unable to receive the autoinjector, IV diazepam may be used at similar doses. The clinician may confuse seizures with the neuromuscular signs of nerve agent poisoning. In the hospital, early electroencephalography is advised to distinguish between nonconvulsive status epilepticus, actual seizures, and postictal paralysis. Recent animal studies have shown that the most effective benzodiazepine in this situation is midazolam, which is not FDA-approved for seizures.

FIGURE 215-5 Antidotes to nerve agents. *A.* MARK I autoinjector set containing one 600-mg dose of 2-pralidoxime chloride and one 2-mg dose of atropine. Such sets are carried by all U.S. military forces in a potentially chemical battlefield and are now being stockpiled by civilian first responders. ***B.*** Diazepam 10-mg autoinjector. These are carried by all U.S. military forces in a potential chemical battlefield and are being stockpiled by civilian first responders.

Peripheral neuropathy and the so-called intermediate syndrome, prominent long-term effects of insecticide poisoning, are not described in nerve agent survivors.

Recent research has explored approaches leading to a transient "immunity," or drugs that would provide protection against lethal nerve agents yet be devoid of side effects. A novel approach is to use enzymes to scavenge these highly toxic nerve agents before they attack their intended targets. The accumulated work has shown that if a scavenger is present at the time of nerve agent exposure, rapid reduction of toxicant levels is observed. This reduction is so rapid and profound that the need to administer a host of pharmacologically active drugs as antidotes is, in theory, eliminated.

INDUSTRIAL CHEMICALS IN TERRORISM

Many of the chemical warfare agents of WWI, including chlorine, phosgene, and cyanide, are used today in large amounts in industry. They are produced in chemical plants, stockpiled in large tanks, and travel up and down highways and railways in large tanker cars. The rupture of any of these by accident or purposefully could cause many injuries and deaths. Hazardous materials (HAZMATs), not used on the battlefield, can also be used as terrorist weapons. Some of these, including insecticides and ammonia, could wreak as much damage and injury as the weaponized chemical agents.

Recently, insurgents in Iraq used chlorine gas, released from tankers following explosions, as a crude form of chemical weaponry. Using this gas, they killed 12 people and intoxicated more than 140 others in three attacks in February 2007. The clinical course and pathophysiology of the noncardiogenic pulmonary edema induced by chlorine (or phosgene) toxic inhalational injury are described in Chap. 262. Table 215-2 describes the physical appearance and initial physiologic effects of chlorine.

216 Radiation Bioterrorism

Zelig A. Tochner, Eli Glatstein

Terror attacks using nuclear or radiation-related devices are an unequivocal threat in the twenty-first century and are capable of unique medical and psychological effects. In this chapter we will focus on the most probable scenarios of possible attacks and the medical principles of handling such threats.

There are two major categories of potential terrorist incidents with widespread radiologic consequences. The first is the use of radiologic dispersal devices. This could cause a purposeful dissemination of radioactive material without nuclear detonation by using conventional explosives with radionuclides, attacking fixed nuclear facilities, or attacking nuclear-powered surface vessels or submarines. Malfunctioning nuclear weapons that are detonated with no nuclear yield (nuclear "duds") and/or installation of radionuclides in food or water are also a possible means of generating a terror attack. The second, and less probable, scenario is the actual use of nuclear weapons. Each scenario has its own medical aspects, including "conventional" blast or thermal injury, introduction to a radiation field, and exposure to either external or internal contamination from a radioactive explosion.

TYPES OF RADIOISOTOPIC RADIATION

Isotopes of atoms with uneven numbers of protons and/or neutrons are typically unstable; such isotopes discharge particles or energy to matter, a process that we define as *radiation*. The main radiation types are alpha, beta, gamma, and neutrons.

Alpha (α) radiation consists of heavy, positively charged particles containing two protons and two neutrons. Alpha particles are usually emitted from isotopes with an atomic number of ≥82, such as uranium or plutonium. Due to their large size, alpha particles have limited penetrating power. Fine obstacles such as cloth or human skin can usually stop them from penetrating into the body, and they represent a small risk to external exposure due to their limited penetration. If they somehow are internalized, then alpha particles can cause significant cellular damage within their immediate proximity.

Beta (β) radiation consists of electrons, which are small, light, negatively charged particles (about 1/2000 the mass of a neutron or proton). They can travel only a short finite distance in tissue, depending on their energy. Exposure to beta particles is common in many radiation accidents. Radioactive iodine, released in nuclear plant accidents, is the best known member of this group. Plastic layers and clothing can stop most beta particles, and their penetration is measured to be a few millimeters. A large quantum of energy to the basal stratum of the skin can cause a burn that is similar to a thermal burn and is treated as such.

Gamma (γ) rays and *x-rays* (both photons) are similar. Gamma rays are uncharged electromagnetic radiation discharged from a nucleus as a wave or photons of energy. X-rays are the product of abrupt mechanical deceleration of electrons striking a heavy target such as tungsten. Gamma and x-rays have similar properties, i.e., no charge and no mass, just energy. Both travel easily through matter, sometimes called *penetrating radiation*, and are the principal type of radiation to cause total-body exposure. If the energy of gamma rays and x-rays is the same, then their biological effects will be the same.

Neutron (η) particles are heavy and uncharged, often emitted during nuclear detonation. They possess a wide energy range; their ability to penetrate tissues is variable, depending upon their energy. They are less likely to be present in most scenarios of radiation bioterrorism.

The ionization resulting from protons, electrons, and gamma rays is either a direct or indirect (i.e., mediated through water) effect of particles or photons on DNA. Ionization of DNA resulting from neutrons is secondary to the neutrons knocking electrons out of their atomic orbit and the formation of free radicals, which can also damage DNA directly.

The commonly used units of radiation are the rad and the gray (Gy). The rad (radiation absorbed dose) is energy deposited within living matter and is equal to 100 ergs/g of tissue.

The traditional rad has been replaced by the Système Internationale (SI) unit of the gray; 100 rad = 1 Gy.

TYPES OF EXPOSURE

Whole-body exposure represents deposition of radiation energy over the entire body. Alpha and beta particles have limited penetration and do not cause significant noncutaneous injury unless emission results from an internalized source. Whole-body exposure from gamma rays, x-rays, or neutrons, which can penetrate through the body (depending on their energy), can result in damage to multiple tissues and organs. The tissue damage is proportional to the radiation exposure of that organ or tissue.

External contamination is a result of fallout of radioactive particles that land on the body surface, clothing, skin, and hair. This is the dominant element to consider in the mass casualty situation resulting from a radioactive terrorist strike. The common contaminants will primarily emit alpha and beta radiation. Alpha particles do not penetrate beyond the skin and thus have minimal systemic effects. Beta emitters can cause significant cutaneous burns and scarring. Gamma emitters may not only cause local damage but can also cause whole-body radiation exposures and injury. The medical treatment is primarily decontamination of the body, including wounds and burns, to prevent the contamination from becoming internalized. Removing the contaminated clothing reduces the contamination significantly and is a first step in the decontamination process. Generally patients will not constitute a significant radiation hazard to health care providers, and life-saving treatment should not be delayed for fear of secondary contamination of the medical team. Any damage to health care personnel will depend directly on the duration of exposure and will be inversely proportional to the square of the distance from any radioactive source. Gowns that can be easily removed are essential to protect health care personnel.

Internal contamination will occur when radioactive material is inhaled, ingested, or able to enter the body through open wounds or burns or via skin absorption. In principle, any externally contaminated casualty should be evaluated for internal contamination. Some isotopes may have toxic effects on specific target organs due to their chemical properties, in addition to radiologic injury. The respiratory system is the main portal of entrance for internal contamination, and the lung is the organ at greatest risk. Aerosol particles <5 μm can reach the alveoli, whereas larger particles will remain in proximal airways. The tiny particles can be absorbed by the lymphatic system or the bloodstream, continuing to irradiate (depending on their biologically active half-life) until being exhaled. Bronchial lavage is often helpful treatment in this situation. Radioactive material entering the gastrointestinal (GI) tract will be absorbed according to its chemical structure and solubility. The insoluble radionuclides may affect the lower GI tract. Intact skin is normally a good barrier to most radionuclides. Penetration through the skin usually takes place when wounds or burns have altered the skin barriers. Therefore, any skin erosion should be cleaned and decontaminated promptly.

Absorbed radioactive materials will travel throughout the body. Liver, kidney, adipose tissue, and bone tend to bind and retain the radioactive material more than other tissues. The medical treatment includes preventing absorption, reducing incorporation, and enhancing elimination (see below).

Localized exposure means close contact between a highly radioactive source and a part of the body, causing discrete damage to the skin and deeper tissues, similar to a thermal burn. Later signs include epilation, erythema, moist desquamation, ulceration, blistering, or necrosis in proportion to exposure. Alopecia, transient or permanent, is dose-related and starts at cutaneous doses >3 Gy. Overt tissue damage can take weeks and even months to develop; the healing process can also be very slow and last for months. Long-term cutaneous changes, including keratosis, fibrosis, and telangiectasias, may appear years after the exposure. Treatment is based on analgesia and infection prophylaxis. Nevertheless, severe burns can often require grafting or even amputation. Long-term radiation effects are characterized by cell loss and cell death.

RADIOLOGIC DISPERSAL EVENTS

Radiologic dispersal incidents are generally of two types resulting from: (1) small, usually localized sources; or (2) wide dispersals over large areas. The radioactive materials can take the form of solid state, aerosol, gas, or liquid. They can be put into food or water, released from vehicles, or be spread by explosion. The principal route of exposure is usually by direct contact between the victim's skin and the radioactive particles, although internal contamination could occur if the material were inhaled or ingested. The radiation field is also a potential source of whole-body exposure. The psychosocial effects that accompany such an event are significant and are beyond the scope of this chapter. A list of radioactive materials, including information on their major properties and medical treatment, is shown in Table 216-1.

In a localized event, the amount and spread of the radioactive materials are usually limited and can be treated like a spill of hazardous material. Protective clothing prevents or minimizes the contamination of emergency responders.

The use of explosives coupled with a large amount of radioactive materials can result in wide dispersion of radiation, which is of far greater concern. Other potential sources of radiation are nuclear reactors, spent nuclear fuel, and transport vehicles. Less probable but still possible is the use of a large source of penetrating radiation without explosion. It is expected that most exposures would be low, and the principal health and psychosocial effects would be similar to the former scenario but on a larger scale.

Whenever an explosion is involved, conventional life-saving treatment should be given first priority. Only then should decontamination and specific treatment be given for the radiation exposure.

Silent exposure represents a scenario in which a powerful radiologic source could be hidden in a crowded place or radiologic materials spread without any awareness or announcement. It might take a long time to recognize the event and the source of exposure. One of the major clues to this situation is the appearance of unusual clinical manifestations in many individuals; such manifestations are often nonspecific and include symptoms of acute radiation sickness (see below) such as headache, fatigue, malaise, and opportunistic infections. GI phenomena such as diarrhea, nausea, vomiting, and anorexia may occur. Dermatologic symptoms (burns, ulceration, and epilation) and hematopoietic manifestations such as bleeding tendency, thrombocytopenia, purpura, lymphopenia, or neutropenia are also possible and dose-related. Careful epidemiologic studies may be necessary to identify the source of such exposure.

NUCLEAR WEAPONS

The most likely scenario of nuclear terror would be the detonation of a single low-yield device. The estimated yield of such device is anywhere between 0.01 and 10 kiloton of TNT, although the probability would more likely be toward the lower yield. Coping with such an event is certainly possible. The effects of such an explosion are a combination of several components: ground shock, air blast, thermal radiation, initial nuclear radiation, residual nuclear radiation, crater formation, and radioactive fallout.

The nuclear detonation, like a conventional explosion, will produce a shock wave that can further damage structures and cause many casualties. In addition, the detonation can produce an extremely hot fireball that can ignite materials and cause severe burns. The detonation also releases an intense pulse of ionizing radiation, mainly gamma rays and neutrons. The radiation produced in the first minute is termed *initial radiation*, while the ongoing radiation due to fallout is termed *residual radiation*. Both types of radiation can cause acute radiation sickness (ARS; see below). The $LD_{50/30}$ (i.e., a dose that causes 50% mortality at 30 days) is ~4 Gy for whole-body exposure without medical support; with medical support, the $LD_{50/30}$ ranges between 8 and 10 Gy. Winds can carry fallout and contaminate large areas.

On top of its effects, a massive blast forms a crater in the soil and usually produces a ground shock compounding the damage and number of casualties. Inhalation of large amounts of radioactive dust causes pneu-

TABLE 216-1 INTERNAL CONTAMINANT RADIONUCLIDES: PROPERTIES AND TREATMENT

Isotope Name	Symbol	Common Usage	Radiation Type $t_{1/2}$ Radiologic $t_{1/2}$ Biologic, days	Exposure Type	Mode of Contamination	Focal Accumulation in Body	Treatment
Manganese	Mn-56	Reactors, research laboratories	β, γ 2.6 h 5.7	External, internal	N/A	Liver	N/A
Cobalt	Co-60	Medical radiotherapy devices, commercial food irradiators	β, γ 5.26 y 9.5	External, internal	Lungs	Liver	Gastric lavage, purgatives; penicillamine in severe cases
Strontium	Sr-90	Fission product of uranium	β 28 y 18,000	Internal	Moderate GI tract	Bones—similar to calcium	Strontium, calcium, ammonium chloride
Molybdenum	Mo-99	Hospitals—scans	β, γ 66.7 h 3	External, internal	N/A	Kidneys	N/A
Technetium	Tc-99m	Hospitals—scans	β, γ 6.049 h 1	External, internal	IV administration	Kidneys, total body	Potassium perchlorate to reduce thyroid dose
Cesium	Cs-137	Medical radiotherapy devices	β, γ 30 y 70	External, internal	Lungs, GI tract, wounds, follows potassium	Renal excretion	Ion-exchange resins, Prussian blue
Gadolinium	Gd-153	Hospitals	β, γ 242 d 1000	External, internal	N/A	N/A	N/A
Iridium	Ir-192	Commercial radiography	β, γ 74 d 50	External, internal	N/A	Spleen	N/A
Radium	Ra-226	Instrument illumination, industrial applications, old medical equipment, former Soviet Union military equipment	α, β, γ 1602 y 16,400	External, internal	GI tract	Bones	$MgSO_4$ lavage, ammonium chloride, calcium alginates
Tritium	H-3	Luminescent gun sights, muzzle-velocity detectors, nuclear weapons	β 12.5 y 12	Internal	Inhalation, GI tract, wounds	Total body	Dilution with controlled water intake, diuretics
Iodine	I-131	Reactor accidents, thyroid ablators	β, γ 8.1 d 138	Internal	Inhalation, GI tract, wounds	Thyroid	Potassium/sodium iodide, propylthiouracil, methimazole
Uranium	U-235	Depleted uranium, natural uranium, fuel rods, weapons-grade material	α, (α, β, γ) 7.1×10^8 y 15	Internal	GI tract	Kidneys, bones	$NaHCO_3$, chelation with EDTA
Plutonium	Pu-239	Produced from uranium in reactors, nuclear weapons	α 2.2×10^4 y 73,000	Internal	Limited lung absorption, high retention	Lungs, bones, bone marrow, liver, gonads	Chelating with DTPA or EDTA
Americium	Am-241	Smoke detectors, nuclear weapon detonation fallout	α 458 y 73,000	Internal	Inhalation, skin wounds	Lungs, liver, bones, bone marrow	Chelating with DTPA or EDTA
Polonium	Po-210	Calibration source	α 138.4 d 60	Internal	Inhalation, wounds	Spleen, kidneys	Lavage, dimercaprol
Thallium	Th-232	Calibration source	α 1.41×10^{10} y 73,000	Internal	N/A	N/A	N/A
Phosphorus	P-32	Research laboratories, medical facilities	β 14.3 d 1155	Internal	Inhalation, GI tract, wounds	Bones, bone marrow, rapidly replicating cells	Lavage, aluminum hydroxide, phosphate

Note: N/A, not available; h, hours; y, years; GI, gastrointestinal.

monitis that can lead to pulmonary fibrosis. Use of a mask covering the mouth and nose can be very helpful. The intense flash of infrared and visible light can cause either temporary or permanent blindness. Cataracts can develop months to years later among those who survive.

ACUTE RADIATION SICKNESS

Radiation interactions with atoms can result in ionization and the formation of free radicals that damage tissue by disrupting chemical bonds and molecular structures in the cell, including DNA. Radiation damage can lead to cell death; those cells that recover may be mutated and at higher risk for subsequent cancer. Cell sensitivity increases as the replication rate increases and the cell differentiation decreases. Bone marrow and mucosal surfaces of the GI tract, which have vast mitotic activity, are significantly more sensitive to radiation than slowly dividing tissues such as bones and muscles. Following exposure of either all or most of the human body to ionizing radiation, ARS can

develop. The clinical manifestations of ARS reflect the dose and type of radiation as well as the part of the body exposed.

Clinical Manifestations ARS manifests as three major groups of signs and symptoms: hematopoietic, gastrointestinal, and neurovascular. There are four major stages in ARS: prodrome, latent phase, illness, and either recovery or death. The higher the radiation doses, the shorter and more severe each stage. The prodrome appears within minutes to 4 days postexposure; lasts between a few hours to a few days; and can include nausea, vomiting, anorexia, and diarrhea. At the end of the prodrome, ARS progresses to the latent phase. Minimal or no symptoms are present during the latent phase, which commonly lasts up to 2.5 weeks, but can last up to 6 weeks. The duration depends on the radiation dose, the health of the patient, and the coexisting illness or injury. Following the latent phase, the exposed person manifests illness that may eventuate in recovery or lead to death.

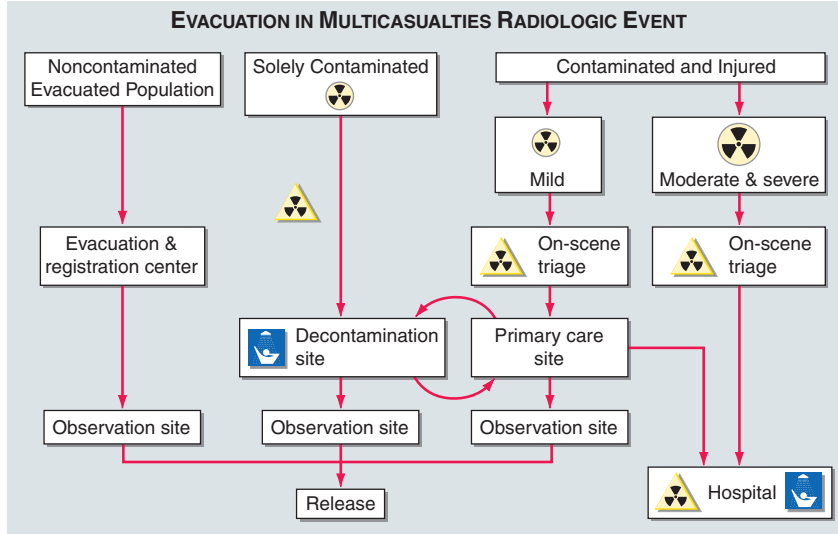

FIGURE 216-1 Algorithm for evacuation in a multicasualties radiologic event.

With exposure to doses <1 Gy, ARS is generally mild. At this dose symptoms can be minimal or nonexistent, even if the entire body is exposed to penetrating radiation. The clinical picture will mainly be transient depression of bone marrow (lymphopenia) that lasts up to 2 to 3 weeks and then recovers.

ARS is significantly more acute and severe with exposure to very high doses—>30 Gy. At this dose the prodrome appears in minutes and is followed by 5 to 6 h of latency before a cardiovascular collapse occurs secondary to irreversible damage to the microcirculation.

The type and dose of radiation and the part of the body exposed will determine not only the timing of the different stages of ARS but also the dominant clinical picture. At low radiation doses of 0.7 to 4 Gy, hematopoietic depression due to bone marrow suppression takes place and constitutes the main illness. The patient may develop infections and bleeding secondary to low leukocyte and platelet counts, respectively. The bone marrow will eventually recover in almost all patients if they are supported with transfusions and fluids; antibiotics are often needed in addition. With exposure to 6 to 8 Gy, the clinical picture is significantly more complicated. At these doses the bone marrow will not always recover and death may ensue. A GI syndrome may also accompany the hematopoietic manifestations and further worsen the patient's condition. Compromise of the absorptive layer of the gut alters absorption of fluids, electrolytes, and nutrients. GI injury can lead to vomiting, diarrhea, GI bleeding, sepsis, and electrolyte and fluid imbalance in a patient whose blood counts are compromised for a period of weeks, often leading to death. Whole-body exposure to doses >9–10 Gy is almost always fatal. Crucial elements of the bone marrow simply will not recover. In addition to the GI syndrome associated with very large exposures, patients may develop a neurovascular syndrome; the latter dominates with whole-body doses >20 Gy. Vascular collapse, seizures, confusion, and death usually occur within days. In this variant the prodrome and latent phase both shorten to a few hours.

℞ ACUTE RADIATION SICKNESS

The treatment of ARS is focused on maintaining homeostasis, giving damaged organs the chance to recover. Aggressive support is given to every damaged system. Treatment for the hematopoietic system includes mainly therapy for neutropenia and infection, transfusion and blood products as needed, and hematopoietic growth factors. The value of bone marrow transplantation in this situation is questionable. None of the transplants that were performed among the victims of the nuclear reactor accident in Chernobyl proved successful. Another major component of the treatment of ARS is partial or total parenteral nutrition, to bypass the damaged GI system. For blast and thermal injuries, standard therapy for trauma is given. Psychological support is essential in many cases.

MEDICAL MANAGEMENT OF RADIATION BIOTERRORISM

Victims of radiation bioterrorism can suffer from conventional thermal or blast injuries, exposure to radiation, and contamination by radioactive materials. Many will have combinations of the above, which can be synergistic and cause higher morbidity and mortality than when they occur alone. The number of casualties will be a major factor in determining the response of the medical system to an act of radiation bioterrorism. If only a few persons are affected, then no significant changes and adaptation of the system are needed to treat the victims. However, if a terror attack results in a large number (dozens, or more) of casualties, then an organized disaster plan at the local and state levels must be invoked to deal with the crisis properly. Medical personnel should have a prior assignment and training and be prepared to function in a scenario with which they are familiar. Stockpiles of specific equipment and medications have to be preplanned (see the Centers for Disease Control and Prevention website—*http://www.bt.cdc.gov*). One of the terrorists' goals is to overwhelm medical facilities and to minimize the salvage of casualties.

Initial management consists of *primary triage and transportation* of the wounded to emergency rooms for treatment. The rationale behind the triage is to sort patients into classes according to the severity of injury, for the purpose of expediting clinical care and maximizing the use of the available clinical services and facilities. Triage requires determination of the level of emergency care needed. The higher the number and range of casualties, the more complex and difficult triage becomes. The mildly wounded and victims of contamination only can be sent to evacuation, registration with disaster response teams, and decontamination and treatment centers. Figure 216-1 illustrates evacuation in a multicasualties radiologic event. In this way, the hospitals themselves can avoid being directly overwhelmed, and those who are severely wounded can receive better treatment. Emergency treatment will be administered initially according to the presence of conventional injuries such as wounds, trauma, and thermal or chemical burns. Individuals with such injuries should be stabilized, if possible, and immediately transported to a medical facility. Removing the victim's clothes and wrapping him or her in clean blankets or nylon sheets reduces both the exposure of the patient and the contamination risk to the staff. However, the possibility of contamination needs to be determined. Less severely injured victims should receive a preliminary decontamination before or during evacuation to a hospital.

One must remember that radionuclide contamination of the skin is commonly not an acute life-threatening situation to the patient or the personnel who care for the patient. Only powerful gamma emitters are likely to cause real damage from contamination. It is important to emphasize that exposure to a radiation field alone does not necessarily

create any contamination. The exposed person, if not contaminated, is not radioactive and does not directly emit any radiation.

In order to protect the staff, protective gear (gowns, gloves, masks, and caps) should be used. Protective masks with filters and chemically protective overgarments provide excellent protection from contamination. Waterproof shoe covers are also important. Remaining in the contaminated area and dealing with life-saving procedures should take place according to the "ALARA" principle: as low as reasonably achievable. It is better to send many people for short exposure times than to send a few people for longer periods of time to do the same job.

Decontamination of victims should take place in the field prior to their arrival at medical facilities, but radiologic decontamination should never interfere with medical care. Removal of outer clothing and shoes will usually reduce the patient's contamination by 80–90%. Contaminated clothes should be carefully removed by rolling them over themselves, placing them in marked plastic bags, and removing them to a predefined area for contaminated clothes and equipment. A radiation detector should then be used to check for the presence of any residual radiologic contamination on the patient's body. In order to prevent internalization of the radioactive materials, one should cover open wounds prior to decontamination. Showering or washing of the entire skin and hair is very important. The skin is dried and reassessed for residual contamination until no radiation is found. Contamination-removing chemical agents are more than sufficient to remove radiologic contamination.

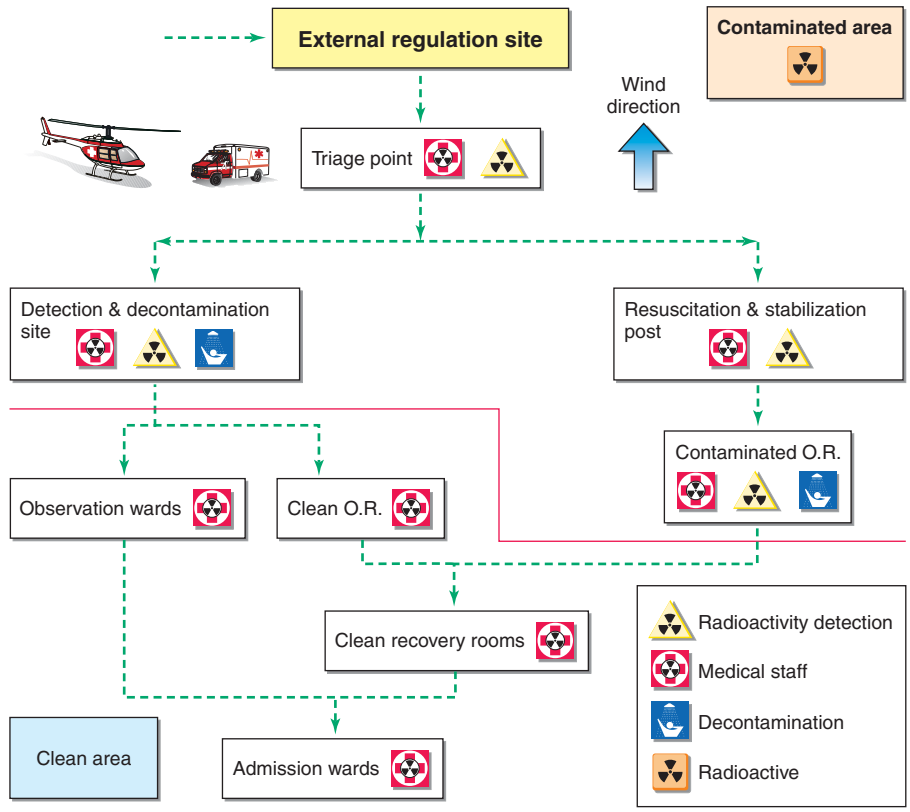

FIGURE 216-2 Flow chart of hospital triage. O.R., operating room.

Wound decontamination should be as conservative as possible. The main goal is to prevent both extensive local damage and internal contamination through lacerated skin. The bandages should be removed and the wounds flushed. The wound should then be dried and assessed for radiation. This procedure can be repeated again and again until contamination is undetectable. Excision of contaminated wounds should be attempted only when surgically necessary.

In the hospital, staff can wear normal hospital barrier clothing, including two pairs of gloves, a gown, shoe covers, a head cover, and a face mask. Eye protection is recommended. Decontamination of medical personnel is obligatory following emergency treatment and decontamination of the patient. All protective clothing should be placed after use in a designated container for contaminated clothing.

Radiation intensity decays rapidly with the square of the distance from the source, and increasing the distance from the source and decreasing the time spent near it are basic principles of radiation safety. Shielding with lead can be used as protection from small radioactive gamma sources. Geiger counters can detect gamma and beta radiation. Pocket chamber (pencil) dosimeters, film badges, and thermoluminescent dosimeters can measure accumulated exposure to gamma radiation. All of these detectors are in common use in medical facilities and should be used to help and define the level of contamination. Alpha radiation is harder to detect due to its poor penetration. An alpha scintillation counter, which is capable of detecting alpha radiation, is not commonly used in medical facilities.

GUIDELINES FOR HOSPITAL MANAGEMENT

Figure 216-2 illustrates a model for hospital arrangement for triage. Persons contaminated either externally or internally should be identified, externally decontaminated, and, if needed, treated immediately and specifically for internal contamination. In all other cases, the need for treatment of radiation injuries does not constitute a medical emergency. Early actions, such as blood sampling both for assessing the degree of severity of the exposure and for blood type and cross-matching for possible transfusion, need to be promptly taken if ARS is evident or if exposure is suspected.

In the hospital entrance, a distinct decontamination area should be set up promptly. Separation between clean and contaminated areas is essential. Medical personnel in this area should wear protective gear as noted above. They also should be rotated in their assignments every 1 to 2 h to ensure minimal exposure to radiation. If patients are critically wounded and require either surgery or resuscitation, they need to pass directly to "contaminated" operating rooms or resuscitation sites for life-saving procedures. Once such patients are stable, they should then be decontaminated. It is important to obtain details concerning the exposure, to look for prodromal signs of radiation sickness, and to do a physical examination. One of the best ways to estimate exposure clinically is to measure the time of prodromal appearance. The earlier the prodromal signs and symptoms appear, the higher the dose of radiation exposure. A few laboratory tests need to be routinely taken, such as complete blood count and urinalysis. If internal contamination is suspected, specific treatment should be given, as outlined below.

Rx RADIONUCLIDE CONTAMINATION

Treatment for internal radionuclide contamination should be started as soon as possible after suspected or known exposure. The goal is to leave the smallest amount of radionuclides as possible in the body. Treatment is given in order to reduce absorption and to enhance elimination and excretion.

Clearance of the GI tract may be achieved by stomach lavage; emetics (such as apomorphine, 5 to 10 mg, or ipecac, 1- to 2-g capsules or 15 mL in syrup); or by using purgatives, laxatives, ion exchangers, and aluminum antacids. Prussian blue, 1 g tid for a minimum of 3 weeks, is an ion exchanger used to treat cesium 137 internal contamination. Aluminum antacids (such as aluminum phosphate gel) may reduce strontium uptake in the gut if given immediately after exposure. Aluminum hydroxide is less effective.

Prevention or reversal of radionuclide interaction with tissues can be done by blocking, diluting, mobilizing, and chelating agents. *Blocking agents* prevent entrance of radioactive materials. A good example is potas-

sium iodide (KI), which blocks the uptake of radioactive iodine (^{131}I) by the thyroid. KI is most effective if taken within the first hour after exposure and is still effective 6 h after exposure. The effectiveness subsequently declines until 24 h after exposure; however, it is recommended that KI be taken up to 48 h postexposure. The KI dose is based on age, predicted thyroid exposure, and pregnancy and lactation status. Adults between the ages of 18–40 should receive 130 mg/d for 7–14 days if exposed to ≥10 cGy of radioactive iodine. Other thyroid-blocking agents include prophylthiouracil, 100 mg tid for 8 days, or methimazole, 10 mg tid for 2 days followed by 5 mg tid for 6 days, but they are somewhat less effective.

Diluting agents decrease the absorption of the radionuclide; for example, water may be used as a diluting agent in the treatment for tritium (^{3}H) contamination. The recommended amount is 3–4 L/d for at least 3 weeks.

Mobilizing agents are most effective when given immediately; however, they may be effective for up to 2 weeks after exposure. These include antithyroid drugs, parathyroid extract, glucocorticoids, ammonium chloride, diuretics, expectorants, and inhalants. All of them should induce the release of radionuclides from tissues.

Chelating agents can bind many radioactive materials, after which the complexes are excreted from the human body. In this regard, diethylenetriaminepentaacetic acid (DTPA) either as Ca-DTPA or Zn-DTPA is superior to ethylenediamine tetraacetic acid (EDTA); it was approved by the U.S. Food and Drug Administration (FDA) to treat internal contamination with plutonium, americium and curium, but it also chelates berkelium, californium, or any material with an atomic number >92. Ca-DTPA is more effective than Zn-DTPA during the first 24 h after internal contamination, and both drugs are equally effective after the initial 24 h. If both drugs are available, then Ca-DTPA should be given as the first dose. If additional treatment is needed, treatment should be switched to Zn-DTPA. The dose is 1 g Ca-DTPA or Zn-DTPA, dissolved in 250 mL of normal saline or 5% glucose, given IV over 1 h daily. The duration of chelation treatment depends on the amount of internal contamination and individual response to treatment. DTPA can also be administrated by nebulized inhalation; 1 g is given in 1:1 dilution with water or saline over 15–20 min. Nebulized Zn-DTPA is recommended if the internal contamination is only by inhalation. The IV route is recommended and should be used if the route of internal contamination

TABLE 216-2 COMMON DRUGS[a] FOR TREATMENT OF INTERNAL CONTAMINATION

Medication	Administered for Radionuclides	Route of Administration	Dosage	Duration	Mechanism of Action
KI	Iodine-131	PO	130 mg/d for adults >40 with thyroid exposure >500 cGy 130 mg/d for adults 18–40 with thyroid exposure >10 cGy 130 mg/d for pregnant or lactating women with thyroid exposure >5 cGy 65 mg/d for children and adolescents 3–18 with thyroid exposure >5 cGy 32.5 mg/d for infants 1 month to 3 years with thyroid exposure >5 cGy 16 mg/d for neonates from birth to 1 month with thyroid exposure >5 cGy	7–14 days	Blocking agent
Zn-DTPA	Plutonium, trans-plutonium, yttrium, americium, curium	IV Inhalation IM	1 g in 250 mL NS or 5% glucose, given in 1–2 h, *or* bolus over 3–4 min 1 g in 1:1 dilution with water or NS over 15–20 min 1 g; not recommended because of pain	Up to 5 days	Chelating agent
Ca-DTPA	Plutonium, *trans*-plutonium, yttrium, americium, curium	IV Inhalation IM	1 g in 250 mL NS or 5% glucose, given in 1–2 h, *or* bolus over 3–4 min 1 g in 1:1 dilution with water or NS over 15–20 min 1 g; not recommended because of pain	Up to 5 days	Chelating agent
Bicarbonate	Uranium	IV PO	2 ampules sodium bicarbonate (44.3 meq each, 7.5%) in 1000 mL NS, 125 mL/L, *or* 1 ampule of sodium bicarbonate (44.3 meq, 7.5%) in 500 mL NS, 500 mL/h 2 tablets every 4 h until urine pH = 7–8, *or* 4 g (8 tablets) 3 tid	Usually IV for the first 24 h, PO for additional 2 days; continuation of treatment for >3 days is rare and can be done according to titration of uranium amounts in the body	Increased excretion via the kidneys
Prussian blue	Cesium-137	PO	1 g tid with 100–200 mL water, up to 10 g/d	≥3 weeks titrated by urine and fecal bioassay and whole-body counting	Ion exchanger
Water	Tritium (H-3)	PO	>3–4 L per day	3 weeks	Excretion of water
Aluminum phosphate gel	Strontium	PO	100 mL immediately after exposure	Once	Decreased gut absorption
Aluminum hydroxide		PO	60–100 mL	Once	Decreased gut absorption

[a]Excluding KI, these drugs have not been approved for this purpose by the U.S. Food and Drug Administration at the time of publication.

Note: NS, normal saline.

is not known or if multiple routes of internal contamination are likely. Treating uranium contamination with DTPA is contraindicated, due to its synergistic damage to the kidneys.

Lung lavage can reduce radiation-induced pneumonitis and is indicated only when a large amount of radionuclide enters the lungs and has the potential for acute radiation injury. The procedure requires anesthesia. **Table 216-2** summarizes the common treatment regimens for internal radionuclide contamination.

MEDICAL ASSAY OF THE RADIATION-EXPOSED PATIENT

One of the major difficulties in treating victims exposed to radiation is the determination of the amount of exposure. Clinical assessment of the patient is the best approach. Appearance of an early prodrome indicates high exposure to radiation. Victims who arrive at the hospital complaining of severe weakness, nausea, vomiting, diarrhea, or seizures probably will not survive despite support measures. Decontamination and the use of radiation-detection equipment are both very important. Few tests can be performed in order to estimate the radiation exposure and the contamination. Baseline laboratory tests should include a complete blood count with differential and platelet count, renal evaluation, and determination of electrolytes. Urine and stool samples should be obtained if internal contamination is suspected. Nasal swabs should be taken from each nostril for determination of inhalation of radionuclides. After exhalation, each swab is labeled and sealed in a plastic bag and sent for analysis to appropriate laboratories. Patients exposed to 0.7–4 Gy will develop pancytopenia from as early as 10 days to as long 8 weeks postexposure. Lymphocytes show the most rapid decline, while other leukocytes and platelets decline less rapidly. Erythrocytes are the least vulnerable blood elements.

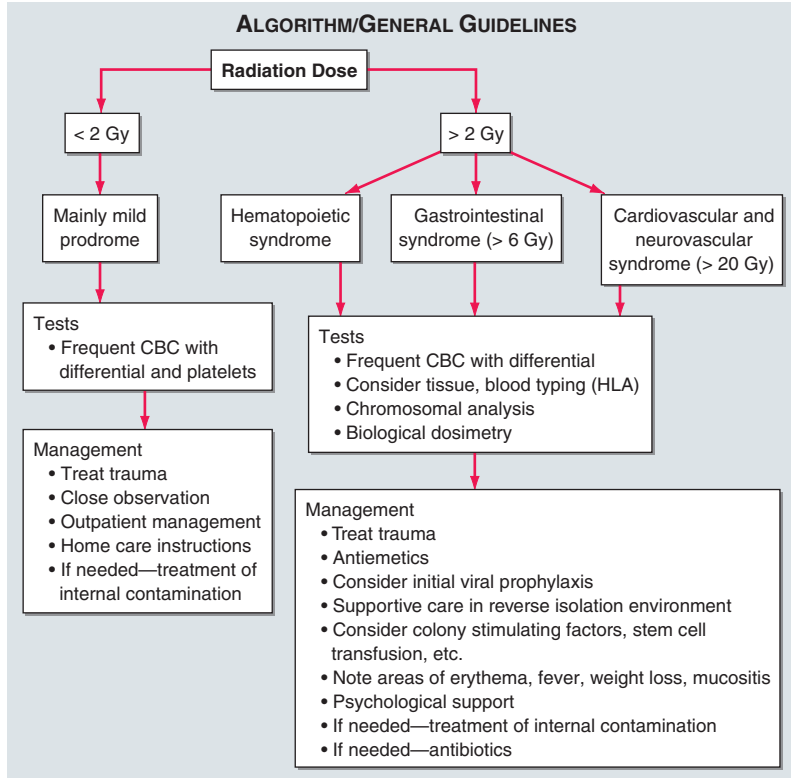

FIGURE 216-3 General guidelines for treatment of radiation casualties. CBC, complete blood count.

Absolute lymphocyte counts should be taken every 4–6 h for 5–6 days; they are the most valuable early indicator because they are recognized to be a sensitive marker for radiation damage and correlate with both the exposure and prognosis. A 50% drop in absolute lymphocyte count within the first 24 h indicates a signficant injury. HLA typing is necessary whenever there is suspicion of irreversible bone marrow damage. Lymphocyte chromosomal analysis can detect radiation exposure as low as 0.03–0.06 Gy, and 15 mL of blood should be drawn as early as possible in a heparinized collection tube and kept cool. Radiation-induced chromosomal aberrations in peripheral blood lymphocytes include dicentric chromosomes and ring forms that last for a few weeks. By calibrating a dose-response curve, the radiation dose can be assessed.

Another method for estimating exposure is the micronucleus (MN/Mni) scoring, which is simple and fast but still empirical. An algorithm for the treatment of radiation casualties is shown in **Fig. 216-3**.

FOLLOW-UP

It is desirable to continue follow-up in some circumstances. In general, only persons who are exposed to <8–10 Gy whole-body irradiation have a chance to survive long term, and they are at risk of developing cataracts; sterility; and lung, kidney, and bone marrow problems. Based on their age, gender, and amount and type of exposure, they should be followed for many years. A major public health issue is the risk of secondary malignancy in individuals and populations who were exposed to low doses of radiation. Leukemia, breast, brain, thyroid, and lung cancer are the most common, but the exposed population is at increased risk for many other cancers as well. Appropriate follow-up protocols should be developed based on the type of exposure and the exposed population. In cases of internal contamination, the long-term follow-up should be focused on the organ at risk. Such is the case with uranium contamination, with its nephrotoxic properties.

SECTION 1 INTRODUCTION TO CARDIOVASCULAR DISORDERS

217 Basic Biology of the Cardiovascular System

Joseph Loscalzo, Peter Libby, Eugene Braunwald

THE BLOOD VESSEL

VASCULAR ULTRASTRUCTURE

Blood vessels participate in homeostasis on a moment-to-moment basis and contribute to the pathophysiology of diseases of virtually every organ system. Hence, an understanding of the fundamentals of vascular biology furnishes a foundation for understanding normal function of all organ systems and many diseases. The smallest blood vessels, capillaries, consist of a monolayer of endothelial cells in close juxtaposition with occasional smooth-muscle–like cells known as *pericytes* (Fig. 217-1*A*). Unlike larger vessels, pericytes do not invest the entire microvessel to form a continuous sheath. Veins and arteries typically have a trilaminar structure (Fig. 217-1*B–E*). The *intima* consists of a monolayer of endothelial cells continuous with those of the capillary trees. The middle layer, or *tunica media*, consists of layers of smooth-muscle cells; in veins, this layer can contain just a few layers of smooth-muscle cells (Fig. 217-1*B*). The outer layer, the *adventitia*, consists of looser extracellular matrix with occasional fibroblasts, mast cells, and nerve terminals. Larger arteries have their own vasculature, the *vasa vasorum*, which nourish the outer aspects of the tunica media. The adventitia of many veins surpasses the intima in thickness.

The tone of muscular arterioles regulates blood pressure and flow through various arterial beds. These smaller arteries have relatively thick tunica media in relation to the adventitia (Fig. 217-1*C*). Medium-size muscular arteries likewise contain a prominent tunica media (Fig. 217-1*D*). Atherosclerosis commonly affects this type of muscular artery. The larger elastic arteries have a much more structured tunica media consisting of concentric bands of smooth-muscle cells interspersed with strata of elastin-rich extracellular matrix sandwiched between continuous layers of smooth-muscle cells (Fig. 217-1*E*). Larger arteries have a clearly demarcated internal elastic lamina that forms the barrier between the intima and media. An external elastic lamina demarcates the media of arteries from the surrounding adventitia.

ORIGIN OF VASCULAR CELLS

The intima in human arteries often contains occasional resident smooth-muscle cells beneath the monolayer of vascular endothelial cells. The embryonic origin of smooth-muscle cells in various types of artery differs. Some upper-body arterial smooth-muscle cells derive from the neural crest, whereas lower body arteries generally recruit smooth-muscle cells during development from neighboring mesodermal structures, such as the somites. Recent evidence suggests that the bone marrow may give rise to both vascular endothelial cells and smooth-muscle cells, particularly under conditions of repair of injury or vascular lesion formation. Indeed, the ability of bone marrow to repair an injured endothelial monolayer may contribute to maintenance of vascular health and may promote arterial disease when this reparative mechanism fails due to injurious stimuli or age. The precise sources of endothelial and mesenchymal progenitor cells or their stem cell precursors remain the subject of active investigation (Chaps. 66–68).

VASCULAR CELL BIOLOGY

Endothelial Cell The key cell of the vascular intima, the endothelial cell, has manifold functions in health and disease. Most obviously, the endothelium forms the interface between tissues and the blood compartment. It must, therefore, regulate the entry of molecules and cells into tissues in a selective manner. The ability of endothelial cells to serve as a permselective barrier fails in many vascular disorders, including atherosclerosis and hypertension. This dysregulation of permselectivity also occurs in pulmonary edema and other situations of "capillary leak."

The endothelium also participates in the local regulation of blood flow and vascular caliber. Endogenous substances produced by endothelial cells, such as prostacyclin, endothelium-derived hyperpolarizing factor, and nitric oxide (NO), provide tonic vasodilatory stimuli under physiologic conditions in vivo (Table 217-1). Impaired production or excess catabolism of NO impairs this endothelium-dependent vasodilator function and may contribute to excessive vasoconstriction under various pathologic situations. By contrast, endothelial cells also produce potent vasoconstrictor substances such as endothelin in a regulated fashion. Excessive production of reactive oxygen species, such as superoxide anion (O_2^-), by endothelial or smooth-muscle cells under pathologic conditions (e.g., excessive exposure to angiotensin II) can promote local oxidative stress and inactivate NO.

The endothelial monolayer contributes critically to inflammatory processes involved in normal host defenses and pathologic states. The normal endothelium resists prolonged contact with blood leukocytes; however, when activated by bacterial products, such as endotoxin or proinflammatory cytokines released during infection or injury, endothelial cells express an array of leukocyte adhesion molecules that bind various classes of leukocytes. The endothelial cells appear to recruit selectively different classes of leukocytes under different pathologic conditions. The gamut of adhesion molecules and chemokines generated during acute bacterial processes tends to recruit granulocytes. In chronic inflammatory diseases, such as tuberculosis or atherosclerosis, endothelial cells express adhesion molecules that favor the recruitment of mononuclear leukocytes that characteristically accumulate in these conditions.

The endothelial monolayer also dynamically regulates thrombosis and hemostasis. NO, in addition to its vasodilatory properties, can limit platelet activation and aggregation. Like NO, prostacyclin produced by endothelial cells under normal conditions not only provides a vasodilatory stimulus but also antagonizes platelet activation and aggregation. Thrombomodulin expressed on the surface of endothelial cells binds thrombin at low concentrations and inhibits coagulation through activation of the protein C pathway, leading to enhanced catabolism of clotting factors Va and VIIIa, thereby combating thrombus formation. The surface of endothelial cells contains heparan sulfate glycosaminoglycans that furnish an endogenous antithrombin coating to the vasculature. Endothelial cells also participate actively in fibrinolysis and its regulation. They express receptors for plasminogen activators and produce tissue-type plasminogen activator. Through local generation of plasmin, the normal endothelial monolayer can promote the lysis of nascent thrombi.

When activated by inflammatory cytokines—bacterial endotoxin, or angiotensin II, for example—endothelial cells can produce substantial quantities of the major inhibitor of fibrinolysis, plasminogen activator inhibitor 1 (PAI-1). Thus, under pathologic circumstances, the endothelial cell may promote local thrombus accumulation rather than combat it. Inflammatory stimuli also induce the expression of the potent procoagulant tissue factor, a contributor to disseminated intravascular coagulation in sepsis.

Endothelial cells also participate in the pathophysiology of a number of immune-mediated diseases. Lysis of endothelial cells mediated by complement provides an example of immunologically mediated tissue

injury. Presentation of foreign histocompatibility complex antigens by endothelial cells in solid organ allografts can trigger immunologic rejection. In addition, immune-mediated endothelial injury may contribute in some patients with thrombotic thrombocytopenic purpura and in patients with hemolytic uremic syndrome. Thus, in addition to contributing to innate immune responses, endothelial cells participate actively in both humoral and cellular limbs of the immune response.

Endothelial cells can also regulate growth of the subjacent smooth-muscle cells. Heparan sulfate glycosaminoglycans elaborated by endothelial cells can hold smooth-muscle proliferation in check. In contrast, when exposed to various injurious stimuli, endothelial cells can elaborate growth factors and chemoattractants, such as platelet-derived growth factor, that can promote the migration and proliferation of vascular smooth-muscle cells. Dysregulated elaboration of these growth-stimulatory molecules may promote smooth-muscle accumulation in arterial hyperplastic diseases, including atherosclerosis and in-stent stenosis.

Clinical Assessment of Endothelial Function Endothelial function can be assessed noninvasively and invasively, and typically involves evaluating one measure of endothelial behavior in vivo, viz., endothelium-dependent vasodilation. Using either pharmacologic or mechanical agonists, the endothelium is stimulated to release acutely molecular effectors that alter underlying smooth-muscle cell tone. Invasively, endothelial function can be assessed with the use of agonists that stimulate release of endothelial NO, such as the cholinergic agonists acetylcholine and methacholine. The typical approach involves measuring quantitatively the change in coronary diameter in response to an intracoronary infusion of these short-lived, rapidly acting agents. Noninvasively, endothelial function can be assessed in the forearm circulation by performing occlusion of brachial artery blood flow with a blood pressure cuff, after which the cuff is deflated and the change in brachial artery blood flow and diameter are measured ultrasonographically (Fig. 217-2). This approach depends upon shear stress-dependent changes in endothelial release of NO following restoration of blood flow, as well as the effect of adenosine released (transiently) from ischemic tissue in the forearm.

Typically, the change in vessel diameter detected by these invasive and noninvasive approaches is ~10%. In individuals with frank atherosclerosis or risk factors for atherosclerosis (especially hypertension, hypercholesterolemia, diabetes mellitus, and smoking), such studies can detect endothelial dysfunction as defined by a smaller change in diameter and, in the extreme case, a so-called paradoxical vasoconstrictor response owing to the direct effect of cholinergic agonists on vascular smooth-muscle cell tone.

TABLE 217-1 ENDOTHELIAL FUNCTIONS IN HEALTH AND DISEASE

Homeostatic Phenotype	Dysfunctional Phenotype
Vasodilatation	Impaired dilatation, vasoconstriction
Antithrombotic, profibrinolytic	Prothrombotic, antifibrinolytic
Anti-inflammatory	Pro-inflammatory
Antiproliferative	Proproliferative
Antioxidant	Prooxidant

VASCULAR SMOOTH-MUSCLE CELL

The vascular smooth-muscle cell, the major cell type of the media layer of blood vessels, also actively contributes to vascular pathobiology. Contraction and relaxation of smooth-muscle cells at the level of the muscular arteries controls blood pressure and, hence, regional blood flow and the afterload experienced by the left ventricle (see below). The vasomotor tone of veins, governed by smooth-muscle cell tone, regulates the capacitance of the venous tree and influences the preload experienced by both ventricles. Smooth-muscle cells in the adult vessel seldom replicate. This homeostatic quiescence of smooth-muscle cells changes under conditions of arterial injury or inflammatory activation. Proliferation and migration of arterial smooth-muscle cells can contribute to the development of arterial stenoses in atherosclerosis, of arteriolar remodeling that can sustain and propagate hypertension, and of the hyperplastic response of arteries injured by angioplasty or stent deployment. In the pulmonary circulation, smooth-muscle migration and proliferation contribute decisively to the pulmonary vascular disease that gradually occurs in response to sustained high-flow states, such as left-to-right shunts. Such pulmonary vascular disease provides a major obstacle to the management of many patients with adult congenital heart disease.

Smooth-muscle cells also secrete the bulk of vascular extracellular matrix. Excessive production of collagen and glycosaminoglycans contributes to the remodeling and altered biology and biomechanics of arteries affected by hypertension or atherosclerosis. In larger elastic arteries, the elastin synthesized by smooth-muscle cells serves to maintain not only normal arterial structure but also hemodynamic function. The ability of the larger arteries, such as the aorta, to store the kinetic energy of systole promotes tissue perfusion during diastole. Arterial stiffness associated with aging or disease, as manifested by a widening pulse pressure, increases left ventricular afterload and portends a poor prognosis.

Like endothelial cells, vascular smooth-muscle cells do not merely respond to vasomotor or inflammatory stimuli elaborated by other

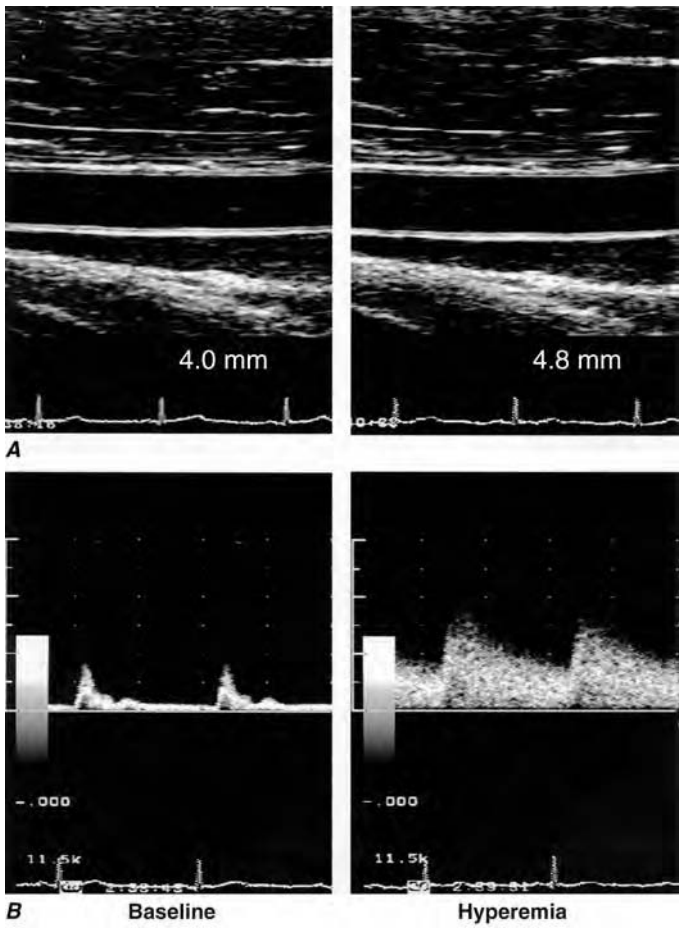

FIGURE 217-2 Assessment of endothelial function in vivo using blood pressure cuff-occlusion and release. Upon deflation of the cuff, changes in diameter (***A***) and blood flow (***B***) of the brachial artery are monitored with an ultrasound probe (***C***). *(Reproduced with permission of J. Vita, MD.)*

cell types but can themselves serve as a source of such stimuli. For example, when stimulated by bacterial endotoxin, smooth-muscle cells can elaborate large quantities of proinflammatory cytokines, such as interleukin 6, as well as lesser quantities of many other proinflammatory mediators. Like endothelial cells, upon inflammatory activation, arterial smooth-muscle cells can produce prothrombotic mediators, such as tissue factor, the antifibrinolytic protein PAI-1, and other molecules that modulate thrombosis and fibrinolysis. Smooth-muscle cells may also elaborate autocrine growth factors that can amplify hyperplastic responses to arterial injury.

Vascular Smooth-Muscle Cell Function A principal function of vascular smooth-muscle cells is to maintain vessel tone. Vascular smooth-muscle cells contract when stimulated by a rise in intracellular calcium concentration by calcium influx through the plasma membrane and by calcium release from intracellular stores (Fig. 217-3). In vascular smooth-muscle cells, voltage-dependent L-type calcium channels open with membrane depolarization, which is regulated by energy-dependent ion pumps such as the Na^+,K^+-ATPase and ion channels such as the Ca^{2+}-sensitive K^+ channel. Local changes in intracellular calcium concentration, termed *calcium sparks*, result from the influx of calcium through the voltage-dependent calcium channel and are caused by the coordinated activation of a cluster of ryanodine-sensitive calcium release channels in the sarcoplasmic reticulum (see below). Calcium sparks lead to a further direct increase in intracellular calcium concentration and indirectly increase intracellular calcium concentration by activating chloride channels. In addition, calcium sparks reduce contractility by activating large-conductance calcium-sensitive K^+ channels, hyperpolarizing the cell membrane and thereby limiting further voltage-dependent increases in intracellular calcium.

Biochemical agonists also increase intracellular calcium concentration, doing so by receptor-dependent activation of phospholipase C with hydrolysis of phosphatidylinositol 4,5-bisphosphate with generation of diacylglycerol (DAG) and inositol 1,4,5-trisphosphate (IP_3). These membrane lipid derivatives, in turn, activate protein kinase C and increase intracellular calcium concentration. In addition, IP_3 binds to its specific receptor found in the sarcoplasmic reticulum membrane to increase calcium efflux from this calcium storage pool into the cytoplasm.

Vascular smooth-muscle cell contraction is principally controlled by the phosphorylation of myosin light chain, which, in the steady state, depends on the balance between the actions of myosin light chain kinase and myosin light chain phosphatase. Myosin light chain kinase is activated by calcium through the formation of a calcium-calmodulin complex; with phosphorylation of myosin light chain by this kinase, the myosin ATPase activity is increased and contraction sustained. Myosin light chain phosphatase dephosphorylates myosin light chain, reducing myosin ATPase activity and contractile force. Phosphorylation of the myosin binding subunit (thr695) of myosin light chain phosphatase by Rho kinase inhibits phosphatase activity and induces calcium sensitization of the contractile apparatus. Rho kinase is itself activated by the small GTPase RhoA, which is stimulated by guanosine exchange factors and inhibited by GTPase-activating proteins.

Both cyclic AMP and cyclic GMP relax vascular smooth-muscle cells, doing so by complex mechanisms. β-Agonists acting through their G-protein-coupled receptors activate adenylyl cyclase to convert ATP to cyclic AMP; NO and atrial natriuretic peptide acting directly and via a G-protein-coupled receptor, respectively, activate guanylyl cyclase to convert GTP to cyclic GMP. These agents, in turn, activate protein kinase A and protein kinase G, respectively, which inactivates myosin light chain kinase and decreases vascular smooth-muscle cell tone. In addition, protein kinase G can directly interact with the myosin-binding substrate subunit of myosin light chain phosphatase, increasing phosphatase activity and decreasing vascular tone. Lastly, several mechanisms drive NO-dependent, protein kinase G–mediated reductions in vascular smooth-muscle cell calcium concentration, including phosphorylation-dependent inactivation of RhoA; decreased IP_3 formation; phosphorylation of the IP_3 receptor–associated cyclic GMP kinase substrate, with subsequent inhibition of IP_3 receptor function; phosphorylation of phospholamban, which increases calcium ATPase activity and sequestration of calcium in the sarcoplasmic reticulum; and protein kinase G–dependent stimulation of plasma membrane calcium ATPase activity, perhaps by activation of the Na^+,K^+-ATPase or hyperpolarization of the cell membrane by activation of calcium-dependent K^+ channels.

Control of Vascular Smooth-Muscle Cell Tone Vascular smooth-muscle cell tone is governed by the autonomic nervous system and by the endothelium in tightly regulated control networks. Autonomic neurons enter the blood vessel media from the adventitia and modulate vascular smooth-muscle cell tone in response to baroreceptors and chemoreceptors within the aortic arch and carotid bodies, and in response to thermoreceptors in the skin. These regulatory components comprise rapidly acting reflex arcs modulated by central inputs that respond to sensory inputs (olfactory, visual, auditory, and tactile) as well as emotional stimuli. Autonomic regulation of vascular tone is mediated by three classes of nerves: *sympathetic*, whose principal neurotransmitters are epinephrine and norepinephrine; *parasympathetic*, whose principal neurotransmitter is acetylcholine; and *nonadrenergic/noncholinergic*, which include two subgroups—nitrergic, whose principal neurotransmitter is NO; and peptidergic, whose principal neurotransmitters are substance P, vasoactive intestinal peptide, calcitonin gene-related peptide, and ATP.

Each of these neurotransmitters acts through specific receptors on the vascular smooth-muscle cell to modulate intracellular calcium and, consequently, contractile tone. Norepinephrine activates α receptors and epinephrine activates α and β receptors (adrenergic receptors); in most blood vessels, norepinephrine activates postjunctional α_1 receptors in large arteries, and α_2 receptors in small arteries and arterioles, leading to vasoconstriction. Most blood vessels express β_2 adrenergic receptors on their vascular smooth-muscle cells and respond to β agonists by cyclic AMP–dependent relaxation. Acetylcholine released from parasympathetic neurons binds to muscarinic receptors (of which there are five subtypes, M_{1-5}) on vascular smooth-muscle cells to yield vasorelaxation. In addition, NO stimulates presynaptic neurons to release acetylcholine, which can stimulate release of NO from the endothelium. Nitrergic neurons release NO produced by neuronal NO synthase, which causes vascular smooth-muscle cell relaxation via the cyclic GMP–dependent and –independent mechanisms described above. The peptidergic neurotransmitters all potently vasodilate, acting either directly or through endothelium-dependent NO release to decrease vascular smooth-muscle cell tone. **The detailed molecular physiology of the autonomic nervous system is provided in Chap. 370.**

The endothelium modulates vascular smooth-muscle tone by the direct release of several effectors, including NO, prostacyclin, and endothelium-derived hyperpolarizing factor, all of which cause vasorelaxation; and endothelin, which causes vasoconstriction. The release of these endothelial effectors of vascular smooth-muscle cell tone is stimulated by mechanical (shear stress, cyclic strain, etc.) and biochemical mediators (purinergic agonists, muscarinic agonists, peptidergic agonists), with the biochemical mediators acting through endothelial receptors specific to each class.

In addition to these local, paracrine modulators of vascular smooth-muscle cell tone, circulating mediators can also affect tone, including norepinephrine and epinephrine, vasopressin, angiotensin II, bradykinin, and the natriuretic peptides (ANP, BNP, CNP, and DNP), as discussed above.

VASCULAR REGENERATION

Growing new blood vessels can occur in response to such conditions as chronic hypoxia or tissue ischemia. Growth factors, including vascular endothelial growth factor, activate a signaling cascade that stimulates endothelial proliferation and tube formation, defined as *angiogenesis*. The development of collateral vascular networks in the ischemic myocardium reflects this process and can result from selective activation of endothelial progenitor cells, which may reside in the blood vessel wall or home to the ischemic tissue subtended by an occluded or severely stenotic vessel from the bone marrow. True arterio-

TABLE 217-2 GENETIC POLYMORPHISMS IN VASCULAR FUNCTION AND DISEASE RISK

Gene	Polymorphic Allele	Clinical Implications
α-adrenergic receptors		
α-1A	Arg492Cys	None
α-2B	Glu9/G1712	Increased CHD events
α-2C	A2cDcl3232-325	Ethnic differences in risk of hypertension or heart failure
Angiotensin-converting enzyme (ACE)	Insertion/deletion polymorphism in intron 16	D allele or DD genotype–increased response to ACE inhibitors; inconsistent data for increased risk of atherosclerotic heart disease, and hypertension
Ang II type I receptor	1166A → C Ala-Cys	Increased response to Ang II and increased risk of pregnancy-associated hypertension
β-Adrenergic receptors		
β-1		
	Ser49Gly	Increased HR and DCM risk
	Arg389Gly	Increased heart failure in blacks
β-2		
	Arg16Gly	Familial hypertension, increased obesity risk
	Glu27Gln	Hypertension in white type II diabetics
	Thr164Ile	Decreased agonist affinity and worse HF outcome
B2-Bradykinin receptor	Cys58Thr, Cys412Gly, Thr21Met	Increased risk of hypertension in some ethnic groups
Endothelial nitric oxide synthase (eNOS)	Nucleotide repeats in introns 4 and 13, Glu298Asp	Increased MI and venous thrombosis
	Thr785Cys	Early coronary artery disease

Note: CHD, coronary heart disease; HR, heart rate; DCM, dilated cardiomyopathy; HF, heart failure; MI, myocardial infarction.

genesis, or the development of a new blood vessel comprising all three cell layers, does not normally occur in the cardiovascular system of mammals. Recent insights into the molecular determinants and progenitor cells that can recapitulate blood vessel development de novo is the subject of ongoing and rapidly advancing study (Chaps. 66–68).

VASCULAR PHARMACOGENOMICS

The past decade has witnessed considerable progress in efforts to define genetic differences underlying individual differences in vascular pharmacologic responses. Many investigators have focused on receptors and enzymes associated with neurohumoral modulation of vascular function, as well as hepatic enzymes that metabolize drugs affecting vascular tone. The genetic polymorphisms thus far associated with differences in vascular response often (but not invariably) relate to functional differences in the activity or expression of the receptor or enzyme of interest. Some of these polymorphisms appear to be differentially expressed in specific ethnic groups or by sex. A summary of recently identified polymorphisms defining these vascular pharmacogenomic differences is provided in Table 217-2.

CELLULAR BASIS OF CARDIAC CONTRACTION

THE CARDIAC ULTRASTRUCTURE

About three-fourths of the ventricle is composed of individual striated muscle cells (myocytes), normally 60–140 μm in length and 17–25 μm in diameter (Fig. 217-4*A*). Each cell contains multiple, rodlike cross-banded strands (myofibrils) that run the length of the cell and are, in turn, composed of serially repeating structures, the sarcomeres. The cytoplasm between the myofibrils contains other cell constituents, including the single centrally located nucleus, numerous mitochondria, and the intracellular membrane system, the sarcoplasmic reticulum.

The *sarcomere*, the structural and functional unit of contraction, lies between two adjacent dark lines, the Z lines. The distance between Z lines varies with the degree of contraction or stretch of the muscle and ranges between 1.6 and 2.2 μm. Within the confines of the sarcomere are alternating light and dark bands, giving the myocardial fibers their striated appearance under the light microscope. At the center of the sarcomere is a dark band of constant length (1.5 μm), the A band, which is flanked by two lighter bands, the I bands, which are of variable length. The sarcomere of heart muscle, like that of skeletal muscle, consists of two sets of interdigitating myofilaments. Thicker filaments, composed principally of the protein myosin, traverse the A band. They are about 10 nm (100 Å) in diameter, with tapered ends. Thinner filaments, composed primarily of actin, course from the Z line through the I band into the A band. They are approximately 5 nm (50 Å) in diameter and 1.0 μm in length. Thus, thick and thin filaments overlap only within the (dark) A band, while the (light) I band contains only thin filaments. On electron-microscopic examination, bridges may be seen to extend between the thick and thin filaments within the A band; these comprise myosin heads (see below) bound to actin filaments.

THE CONTRACTILE PROCESS

The sliding filament model for muscle contraction rests on the fundamental observation that both the thick and thin filaments are constant in overall length during both contraction and relaxation. With activation, the actin filaments are propelled further into the A band. In the process, the A band remains constant in length, whereas the I band shortens and the Z lines move toward one another.

The *myosin* molecule is a complex, asymmetric fibrous protein with a molecular mass of about 500,000 Da; it has a rodlike portion that is about 150 nm (1500 Å) in length with a globular portion (head) at its end. These globular portions of myosin form the bridges between the myosin and actin molecules and are the site of ATPase activity. In forming the thick myofilament, which is composed of ~300 longitudinally stacked myosin molecules, the rodlike segments of the myosin molecules are laid down in an orderly, polarized manner, leaving the globular portions projecting outward so that they can interact with actin to generate force and shortening (Fig. 217-4*B*).

Actin has a molecular mass of about 47,000 Da. The thin filament consists of a double helix of two chains of actin molecules wound about each other on a larger molecule, tropomyosin. A group of regulatory proteins—troponins C, I, and T—are spaced at regular intervals on this filament (Fig. 217-5). In contrast to myosin, actin lacks intrinsic enzymatic activity but does combine reversibly with myosin in the presence of ATP and Ca^{2+}. The calcium ion activates the myosin ATPase, which in turn breaks down ATP, the energy source for contraction (Fig. 217-5). The activity of myosin ATPase determines the rate of forming and breaking of the actomyosin cross-bridges and, ultimately, the velocity of muscle contraction. In relaxed muscle, tropomyosin inhibits this interaction. *Titin* (Fig. 217-4*D*) is a large, flexible, myofibrillar protein that connects myosin to the Z line. Its stretching contributes to the elasticity of the heart.

During activation of the cardiac myocyte, Ca^{2+} becomes attached to troponin C, which results in a conformational change in the regulatory protein tropomyosin; the latter, in turn, exposes the actin cross-bridge interaction sites (Fig. 217-5). Repetitive interaction between myosin heads and actin filaments is termed *cross-bridge cycling*, which results in sliding of the actin along the myosin filaments, ultimately causing muscle shortening and/or the development of tension. The splitting of ATP then dissociates the myosin cross-bridge from actin. In the presence of

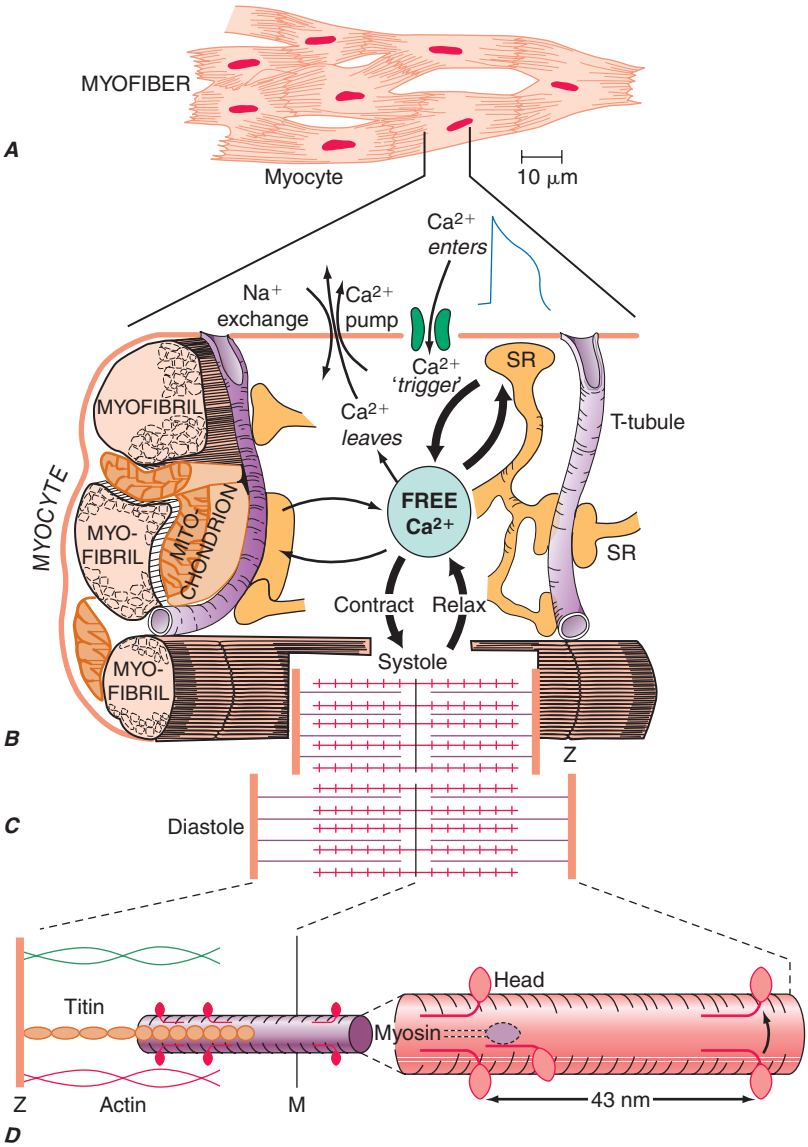

FIGURE 217-4 ***A*** shows the branching myocytes making up the cardiac myofibers. ***B*** illustrates the critical role played by the changing [Ca^{2+}] in the myocardial cytosol. Ca^{2+} ions are schematically shown as entering through the calcium channel that opens in response to the wave of depolarization that travels along the sarcolemma. These Ca^{2+} ions "trigger" the release of more calcium from the sarcoplasmic reticulum (SR) and thereby initiate a contraction-relaxation cycle. Eventually the small quantity of Ca^{2+} that has entered the cell leaves predominantly through an Na^+/Ca^{2+} exchanger, with a lesser role for the sarcolemmal Ca^{2+} pump. The varying actin-myosin overlap is shown for (***B***) systole, when [Ca^{2+}] is maximal, and (***C***) diastole, when [Ca^{2+}] is minimal. ***D.*** The myosin heads, attached to the thick filaments, interact with the thin actin filaments. *(From LH Opie, Heart Physiology, reprinted with permission. Copyright LH Opie, 2004.)*

ATP (Fig. 217-5), linkages between actin and myosin filaments are made and broken cyclically as long as sufficient Ca^{2+} is present; these linkages cease when [Ca^{2+}] falls below a critical level, and the troponin-tropomyosin complex once more prevents interactions between the myosin cross-bridges and actin filaments (Fig. 217-6).

Intracytoplasmic Ca^{2+} is a principal mediator of the inotropic state of the heart. The fundamental action of most agents that stimulate myocardial contractility (positive inotropic stimuli), including the digitalis glycosides and β-adrenergic agonists, is to raise the [Ca^{2+}] in the vicinity of the myofilaments, which, in turn, triggers cross-bridge cycling. Increased impulse traffic in the cardiac adrenergic nerves stimulates myocardial contractility as a consequence of the release of norepinephrine from cardiac adrenergic nerve endings. Norepinephrine activates myocardial β receptors and, through the G_s-stimulated guanine nucleotide binding protein, activates the enzyme adenylyl cyclase, which leads to the formation of the intracellular second messenger cyclic AMP from ATP (Fig. 217-6). Cyclic AMP, in turn, activates protein kinase A (PKA), which phosphorylates the Ca^{2+} channel in the myocardial sarcolemma, thereby enhancing the influx of Ca^{2+} into the myocyte. Other functions of PKA are discussed below.

The *sarcoplasmic reticulum* (SR) (Fig. 217-7) is a complex network of anastomosing intracellular channels that invests the myofibrils. Its longitudinally disposed membrane-lined tubules closely invest the surfaces of individual sarcomeres but have no direct continuity with the outside of the cell. However, closely related to the SR, both structurally and functionally, are the transverse tubules, or T system, formed by tubelike invaginations of the sarcolemma that extend into the myocardial fiber along the Z lines, i.e., the ends of the sarcomeres.

CARDIAC ACTIVATION

In the inactive state, the cardiac cell is electrically polarized, i.e., the interior has a negative charge relative to the outside of the cell, with a transmembrane potential of –80 to –100 mV (Chap. 224). The sarcolemma, which in the resting state is largely impermeable to Na^+, has a Na^+- and K^+-stimulating pump energized by ATP that extrudes Na^+ from the cell; this pump plays a critical role in establishing the resting potential. Thus, intracellular [K^+] is relatively high and [Na^+] is far lower, while, conversely, extracellular [Na^+] is high and [K^+] is low. At the same time, in the resting state, extracellular [Ca^{2+}] greatly exceeds free intracellular [Ca^{2+}].

The four phases of the action potential are illustrated in Fig. 224-1*B*. During the plateau of the action potential (phase 2), there is a slow inward current through L-type Ca^{2+} channels in the sarcolemma (Fig. 217-7). The depolarizing current not only extends across the surface of the cell but penetrates deeply into the cell by way of the ramifying T tubular system. The absolute quantity of Ca^{2+} that crosses the sarcolemma and T system is relatively small and itself appears to be insufficient to bring about full activation of the contractile apparatus. However, this Ca^{2+} current triggers the release of much larger quantities of Ca^{2+} from the SR, a process termed *Ca^{2+}-induced Ca^{2+} release*. The latter is a major determinant of intracytoplasmic [Ca^{2+}] and therefore of myocardial contractility.

Ca^{2+} is released from the SR through a Ca^{2+} release channel, a cardiac isoform of the ryanodine receptor (RyR2), which controls intracytoplasmic [Ca^{2+}] and, as in vascular smooth-muscle cells, leads to the local changes in intracellular [Ca^{2+}] called calcium sparks. A number of regulatory proteins, including *calstabin 2*, inhibit RyR2 and, thereby, the release of Ca^{2+} from the SR. PKA dissociates calstabin from the RyR2, enhancing Ca^{2+} release and, thereby, myocardial contractility. Excessive plasma catecholamine levels and cardiac sympathetic neuronal release of norepinephrine cause hyperphosphorylation of PKA, leading to calstabin 2–depleted RyR2. The latter depletes SR Ca^{2+} stores and, thereby, impairs cardiac contraction, leading to heart failure, and also triggers ventricular arrhythmias.

The Ca^{2+} released from the SR then diffuses toward the myofibrils, where, as already described, it combines with troponin C (Fig. 217-6). By repressing this inhibitor of contraction, Ca^{2+} activates the myofilaments to shorten. During repolarization, the activity of the Ca^{2+} pump in the SR, the SR Ca^{2+} ATPase ($SERCA_{2A}$), reaccumulates Ca^{2+} against a concentration gradient, and the Ca^{2+} is stored in the SR by its attachment to a protein, *calsequestrin*. This reaccumulation of Ca^{2+} is

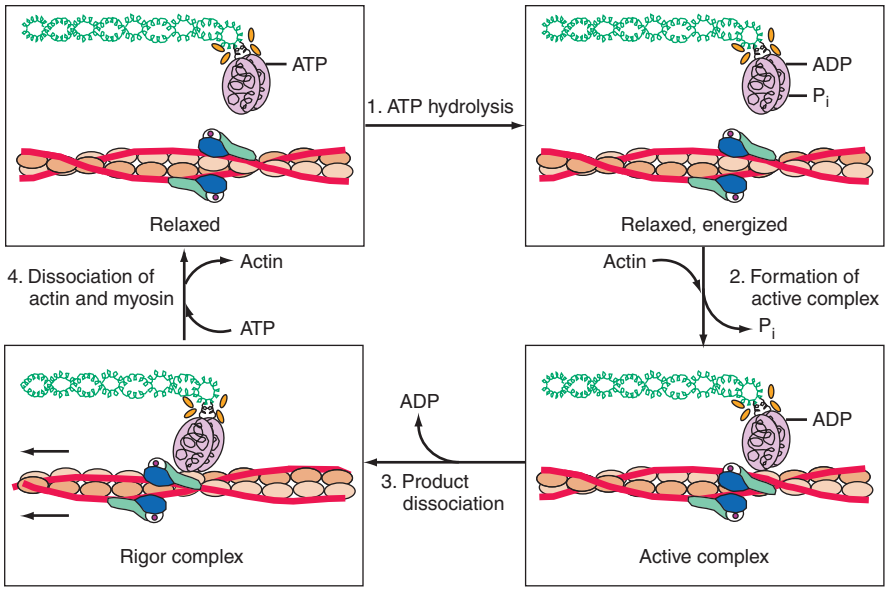

FIGURE 217-5 Four steps in cardiac muscle contraction and relaxation. In relaxed muscle ***(upper left)***, ATP bound to the myosin cross-bridge dissociates the thick and thin filaments. **Step 1:** Hydrolysis of myosin-bound ATP by the ATPase site on the myosin head transfers the chemical energy of the nucleotide to the activated cross-bridge ***(upper right)***. When cytosolic Ca^{2+} concentration is low, as in relaxed muscle, the reaction cannot proceed because tropomyosin and the troponin complex on the thin filament do not allow the active sites on actin to interact with the cross-bridges. Therefore, even though the cross-bridges are energized, they cannot interact with actin. **Step 2:** When Ca^{2+} binding to troponin C has exposed active sites on the thin filament, actin interacts with the myosin cross-bridges to form an active complex ***(lower right)*** in which the energy derived from ATP is retained in the actin-bound cross-bridge, whose orientation has not yet shifted. **Step 3:** The muscle contracts when ADP dissociates from the cross-bridge. This step leads to the formation of the low-energy rigor complex ***(lower left)*** in which the chemical energy derived from ATP hydrolysis has been expended to perform mechanical work (the "rowing" motion of the cross-bridge). **Step 4:** The muscle returns to its resting state, and the cycle ends when a new molecule of ATP binds to the rigor complex and dissociates the cross-bridge from the thin filament. This cycle continues until calcium is dissociated from troponin C in the thin filament, which causes the contractile proteins to return to the resting state with the cross-bridge in the energized state. ATP, adenosine triphosphate; ATPase, adenosine triphosphatase; ADP, adenosine disphosphate. *[From AM Katz: Heart failure: Cardiac function and dysfunction, in Atlas of Heart Diseases, 3d ed, WS Colucci (ed). Philadelphia, Current Medicine, 2002. Reprinted with permission.]*

an energy (ATP) requiring process that lowers the cytoplasmic $[Ca^{2+}]$ to a level that inhibits the actomyosin interaction responsible for contraction and in this manner leads to myocardial relaxation. Also, there is an exchange of Ca^{2+} for Na^+ at the sarcolemma (Fig. 217-7), reducing the cytoplasmic $[Ca^{2+}]$. Cyclic AMP–dependent PKA phosphorylates the SR protein *phospholamban*; the latter, in turn, permits activation of the Ca^{2+} pump, thereby increasing the uptake of Ca^{2+} by the SR, accelerating the rate of relaxation and providing larger quantities of Ca^{2+} in the SR for release by subsequent depolarization, thereby stimulating contraction.

Thus, the combination of the cell membrane, transverse tubules, and SR, with their ability to transmit the action potential and to release and then reaccumulate Ca^{2+}, play a fundamental role in the rhythmic contraction and relaxation of heart muscle. Genetic or pharmacologic alterations of any component, whatever its etiology, can disturb these functions.

CONTROL OF CARDIAC PERFORMANCE AND OUTPUT

The extent of shortening of heart muscle and, therefore, the stroke volume of the ventricle in the intact heart depend on three major influences: (1) the length of the muscle at the onset of contraction, i.e., the preload; (2) the tension that the muscle is called upon to develop during contraction, i.e., the afterload; and (3) the contractility of the muscle, i.e., the extent and velocity of shortening at any given preload and afterload. The major determinants of preload, afterload, and contractility are shown in Table 217-3.

The Role of Muscle Length (Preload)

The preload determines the length of the sarcomeres at the onset of contraction. The length of the sarcomeres associated with the most forceful contraction is ~2.2 μm. At this length, the two sets of myofilaments are configured so as to provide the greatest area for their interaction. The length of the sarcomere also regulates the extent of activation of the contractile system, i.e., its sensitivity to Ca^{2+}. According to this concept, termed *length-dependent activation*, the myofilament sensitivity to Ca^{2+} is also maximal at the optimal sarcomere length.

The relation between the initial length of the muscle fibers and the developed force has prime importance for the function of heart muscle. This relationship forms the basis of Starling's law of the heart, which states that, within limits, the force of ventricular contraction depends on the end-diastolic length of the cardiac muscle; in the intact heart the latter relates closely to the ventricular end-diastolic volume.

Cardiac Performance

The ventricular end-diastolic or "filling" pressure is sometimes used as a surrogate for the end-diastolic volume. In isolated heart and heart-lung preparations, the stroke volume varies directly with the end-diastolic fiber length (preload) and inversely with the arterial resistance (afterload), and as the heart fails—i.e., as its contractility declines—it delivers a progressively smaller stroke volume from a normal or even elevated end-diastolic volume. The relation between the ventricular end-diastolic pressure and the stroke work of the ventricle (the ventricular function curve) provides a useful definition of the level of contractility of the heart in the intact organism. An increase in contractility is accompanied by a shift of the ventricular function curve upward and to the left (greater stroke work at any level of ventricular end-diastolic pressure, or lower end-diastolic volume at any level of stroke work), while a shift downward and to the right characterizes depression of contractility (Fig. 217-8).

Ventricular Afterload

In the intact heart, as in isolated cardiac muscle, the extent (and velocity) of shortening of ventricular muscle fibers at any level of preload and of myocardial contractility relate inversely to the afterload, i.e., the load that opposes shortening. In the intact heart, the afterload may be defined as the tension developed in the ventricular wall during ejection. Afterload is determined by the aortic pressure as well as by the volume and thickness of the ventricular cavity. Laplace's law indicates that the tension of the myocardial fiber is a function of the product of the intracavitary ventricular pressure and ventricular radius divided by the wall thickness. Therefore, at any given level of aortic pressure, the afterload on a dilated left ventricle is higher than that on a normal-sized ventricle. Conversely, at the same aortic pressure and ventricular diastolic volume, the afterload on a hypertrophied ventricle is lower than of a normal chamber. The aortic pressure, in turn, depends on the peripheral vascular resistance, the physical characteristics of the arterial tree, and the volume of blood it contains at the onset of ejection.

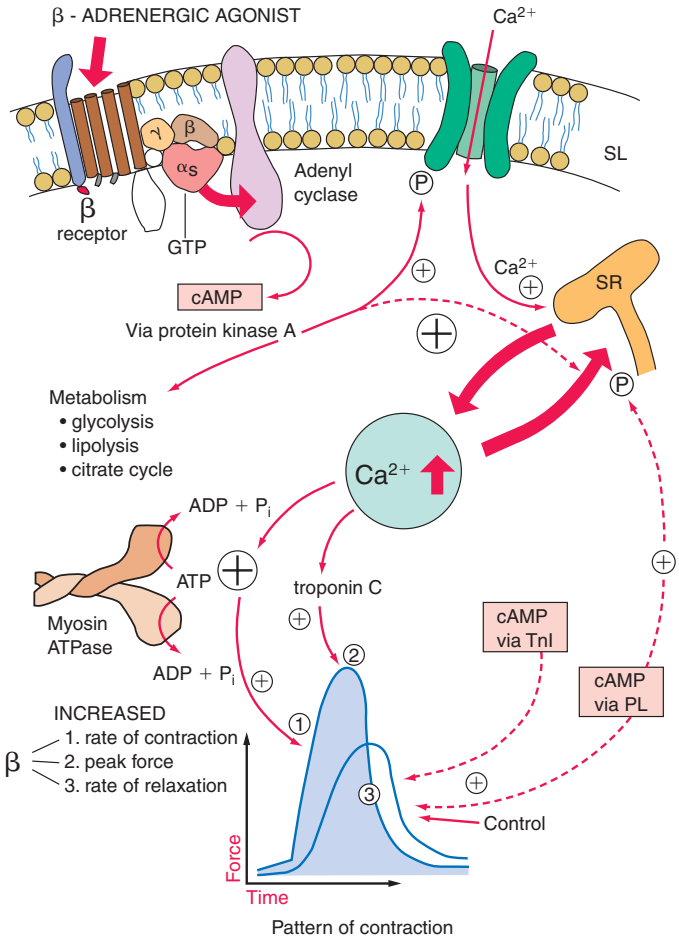

FIGURE 217-6 Signal systems involved in positive intropic and lusitropic (enhanced relaxation) effects of β-adrenergic stimulation. When the β-adrenergic agonist interacts with the β receptor, a series of G protein–mediated changes leads to activation of adenylyl cyclase and formation of cyclic adenosine monophosphate (cAMP). The latter acts via protein kinase A to stimulate metabolism ***(left)*** and to phosphorylate the Ca^{2+} channel protein ***(right)***. The result is an enhanced opening probability of the Ca^{2+} channel, thereby increasing the inward movement of Ca^{2+} ions through the sarcolemma (SL) of the T tubule. These Ca^{2+} ions release more calcium from the sarcoplasmic reticulum (SR) to increase cytosolic Ca^{2+} and to activate troponin C. Ca^{2+} ions also increase the rate of breakdown of adenosine triphosphate (ATP) to adenosine diphosphate (ADP) and inorganic phosphate (Pi). Enhanced myosin ATPase activity explains the increased rate of contraction, with increased activation of troponin C explaining increased peak force development. An increased rate of relaxation is explained because cAMP also activates the protein phospholamban, situated on the membrane of the SR, that controls the rate of uptake of calcium into the SR. The latter effect explains enhanced relaxation (lusitropic effect). P, phosphorylation; PL, phospholamban; TnI, troponin I. *(Modified from LH Opie, Heart Physiology, reprinted with permission. FIGURE 217-7 The Ca^{2+} fluxes and key structures involved in cardiac excitation-contraction coupling. The arrows denote the direction of Ca^{2+} fluxes. The thickness of each arrow indicates the magnitude of the calcium flux. Two Ca^{2+} cycles regulate excitation-contraction coupling and relaxation. The larger cycle is entirely intracellular and involves Ca^{2+} fluxes into and out of the sarcoplasmic reticulum, as well as Ca^{2+} binding to and release from troponin C. The smaller extracellular Ca^{2+} cycle occurs when this cation moves into and out of the cell. The action potential opens plasma membrane Ca^{2+} channels to allow passive entry of Ca^{2+} into the cell from the extracellular fluid ***(arrow A)***. Only a small portion of the Ca^{2+} that enters the cell directly activates the contractile proteins ***(arrow A1)***. The extracellular cycle is completed when Ca^{2+} is actively transported back out to the extracellular fluid by way of two plasma membrane fluxes mediated by the sodium-calcium exchanger ***(arrow B1)*** and the plasma membrane calcium pump ***(arrow B2)***. In the intracellular Ca^{2+} cycle, passive Ca^{2+} release occurs through channels in the cisternae ***(arrow C)*** and initiates contraction; active Ca^{2+} uptake by the Ca^{2+} pump of the sarcotubular network ***(arrow D)*** relaxes the heart. Diffusion of Ca^{2+} within the sarcoplasmic reticulum ***(arrow G)*** returns this activator cation to the cisternae, where it is stored in a complex with calsequestrin and other calcium-binding proteins. Ca^{2+} released from the sarcoplasmic reticulum initiates systole when it binds to troponin C ***(arrow E)***. Lowering of cytosolic [Ca^{2+}] by the sarcoplasmic reticulum (SR) cause this ion to dissociate from troponin ***(arrow F)*** and relaxes the heart. Ca^{2+} may also move between mitochondria and cytoplasm (H). *(Adapted from Katz, with permission.)*

Ventricular afterload critically regulates cardiovascular performance (Fig. 217-9). As already noted, elevations of both preload and contractility increase myocardial fiber shortening, while increases in afterload reduce it. The extent of myocardial fiber shortening and left ventricular size determine stroke volume. An increase in arterial pressure induced by vasoconstriction, for example, augments afterload, which opposes myocardial fiber shortening, reducing stroke volume.

When myocardial contractility becomes impaired and the ventricle dilates, afterload rises (Laplace's law) and limits cardiac output. Increased afterload may also result from neural and humoral stimuli that occur in response to a fall in cardiac output. This increased afterload may reduce cardiac output further, thereby increasing ventricular volume and initiating a vicious circle, especially in patients with ischemic heart disease and limited myocardial O_2 supply. Treatment with vasodilators has the opposite effect; by reducing afterload, cardiac output rises (Chap. 227).

Under normal circumstances, the various influences acting on cardiac performance enumerated above interact in a complex fashion to maintain cardiac output at a level appropriate to the requirements of the metabolizing tissues (Fig. 217-9); interference with a single mechanism may not influence the cardiac output. For example, a moderate reduction of blood volume or the loss of the atrial contribution to ventricular contraction can ordinarily be sustained without a reduction in the cardiac output at rest. Under these circumstances, other factors, such as increases in the frequency of adrenergic nerve impulses to the

heart, in heart rate, and in venous tone, will serve as compensatory mechanisms and sustain cardiac output in a normal individual.

Exercise The integrated response to exercise illustrates the interactions among the three determinants of stroke volume, i.e., preload, afterload, and contractility (Fig. 217-8). Hyperventilation, the pumping action of the exercising muscles, and venoconstriction during exercise all augment venous return and, hence, ventricular filling and preload (Table 217-3). Simultaneously, the increase in the adrenergic nerve impulse traffic to the myocardium, the increased concentration of circulating catecholamines, and the tachycardia that occur during exercise combine to augment the contractility of the myocardium (Fig. 217-8, curves 1 and 2) and together elevate stroke volume and stroke work, without a change or even a reduction of end-diastolic pressure and volume (Fig. 217-8, points A and B). Vasodilatation occurs in the exercising muscles, thus tending to limit the increase in arterial pressure that would otherwise occur as cardiac output rises to levels as high as five times greater than basal levels during maximal exercise. This vasodilatation ultimately allows the achievement of a greatly elevated cardiac output during exercise, at an arterial pressure only moderately higher than in the resting state.

ASSESSMENT OF CARDIAC FUNCTION

Several techniques can define impaired cardiac function in clinical practice. The cardiac output and stroke volume may be depressed in the presence of heart failure, but, not uncommonly, these variables are within normal limits in this condition. A somewhat more sensitive index of cardiac function is the ejection fraction, i.e., the ratio of stroke volume to end-diastolic volume (normal value = 67 ± 8%), which is frequently depressed in systolic heart failure, even when the stroke volume itself is normal. Alternatively, abnormally elevated ventricular end-diastolic volume (normal value = 75 ± 20 mL/m^2) or end-systolic volume (normal value = 25 ± 7 mL/m^2) signify impairment of left ventricular systolic function.

Noninvasive techniques, particularly echocardiography as well as radionuclide scintigraphy and cardiac MRI (Chap. 222), have great value in the clinical assessment of myocardial function. They provide mea-

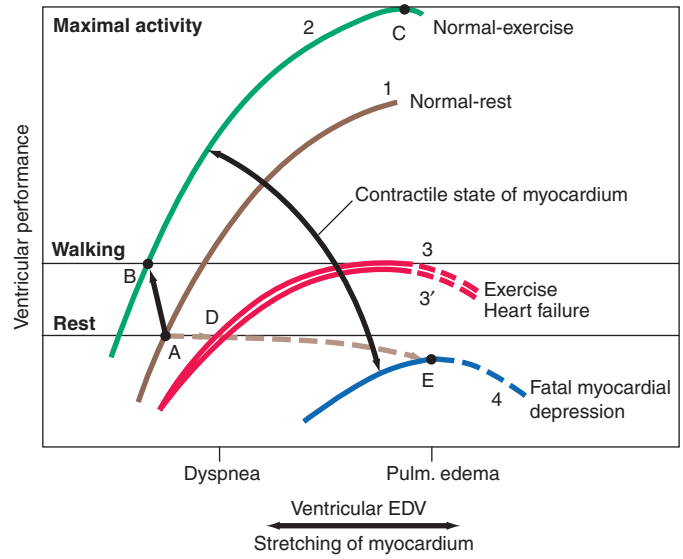

FIGURE 217-8 The interrelations among influences on ventricular end-diastolic volume (EDV) through stretching of the myocardium and the contractile state of the myocardium. Levels of ventricular EDV associated with filling pressures that result in dyspnea and pulmonary edema are shown on the abscissa. Levels of ventricular performance required when the subject is at rest, while walking, and during maximal activity are designated on the ordinate. The broken lines are the descending limbs of the ventricular-performance curves, which are rarely seen during life but show the level of ventricular performance if end-diastolic volume could be elevated to very high levels. For further explanation, see text. *[Modified from WS Colucci and E Braunwald: Pathophysiology of Heart Failure, in Braunwald's Heart Disease, 7th ed, DP Zipes et al (eds). Philadelphia: Elsevier, 2005, pp 509–538.]*

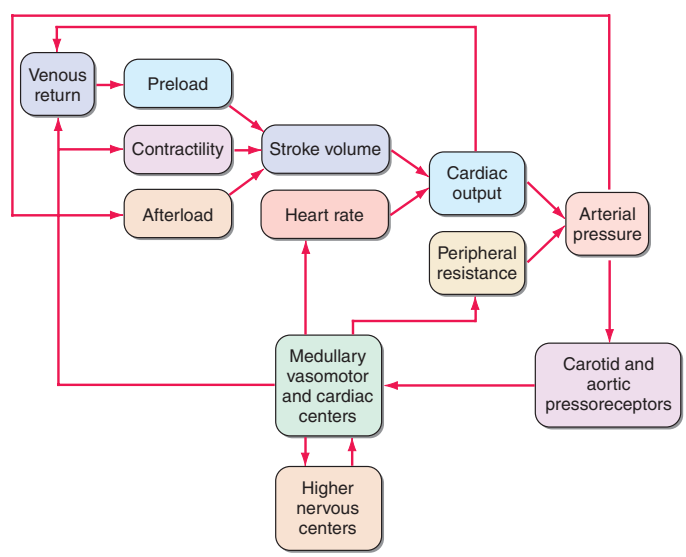

FIGURE 217-9 Interactions in the intact circulation of preload, contractility, and afterload in producing stroke volume. Stroke volume combined with heart rate determines cardiac output, which, when combined with peripheral vascular resistance, determines arterial pressure for tissue perfusion. The characteristics of the arterial system also contribute to afterload, an increase of which reduces stroke volume. The interaction of these components with carotid and aortic arch baroreceptors provides a feedback mechanism to higher medullary and vasomotor cardiac centers and to higher levels in the central nervous system to affect a modulating influence on heart rate, peripheral vascular resistance, venous return, and contractility. *[From MR Starling: Physiology of myocardial contraction, in Atlas of Heart Failure: Cardiac Function and Dysfunction, 3d ed, WS Colucci and E Braunwald (eds). Philadelphia: Current Medicine, 2002, pp 19–35.]*

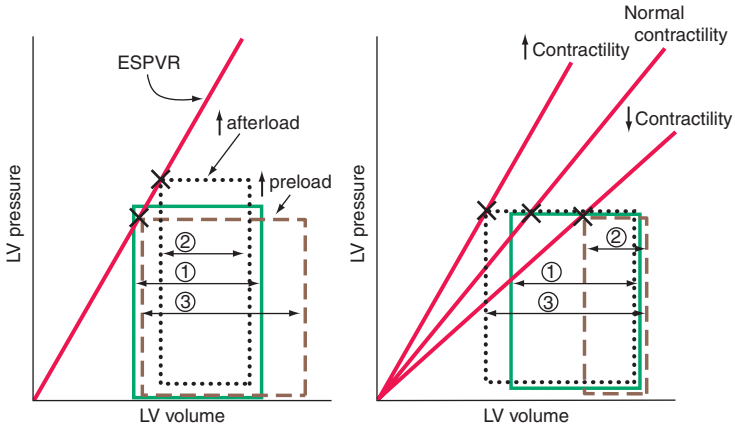

FIGURE 217-10 The responses of the left ventricle to increased afterload, increased preload, and increased and reduced contractility are shown in the pressure-volume plane. ***Left.*** Effects of increases in preload and afterload on the pressure-volume loop. Since there has been no change in contractility, ESPVR (the end-systolic pressure volume relation) is unchanged. With an increase in afterload, stroke volume falls (1 → 2); with an increase in preload, stroke volume rises (1 → 3). ***Right.*** With increased myocardial contractility and constant LV end-diastolic volume, the ESPVR moves to the left of the normal line (lower end-systolic volume at any end-systolic pressure) and stroke volume rises (1 → 3). With reduced myocardial contractility, the ESPVR moves to the right; end-systolic volume is increased and stroke volume falls (1 → 2).

surements of end-diastolic and end-systolic volumes, ejection fraction, and systolic shortening rate, and they allow assessment of ventricular filling (see below) as well as regional contraction and relaxation. The latter measurements are particularly important in ischemic heart disease, as myocardial infarction causes regional myocardial damage.

A limitation of measurements of cardiac output, ejection fraction, and ventricular volumes in assessing cardiac function is that ventricular loading conditions strongly influence these variables. Thus, a depressed ejection fraction and lowered cardiac output may be observed in patients with normal ventricular function but with reduced preload, as occurs in hypovolemia, or with increased afterload, as occurs in acutely elevated arterial pressure.

The end-systolic left ventricular pressure-volume relationship is a particularly useful index of ventricular performance since it does not depend on preload and afterload (Fig. 217-10). At any level of myocardial contractility, left ventricular end-systolic volume varies inversely with end-systolic pressure; as contractility declines, end-systolic volume (at any level of end-systolic pressure) rises.

DIASTOLIC FUNCTION

Ventricular filling is influenced by the extent and speed of myocardial relaxation, which in turn is determined by the rate of uptake of Ca^{2+} by the SR; the latter may be enhanced by adrenergic activation and reduced by ischemia, which reduces the ATP available for pumping Ca^{2+} into the SR (see above). The stiffness of the ventricular wall may also impede filling. Ventricular stiffness increases with hypertrophy and conditions that infiltrate the ventricle, such as amyloid, or by an extrinsic constraint (e.g., pericardial compression) (Fig. 217-11).

Ventricular filling can be assessed by continuously measuring the velocity of flow across the mitral valve using Doppler ultrasound. Normally, the velocity of inflow is more rapid in early diastole than during atrial systole; with mild to moderately impaired relaxation, the rate of early diastolic filling declines, while the rate of presystolic filling rises. With further impairment of filling, the pattern is "pseudo-normalized," and early ventricular filling becomes more rapid as left atrial pressure upstream to the stiff left ventricle rises.

CARDIAC METABOLISM

The heart requires a continuous supply of energy (in the form of ATP) to perform not only its mechanical pumping functions but also to regulate intracellular and transsarcolemmal ionic movements and concentration gradients. Among its pumping functions, the development of tension, the frequency of contraction, and the level of myocardial contractility are the principal determinants of the heart's substantial energy needs, making its O_2 requirements approximately 15% of that of the entire organism.

Most ATP production depends on the oxidation of substrate [glucose and free fatty acids (FFAs)]. Myocardial FFAs are derived from circulating FFAs, which result principally from lipolysis of adipose tissue, while the myocyte's glucose is obtained from plasma as well as from the cell's breakdown of its glycogen stores (glycogenolysis). There is a reciprocal relation between the utilization of these two principal sources of acetyl CoA in cardiac muscle. Glucose is broken down in the cytoplasm into a three-carbon product, pyruvate, which passes into the mitochondria, where it is metabolized to the two-carbon fragment, acetyl coenzyme A, and undergoes oxidation. FFAs are converted to acyl-CoA in the cytoplasm and acetyl coenzyme A (Co-A) in the mitochondria. Acetyl Co-A enters the citric acid (Krebs) cycle to produce ATP by oxidative phosphorylation within the mitochondria; ATP then enters the cytoplasm from the mitochondrial compartment. Intracellular ADP, resulting from the breakdown of ATP, enhances mitochondrial ATP production.

In the fasted, resting state, circulating FFA concentrations and their myocardial uptake are high, and they are the principal source of acetyl CoA (~70%). In the fed state, with elevations of blood glucose and insulin, glucose oxidation increases and FFA oxidation subsides. Increased cardiac work, the administration of inotropic agents, hypoxia, and mild ischemia all enhance myocardial glucose uptake, glucose production resulting from glycogenolysis, and glucose metabolism to pyruvate (glycolysis). By contrast, β-adrenergic stimulation, as occurs during stress, raises the circulating levels and metabolism of FFAs in favor of glucose. Severe ischemia inhibits the cytoplasmic enzyme pyruvate dehydrogenase, and despite both glycogen and glucose breakdown, glucose is metabolized only to lactic acid (anaerobic glycolysis), which does not enter the citric acid cycle. Anaerobic glycolysis produces much less ATP than aerobic glucose metabolism, in which glucose is metabolized to pyruvate and subsequently

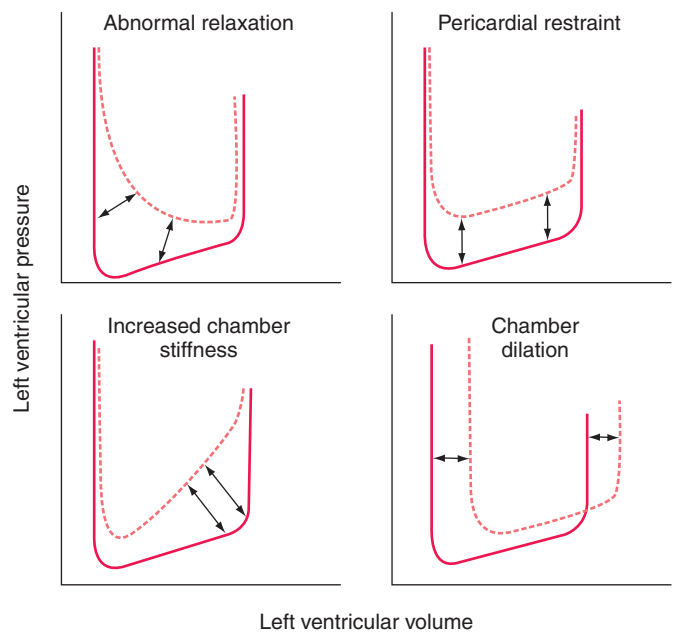

FIGURE 217-11 Mechanisms that cause diastolic dysfunction reflected in the pressure-volume relation. The bottom half of the pressure-volume loop is depicted. Solid lines represent normal subjects; broken lines represent patients with diastolic dysfunction. *(From JD Carroll et al: The differential effects of positive inotropic and vasodilator therapy on diastolic properties in patients with congestive cardiomyopathy. Circulation 74:815, 1986; with permission.)*

oxidized to CO_2. High concentrations of circulating FFAs, which can occur when adrenergic stimulation is superimposed on severe ischemia, reduce oxidative phosphorylation and also cause ATP wastage; the myocardial content of ATP declines, and myocardial contraction becomes impaired. In addition, products of FFA breakdown can exert toxic effects on cardiac cell membranes and may be arrhythmogenic.

Myocardial energy is stored as creatine phosphate (CP), which is in equilibrium with ATP, the immediate source of energy. In states of reduced energy availability, the CP stores decline first. Cardiac hypertrophy, fibrosis, tachycardia, increased wall tension resulting from ventricular dilatation, and increased intracytoplasmic $[Ca^{2+}]$ all contribute to increased myocardial energy needs. When coupled with reduced coronary flow reserve, as occurs with obstruction of coronary arteries or abnormalities of the coronary microcirculation, an imbalance in myocardial ATP production relative to demand may occur, and the resulting ischemia can worsen or cause heart failure.

REGENERATING CARDIAC TISSUE

Until very recently, the mammalian myocardium was viewed as an end-differentiated organ without regeneration potential. Resident and bone marrow–derived stem cells have now been identified, are currently being evaluated as sources of regenerative potential for the heart, and offer the exciting possibility of reconstructing an infarcted or failing ventricle (Chaps. 66, 67).

218 Epidemiology of Cardiovascular Disease

Thomas A. Gaziano, J. Michael Gaziano

Cardiovascular disease (CVD) is now the most common cause of death worldwide. Before 1900, infectious diseases and malnutrition were the most common causes of death throughout the world, and CVD was responsible for <10% of all deaths. Today CVD accounts for ~30% of deaths worldwide, including nearly 40% in high-income countries and about 28% in low- and middle-income countries.

THE EPIDEMIOLOGIC TRANSITION

The global rise in CVD is the result of an unprecedented transformation in the causes of morbidity and mortality during the 20th century. Known as the *epidemiologic transition*, this shift is driven by industrialization, urbanization, and associated lifestyle changes, and it is taking place in every part of the world among all races, ethnic groups, and cultures. The transition is divided into four basic stages: pestilence and famine, receding pandemics, degenerative and human-made diseases, and delayed degenerative diseases. A fifth stage, characterized by an epidemic of inactivity and obesity, may be emerging in some countries (Table 218-1).

Malnutrition, infectious diseases, and high infant and child mortality that are offset by high fertility mark the *age of pestilence and famine*. Tuberculosis, dysentery, cholera, and influenza are often fatal, resulting in a mean life expectancy of about 30 years. Cardiovascular disease, which accounts for <10% of deaths, takes the form of rheumatic heart disease and cardiomyopathies due to infection and malnutrition. Approximately 10% of the world's population remains in the age of pestilence and famine.

Per capita income and life expectancy increase during the *age of receding pandemics* as the emergence of public health systems, cleaner water supplies, and improved nutrition combine to drive down deaths from infectious disease and malnutrition. Infant and childhood mortal-

TABLE 218-1 FIVE STAGES OF EPIDEMIOLOGIC TRANSITION

Stage	Description	Deaths Related to CVD	Predominant CVD Type
Pestilence and famine	Predominance of malnutrition and infectious diseases as causes of death; high rates of infant and child mortality; low mean life expectancy	<10%	Rheumatic heart disease, cardiomyopathies caused by infection and malnutrition
Receding pandemics	Improvements in nutrition and public health, leading to decrease in rates of deaths related to malnutrition and infection; precipitous decline in infant and child mortality rates	10–35%	Rheumatic valvular disease, hypertension, CHD, and stroke (predominantly hemorrhagic)
Degenerative and human-made diseases	Increased fat and caloric intake and decrease in physical activity, leading to emergence of hypertension and atherosclerosis; with increase in life expectancy, mortality from chronic, noncommunicable diseases exceeds mortality from malnutrition and infectious disease	35–65%	CHD and stroke (ischemic and hemorrhagic)
Delayed degenerative diseases	CVD and cancer the major causes of morbidity and mortality; fewer deaths among those with disease and primary events delayed due to better treatment and prevention efforts; decline of age-adjusted CVD mortality; CVD affecting older and older individuals	40–50%	CHD, stroke, and congestive heart failure
Inactivity and obesity	Overweight and obesity increase at alarming rate; diabetes and hypertension increase; leveling off of decline in smoking-rate; physical activity recommendations met by a minority of the population	Possible reversal of age-adjusted declines in mortality	CHD, stroke, and congestive heart failure, peripheral vascular disease

Note: CHD, coronary heart disease; CVD, cardiovascular disease.
Source: Adapted from AR Omran: Milbank Mem Fund Q 49:509, 1971; and SJ Olshansky, AB Ault: Milbank Q 64:355, 1986.

ity also decline, but deaths due to CVD increase to between 10 and 35% of all deaths. Rheumatic valvular disease, hypertension, coronary heart disease, and stroke are the predominant forms of CVD. Almost 40% of the world's population is currently in this stage.

The *age of degenerative and human-made diseases* is distinguished by mortality from noncommunicable diseases—primarily CVD—surpassing mortality from malnutrition and infectious diseases. Caloric intake, particularly from animal fat, increases. Coronary heart disease and stroke are prevalent, and between 35 and 65% of all deaths can be traced to CVD. Typically, the rate of death from coronary heart disease (CHD) exceeds that of stroke by a ratio of 2:1–3:1. During this period, average life expectancy surpasses 50. Roughly 35% of the world's population falls into this category.

In the *age of delayed degenerative diseases*, CVD and cancer remain the major causes of morbidity and mortality, with CVD accounting for 40–50% of all deaths. However, age-adjusted CVD mortality declines, aided by preventive strategies, such as smoking cessation programs and effective blood pressure control; by acute hospital management; and by technological advances, such as the availability of bypass surgery. CHD, stroke, and congestive heart failure are the primary forms of CVD. About 15% of the world's population is now in the age of delayed degenerative diseases or is exiting this age and moving into the fifth stage of the epidemiologic transition.

In the industrialized world, physical activity continues to decline while total caloric intake increases. The resulting epidemic of overweight and obesity may signal the start of the *age of inactivity and obesity*. Rates of type 2 diabetes mellitus, hypertension, and lipid abnormalities are on the rise, trends that are particularly evident in children. If these risk factor trends continue, age-adjusted CVD mortality rates could increase in the coming years.

THE EPIDEMIOLOGIC TRANSITION IN THE UNITED STATES

The United States, like other high-income countries, has proceeded through four stages of the epidemiologic transition. Recent trends, however, suggest that the rates of decline of some chronic and degenerative diseases have slowed. Given the large amount of available data, the United States serves as a useful reference point for comparisons.

The Age of Pestilence and Famine (Before 1900) The American colonies were born into pestilence and famine, with half of the original Pilgrims who arrived in 1620 dying of infection and malnutrition by the following spring. At the end of the 1800s, the U.S. economy was still largely agrarian, with >60% of the population living in rural settings. By 1900, average life expectancy had increased to about 50 years. However, tuberculosis, pneumonia, and other infectious diseases still accounted for more deaths than any other cause. CVD accounted for <10% of all deaths.

The Age of Receding Pandemics (1900–1930) By 1900, a public health infrastructure was in place: 40 states had health departments, many larger towns had major public works efforts to improve the water supply and sewage systems, municipal use of chlorine to disinfect water was widespread, pasteurization and other improvements in food handling were introduced, and the educational quality of health care personnel improved. These changes led to dramatic declines in infectious disease mortality rates. However, the continued shift from a rural, agriculture-based economy to an urban, industrial economy had a number of consequences for risk behaviors and factors for CVD. In particular, consumption of fresh fruits and vegetables declined and consumption of meat and grains increased, resulting in diets that were higher in animal fat and processed carbohydrates. In addition, the availability of factory-rolled cigarettes made them more accessible and affordable for the mass population. Age-adjusted CVD mortality rates rose from 300 per 100,000 people in 1900 to approximately 390 per 100,000 people during this period, driven by rapidly rising CHD rates.

The Age of Degenerative and Human-Made Diseases (1930–1965) During this period, deaths from infectious diseases fell to fewer than 50 per 100,000 population per year, and life expectancy increased to almost 70 years. At the same time, the country became increasingly urbanized and industrialized, precipitating a number of important lifestyle changes. By 1955, 55% of adult men were smoking, and fat consumption represented approximately 40% of total calories. Lower activity levels, high-fat diets, and increased smoking pushed CVD death rates to their peak levels.

The Age of Delayed Degenerative Diseases (1965–) Substantial declines in age-adjusted CVD mortality rates began in the mid-1960s. In the 1970s and 1980s, age-adjusted CHD mortality rates fell approximately 2% per year, and stroke rates fell 3% per year. A main characteristic of this phase is the steadily rising age at which a first CVD event occurs. Two significant advances have been attributed to the decline in CVD mortality rates: new therapeutic approaches and the implementation of prevention measures. Treatments once considered advanced, such as angioplasty, bypass surgery, and implantation of defibrillators, are now considered the standard of care. Treatment for hypertension and elevated cholesterol along with the widespread use of aspirin has also made major contributions to reducing deaths from CVD. In addition, Americans were exposed to public health campaigns promoting lifestyle modifications effective at reducing the prevalence of smoking, hypertension, and dyslipidemia.

Is the United States Entering a Fifth Age? Starting in the 1990s, the age-standardized death rate had decreased to an average of about 2% per year for CHD and 1% for stroke. In 2003, the age-standardized death rate for total CVD was 306 per 100,000. The slowing of the decline may be due, in part, to a slowing of the rate of decline in risk factors, such as smoking, and alarming increases in other risk factors, such as obesity and physical inactivity.

CURRENT WORLDWIDE VARIATIONS

An epidemiologic transition much like that which occurred in the United States is occurring throughout the world, but unique regional features have modified aspects of the transition in various parts of the world. In terms of economic development, the world can be divided into two broad categories: (1) high-income countries; and (2) low- and middle-income countries, which can be further subdivided into six distinct economic/geographic regions. Currently, 85% of the world's population lives in low- and middle-income countries, and it is these countries that are driving the rates of change in the global burden of CVD (Fig. 218-1). Three million CVD deaths occurred in high-income countries in 2001, compared to 13 million in the rest of the world.

High-Income Countries Approximately 940 million people live in the high-income countries, where CHD is the dominant form of CVD, with rates that tend to be twofold to fivefold higher than stroke rates. The rates of CVD in Canada, New Zealand, Australia, and Western Europe tend to be similar to those in the United States; however, among the countries of Western Europe, the absolute rates vary threefold with a clear north/south gradient. The highest CVD death rates are in the northern countries, such as Finland, Ireland, and Scotland, with the lowest CVD rates in the Mediterranean countries of France, Spain, and Italy. Japan is unique among the high-income countries: stroke rates increased dramatically over the last century, but CHD rates did not rise as sharply. This difference may stem in part from genetic factors, but it is more likely that the fish- and plant-based, low-fat diet and resulting low cholesterol levels have played a larger role. Importantly, Japanese dietary habits are undergoing substantial changes, reflected in an increase in cholesterol levels.

Low- and Middle-Income Countries The World Bank groups the low- and middle-income countries (gross national income per capita lower than U.S. $9200) into six geographic regions: East Asia and the Pacific, (Eastern) Europe and Central Asia, Latin America and the Caribbean, Middle East and North Africa, South Asia, and Sub-Saharan Africa. Although communicable diseases continue to be a major cause of death, CVD has emerged as a significant health concern in the low- and middle-income countries (Fig. 218-2). In most of these countries, there is an urban/rural gradient for CHD, stroke, and hypertension, with higher rates in urban centers.

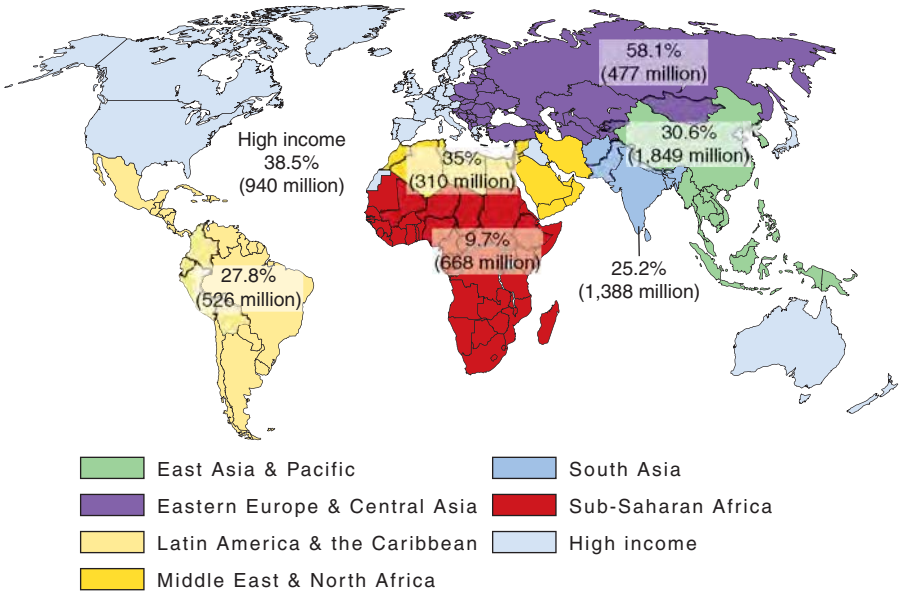

FIGURE 218-1 CVD death as a percentage of total deaths, and total population, in seven economic regions of the world defined by the World Bank. *(Based on data from CD Mathers et al: Deaths and Disease Burden by Cause: Global Burden of Disease Estimates for 2001 by World Bank Country Groups. Disease Control Priorities Working Paper 18. April 2004, revised January 2005.)*

While CVD rates are rapidly rising, there are vast differences among the regions and countries, and even within the countries themselves. Many factors contribute to the heterogeneity. First, the regions are at various stages of the epidemiologic transition. Second, vast differences in lifestyle and behavioral risk factors exist. Third, racial and ethnic differences may lead to altered susceptibilities to various forms of CVD. In addition, it should be noted that for most countries in these regions, accurate country-wide data on cause-specific mortality are not precise, as death certificate completion is not routine, and most countries do not have a centralized registry for deaths.

The *East Asia and Pacific* region appears to be straddling the second and third phases of the epidemiologic transition, with China, Indonesia, and Sri Lanka's large combined population driving most of the trends. Overall, CVD is a major cause of death in China, but like Japan, stroke (particularly hemorrhagic) causes more deaths than CHD. China also appears to have a geographic gradient like that of Western Europe, with higher CVD rates in northern China than in southern China. Other countries, such as Vietnam and Cambodia, are just emerging from the pestilence and famine stage.

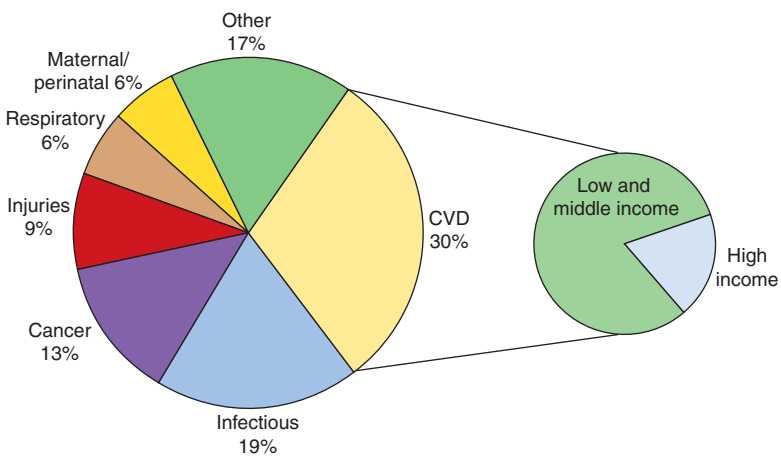

FIGURE 218-2 CVD compared to other causes of death. CVD: cardiovascular disease. *(Based on data from CD Mathers et al: Deaths and Disease Burden by Cause: Global Burden of Disease Estimates for 2001 by World Bank Country Groups. Disease Control Priorities Working Paper 18. April 2004, revised January 2005.)*

The *Eastern Europe and Central Asia* region is firmly in the peak of the third phase, with the highest death rates (58%) due to CVD in the world, nearly double the rate of high-income countries. There is, however, also regional variability. In Russia, increased CVD rates have contributed to falling life expectancy, particularly for men, whose life expectancy has dropped from 71.6 in 1986 to 59 years today. In Poland, by contrast, the age-adjusted mortality rate decreased by approximately 30% for men during the 1990s, and slightly more among women.

In general, the *Latin America and Caribbean* region appears to be in the third phase of the epidemiologic transition, although as in other low- and middle-income regions, there is vast regional heterogeneity, with some areas in the second phase of the transition and some in the fourth. Today, approximately 28% of all deaths in this region are attributable to CVD, with CHD rates higher than stroke rates. Approximately one-quarter of the citizens live in poverty, and many are still dealing with infectious diseases and malnutrition as major problems.

The *Middle East and North Africa* region appears to be entering the third phase of the epidemiologic transition, with rates just below high-income nations. In this region, increasing economic wealth has been accompanied characteristically by urbanization but uncharacteristically by increasing fertility rates as infant and childhood mortality rates have declined. The traditional high-fiber diet, low in fat and cholesterol, has changed rapidly. Over the past few decades, daily fat consumption has increased in most of these countries, ranging from a 13.6% increase in Sudan to a 143.3% increase in Saudi Arabia.

Most people in *South Asia* live in rural India, a country that is experiencing an alarming increase in heart disease. CVD accounted for 32% of all deaths in 2000, and the World Health Organization (WHO) estimates that 60% of the world's cardiac patients will be Indian by 2010. The transition appears to be in the Western style, with CHD as the dominant form of CVD. In 1960, CHD represented 4% of all CVD deaths in India, whereas in 1990 the proportion was >50%. This is somewhat unexpected because stroke tends to be a more dominant factor early in the epidemiologic transition. This finding may reflect inaccuracies in cause-specific mortality estimates or possibly an underlying genetic component. It has been suggested that Indians have exaggerated insulin insensitivity in response to the Western lifestyle pattern that may differentially increase rates of CHD over stroke. Certain remote areas, however, are still emerging from the age of pestilence and famine, with CVD accounting for <10% of total deaths. Rheumatic heart disease continues to be a major cause of morbidity and mortality.

Sub-Saharan Africa remains largely in the first phase of the epidemiologic transition, with CVD rates half of those in high-income nations. Life expectancy has decreased by an average of five years since the early 1990s largely because of HIV/AIDS and other chronic diseases, according to the World Bank; life expectancies are the lowest in the world. While HIV/AIDS is the leading overall cause of death in this region, CVD is the third leading killer and is first among those over the age of 30. Hypertension is now a major public health concern and has resulted in stroke being the dominant form of CVD. Rheumatic heart disease remains an important cause of CVD mortality and morbidity.

GLOBAL TRENDS IN CARDIOVASCULAR DISEASE

In 1990, CVD accounted for 28% of the world's 50.4 million deaths and 9.7% of the 1.4 billion lost disability-adjusted life

TABLE 218-2 ESTIMATED MORBIDITY RELATED TO HEART DISEASE: 2010–2030

Deaths	By 2010	By 2030
CVD deaths: annual number of all deaths	18.1 million	24.2 million
CVD deaths: percentage of all deaths	30.8%	32.5%
CHD deaths: percentage of all male deaths	13.1%	14.9%
CHD deaths: percentage of all female deaths	13.6%	13.1%
Stroke deaths: percentage of all male deaths	9.2%	10.4%
Stroke deaths: percentage of all female deaths	11.5%	11.8%

Note: CVD, cardiovascular disease; CHD, coronary heart disease.
Source: Adapted from Mackay and Mensah.

years (DALYs). By 2001, CVD was responsible for 29% of all deaths and 14% of the 1.5 billion lost DALYs. By 2030, when the population is expected to reach 8.2 billion, 32.5% of all deaths will be the result of CVD (Table 218-2). Of these, 14.9% of deaths in men and 13.1% of deaths in women will be due to CHD. Stroke will be responsible for 10.4% of all male deaths and 11.8% of all female deaths.

In *high-income countries*, population growth will be fueled by emigration from low- and middle-income countries, but the population of high-income countries will shrink as a proportion of the world's population. In high-income countries, the modest decline in CVD death rates begun in the latter third of the 20th century will continue, but the rate of decline appears to be slowing. However, these countries are expected to see an increase in the prevalence of CVD as well as the absolute number of deaths as the population ages.

Significant portions of the population living in *low- and middle-income countries* have entered the third phase of the epidemiologic transition, and some are entering the fourth stage. Changing demographics play a significant role in future predictions for CVD throughout the world. For example, between 1990 and 2001, the population of Eastern Europe and Central Asia grew by 1 million people per year, whereas South Asia added 25 million people each year.

Higher CVD rates will also have an economic impact. Even assuming no increase in CVD risk factors, most countries, but especially India and South Africa, will see a large number of people between 35 and 64 die of CVD over the next 30 years, as well as an increasing level of morbidity among middle-aged people related to heart disease and stroke. In China, it is estimated that there will be 9 million deaths from CVD in 2030—up from 2.4 million in 2002—with half occurring in individuals between 35 and 64 years old.

REGIONAL TRENDS IN RISK FACTORS

As indicated earlier, the global variation in CVD rates is related to temporal and regional variations in known risk behaviors and factors. Ecologic analyses of major CVD risk factors and mortality demonstrate high correlations between expected and observed mortality rates for the three main risk factors—smoking, serum cholesterol, and hypertension—and suggest that many of the regional variations are based on differences in conventional risk factors.

BEHAVIORAL RISK FACTORS

Tobacco Every year, more than 5.5 trillion cigarettes are produced—enough to provide every person on the planet with 1,000 cigarettes. Worldwide, 1.2 billion people smoked in 2000, a number that is projected to increase to 1.6 billion by 2030. Tobacco currently causes an estimated 5 million deaths annually (9% of all deaths). If current smoking patterns continue, by 2030 the global burden of disease attributable to tobacco will reach 10 million deaths annually. A unique feature of low- and middle-income countries is easy access to smoking during the early stages of the epidemiologic transition due to the availability of relatively inexpensive tobacco products.

Diet Total caloric intake per capita increases as countries develop. With regard to CVD, a key element of dietary change is an increase in intake of saturated animal fats and hydrogenated vegetable fats, which contain atherogenic *trans* fatty acids, along with a decrease in intake of plant-based foods and an increase in simple carbohydrates. Fat contributes less than 20% of calories in rural China and India, less than 30% in Japan, and well above 30% in the United States. Caloric contributions from fat appear to be falling in the high-income countries. In the United States, between 1971 and 2000, the percentage of calories derived from saturated fat decreased from 13 to 11%.

Physical Inactivity The increased mechanization that accompanies the economic transition leads to a shift from physically demanding, agriculture-based work to largely sedentary industry- and office-based work. In the United States, approximately one-quarter of the population does not participate in any leisure-time physical activity, and only 22% report engaging in sustained physical activity for at least 30 min on five or more days per week (the current recommendation). In contrast, in countries like China, physical activity is still integral to everyday life. Approximately 90% of the urban population walks or rides a bicycle to work, shopping, or school daily.

METABOLIC RISK FACTORS

Lipid Levels Worldwide, high cholesterol levels are estimated to cause 56% of ischemic heart disease and 18% of strokes, amounting to 4.4 millions deaths annually. As countries move through the epidemiologic transition, mean population plasma cholesterol levels tend to rise. Social and individual changes that accompany urbanization clearly play a role because plasma cholesterol levels tend to be higher among urban residents than among rural residents. This shift is largely driven by greater consumption of dietary fats—primarily from animal products and processed vegetable oils—and decreased physical activity. In high-income countries, mean population cholesterol levels are generally falling, but in low- and middle-income countries, there is wide variation in these levels.

Hypertension Elevated blood pressure is an early indicator of the epidemiologic transition. Worldwide, approximately 62% of strokes and 49% of cases of ischemic heart disease are attributable to suboptimal (>115 mmHg systolic) blood pressure, which is believed to account for more than 7 million deaths annually. Rising mean blood pressure is apparent as populations industrialize and move from rural to urban settings. Among urban-dwelling men and women in India, for example, the prevalence of hypertension is 25.5% and 29.0%, respectively, whereas it is 14.0% and 10.8%, respectively, in rural communities. One major concern in low- and middle-income countries is the high rate of undetected, and therefore untreated, hypertension. This may explain, at least in part, the higher stroke rates in these countries in relation to CHD rates during the early stages of the transition. The high rates of hypertension, especially undiagnosed hypertension, throughout Asia probably contribute to the high prevalence of hemorrhagic stroke in the region.

Obesity Although clearly associated with increased risk of CHD, much of the risk posed by obesity may be mediated by other CVD risk factors, including hypertension, diabetes mellitus, and lipid profile imbalances. In the mid-1980s, the WHO's MONICA (multinational *moni*toring of trends and determinants in *ca*rdiovascular disease) project sampled 48 populations for cardiovascular risk factors. In all but one male population (China) and in most of the female populations, between 50 and 75% of adults ages 35–64 were overweight or obese. In addition, the prevalence of extreme obesity (BMI ≥40 kg/m^2) more than tripled over a decade, increasing from 1.3 to 4.9%. In many of the low- and middle-income countries, obesity appears to coexist with undernutrition and malnutrition. Although the prevalence of obesity in low- and middle-income countries is certainly less than among high-income countries, it is on the rise in the former, as well. For example, a survey undertaken in 1998 found that as many as 58% of African women living in South Africa may be overweight or obese.

Diabetes Mellitus As a consequence of, or in addition to, increasing body mass index and decreasing levels of physical activity, worldwide rates of diabetes—predominantly type 2 diabetes—are on the rise. In 2003, 194 million adults, or 5% of the world's population, had diabetes,

with nearly three-quarters living in high-income countries. By 2025, this number is predicted to increase 72% to 333 million. By 2025, the number of people with type 2 diabetes is projected to double in three of the six low- and middle-income regions: Middle East and North Africa, South Asia, and Sub-Saharan Africa. There appear to be clear genetic susceptibilities to diabetes mellitus in various racial and ethnic groups. For example, migration studies suggest that South Asians and Indians tend to be at higher risk than those of European extraction.

SUMMARY

Although CVD rates are declining in high-income countries, they are increasing in virtually every other region of the world. The consequences of this preventable epidemic will be substantial on many levels—individual mortality and morbidity, family suffering, and staggering economic costs.

Three complementary strategies can be used to lessen the impact. First, the overall burden of CVD risk factors can be lowered through population-wide public health measures, such as national campaigns against cigarette smoking, unhealthy diets, and physical inactivity. Second, it is important to identify higher-risk subgroups of the population who stand to benefit the most from specific, low-cost prevention interventions, including screening for and treatment of hypertension and elevated cholesterol. Simple, low-cost interventions, such as the "polypill," a regimen of aspirin, a statin, and an antihypertensive agent, also need to be explored. Third, resources should be allocated to acute as well as secondary prevention interventions. For countries with limited resources, a critical first step in developing a comprehensive plan is better assessment of cause-specific mortality and morbidity, as well as the prevalence of the major preventable risk factors.

In the meantime, the high-income countries must continue to bear the burden of research and development aimed at prevention and treatment, being mindful of the economic limitations of many countries. The concept of the epidemiologic transition provides insight into how to alter the course of the CVD epidemic. The efficient transfer of low-cost preventive and therapeutic strategies could alter the natural course of this epidemic and thereby reduce the excess global burden of preventable CVD.

219 Approach to the Patient with Possible Cardiovascular Disease

Eugene Braunwald

THE MAGNITUDE OF THE PROBLEM

Cardiovascular diseases comprise the most prevalent serious disorders in industrialized nations and are a rapidly growing problem in developing nations (Chap. 218). Although age-adjusted death rates for coronary heart disease have declined by two-thirds in the past four decades in the United States, cardiovascular diseases remain the most common causes of death, responsible for 40% of all deaths, almost 1 million deaths each year. Approximately one-fourth of these deaths are sudden. The growing prevalence of obesity (Chap. 74), type 2 diabetes mellitus (Chap. 338), and metabolic syndrome (Chap. 236), which are important risk factors for atherosclerosis, now threatens to reverse the progress that has been made in the age-adjusted reduction of mortality of coronary heart disease.

For many years cardiovascular disease was considered to be more frequent in men than in women. In fact, the percentage of all deaths secondary to cardiovascular disease is higher among women (43%) than among men (37%). In addition, while the absolute number of deaths secondary to cardiovascular disease has declined over the past decades in men, this number has actually risen in women. Inflammation and the above-mentioned risk factors, i.e., obesity, type 2 diabetes mellitus, and the metabolic syndrome, appear to play a more prominent role in the development of coronary atherosclerosis in women than in men. Coronary artery disease (CAD) is more frequently associated with dysfunction of the coronary microcirculation in women than in men. Exercise electrocardiography has a lower diagnostic accuracy in the prediction of epicardial obstruction in women.

CARDIAC SYMPTOMS

The symptoms caused by heart disease result most commonly from myocardial ischemia, from disturbance of the contraction and/or relaxation of the myocardium, from obstruction to blood flow, or from an abnormal cardiac rhythm or rate.

Ischemia, which is caused by an imbalance between the heart's oxygen supply and demand, is manifest most frequently as chest discomfort (Chap. 13), while reduction of the pumping ability of the heart commonly leads to fatigue and elevated intravascular pressure upstream to the failing ventricle. The latter results in abnormal fluid accumulation, with peripheral edema (Chap. 36) or pulmonary congestion and dyspnea (Chap. 33). Obstruction to blood flow, as occurs in valvular stenosis, can cause symptoms resembling those resulting from myocardial failure (Chap. 227). Cardiac arrhythmias often develop suddenly, and the resulting symptoms and signs—palpitations (Chap. 37), dyspnea, hypotension, and syncope (Chap. 21)—generally occur abruptly and may disappear as rapidly as they develop.

Although dyspnea, chest discomfort, edema, and syncope are cardinal manifestations of cardiac disease, they occur in other conditions as well. Thus, dyspnea is observed in disorders as diverse as pulmonary disease, marked obesity, and anxiety (Chap. 33). Similarly, chest discomfort may result from a variety of noncardiac and cardiac causes other than myocardial ischemia (Chap. 13). Edema, an important finding in untreated or inadequately treated heart failure, may also occur with primary renal disease and in hepatic cirrhosis (Chap. 36). Syncope occurs not only with serious cardiac arrhythmias but in a number of neurologic conditions, as well (Chap. 21). Whether or not heart disease is responsible for these symptoms can frequently be determined by carrying out a careful clinical examination (Chap. 220), supplemented by noninvasive testing using electrocardiography at rest and during exercise (Chap. 221), echocardiography, roentgenography, and other forms of myocardial imaging (Chap. 222).

Myocardial or coronary function that may be adequate at rest may be insufficient during exertion. Thus, dyspnea and/or chest discomfort that appear during activity are characteristic of patients with heart disease, while the opposite pattern, i.e., the appearance of these symptoms at rest and their remission during exertion, is rarely observed in such patients. It is important, therefore, to question the patient carefully about the relation of symptoms to exertion.

Many patients with cardiovascular disease may be asymptomatic, both at rest and during exertion, but may present an abnormal physical finding, such as a heart murmur, elevated arterial pressure, or an abnormality of the electrocardiogram (ECG) or of the cardiac silhou-

TABLE 219-1 NEW YORK HEART ASSOCIATION FUNCTIONAL CLASSIFICATION

Class I	Class III
No limitation of physical activity	Marked limitation of physical activity
No symptoms with ordinary exertion	Less than ordinary activity causes symptoms
Class II	Asymptomatic at rest
Slight limitation of physical activity	Class IV
Ordinary activity causes symptoms	Inability to carry out any physical activity without discomfort
	Symptoms at rest

Modified from The Criteria Committee of the New York Heart Association.

ette on the chest roentgenogram or other imaging test. It is important to assess the global risk of CAD in asymptomatic individuals, using a combination of clinical assessment and measurement of cholesterol and its fractions, as well as other biomarkers such as C-reactive protein in some patients (Chap. 235). Since the first clinical manifestation of CAD may be catastrophic—sudden cardiac death, acute myocardial infarction, or stroke in previous asymptomatic persons—it is mandatory to identify those at high risk of such events and institute further testing and preventive measures.

DIAGNOSIS

As outlined by the New York Heart Association, the elements of a complete cardiac diagnosis include the systematic consideration of the following:

1. *The underlying etiology*. Is the disease congenital, hypertensive, ischemic, or inflammatory in origin?
2. *The anatomic abnormalities*. Which chambers are involved? Are they hypertrophied, dilated, or both? Which valves are affected? Are they regurgitant and/or stenotic? Is there pericardial involvement? Has there been a myocardial infarction?
3. *The physiologic disturbances*. Is an arrhythmia present? Is there evidence of congestive heart failure or of myocardial ischemia?
4. *Functional disability*. How strenuous is the physical activity required to elicit symptoms? The classification provided by the New York Heart Association has been found to be useful in describing functional disability (Table 219-1).

One example may serve to illustrate the importance of establishing a complete diagnosis. In a patient who presents with exertional chest discomfort, the identification of myocardial ischemia as the etiology is of great clinical importance. However, the simple recognition of ischemia is insufficient to formulate a therapeutic strategy or prognosis until the underlying anatomic abnormalities responsible for the myocardial ischemia, e.g., coronary atherosclerosis or aortic stenosis, are identified and a judgment is made as to whether other physiologic disturbances that cause an imbalance between myocardial oxygen supply and demand, such as severe anemia, thyrotoxicosis, or supraventricular tachycardia, play a contributory role. Finally, the severity of the disability should govern the extent and tempo of the workup and strongly influence the therapeutic strategy that is selected.

The establishment of a correct and complete cardiac diagnosis usually commences with the history and physical examination (Chap. 220). Indeed, the clinical examination remains the basis for the diagnosis of a wide variety of disorders. The clinical examination may then be supplemented by five types of laboratory tests: (1) ECG (Chap. 221); (2) noninvasive imaging examinations (chest roentgenogram, echocardiogram, radionuclide, computer tomographic and magnetic resonance imaging; Chap. 222); (3) blood tests to assess risk [e.g., lipid determinations, C-reactive protein (Chap. 235)], or cardiac function [e.g., brain natriuretic peptide (BNP); Chap. 227]; (4) occasionally specialized invasive examinations, i.e., cardiac catheterization and coronary arteriography (Chap. 223); and (5) genetic tests to identify monogenic cardiac diseases [e.g., hypertrophic cardiomyopathy (Chap. 231), Marfan syndrome (Chap. 357), and abnormalities of cardiac ion channels that lead to prolongation of the QT interval and an increase in risk of sudden death (Chap. 226)]. These tests are becoming more widely available.

FAMILY HISTORY

In eliciting the history of a patient with known or suspected cardiovascular disease, particular attention should be directed to the family history. Familial clustering is common in many forms of heart disease. Mendelian transmission of single-gene defects may occur, as in hypertrophic cardiomyopathy (Chap. 231), the Marfan syndrome (Chap. 357), and sudden death associated with a prolonged QT syndrome (Chap. 226). Premature coronary disease and essential hypertension, type 2 diabetes mellitus, and hyperlipidemia (the most important risk factors for coronary artery disease) are usually polygenic disorders. While familial transmission may be less obvious than in the single-gene disorders, it is also helpful in assessing risk and prognosis in polygenic disorders. Familial clustering of cardiovascular diseases may occur not only on a genetic basis but may also be related to familial dietary or behavior patterns, such as excessive ingestion of salt or calories or cigarette smoking.

ASSESSMENT OF FUNCTIONAL IMPAIRMENT

When an attempt is made to determine the severity of functional impairment in a patient with heart disease, it is helpful to ascertain the level of activity and the rate at which it is performed before symptoms develop. Thus, it is not sufficient to state that the patient complains of dyspnea. The breathlessness that occurs after running up two long flights of stairs denotes far less functional impairment than similar symptoms occurring after taking a few steps on level ground. Also, the degree of customary physical activity at work and during recreation should be considered. The development of two-flight dyspnea in a well-conditioned marathon runner may be far more significant than the development of one-flight dyspnea in a previously sedentary person. The history should include a detailed consideration of the patient's therapeutic regimen. For example, the persistence or development of edema, breathlessness, and other manifestations of heart failure in a patient whose diet is rigidly restricted in sodium content and who is receiving optimal doses of diuretics and other therapies for heart failure (Chap. 227) is far graver than are similar manifestations in the absence of these measures. Similarly, the presence of angina pectoris despite treatment with optimal doses of multiple antianginal drugs (Chap. 237) is more serious than it is in a patient on no therapy. In an effort to determine the progression of symptoms, and thereby the severity of the underlying illness, it may be useful to ascertain what, if any, specific tasks the patient could have carried out 6 months or 1 year earlier that he or she cannot carry out at present.

ELECTROCARDIOGRAM

(See also Chap. 221) Although an ECG should usually be recorded in patients with known or suspected heart disease, with the exception of the identification of arrhythmias, of ventricular hypertrophy, and of acute myocardial infarction, it rarely permits establishment of a specific diagnosis. The range of normal electrocardiographic findings is wide, and the tracing can be affected significantly by many noncardiac factors, such as age, body habitus, and serum electrolyte concentrations. In the absence of other abnormal findings, electrocardiographic changes must not be overinterpreted.

ASSESSMENT OF THE PATIENT WITH A HEART MURMUR

(Fig. 219-1) The cause of a heart murmur can often be readily elucidated from a systematic evaluation of its major attributes: timing, duration, intensity, quality, frequency, configuration, location, and radiation when considered in the light of the history, general physical examination, and other features of the cardiac examination, as described in Chap. 220.

The majority of heart murmurs are midsystolic and soft (grades I to II/VI). When such a murmur occurs in an asymptomatic child or young adult *without* other evidence of heart disease on clinical examination, it is usually benign and echocardiography is not generally required. On

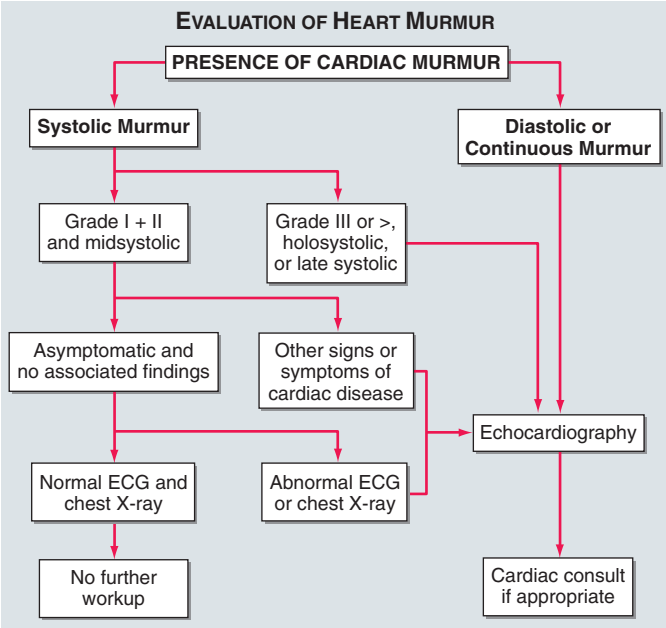

FIGURE 219-1 An alternative "echocardiography first" approach to the evaluation of a heart murmur that also uses the results of the electrocardiogram (ECG) and chest x-ray in asymptomatic patients with soft midsystolic murmurs and no other physical findings. This algorithm is useful for patients over age 40 years in whom the prevalence of coronary artery disease and aortic stenosis increases as the cause of systolic murmur. *[From RA O'Rourke, in Primary Cardiology, 2d ed, E Braunwald, L Goldman (eds). Philadelphia, Saunders, 2003.]*

the other hand, two-dimensional and Doppler echocardiography (Chap. 222) are indicated in patients with loud systolic murmurs (grades ≥III/VI), especially those that are holosystolic or late systolic, and in most patients with diastolic or continuous murmurs.

NATURAL HISTORY

Cardiovascular disorders often present acutely, as in a previously asymptomatic person who develops an acute myocardial infarction (Chap. 239) or the previously asymptomatic patient with hypertrophic cardiomyopathy (Chap. 231) or with a prolonged QT interval (Chap. 226) whose first clinical manifestation is syncope or even sudden death. However, the alert physician may recognize the patient at risk of these complications long before they occur and can often take measures to prevent their occurrence. For example, the patient with acute myocardial infarction will often have had risk factors for atherosclerosis for many years. Had these been recognized, their elimination or reduction might have delayed or even prevented the infarction. Similarly, the patient with hypertrophic cardiomyopathy may have had a heart murmur for years, and a family history of this disorder. These findings could have led to an echocardiographic examination and the recognition of the condition and appropriate therapy long before the occurrence of a serious acute manifestation.

Patients with valvular heart disease or idiopathic dilated cardiomyopathy, on the other hand, may have a prolonged course of gradually increasing dyspnea and other manifestations of chronic heart failure that is punctuated by episodes of acute deterioration only late in the course of the disease. It is of great importance to understand the natural history of various cardiac disorders so as to apply diagnostic and therapeutic measures that are appropriate to each stage of the condition as well as to provide the patient and family with an estimate of the prognosis.

PITFALLS IN CARDIOVASCULAR MEDICINE

Increasing subspecialization in internal medicine and the perfection of advanced diagnostic techniques in cardiology can lead to several undesirable consequences. Examples include:

1. Failure by the *noncardiologist* to recognize important cardiac manifestations of systemic illnesses, e.g., the presence of mitral stenosis, patent foramen ovale, and/or transient atrial arrhythmia in a patient with stroke or the presence of pulmonary hypertension and cor pulmonale in a patient with scleroderma or Raynaud's syndrome. A cardiovascular examination should be carried out to identify and estimate the severity of cardiovascular involvement that accompanies many noncardiac disorders.
2. Failure by the *cardiologist* to recognize underlying systemic disorders in patients with heart disease. For example, hyperthyroidism should be tested for in an elderly patient with atrial fibrillation and unexplained heart failure. Similarly, Lyme disease should be considered in a patient with unexplained fluctuating atrioventricular block. A cardiovascular abnormality may provide the clue critical to the recognition of some systemic disorders. For instance, an unexplained pericardial effusion may provide an early clue to the diagnosis of tuberculosis or neoplasm.
3. Overreliance on and overutilization of laboratory tests, particularly invasive techniques for the examination of the cardiovascular system. Cardiac catheterization and coronary arteriography (Chap. 223) provide precise diagnostic information that is critical to clinical evaluation which may be crucial in developing a therapeutic plan in patients with known or suspected CAD. Although a great deal of attention has been directed to these examinations, it is important to recognize that they serve to *supplement*, not *supplant*, a careful examination carried out by clinical and noninvasive techniques. A coronary arteriogram should not be carried out in lieu of a careful history in patients with chest pain suspected of having ischemic heart disease. Although coronary arteriography may establish whether the coronary arteries are obstructed, and if so the severity of the obstruction, the results of the procedure by themselves often do not provide a definite answer to the question of whether a patient's complaint of chest discomfort is attributable to coronary arteriosclerosis and whether or not revascularization is indicated.

Despite the value of invasive tests in certain circumstances, they entail some small risk to the patient, involve discomfort and substantial cost, and place a strain on medical facilities. Therefore, they should be carried out only if, after the results of clinical examination and assessment by noninvasive tests have been considered, the results (of the invasive examination) can be expected to modify the patient's management.

DISEASE PREVENTION AND MANAGEMENT

The prevention of heart disease, especially of CAD, is one of the most important tasks of primary care health givers as well as cardiologists. Prevention begins with risk assessment, followed by attention to lifestyle, such as achieving optimal weight and discontinuing smoking, and aggressive treatment of all abnormal risk factors, such as hypertension, hyperlipidemia, and diabetes mellitus (Chap. 338).

After a complete diagnosis has been established in patients with known heart disease, a number of management options are usually available. Several examples may be used to demonstrate some of the principles of cardiovascular therapeutics:

1. In the absence of evidence of heart disease, a clear, definitive statement to that effect should be made and the patient should *not* be asked to return at intervals for repeated examinations. If there is no evidence for disease, such continued attention may lead to the patient developing inappropriate anxiety and fixation on the heart.
2. If there is no evidence of cardiovascular disease but the patient has one or more risk factors for the development of ischemic heart disease (Chap. 237), a plan for their reduction should be developed and the patient should be retested at intervals to assess compliance and that these risk factors are in fact being reduced.
3. Asymptomatic or mildly symptomatic patients with valvular heart disease that is anatomically severe should be evaluated periodically, every 6 to 12 months, by clinical and noninvasive examinations. Early signs of deterioration of ventricular function may signify the need for surgical treatment before the development of disabling symptoms, irreversible myocardial damage, and excessive risk of surgical treatment (Chap. 230).

4. In patients with CAD (Chap. 237), available practice guidelines should be considered in the decision on the form of treatment (medical, percutaneous coronary intervention, or surgical revascularization). Mechanical revascularization, i.e., the latter two modalities, may be employed too frequently in the United States and perhaps too infrequently in Eastern Europe and developing nations. The mere presence of angina pectoris and/or the demonstration of critical coronary arterial narrowing at angiography should not reflexly evoke a decision to treat the patient by revascularization. Instead, these procedures should be limited to patients with CAD whose angina has not responded adequately to medical treatment or in whom revascularization has been shown to improve the natural history (e.g., acute coronary syndrome, or multivessel CAD with left ventricular dysfunction).

SECTION 2 DIAGNOSIS OF CARDIOVASCULAR DISORDERS

220 Physical Examination of the Cardiovascular System

Robert A. O'Rourke, Eugene Braunwald

A precise and detailed physical examination is an often underutilized low-cost method for assessing the cardiovascular system. It frequently provides important information for the appropriate selection of additional noninvasive or invasive tests. First, the general physical appearance should be evaluated. The patient may appear tired because of a chronic low cardiac output; the respiratory rate may be rapid in cases of pulmonary venous congestion. Central cyanosis, often associated with clubbing of the fingers and toes, indicates right-to-left cardiac or extracardiac shunting or inadequate oxygenation of blood by the lungs. Cyanosis in the distal extremities, cool skin, and increased sweating result from vasoconstriction in patients with severe heart failure (Chap. 35). Noncardiovascular details can be equally important. For example, infective endocarditis is the likely diagnosis in patients with petechiae, Osler's nodes, and Janeway lesions (Chap. 118).

The blood pressure should be taken in both arms and with the patient supine and upright; the heart rate should be timed for 30 s. Orthostatic hypotension and tachycardia may indicate a reduced blood volume, while resting tachycardia may be due to heart failure or hypovolemia.

EXAMINATION OF THE RETINA

Visualization of the smaller vessels of the body is possible in the retina. The optic disc should be observed first, with a search for evidence of edema and blurred margins and for cupping with sharp contours. Neovascularization or the pallor of optic atrophy should be excluded. Next, the examiner should scan along the superior temporal arcade, inspecting the arteries for embolic plaques at each bifurcation and noting the arteriovenous crossings for evidence of obscuration of the vein and for marked nicking and narrowing of the vessels, as occurs in hypertension (Chap. 241).

Early diabetic microaneurysms, a manifestation of diabetic microvascular disease, are found just temporal to the fovea, along the horizontal raphe, and cotton-wool infarcts are found circularly around the disc (see Fig. 338-9). Thus, the retina can be searched efficiently for evidence of cardiovascular disease.

Variations in the caliber of a single vessel are more important than arteriovenous ratios. These occur in the form of focal narrowing, or *beading*, and are seen in hypercholesterolemia or spasm. In severe hypertension, hypertensive retinopathy with scattered flame-shaped hemorrhages, very constricted arterioles, and cotton-wool spots are evident (see Fig. 29-7).

Retinal emboli have particular cardiovascular importance. Of these, platelet emboli are both the most common and the most evanescent. Hollenhorst cholesterol plaques may be detected at the same bifurcations for months to years after the embolic shower. Platelet emboli, Hollenhorst plaques, and calcium emboli are usually seen along the course of a retinal artery, and their presence indicates that a patient is shedding from the heart, aorta, great vessels, or carotid arteries (see Fig. 29-5).

EXAMINATION OF THE ABDOMEN

The diameter of the *abdominal* aorta should be estimated. A pulsatile, expansible mass is indicative of an abdominal aortic aneurysm (Chap. 242). An abdominal aortic aneurysm may be missed if the examiner does not assess the area above the umbilicus.

Specific abnormalities of the abdomen may be secondary to heart disease. A large, tender liver is common in patients with heart failure or constrictive pericarditis. Systolic hepatic pulsations are frequent in patients with tricuspid regurgitation. A palpable spleen is a late sign in patients with severe heart failure and is also often evident in patients with infective endocarditis. Ascites may occur with heart failure alone, but it is less common with the use of diuretic therapy. Constrictive pericarditis should be considered when the ascites is out of proportion to peripheral edema. When there is an arteriovenous fistula, a continuous murmur may be heard over the abdomen. A systolic bruit heard over the kidney areas may signify renal artery stenosis in patients with systemic hypertension.

EXAMINATION OF THE EXTREMITIES

Examination of the upper and lower extremities may provide important diagnostic information. Palpation of the peripheral arterial pulses in the upper and lower extremities is necessary to define the adequacy of systemic blood flow and to detect the presence of occlusive arterial lesions. Atherosclerosis of the peripheral arteries may produce intermittent claudication of the buttock, calf, thigh, or foot, with severe disease resulting in tissue damage of the toes. Peripheral atherosclerosis is an important risk factor for coincident ischemic heart disease.

The ankle-brachial index (ABI) is useful in cardiovascular risk assessment. The ABI is the ratio of the systolic blood pressure at the ankle di-

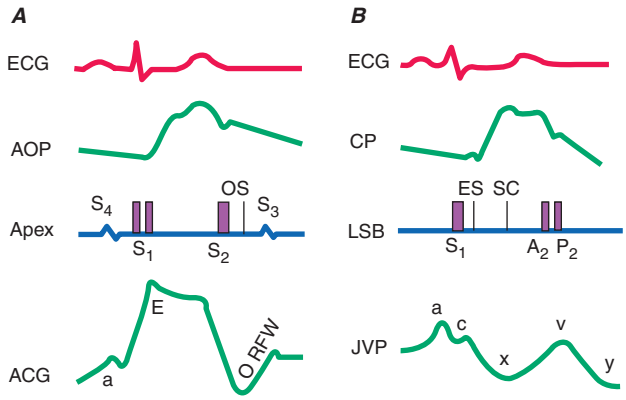

FIGURE 220-1 ***A.*** Schematic representation of electrocardiogram, aortic pressure pulse (AOP), phonocardiogram recorded at the apex, and apex cardiogram (ACG). On the phonocardiogram, S_1, S_2, S_3, and S_4 represent the first through fourth heart sounds; OS represents the opening snap of the mitral valve, which occurs coincident with the O point of the apex cardiogram. S_3 occurs coincident with the termination of the rapid-filling wave (RFW) of the ACG, while S_4 occurs coincident with the *a* wave of the ACG. ***B.*** Simultaneous recording of electrocardiogram, indirect carotid pulse (CP), phonocardiogram along the left sternal border (LSB), and indirect jugular venous pulse (JVP). ES, ejection sound; SC, systolic click.

vided by the higher of the two arm systolic blood pressures. It reflects the degree of lower-extremity arterial occlusive disease, which is manifest by reduced blood pressure distal to stenotic lesions. Either posterior tibial or dorsalis pedis artery pressures can be used. It is important to note that each equally reflects the status of the aortoiliac and femoropopliteal segments but different tibial arteries; therefore, the resulting ABIs may differ. An arm systolic pressure of 120 mmHg and an ankle systolic pressure of 60 mmHg yields an ABI of 0.5 (60/120). The ABI is inversely related to disease severity. A resting ABI <0.9 is considered abnormal. Lower values correspond to progressively more severe occlusive peripheral arterial disease (PAD) and disabling claudication. An ABI <0.3 is consistent with critical ischemia, rest pain, and tissue loss.

Thrombophlebitis often causes pain (in the calf or thigh) or edema, and when present, pulmonary emboli should be considered as well. Edema of the lower extremities is a sign of heart failure but may also be secondary to local factors, such a varicose veins or thrombophlebitis, or to the removal of veins at coronary artery bypass surgery. Under such circumstances, the edema is often unilateral.

ARTERIAL PRESSURE PULSE

The normal central aortic pulse wave is characterized by a fairly rapid rise to a somewhat rounded peak (Fig. 220-1). The anacrotic shoulder, present on the ascending limb, occurs at the time of peak rate of aortic flow just before maximum pressure is reached. The less-steep descending limb is interrupted by a sharp downward deflection, coincident with aortic valve closure, called the *incisura*. As the pulse wave is transmitted distally, the initial upstroke becomes steeper, the anacrotic shoulder becomes less apparent, and the smoother dicrotic notch replaces the incisure. Accordingly, palpation of a peripheral arterial pulse (e.g., the radial pulse) frequently gives less information than examination of a more central pulse (e.g., the carotid pulse) regarding alterations in left ventricular ejection or aortic valve function. However, certain findings, such as the bisferiens pulse of aortic regurgitation or pulsus alternans, are more evident in peripheral arteries (Fig. 220-2).

The carotid pulse is best examined with the sternocleidomastoid muscle relaxed and with the patient's head rotated slightly toward the examiner. In palpating the brachial arterial pulse, the examiner can support the patient's relaxed elbow with the right arm while compressing the brachial pulse with the thumb. The usual technique is to compress the artery with the thumb or forefinger until the maximum pulse is sensed. Varying degrees of pressure should then be applied while concentrating on the separate phases of the pulse wave. This method, known as *trisection*, is useful for assessing the sharpness of the upstroke, systolic peak, and diastolic slope of the arterial pulse. In most normal persons, a dicrotic wave is not palpable.

A small weak pulse, *pulsus parvus*, is common in conditions with a diminished left ventricular stroke volume, a narrow pulse pressure, and increased peripheral vascular resistance. A *hypokinetic* pulse may be due to hypovolemia, to left ventricular failure, to restrictive pericardial disease, or to mitral valve stenosis. In aortic valve stenosis, the delayed systolic peak, *pulsus tardus*, results from obstruction to left ventricular ejection (Fig. 220-2*B*). In contrast, a large, bounding (hyperkinetic) pulse is usually associated with an increased left ventricular stroke volume, a wide pulse pressure, and a decrease in peripheral vascular resistance. This pattern occurs characteristically in patients with an elevated stroke volume, as in complete heart block; with hyperkinetic circulation due to anxiety, anemia, exercise, or fever; or with a rapid runoff of blood from the arterial system (due to a patent ductus arteriosus or peripheral arteriovenous fistula). Patients with mitral regurgitation or a ventricular septal defect may also have a bounding pulse, since vigorous left ventricular ejection produces a rapid upstroke in the arterial pulse, even though the duration of systole and the forward stroke volume may be reduced. In aortic regurgitation, the rapidly rising, bounding arterial pulse results from an increased left ventricular stroke volume and an increased rate of ventricular ejection.

The *bisferiens pulse*, which has two systolic peaks (Fig. 220-2*C*), is characteristic of aortic regurgitation (with or without accompanying

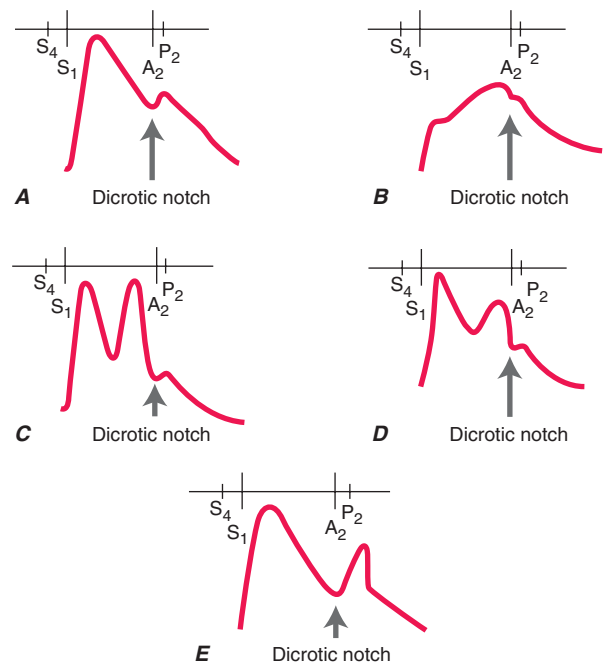

FIGURE 220-2 Schematic diagrams of the configurational changes in carotid pulse and their differential diagnoses. Heart sounds are also illustrated. ***A.*** Normal. A_2, aortic component of the second heart sound; S_1, first heart sound; S_4, atrial sound. ***B.*** Anacrotic pulse with a slow initial upstroke. The peak is close to S_2. These features suggest fixed left ventricular outflow obstruction, such as occurs with valvular aortic stenosis. ***C.*** Pulsus bisferiens with both percussion and tidal waves occurring during systole. This type of carotid pulse contour is most frequently observed in patients with hemodynamically significant aortic regurgitation or combined aortic stenosis and regurgitation with dominant regurgitation. It is rarely appreciated at the bedside by palpation. ***D.*** In hypertrophic obstructive cardiomyopathy, the pulse wave upstroke rises rapidly and the trough is followed by a smaller slowly rising positive pulse. ***E.*** A dicrotic pulse results from an accentuated dicrotic wave and tends to occur in patients with sepsis, severe heart failure, hypovolemic shock, cardiac tamponade, and aortic valve replacement. *[From K Chatterjee: Bedside evaluation of the heart: The physical examination, in Cardiology: An Illustrated Text/Reference, K Chatterjee, W Parmley (eds). Philadelphia, JB Lippincott, 1991.]*

stenosis) and of hypertrophic cardiomyopathy (Chap. 231). In the latter condition, the pulse wave upstroke rises rapidly and forcefully, producing the first systolic peak ("percussion wave") (Fig. 220-2*D*). A brief decline in pressure follows because of the sudden midsystolic decrease in the rate of left ventricular ejection, when severe obstruction often develops. This pressure trough is followed by a smaller and more slowly rising positive pulse wave ("tidal wave") produced by continued ventricular ejection and by reflected waves from the periphery. The dicrotic pulse has two palpable waves, one in the systole and one in diastole (Fig. 220-2*E*). It usually denotes a very low stroke volume, particularly in patients with dilated cardiomyopathy.

Pulsus alternans is a pattern in which there is regular alteration of the pressure pulse amplitude, despite a regular rhythm. It is due to alternating left ventricular contractile force, usually indicates severe impairment of left ventricular function, and commonly occurs in patients who also have a loud third heart sound. Pulsus alternans may also occur during or following paroxysmal tachycardia or for several beats following a premature beat in patients without heart disease. In *pulsus bigeminus*, there is also a regular alteration of pressure pulse amplitude, but it is caused by a premature ventricular contraction that follows each regular beat. In *pulsus paradoxus*, the decrease in systolic arterial pressure that normally accompanies the reduction in arterial pulse amplitude during inspiration is accentuated. In patients with pericardial tamponade (Chap. 232), airway obstruction, or superior vena cava obstruction, the decrease in systolic arterial pressure frequently exceeds the normal decrease of 10 mmHg and the peripheral pulse may disappear completely during inspiration.

Simultaneous palpation of the radial and femoral arterial pulses, which normally are virtually coincident, is important to rule out aortic coarctation, in which the latter pulse is weakened and delayed (Chap. 229).

JUGULAR VENOUS PULSE (JVP)

The two main objectives of the examination of the neck veins are inspection of their waveform and estimation of the central venous pressure (CVP). In most patients, the right internal jugular vein is best for both purposes. Usually, the pulsation of the internal jugular vein is greatest when the trunk is inclined by less than 30°. In patients with elevated venous pressure, it may be necessary to elevate the trunk further, sometimes to as much as 90°. When the neck muscles are relaxed, shining a beam of light tangentially across the skin overlying the vein exposes the pulsations of the internal jugular vein. Simultaneous palpation of the left carotid artery aids the examiner in deciding which pulsations are venous and in relating the venous pulsations to their timing in the cardiac cycle.

The normal JVP reflects phasic pressure changes in the right atrium and consists of two or sometime three positive waves and two negative troughs (Fig. 220-1*B* and 220-3). The positive presystolic *a* wave is produced by venous distention due to right atrial contraction and is the dominant wave in the JVP, particularly during inspiration. Large *a* waves indicate that the right atrium is contracting against an increased resistance, such as occurs with tricuspid stenosis (Fig. 220-3) or more commonly with increased resistance to right ventricular filling (pulmonary hypertension or pulmonic stenosis). Large *a* waves also occur during arrhythmias whenever the right atrium contracts while the tricuspid valve is closed by right ventricular systole. Such "cannon" *a* waves may occur regularly (as during junctional rhythm) or irregularly (as in atrioventricular dissociation with ventricular tachycardia or complete heart block). The *a* wave is absent in patients with atrial fibrillation, and there is an increased delay between the *a* wave and the carotid arterial pulse in patients with first-degree atrioventricular block.

The *c* wave, often observed in the JVP (Fig. 220-1), is a positive wave produced by the bulging of the tricuspid valve into the right atrium during right ventricular isovolumetric systole and by the impact of the carotid artery adjacent to the jugular vein. The *x* descent is due both to atrial relaxation and to the downward displacement of the tricuspid valve during ventricular systole. The *x* descent wave during systole is often accentuated in patients with constrictive pericarditis (Fig. 220-3), but the nadir of this wave is reduced with right ventricular dilation and is often reversed in tricuspid regurgitation. The positive,

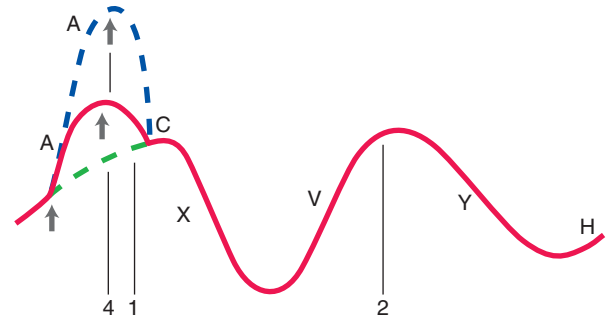

FIGURE 220-3 Jugular venous pulse. The normal contour is shown by the solid red line. The A-wave (*a*) is absent in atrial fibrillation (dashed green line). The A-wave becomes large when the right atrium contracts against a greater than normal volume of blood, a noncompliant or hypertrophied right ventricle, or a closing or closed tricuspid valve (dashed blue line). Arrows indicate the beginning and the peak of the A-wave. The numbers represent the heart sounds. The fourth heart sound coincides with the peak of the large or giant A-wave. *[From TC Evans et al: Physical examination, in Cardiology: Fundamentals and Practice, 2d ed, ER Giuliani (ed). St. Louis, Mosby-Year Book, 1991, by permission of the Mayo Foundation.]*

late systolic *v* wave results from the increasing volume of blood in the right atrium during ventricular systole when the tricuspid valve is closed. Tricuspid regurgitation causes the *v* wave to be more prominent; when tricuspid regurgitation becomes severe, the combination of a prominent *v* wave and obliteration of the *x* descent results in a single large positive systolic wave. After the *v* wave peaks, the right atrial pressure falls because of the decreased bulging of the tricuspid valve into the right atrium as right ventricular pressure declines and tricuspid valve opens (Fig. 220-3).

This negative descending limb—the *y* descent of the JVP—is produced mainly by the opening of the tricuspid valve and the subsequent rapid inflow of blood into the right ventricle. A rapid, deep *y* descent in early diastole occurs with severe tricuspid regurgitation. A venous pulse characterized by a sharp *y* descent, a deep *y* trough, and a rapid ascent to the baseline is seen in patients with constrictive pericarditis or with severe right-sided heart failure and a high venous pressure. A slow *y* descent in the JVP suggests an obstruction to right ventricular filling, as occurs with tricuspid stenosis or right atrial myxoma.

The right internal jugular is the best vein to use for accurate estimation of the CVP. The sternal angle is used as the reference point because the center of the right atrium lies approximately 5 cm below the sternal angle in the average patient, regardless of body position. The patient is examined at the optimal degree of trunk elevation for visualization of venous pulsations. The vertical distance between the top of the oscillating venous column and the level of the sternal angle is determined; generally it is less than 3 cm (3 cm + 5 cm = 8 cm blood). The most common cause of a high venous pressure is an elevated right ventricular diastolic pressure.

In patients suspected of having right ventricular failure who have a normal CVP at rest, the *abdominojugular reflux test* may be helpful. The palm of the examiner's hand is placed over the abdomen, and firm pressure is applied for 10 s or more. In normal persons, this maneuver does not alter the jugular venous pressure significantly, but when right heart function is impaired, the upper level of venous pulsation usually increases. A positive abdominojugular test is best defined as an increase in JVP during 10 s of firm midabdominal compression followed by a rapid drop in pressure of 4 cm blood on release of the compression. The most common cause of a positive test is right-sided heart failure secondary to elevated left heart filling pressures. Also, abdominal compression may elicit the JVP pattern typical of tricuspid regurgitation when the resting pulse wave is normal. *Kussmaul's sign*—an increase rather than the normal decrease in the CVP during inspiration—is most often caused by severe right-sided heart failure; it is a frequent finding in patients with constrictive pericarditis or right ventricular infarction.

PRECORDIAL PALPATION

The location, amplitude, duration, and direction of the cardiac impulse usually can be best appreciated with the fingertips. The normal left ventricular apex impulse is located at or medial to the left midclavicular line in the fourth or fifth intercostal space. Left ventricular hypertrophy results in exaggeration of the amplitude, duration, and often size of the normal left ventricular thrust. The impulse may be displaced laterally and downward into the sixth or seventh intercostal space, particularly in patients with a left ventricular volume load such as occurs in cases of aortic regurgitation or dilated cardiomyopathy. Right ventricular hypertrophy often results in a sustained systolic lift at the lower left parasternal area, which starts in early systole and is synchronous with the left ventricular apical impulse.

Abnormal precordial pulsations occur during systole in patients with left ventricular dyssynergy due to ischemic heart disease or to diffuse myocardial disease from some other cause. They are most commonly felt in the left midprecordium one or two interspaces above the left ventricular apex.

A left parasternal lift is frequently present in patients with severe mitral regurgitation and is due to anterior displacement of the right ventricle by an enlarged, expanding left atrium. Pulmonary artery pulsation is often visible and palpable in the second left intercostal space. This pulsation usually denotes pulmonary hypertension or increased pulmonary blood flow.

Thrills are palpable, low frequency vibrations associated with heart murmurs. The systolic murmur of mitral regurgitation may be palpated at the cardiac apex. When the palm of the hand is placed over the precordium, the thrill of aortic stenosis crosses the palm toward the right side of the neck, while the thrill of pulmonic stenosis radiates more often to the left side of the neck. The thrill due to a ventricular septal defect is usually located in the third or fourth intercostal spaces near the left sternal border.

Percussion should be performed to identify normal or abnormal position of the heart, stomach, and liver.

CARDIAC AUSCULTATION

To obtain the most information from cardiac auscultation, the observer should keep in mind several principles: (1) Auscultation should be performed in a quiet room to avoid the distracting noises of normal activity. (2) For optimal auscultation, attention must be focused on the phase of the cardiac cycle during which the auscultatory event is expected to occur. (3) The timing of a heart sound or murmur can be determined accurately from its relation to other observable events in the cardiac cycle—the carotid arterial pulse, the apical impulse, or the JVP.

HEART SOUNDS

The major components of heart sounds are vibrations associated with the abrupt acceleration or deceleration of blood in the cardiovascular system. Studies using simultaneous echocardiographic-phonocardiographic recordings indicate that the first and second heart sounds are produced primarily by the closure of the atrioventricular (AV) and semilunar valves and the events that accompany these closures. The intensity of the *first heart sound* (S_1) is influenced by (1) the position of the mitral leaflets at the onset of ventricular systole; (2) the rate of rise of the left ventricular pressure pulse; (3) the presence or absence of structural disease of the mitral valve; and (4) the amount of tissue, air, or fluid between the heart and the stethoscope. S_1 is louder if diastole is shortened because of tachycardia, if AV flow is increased because of high cardiac output or prolonged because of mitral stenosis, or if atrial contraction precedes ventricular contraction by an unusually short interval, reflected in a short PR interval. The loud S_1 in mitral stenosis usually signifies that the valve is pliable and that it remains open at the onset of isovolumetric contraction because of the elevated left atrial pressure. A soft S_1 may be due to poor conduction of sound through the chest wall, a slow rise of the left ventricular pressure pulse, a long PR interval, or imperfect closure due to reduced valve substance, as in mitral regurgitation. S_1 is also soft when the anterior mitral leaflet is immobile because of rigidity and calcification, even in the presence of predominant mitral stenosis.

Splitting of the two high-pitched components of S_1 by 10–30 ms is a normal phenomenon (Fig. 220-1*A*). The first component of S_1 is usually attributed to mitral valve closure, and the second to tricuspid valve closure. Widening of the S_1 is due most often to complete right bundle branch block and the resulting delay in onset of the right ventricular pressure pulse.

Splitting of the Second Heart Sound This sound (S_2) normally splits into audibly distinct aortic (A_2) and pulmonic (P_2) components during inspiration, when the augmented inflow into the right ventricle increases its stroke volume and ejection period and thus delays closure of the pulmonic valve. P_2 is coincident with the incisura of the pulmonary artery pressure curve, which is separated from the right ventricular pressure tracing by an interval termed the *hangout time*. The absolute value of this interval reflects the resistance to pulmonary vascular bed. This interval is prolonged, and physiologic splitting of S_2 is accentuated, in conditions associated with right ventricular volume overload and a distensible pulmonary vascular bed. However, in patients with an increase in pulmonary vascular resistance, the hangout time is markedly reduced, and narrow splitting of S_2 is present. Splitting that persists with expiration (heard best at the pulmonic area or left sternal border) is usually abnormal when the patient is in the upright position. Such splitting may be due to many causes: delayed activation of the right ventricle (right bundle branch block); left ventricular ectopic beats; a left ventricular pacemaker; prolongation of right ventricular contraction with an increased right ventricular pressure load (pulmonary embolism or pulmonic stenosis); or delayed pulmonic valve closure because of right ventricular volume overload associated with right ventricular failure or diminished impedance of the pulmonary vascular bed and a prolonged hangout time (atrial septal defect).

In pulmonary hypertension, P_2 is loud, and splitting of S_2 may be diminished, normal, or accentuated, depending on the cause of the pulmonary hypertension, the pulmonary vascular resistance, and the presence or absence of right ventricular decompensation. Early aortic valve closure, occurring with mitral regurgitation or a ventricular septal defect, may also produce splitting that persists during expiration. In patients with an atrial septal defect, the proportion of right atrial filling contributed by the left atrium and the venae cavae varies reciprocally during the respiratory cycle, so that right atrial inflow remains relatively constant. Therefore, the volume and duration of right ventricular ejection are not significantly increased by inspiration, and there is little inspiratory exaggeration of the splitting of S_2. This phenomenon, termed *fixed splitting* of the second heart sound, is of considerable diagnostic value.

A delay in aortic valve closure causing P_2 to precede A_2 results in so-called reversed (paradoxic) splitting of S_2. Splitting is then maximal in expiration and decreases during inspiration with the normal delay of pulmonic valve closure. The most common causes of reversed splitting of S_2 are left bundle branch block and delayed excitation of the left ventricle from a right ventricular ectopic beat. Mechanical prolongation of left ventricular systole, resulting in reversed splitting of S_2, may also be caused by severe aortic outflow obstruction, a large aorta-to-pulmonary artery shunt, systolic hypertension, and ischemic heart disease or cardiomyopathy with left ventricular failure. P_2 is normally softer than A_2 in the second left intercostal space; a P_2 that is greater than A_2 in this area suggests pulmonary hypertension (except in patients with atrial septal defect).

Systolic Sounds The *ejection sound* is a sharp, high-pitched event occurring in early systole and closely following the first heart sound (Fig. 220-1*B*, ES). Ejection sounds occur in the presence of semilunar valve stenosis and in conditions associated with dilation of the aorta or pulmonary artery. *Nonejection clicks*, or *midsystolic clicks*, occurring with or without a late systolic murmur, often denote prolapse of one or both leaflets of the mitral valve (Chap. 230). They probably result from chordae tendineae that are functionally unequal in length and are best heard along the lower left sternal border and at the left ventricular apex. Systolic clicks usually occur later than the systolic ejection sound.

Diastolic Sounds The *opening snap* (OS) (Fig. 220-1*A*) is a brief, high-pitched, early diastolic sound, which is usually due to stenosis of an AV valve, most often the mitral valve. It is generally heard best at the lower left sternal border and radiates well to the base of the heart. The A_2-OS interval is inversely related to the height of the mean left atrial pressure and ranges from 0.04 to 0.12 s. The OS of tricuspid stenosis occurs later in diastole than the mitral OS and is often overlooked. A tumor plop in patients with left atrial myxoma may have the timing of an opening snap, but it is usually lower-pitched.

The *third heart sound* (S_3) (Fig. 220-1*A*) is a low-pitched sound produced in the ventricle 0.14–0.16 s after A_2, at the termination of rapid filling. This sound is frequent in normal children and in patients with high cardiac output. However, in patients over 40 years, an S_3 usually indicates impairment of ventricular function, AV valve regurgitation, or other conditions that increase the rate or volume of ventricular filling. The left-sided S_3 is best heard with the bell piece of the stethoscope at the left ventricular apex during expiration and with the patient in the left lateral position. The right-sided S_3 is best heard at the left sternal border or just beneath the xiphoid and is usually louder with inspiration. Third heart sounds often disappear with treatment of heart failure. An S_3 that is earlier (0.10–0.12 s after A_2) and higher-pitched than normal (a pericardial knock) often occurs in patients with constrictive pericarditis (Chap. 232); its presence depends on the restrictive effect of the adherent pericardium, which abruptly halts diastolic filling.

The *fourth heart sound* (S_4) is a low-pitched, presystolic sound produced in the ventricle during ventricular filling; it is associated with an effective atrial contraction and is best heard with the bell piece of the stethoscope. The sound is absent in patients with atrial fibrillation. The S_4 occurs when diminished ventricular compliance increases the resistance to ventricular filling; it is frequently present in patients with systemic hypertension, aortic stenosis, hypertrophic cardiomyopathy, ischemic heart disease, and acute mitral regurgitation. Most patients with an acute myocardial infarction and sinus rhythm have an audible S_4. The S_4 is loudest at the left ventricular apex when the patient is in the left lateral position and is accentuated by mild isotonic or isometric exercise in the supine position. The right-sided S_4 is present in patients with right ventricular hypertrophy secondary to either pulmonic stenosis or pulmonary hypertension and frequently accompanies a prominent presystolic *a* wave in the JVP. An S_4 frequently accompanies delayed AV conduction, even in the absence of clinically detectable heart disease. The incidence of an audible S_4 increases with increasing age. Whether an audible S_4 in adults without other evidence of cardiac disease is abnormal remains controversial.

HEART MURMURS

(See also **Chap. e8**) The evaluation of the patient with a heart murmur may vary greatly depending on its intensity, timing, location and radiation, and response to various physiologic maneuvers. The intensity (loudness) of murmurs may be graded from I to VI. A grade I murmur is so faint that it can be heard only with special effort; a grade IV murmur is commonly accompanied by a thrill; and a grade VI murmur is audible with the stethoscope removed from contact with the chest. The configuration of a murmur may be crescendo, decrescendo, crescendo-decrescendo (diamond-shaped), or plateau **(Fig. 220-4)**. The precise time of onset and time of cessation of a murmur depend on the instant in the cardiac cycle at which an adequate pressure difference between two chambers arises and disappears.

The location on the chest wall where the murmur is best heard and the areas to which it radiates can aid in identifying the cardiac structure from which the murmur originates. For example, the murmur of aortic valve stenosis is usually loudest in the second right intercostal space and radiates to the carotid arteries. By contrast, the murmur of mitral regurgitation is most often loudest at the cardiac apex, but it may radiate to the left sternal border and base of the heart when the posterior mitral leaflet is predominantly involved or to the axilla and back when the anterior leaflet is more severely affected.

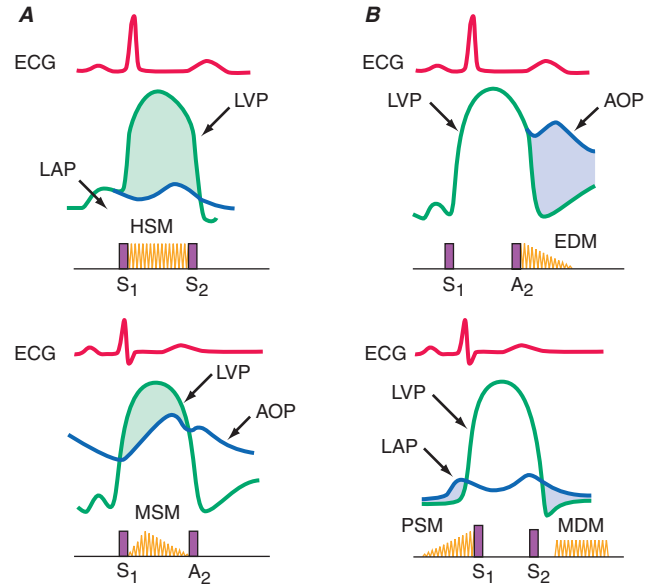

FIGURE 220-4 ***A.*** Schematic representation of ECG, aortic pressure (AOP), left ventricular pressure (LVP), and left atrial pressure (LAP). The shaded areas indicate a transvalvular pressure difference during systole. HSM, holosystolic murmur; MSM, midsystolic murmur. ***B.*** Graphic representation of ECG, aortic pressure (AOP), left ventricular pressure (LVP), and left atrial pressure (LAP) with shaded areas indicating transvalvular diastolic pressure difference. EDM, early diastolic murmur; PSM, presystolic murmur; MDM, middiastolic murmur.

Effects of Physiologic Interventions By noting changes in the characteristics of the murmur during maneuvers that alter cardiac hemodynamics, its correct origin and significance can usually be identified **(Table 220-1)**.

Systolic Murmurs • ***HOLOSYSTOLIC (PANSYSTOLIC) MURMURS*** These are generated when there is flow between two chambers that have widely different pressures throughout systole, such as the left ventricle and either the left atrium or the right ventricle. The pressure gradient occurs early in contraction and lasts until relaxation is almost complete. Therefore, holosystolic murmurs begin before aortic ejection, and at the area of maximal intensity they begin with S_1 and end after S_2. Holosystolic murmurs accompany mitral or tricuspid regurgitation and ventricular septal defect.

The murmur of tricuspid regurgitation associated with pulmonary hypertension is holosystolic and frequently increases during inspiration. Not all patients with mitral or tricuspid regurgitation or ventricular septal defect have holosystolic murmurs. Often, a mild valvular regurgitant jet, detected by color-flow Doppler techniques (Chap. 222), is not associated with an audible murmur.

MIDSYSTOLIC MURMURS These are also called *systolic ejection murmurs*, which are often crescendo-decrescendo in shape and occur when blood is ejected across the aortic or pulmonic outflow tracts (Fig. 220-4). The murmur starts shortly after S_1, when the ventricular pressure becomes high enough to open the semilunar valve. As the velocity of ejection increases, the murmur gets louder; as ejection declines, it diminishes. The murmur ends before the ventricular pressure falls enough to permit closure of the aortic or pulmonic leaflets. When the semilunar valves are normal, an increased flow rate (as occurs in states of elevated cardiac output), ejection into a dilated vessel beyond the valve, or increased transmission of sound through a thin chest wall may be responsible for this murmur. Most benign, functional murmurs are midsystolic and originate from the pulmonary outflow tract. Valvular or subvalvular obstruction of either ventricle may also cause such a midsystolic murmur, the intensity being related to the flow rate.

The murmur of aortic stenosis is the prototype of the left-sided midsystolic murmur. The location and radiation of this murmur are

TABLE 220-1 EFFECTS OF PHYSIOLOGIC AND PHARMACOLOGIC INTERVENTIONS ON THE INTENSITY OF HEART MURMURS AND SOUNDS

Respiration	Systolic murmurs due to TR or pulmonic blood flow through a normal or stenotic valve and diastolic murmurs of TS or PR generally increase with inspiration, as do right-sided S_3 and S_4. Left-sided murmurs and sounds usually are louder during expiration, as is the PES.
Valsalva maneuver	Most murmurs decrease in length and intensity. Two exceptions are the systolic murmur of HCM, which usually becomes much louder, and that of MVP, which becomes longer and often louder. Following release of the Valsalva maneuver, right-sided murmurs tend to return to control intensity earlier than left-sided murmurs.
After VPB or AF	Murmurs originating at normal or stenotic semilunar valves increase in the cardiac cycle following a VPB or in the cycle after a long cycle length in AF. By contrast, systolic murmurs due to AV valve regurgitation either do not change, diminish (papillary muscle dysfunction), or become shorter (MVP).
Positional changes	With *standing,* most murmurs diminish, two exceptions being the murmur of HCM, which becomes louder, and that of MVP, which lengthens and often is intensified. With *squatting,* most murmurs become louder, but those of HCM and MVP usually soften and may disappear. Passive leg raising usually produces the same results.
Exercise	Murmurs due to blood flow across normal or obstructed valves (e.g., PS, MS) become louder with both isotonic and submaximal isometric (handgrip) exercise. Murmurs of MR, VSD, and AR also increase with handgrip exercise. However, the murmur of HCM often decreases with near maximum handgrip exercise. Left-sided S_4 and S_3 are often accentuated by exercise, particularly when due to ischemic heart disease.

Note: TR, tricuspid regurgitation; TS, tricuspid stenosis; PR, pulmonic regurgitation; HCM, hypertrophic cardiomyopathy; MVP, mitral valve prolapse; PS, pulmonic stenosis; MS, mitral stenosis; MR, mitral regurgitation; PES, pulmonic ejection sound; VSD, ventricular septal defect; AR, aortic regurgitation; VPB, ventricular premature beat; AF, atrial fibrillation.

influenced by the direction of the high-velocity jet within the aortic root. In *valvular aortic stenosis*, the murmur is usually maximal in the second right intercostal space, with radiation into the neck. The murmur may disappear over the sternum and reappear at the apex, leaving a false impression that mitral regurgitation is present (Gallavardin Phenomenon). In hypertrophic cardiomyopathy, the midsystolic murmur originates in the left ventricular cavity and is usually maximal at the lower left sternal edge and apex, with relatively little radiation to the carotids. When the aortic valve is immobile (calcified), the aortic closure sound (A_2) may be soft and inaudible so that the length and configuration of the murmur are difficult to determine.

The patient's age and the area of maximal intensity aid in determining the significance of midsystolic murmurs. Thus, in a young adult with a thin chest and a high velocity of blood flow, a faint or moderate midsystolic murmur heard only in the pulmonic area is usually without clinical significance, while a somewhat louder murmur in the aortic area may indicate congenital aortic stenosis. In elderly patients, pulmonic flow murmurs are rare, while aortic systolic murmurs are common and may be due to aortic dilation, a significant degree of valvular aortic stenosis, or nonstenotic thickening of the aortic valve leaflets. Midsystolic aortic and pulmonic murmurs are intensified during the cardiac cycle following a premature ventricular beat, while those due to mitral regurgitation are unchanged or softer. Echocardiography may be necessary to separate a prominent and exaggerated functional murmur from one due to congenital or acquired semilunar valve stenosis.

EARLY SYSTOLIC MURMURS These murmurs begin with the first heart sound and end in midsystole. In *large ventricular septal defects with pulmonary hypertension*, the shunting at the end of systole may be small or absent, resulting in an early systolic murmur. A similar murmur may occur with very small *muscular ventricular septal defects*. An early systolic murmur is a feature of *tricuspid regurgitation occurring in the absence of pulmonary hypertension*, a lesion that is common in narcotics abusers with infective endocarditis. Patients with acute mitral regurgitation into a noncompliant left atrium and a large *v* wave often have a loud early systolic murmur that diminishes as the pressure gradient between the left ventricle and left atrium decreases the late systole (Chap. 230).

LATE SYSTOLIC MURMURS These murmurs are faint or moderately loud, high-pitched apical murmurs that start well after ejection and do not mask either heart sound. They are probably related to papillary muscle dysfunction caused by infarction or ischemia of these muscles or to their distortion by left ventricular dilation. They may appear only during angina but are common in patients with myocardial infarction or diffuse myocardial disease. Late systolic murmurs following midsystolic clicks are due to late systolic mitral regurgitation caused by prolapse of the mitral valve into the left atrium (Chap. 230).

Diastolic Murmurs • ***EARLY DIASTOLIC MURMURS*** These murmurs begin with or shortly after S_2, as soon as the corresponding ventricular pressure falls enough below that in the aorta or pulmonary artery. The high-pitched murmurs of aortic regurgitation or of pulmonic regurgitation due to pulmonary hypertension are generally decrescendo, since there is a progressive decline in the volume or rate of regurgitation during diastole. Faint, high-pitched murmurs of aortic regurgitation are difficult to hear unless they are specifically sought by applying firm pressure with the diaphragm over the left midsternal border while the patient sits leaning forward and holds a breath in full expiration. The diastolic murmur of aortic regurgitation is enhanced by an acute elevation of the arterial pressure, such as occurs with handgrip.

MIDDIASTOLIC MURMURS These usually arise from the mitral or tricuspid valves, occur during early ventricular filling, and are due to disproportion between valve orifice sizes and flow rate. Such murmurs may be quite loud (grade III/VI), despite only slight AV valve stenosis, when there is normal or increased blood flow. Conversely, the murmurs may be soft or even absent despite severe obstruction if the cardiac output is markedly reduced. When stenosis is marked, the diastolic murmur is prolonged, and the duration of the murmur is more reliable than its intensity as an index of the severity of valve obstruction.

The low-pitched, middiastolic murmur of mitral stenosis characteristically follows the OS. It should be specifically sought by placing the bell of the stethoscope at the site of the left ventricular impulse, which is best localized with the patient on the left side. Frequently, the murmur of mitral stenosis is present only at the left ventricular apex, and it may be increased in intensity by mild supine exercise. In tricuspid stenosis, the middiastolic murmur is localized to a relatively limited area along the left sternal edge and may be louder during inspiration.

Middiastolic murmurs may be generated across the mitral valve in cases of mitral regurgitation, patent ductus arteriosus, or ventricular septal defect, and across the tricuspid valve in cases of tricuspid regurgitation or atrial septal defect. These murmurs are related to the very rapid flow across an AV valve, usually follow an S_3, and tend to occur with large left-to-right shunts or severe AV valve regurgitation.

In acute, severe aortic regurgitation, the left ventricular diastolic pressure may exceed the left atrial pressure, resulting in a middiastolic murmur due to "diastolic mitral regurgitation." In severe, chronic aortic regurgitation, a murmur is frequently present that may be either middiastolic or presystolic (Austin-Flint murmur). This murmur appears to originate at the anterior mitral valve leaflet when blood enters the left ventricle simultaneously from both the aortic root and the left atrium.

PRESYSTOLIC MURMURS These murmurs begin during the period of ventricular filling that follows atrial contraction and therefore occur in sinus rhythm. They are usually due to AV valve stenosis and have the same quality as the middiastolic-filling rumble, but they are usually crescendo, reaching peak intensity at the time of a loud S_1. The presystolic murmur corresponds to the AV valve gradient, which may be minimal until the moment of right or left atrial contraction. It is the presystolic murmur that is most characteristic of tricuspid stenosis and sinus rhythm. A right or left *atrial myxoma* may occasionally

cause either middiastolic or presystolic murmurs that resemble the murmurs of mitral or tricuspid stenosis.

CONTINUOUS MURMURS These begin in systole, peak near S_2, and continue into all or part of diastole. These murmurs result from continuous flow due to a communication between high- and low-pressure areas that persists through the end of systole and the beginning of diastole. A *patent ductus arteriosus* causes a continuous murmur as long as the pressure in the pulmonary artery is much below that in the aorta. When pulmonary hypertension is present, the diastolic portion may disappear, leaving the murmur confined to systole. Surgically produced connections and the subclavian-pulmonary artery anastomosis result in murmurs similar to that of a patent ductus.

Continuous murmurs may result from congenital or acquired *systemic arteriovenous fistula*, *coronary arteriovenous fistula*, anomalous origin of the left coronary artery from the pulmonary artery, and *communications between the sinus of Valsalva and the right side of the heart*. Murmurs associated with *pulmonary arteriovenous fistulas* may be continuous but are usually only systolic. Continuous murmurs may also be due to disturbances of flow pattern in constricted systemic (e.g., renal) or pulmonary arteries when marked pressure differences between the two sides of the narrow segment persist; a continuous murmur in the back may be present in *coarctation of the aorta*; *pulmonary embolism* may cause continuous murmurs in partially occluded vessels.

The "mammary souffle," an innocent murmur heard over the breasts during late pregnancy and in the early postpartum period, may be systolic or continuous. The innocent cervical venous hum is a continuous murmur usually audible over the medial aspect of the right supraclavicular fossa with the patient upright. The hum is usually louder during diastole and can be abolished instantaneously by digital compression of the ipsilateral internal jugular vein. Transmission of a loud venous hum to the area below the clavicles may result in a mistaken diagnosis of patent ductus arteriosus.

Pericardial Friction Rub (See also Chap. 232) These adventitious sounds may have presystolic, systolic, and early diastolic scratchy components and may be confused with a murmur or extracardiac sound when heard only in systole. A pericardial friction rub is best appreciated with the patient upright and leaning forward and may be accentuated during expiration.

221 Electrocardiography

Ary L. Goldberger

The electrocardiogram (ECG or EKG) is a graphic recording of electric potentials generated by the heart. The signals are detected by means of metal electrodes attached to the extremities and chest wall and are then amplified and recorded by the electrocardiograph. ECG *leads* actually display the instantaneous *differences* in potential between these electrodes.

The clinical utility of the ECG derives from its immediate availability as a noninvasive, inexpensive, and highly versatile test. In addition to its use in detecting arrhythmias, conduction disturbances, and myocardial ischemia, electrocardiography may reveal other findings related to life-threatening metabolic disturbances (e.g., hyperkalemia) or increased susceptibility to sudden cardiac death (e.g., QT prolongation syndromes). The widespread use of coronary fibrinolysis and acute percutaneous coronary interventions in the early therapy of acute myocardial infarction (Chap. 239) has refocused attention on the sensitivity and specificity of ECG signs of myocardial ischemia.

ELECTROPHYSIOLOGY

(See also Chaps. 225 and 226) Depolarization of the heart is the initiating event for cardiac contraction. The electric currents that spread through the heart are produced by three components: cardiac pacemaker cells, specialized conduction tissue, and the heart muscle itself. The ECG, however, records only the depolarization (stimulation) and repolarization (recovery) potentials generated by the atrial and ventricular myocardium.

The depolarization stimulus for the normal heartbeat originates in the *sinoatrial* (SA) *node* (Fig. 221-1), or *sinus node*, a collection of *pacemaker cells*. These cells fire spontaneously; that is, they exhibit *automaticity*. The first phase of cardiac electrical activation is the spread of the depolarization wave through the right and left atria, followed by atrial contraction. Next, the impulse stimulates pacemaker and specialized conduction tissues in the atrioventricular (AV) nodal and His-bundle areas; together, these two regions constitute the AV junction. The bundle of His bifurcates into two main branches, the right and left bundles, which rapidly transmit depolarization wavefronts to the right and left ventricular myocardium by way of Purkinje fibers. The main left bundle bifurcates into two primary subdivisions, a left anterior fascicle and a left posterior fascicle. The depolarization wavefronts then spread through the ventricular wall, from endocardium to epicardium, triggering ventricular contraction.

Since the cardiac depolarization and repolarization waves have direction and magnitude, they can be represented by vectors. *Vectorcardiograms* that measure and display these instantaneous potentials are no longer used much in clinical practice. However, the general princi-

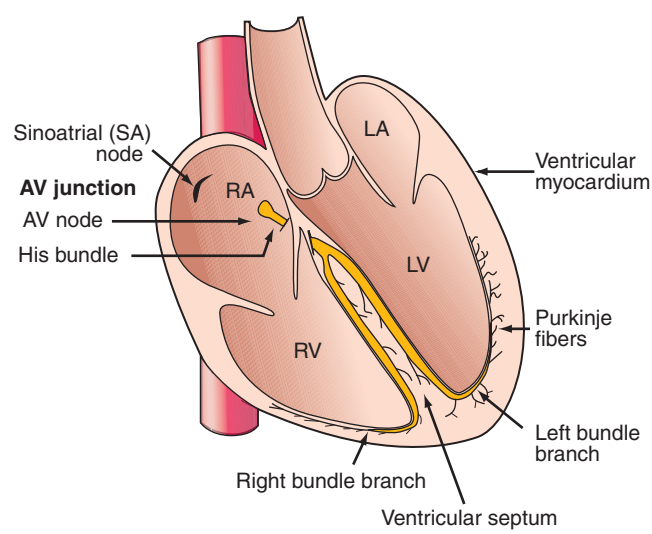

FIGURE 221-1 Schematic of the cardiac conduction system.

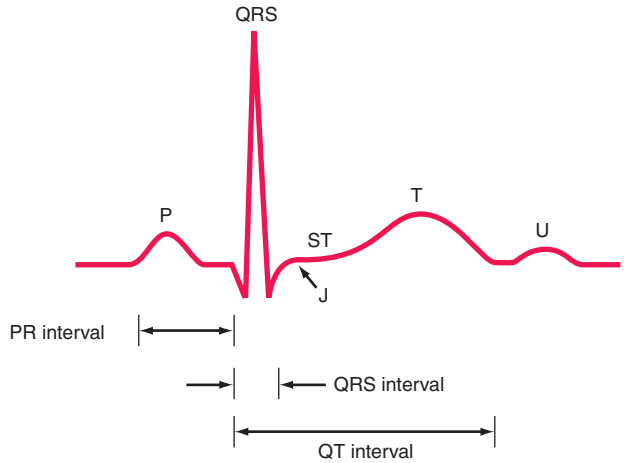

FIGURE 221-2 Basic ECG waveforms and intervals. Not shown is the R-R interval, the time between consecutive QRS complexes.

ples of vector analysis remain fundamental to understanding the genesis of normal and pathologic ECG waveforms. Vector analysis illustrates a central concept of electrocardiography—that the ECG records the complex spatial and temporal summation of electrical potentials from multiple myocardial fibers conducted to the surface of the body. This principle accounts for inherent limitations in both ECG *sensitivity* (activity from certain cardiac regions may be canceled out or may be too weak to be recorded) and *specificity* (the same vectorial sum can result from either a selective gain or a loss of forces in opposite directions).

ECG WAVEFORMS AND INTERVALS

The ECG waveforms are labeled alphabetically, beginning with the P wave, which represents atrial depolarization (Fig. 221-2). The QRS complex represents ventricular depolarization, and the ST-T-U complex (ST segment, T wave, and U wave) represents ventricular repolarization. The J point is the junction between the end of the QRS complex and the beginning of the ST segment. Atrial repolarization is usually too low in amplitude to be detected, but it may become apparent in such conditions as acute pericarditis or atrial infarction.

The QRS-T waveforms of the surface ECG correspond in a general way with the different phases of simultaneously obtained ventricular *action potentials*, the intracellular recordings from single myocardial fibers (Chap. 225). The rapid upstroke (phase 0) of the action potential corresponds to the onset of QRS. The plateau (phase 2) corresponds to the isoelectric ST segment, and active repolarization (phase 3) to the inscription of the T wave. Factors that decrease the slope of phase 0 by impairing the influx of Na^+ (e.g., hyperkalemia, or drugs such as flecainide) tend to increase QRS duration. Conditions that prolong phase 2 (use of amiodarone, hypocalcemia) increase the QT interval. In contrast, shortening of ventricular repolarization (phase 2), as by digitalis administration or hypercalcemia, abbreviates the ST segment.

The electrocardiogram is ordinarily recorded on special graph paper which is divided into 1-mm^2 gridlike boxes. Since the ECG paper speed is generally 25 mm/s, the smallest (1 mm) horizontal divisions correspond to 0.04 (40 ms), with heavier lines at intervals of 0.20 s (200 ms). Vertically, the ECG graph measures the amplitude of a given wave or deflection (1 mV = 10 mm with standard calibration; the voltage criteria for hypertrophy mentioned below are given in millimeters). There are four major ECG intervals: R-R, PR, QRS, and QT (Fig. 221-2). The heart rate (beats per minute) can be readily computed from the interbeat (R-R) interval by dividing the number of large (0.20 s) time units between consecutive R waves into 300 or the number of small (0.04 s) units into 1500. The PR interval measures the time (normally 120–200 ms) between atrial and ventricular depolarization, which includes the physiologic delay imposed by stimulation of cells in the AV junction area. The QRS interval (normally 100-110 ms or less) reflects the duration of ventricular depolarization. The QT interval includes both ventricular depolarization and repolarization times and varies inversely with the heart rate. A rate-related ("corrected") QT interval, QT_c, can be calculated as $QT/\sqrt{RR}$ and normally is ≤0.44 s. (Some references give QT_c upper normal limits as 0.43 s in men and 0.45 s in women.)

The QRS complex is subdivided into specific deflections or waves. If the initial QRS deflection in a given lead is negative, it is termed a *Q wave*; the first positive deflection is termed an *R wave*. A negative deflection after an R wave is an *S wave*. Subsequent positive or negative waves are labeled R′ and S′, respectively. Lowercase letters (qrs) are used for waves of relatively small amplitude. An entirely negative QRS complex is termed a *QS wave*.

ECG LEADS

The 12 conventional ECG leads record the difference in potential between electrodes placed on the surface of the body. These leads are divided into two groups: six limb (extremity) leads and six chest (precordial) leads. The limb leads record potentials transmitted onto the *frontal plane* (Fig. 221-3*A*), and the chest leads record potentials transmitted onto the *horizontal plane* (Fig. 221-3*B*). The six limb leads are further subdivided into three standard "*bipolar*" *leads* (I, II, and III) and three augmented "*unipolar*" *leads* (aVR, aVL, and aVF). Each standard lead measures the difference in potential between electrodes at two extremities: lead I = left arm – right arm voltages, lead II = left leg – right arm, and lead III = left leg – left arm. The unipolar leads measure the voltage (V) at one locus relative to an electrode (called the *central terminal* or *indifferent electrode*) that has approximately zero potential. Thus, aVR = right arm, aVL = left arm, and aVF = left leg (foot). The lowercase *a* indicates that these unipolar potentials are electrically augmented by 50%. The right leg electrode functions as a ground. The spatial orientation and polarity of the six frontal plane leads is represented on the hexaxial diagram (Fig. 221-4).

The six chest leads (Fig. 221-5) are unipolar recordings obtained by electrodes in the following positions: lead V_1, fourth intercostal space, just to the right of the sternum; lead V_2, fourth intercostal space, just to the left of the sternum; lead V_3, midway between V_2 and V_4; lead V_4, midclavicular line, fifth intercostal space; lead V_5, anterior axillary line, same level as V_4; and lead V_6, midaxillary line, same level as V_4 and V_5.

Together, the frontal and horizontal plane electrodes provide a three-dimensional representation of cardiac electrical activity. Each lead can be likened to a different camera angle "looking" at the same events—atrial and ventricular depolarization and repolarization—from different spatial orientations. The conventional 12-lead ECG can be supplemented with additional leads under special circumstances. For example, right precordial leads V_3R, V_4R, etc., are useful in detect-

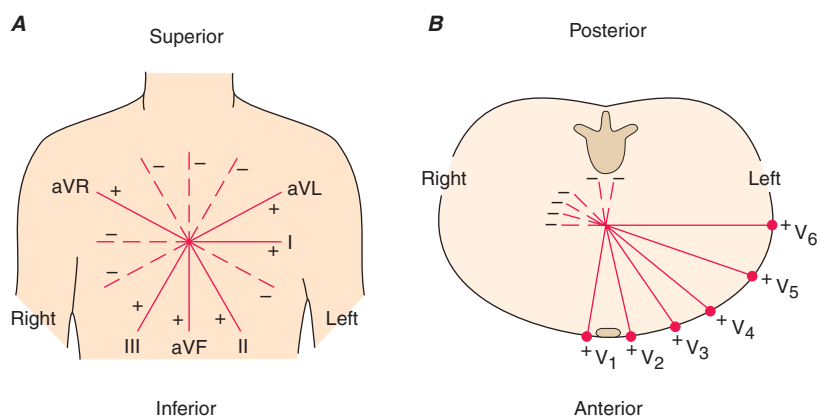

FIGURE 221-3 The six frontal plane (*A*) and six horizontal plane (*B*) leads provide a three-dimensional representation of cardiac electrical activity.

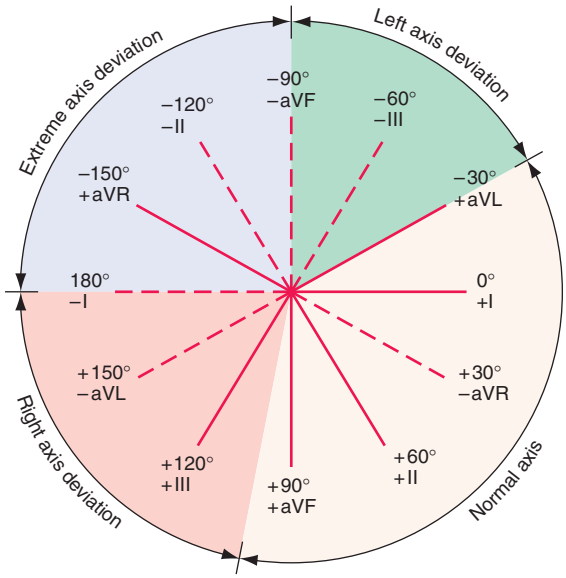

FIGURE 221-4 The frontal plane (limb or extremity) leads are represented on a hexaxial diagram. Each ECG lead has a specific spatial orientation and polarity. The positive pole of each lead axis (*solid line*) and negative pole (*hatched line*) are designated by their angular position relative to the positive pole of lead I (0°). The mean electrical axis of the QRS complex is measured with respect to this display.

ing evidence of acute right ventricular ischemia. Bedside monitors and ambulatory ECG (Holter) recordings usually employ only one or two modified leads. **Intracardiac electrocardiography and electrophysiologic testing are discussed in Chaps. 225 and 226.**

The ECG leads are configured so that a positive (upright) deflection is recorded in a lead if a wave of depolarization spreads toward the positive pole of that lead, and a negative deflection if the wave spreads toward the negative pole. If the mean orientation of the depolarization vector is at right angles to a given lead axis, a biphasic (equally positive and negative) deflection will be recorded.

GENESIS OF THE NORMAL ECG

P WAVE

The normal atrial depolarization vector is oriented downward and toward the subject's left, reflecting the spread of depolarization from the sinus node to the right and then the left atrial myocardium. Since this vector points toward the positive pole of lead II and toward the negative pole of lead aVR, the normal P wave will be positive in lead II and negative in lead aVR. By contrast, activation of the atria from an ectopic pacemaker in the lower part of either atrium or in the AV junction region may produce retrograde P waves (negative in lead II, positive in lead aVR). The normal P wave in lead V_1 may be biphasic with a positive component reflecting right atrial depolarization, followed by a small (<1 mm^2) negative component reflecting left atrial depolarization.

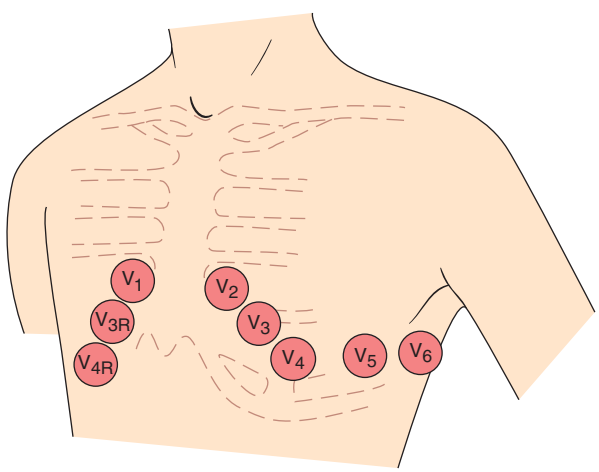

FIGURE 221-5 The horizontal plane (chest or precordial) leads are obtained with electrodes in the locations shown.

QRS COMPLEX

Normal ventricular depolarization proceeds as a rapid, continuous spread of activation wavefronts. This complex process can be divided into two major, sequential phases, and each phase can be represented by a mean vector **(Fig. 221-6)**. The first phase is depolarization of the interventricular septum from the left to the right and anteriorly (vector 1). The second results from the simultaneous depolarization of the right and left ventricles; it is normally dominated by the more massive left ventricle, so that vector 2 points leftward and posteriorly. Therefore, a right precordial lead (V_1) will record this biphasic depolarization process with a small positive deflection (septal r wave) followed by a larger negative deflection (S wave). A left precordial lead, e.g. V_6, will record the same sequence with a small negative deflection (septal q wave) followed by a relatively tall positive deflection (R wave). Intermediate leads show a relative increase in R-wave amplitude (normal R-wave progression) and a decrease in S-wave amplitude progressing across the chest from the right to left. The precordial lead where the R and S waves are of approximately equal amplitude is referred to as the *transition zone* (usually V_3 or V_4) **(Fig. 221-7)**.

The QRS pattern in the extremity leads may vary considerably from one normal subject to another depending on the *electrical axis* of the

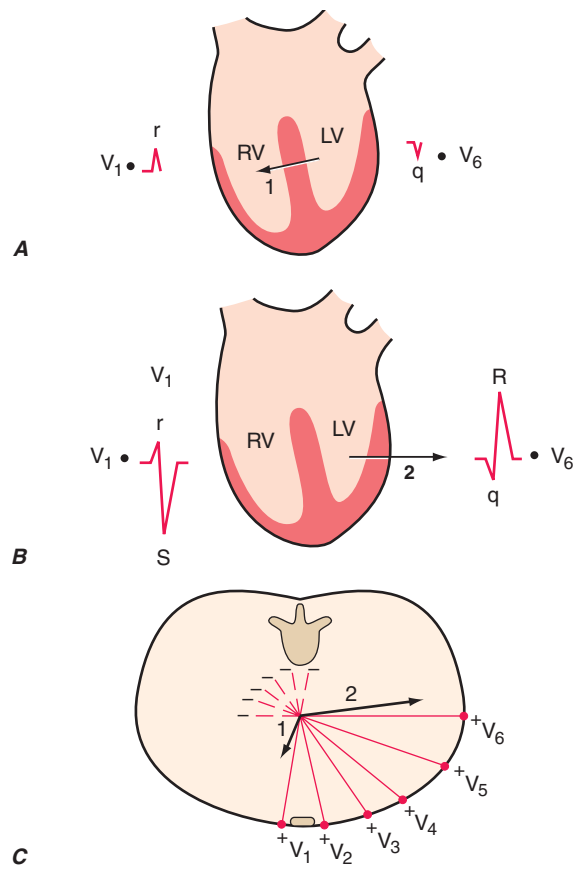

FIGURE 221-6 Ventricular depolarization can be divided into two major phases, each represented by a vector. *A.* The first phase (*arrow 1*) denotes depolarization of the ventricular septum, beginning on the left side and spreading to the right. This process is represented by a small "septal" r wave in lead V_1 and a small septal q wave in lead V_6. ***B.*** Simultaneous depolarization of the left and right ventricles (LV and RV) constitutes the second phase. Vector 2 is oriented to the left and posteriorly, reflecting the electrical predominance of the LV. ***C.*** Vectors (*arrows*) representing these two phases are shown in reference to the horizontal plane leads. *(After Goldberger, 2006.)*

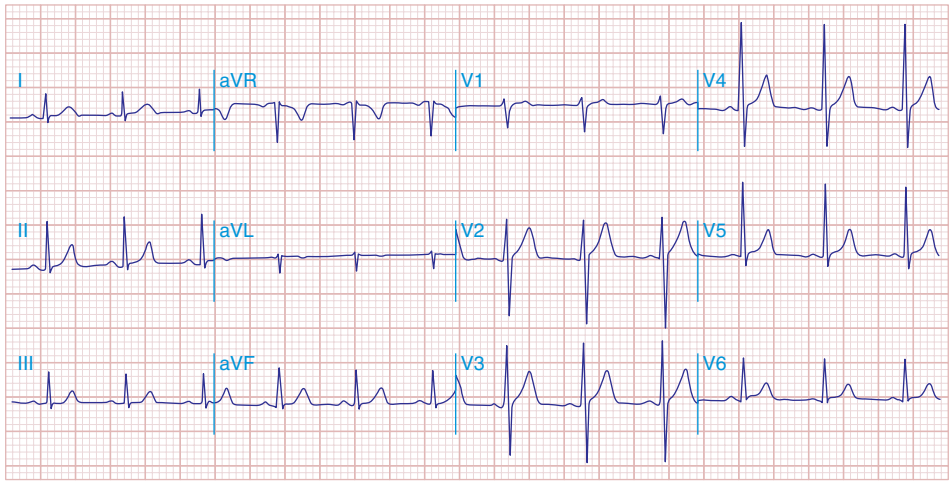

FIGURE 221-7 Normal electrocardiogram from a healthy subject. Sinus rhythm is present with a heart rate of 75 beats per minute. PR interval is 0.16 s; QRS interval (duration) is 0.08 s; QT interval is 0.36 s; QT_c is 0.40 s; the mean QRS axis is about +70°. The precordial leads show normal R-wave progression with the transition zone (R wave = S wave) in lead V_3.

QRS, which describes the mean orientation of the QRS vector with reference to the six frontal plane leads. Normally, the QRS axis ranges from –30° to +100° (Fig. 221-4). An axis more negative than –30° is referred to as *left axis deviation*, while an axis more positive than +100° is referred to as *right axis deviation*. Left axis deviation may occur as a normal variant but is more commonly associated with left ventricular hypertrophy, a block in the anterior fascicle of the left bundle system (left anterior fascicular block or hemiblock), or inferior myocardial infarction. Right axis deviation may also occur as a normal variant (particularly in children and young adults); as a spurious finding due to reversal of the left and right arm electrodes; or in conditions such as right ventricular overload (acute or chronic), infarction of the lateral wall of the left ventricle, dextrocardia, left pneumothorax, or left posterior fascicular block.

T WAVE AND U WAVE

Normally, the mean T-wave vector is oriented roughly concordant with the mean QRS vector (within about 45° in the frontal plane). Since depolarization and repolarization are electrically opposite processes, this normal QRS–T-wave vector concordance indicates that repolarization must normally proceed in the reverse direction from depolarization (i.e., from ventricular epicardium to endocardium). The normal U wave is a small, rounded deflection (≤1 mm) that follows the T wave and usually has the same polarity as the T wave. An abnormal increase in U-wave amplitude is most commonly due to drugs (e.g., dofetilide, amiodarone, sotalol, quinidine, procainamide, disopyramide) or to hypokalemia. Very prominent U waves are a marker of increased susceptibility to the *torsades de pointe* type of ventricular tachycardia (Chap. 226). Inversion of the U wave in the precordial leads is abnormal and may be a subtle sign of ischemia.

MAJOR ECG ABNORMALITIES

CARDIAC ENLARGEMENT AND HYPERTROPHY

Right atrial overload (acute or chronic) may lead to an increase in P-wave amplitude (≥2.5 mm) (Fig. 221-8). Left atrial overload typically produces a biphasic P wave in V_1 with a broad negative component or a broad (≥120 ms), often notched P wave in one or more limb leads (Fig. 221-8). This pattern may also occur with left atrial conduction delays in the absence of actual atrial enlargement, leading to the more general designation of *left atrial abnormality*.

Right ventricular hypertrophy due to a pressure load (as from pulmonic valve stenosis or pulmonary artery hypertension) is characterized by a relatively tall R wave in lead V_1 (R ≥ S wave), usually with right axis deviation (Fig. 221-9); alternatively, there may be a qR pattern in V_1 or V_3R. ST depression and T-wave inversion in the right to midprecordial leads are also often present. This pattern, formerly called right ventricular "strain," is attributed to repolarization abnormalities in acutely or chronically overloaded muscle. Prominent S waves may occur in the left lateral precordial leads. Right ventricular hypertrophy due to ostium secundum–type atrial septal defects, with the accompanying right ventricular volume overload, is commonly associated with an incomplete or complete right bundle branch block pattern with a rightward QRS axis.

Acute cor pulmonale due to pulmonary embolism (Chap. 256), for example, may be associated with a normal ECG or a variety of abnormalities. Sinus tachycardia is the most common arrhythmia, although other tachyarrhythmias, such as atrial fibrillation or flutter, may occur. The QRS axis may shift to the right, sometimes in concert with the so-called $S_1Q_3T_3$ pattern (prominence of the S wave in lead I, Q wave in lead III, with T-wave inversion in lead III). Acute right ventricular dilation may also be associated with slow R-wave progression and T-wave inversions in V_1 to V_4 simulating acute anterior infarction. A right ventricular conduction disturbance may appear.

Chronic cor pulmonale due to obstructive lung disease (Chap. 227) usually does not produce the classic ECG patterns of right ventricular hypertrophy noted above. Instead of tall right precordial R waves, chronic lung disease more typically is associated with small R waves in right-to-midprecordial leads (slow R-wave progression) due in part to downward displacement of the diaphragm and the heart. Low-voltage complexes are commonly present, owing to hyperaeration of the lungs.

A number of different voltage criteria for *left ventricular hypertrophy* (Fig. 221-9) have been proposed on the basis of the presence of tall left precordial R waves and deep right precordial S waves [e.g., SV_1 + (RV_5 or RV_6) > 35 mm]. Repolarization abnormalities (ST depression with T-wave inversions, formerly called the left ventricular "strain"

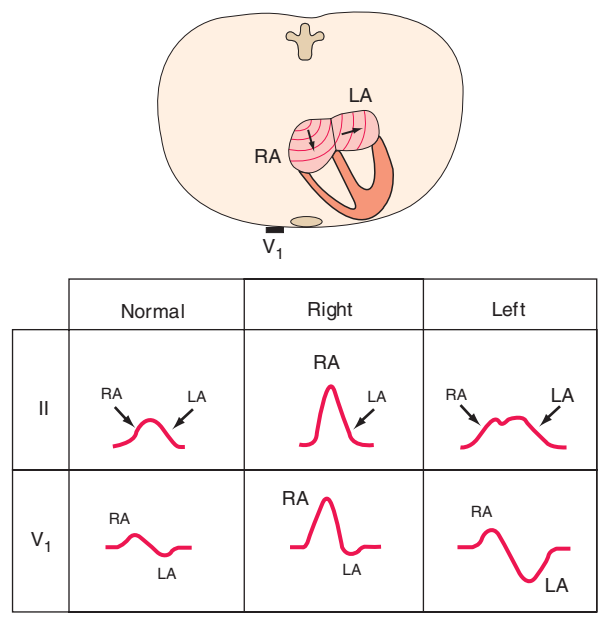

FIGURE 221-8 Right atrial (RA) overload may cause tall, peaked P waves in the limb or precordial leads. Left atrial (LA) abnormality may cause broad, often notched P waves in the limb leads and a biphasic P wave in lead V1 with a prominent negative component representing delayed depolarization of the LA. *(After MK Park, WG Guntheroth: How to Read Pediatric ECGs, 4th ed. St. Louis, Mosby/Elsevier, 2006.)*

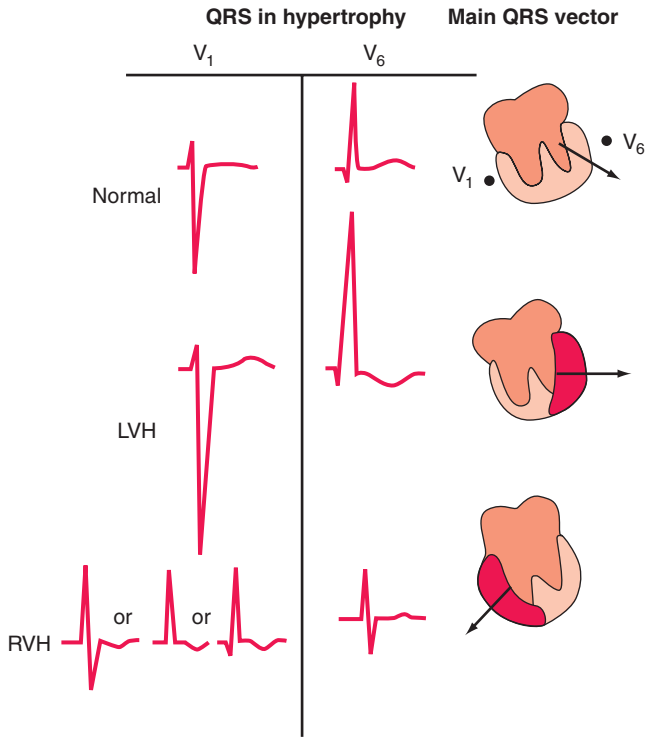

FIGURE 221-9 Left ventricular hypertrophy (LVH) increases the amplitude of electrical forces directed to the left and posteriorly. In addition, repolarization abnormalities may cause ST-segment depression and T-wave inversion in leads with a prominent R wave. Right ventricular hypertrophy (RVH) may shift the QRS vector to the right; this effect usually is associated with an R, RS, or qR complex in lead V_1. T-wave inversions may be present in right precordial leads.

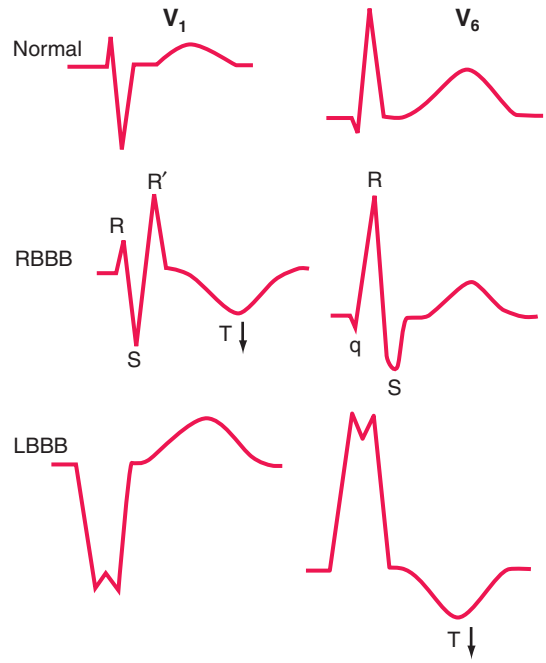

FIGURE 221-10 Comparison of typical QRS-T patterns in right bundle branch block (RBBB) and left bundle branch block (LBBB) with the normal pattern in leads V_1 and V_6. Note the secondary T-wave inversions (*arrows*) in leads with an rSR′ complex with RBBB and in leads with a wide R wave with LBBB.

pattern) may also appear in leads with prominent R waves. However, prominent precordial voltages may occur as a normal variant, especially in athletic or young individuals. Left ventricular hypertrophy may increase limb lead voltage with or without increased precordial voltage (e.g., RaVL + SV_3 > 20 mm in women and > 28 mm in men). The presence of left atrial abnormality increases the likelihood of underlying left ventricular hypertrophy in cases with borderline voltage criteria. Left ventricular hypertrophy often progresses to incomplete or complete left bundle branch block. The sensitivity of conventional voltage criteria for left ventricular hypertrophy is decreased in obese persons and in smokers. ECG evidence for left ventricular hypertrophy is a major noninvasive marker of increased risk of cardiovascular morbidity and mortality, including sudden cardiac death. However, because of false-positive and false-negative diagnoses, the ECG is of limited utility in diagnosing atrial or ventricular enlargement. More definitive information is provided by echocardiography (Chap. 222).

BUNDLE BRANCH BLOCKS

Intrinsic impairment of conduction in either the right or left bundle system (intraventricular conduction disturbances) leads to prolongation of the QRS interval. With complete bundle branch blocks, the QRS interval is ≥120 ms in duration; with incomplete blocks the QRS interval is between 100 and 120 ms. The QRS vector is usually oriented in the direction of the myocardial region where depolarization is delayed (Fig. 221-10). Thus, with right bundle branch block, the terminal QRS vector is oriented to the right and anteriorly (rSR′ in V_1 and qRS in V_6, typically). Left bundle branch block alters both early and later phases of ventricular depolarization. The major QRS vector is directed to the left and posteriorly. In addition, the normal early left-to-right pattern of septal activation is disrupted such that septal depolarization proceeds from right to left as well. As a result, left bundle branch block generates wide, predominantly negative (QS) complexes in lead V_1 and entirely positive (R) complexes in lead V_6. A pattern identical to that of left bundle branch block, preceded by a sharp spike, is seen in most cases of electronic right ventricular pacing because of the relative delay in left ventricular activation.

Bundle branch block may occur in a variety of conditions. In subjects without structural heart disease, right bundle branch block is seen more commonly than left bundle branch block. Right bundle branch block also occurs with heart disease, both congenital (e.g., atrial septal defect) and acquired (e.g., valvular, ischemic). Left bundle branch block is often a marker of one of four underlying conditions associated with increased risk of cardiovascular morbidity and mortality: coronary heart disease (frequently with impaired left ventricular function), hypertensive heart disease, aortic valve disease, and cardiomyopathy. Bundle branch blocks may be chronic or intermittent. A bundle branch block may be rate-related; for example, it often occurs when the heart rate exceeds some critical value.

Bundle branch blocks and depolarization abnormalities secondary to artificial pacemakers not only affect ventricular depolarization (QRS) but are also characteristically associated with *secondary repolarization* (ST-T) abnormalities. With bundle branch blocks, the T wave is typically opposite in polarity to the last deflection of the QRS (Fig. 221-10). This discordance of the QRS–T-wave vectors is caused by the altered sequence of repolarization that occurs secondary to altered depolarization. In contrast, *primary repolarization* abnormalities are independent of QRS changes and are related instead to actual alterations in the electrical properties of the myocardial fibers themselves (e.g., in the resting membrane potential or action potential duration), not just to changes in the sequence of repolarization. Ischemia, electrolyte imbalance, and drugs such as digitalis all cause such primary ST–T-wave changes. Primary and secondary T-wave changes may coexist. For example, T-wave inversions in the right precordial leads with left bundle branch block or in the left precordial leads with right bundle branch block may be important markers of underlying ischemia or other abnormalities. A distinctive abnormality simulating right bundle branch block with ST-segment elevations in the right chest leads is seen with the Brugada pattern (Chap. 226).

Partial blocks (fascicular or "hemiblocks") in the left bundle system (left anterior or posterior fascicular blocks) generally do not prolong the QRS duration substantially but instead are associated with shifts in

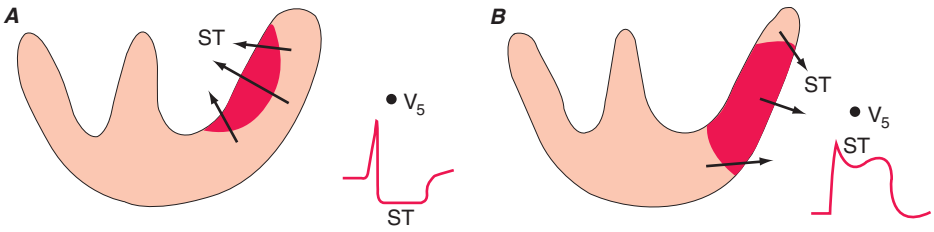

FIGURE 221-11 Acute ischemia causes a current of injury. With predominant subendocardial ischemia (***A***), the resultant ST vector will be directed toward the inner layer of the affected ventricle and the ventricular cavity. Overlying leads therefore will record ST depression. With ischemia involving the outer ventricular layer (***B***) (transmural or epicardial injury), the ST vector will be directed outward. Overlying leads will record ST elevation.

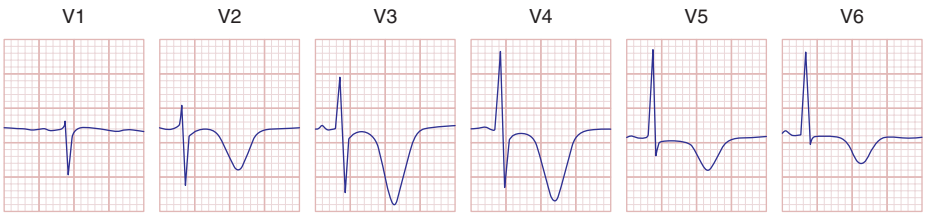

FIGURE 221-12 Severe anterior wall ischemia (with or without infarction) may cause prominent T-wave inversions in the precordial leads. This pattern is usually associated with a high-grade stenosis of the left anterior descending coronary artery.

the frontal plane QRS axis (leftward or rightward, respectively). More complex combinations of fascicular and bundle branch blocks may occur involving the left and right bundle system. Examples of *bifascicular block* include right bundle branch block and left posterior fascicular block, right bundle branch block with left anterior fascicular block, and complete left bundle branch block. Chronic bifascicular block in an asymptomatic individual is associated with a relatively low risk of progression to high-degree AV heart block. In contrast, new bifascicular block with acute anterior myocardial infarction carries a much greater risk of complete heart block. Alternation of right and left bundle branch block is a sign of *trifascicular disease*. However, the presence of a prolonged PR interval and bifascicular block does not necessarily indicate trifascicular involvement, since this combination may arise with AV node disease and bifascicular block. Intraventricular conduction delays can also be caused by extrinsic (toxic) factors that slow ventricular conduction, particularly hyperkalemia or drugs (e.g., class 1 antiarrhythmic agents, tricyclic antidepressants, phenothiazines).

Prolongation of QRS duration does not necessarily indicate a conduction delay but may be due to *preexcitation* of the ventricles via a bypass tract, as in Wolff-Parkinson-White (WPW) patterns (Chap. 226) and related variants. The diagnostic triad of WPW consists of a wide QRS complex associated with a relatively short PR interval and slurring of the initial part of the QRS (delta wave), the latter effect due to aberrant activation of ventricular myocardium. The presence of a bypass tract predisposes to reentrant supraventricular tachyarrhythmias.

MYOCARDIAL ISCHEMIA AND INFARCTION

(See also Chap. 239) The ECG is a cornerstone in the diagnosis of acute and chronic ischemic heart disease. The findings depend on several key factors: the nature of the process [reversible (i.e., ischemia) versus irreversible (i.e., infarction)], the duration (acute versus chronic), extent (transmural versus subendocardial), and localization (anterior versus inferoposterior), as well as the presence of other underlying abnormalities (ventricular hypertrophy, conduction defects).

Ischemia exerts complex time-dependent effects on the electrical properties of myocardial cells. Severe, acute ischemia lowers the resting membrane potential and shortens the duration of the action potential. Such changes cause a voltage gradient between normal and ischemic zones. As a consequence, current flows between these regions. These currents of injury are represented on the surface ECG by deviation of the ST segment (Fig. 221-11). When the acute ischemia is *transmural*, the ST vector is usually shifted in the direction of the outer (epicardial) layers, producing ST elevations and sometimes, in the earliest stages of ischemia, tall, positive so-called hyperacute T waves over the ischemic zone. With ischemia confined primarily to the *subendocardium*, the ST vector typically shifts toward the subendocardium and ventricular cavity, so that overlying (e.g., anterior precordial) leads show ST-segment depression (with ST elevation in lead aVR). Multiple factors affect the amplitude of acute ischemic ST deviations. Profound ST elevation or depression in multiple leads usually indicates very severe ischemia. From a clinical viewpoint, the division of acute myocardial infarction into ST segment elevation and non-ST elevation types is useful since the efficacy of acute reperfusion therapy is limited to the former group.

The ECG leads are more helpful in localizing regions of ST elevation than non-ST elevation ischemia. For example, acute transmural anterior (including apical and lateral) wall ischemia is reflected by ST elevations or increased T-wave positivity in one or more of the precordial leads (V_1–V_6) and leads I and aVL. Inferior wall ischemia produces changes in leads II, III, and aVF. Posterior wall ischemia may be indirectly recognized by *reciprocal* ST depressions in leads V_1 to V_3. Prominent reciprocal ST depressions in these leads also occur with certain inferior wall infarcts, particularly those with posterior or lateral wall extension. Right ventricular ischemia usually produces ST elevations in right-sided chest leads (Fig. 221-5). When ischemic ST elevations occur as the earliest sign of acute infarction, they are typically followed within a period ranging from hours to days by evolving T-wave inversions and often by Q waves occurring in the same lead distribution. (T-wave inversions due to evolving or chronic ischemia correlate with prolongation of repolarization and are often associated with QT lengthening.) Reversible transmural ischemia, for example, due to coronary vasospasm (Prinzmetal's variant angina, and possibly the tako-tsubo cardiomyopathy syndrome), may cause transient ST-segment elevations without development of Q waves. Depending on the severity and duration of such ischemia, the ST elevations may either resolve completely in minutes or be followed by T-wave inversions that persist for hours or even days. Patients with ischemic chest pain who present with deep T-wave inversions in multiple precordial leads (e.g., V_1–V_4) with or without cardiac enzyme elevations typically have severe obstruction in the left anterior descending coronary artery system (Fig. 221-12). In contrast, patients whose baseline ECG already shows abnormal T-wave inversions may develop T-wave normalization (pseudonormalization) during episodes of acute transmural ischemia.

With infarction, depolarization (QRS) changes often accompany repolarization (ST-T) abnormalities. Necrosis of sufficient myocardial tissue may lead to decreased R-wave amplitude or abnormal Q waves in the anterior or inferior leads (Fig. 221-13). Previously, abnormal Q waves were considered to be markers of transmural myocardial infarction, while subendocardial infarcts were thought not to produce Q waves. However, careful ECG-pathology correlative studies have indicated that transmural infarcts may occur without Q waves and that subendocardial (nontransmural) infarcts may sometimes be associated with Q waves. Therefore, infarcts are more appropriately classified as "Q-wave" or "non-Q-wave." The major acute ECG changes in syndromes of ischemic heart disease are summarized schematically in Fig. 221-14. Loss of depolarization forces due to posterior or lateral infarction may cause reciprocal increases in R-wave amplitude in leads V_1 and V_2 without diagnostic Q waves in any of

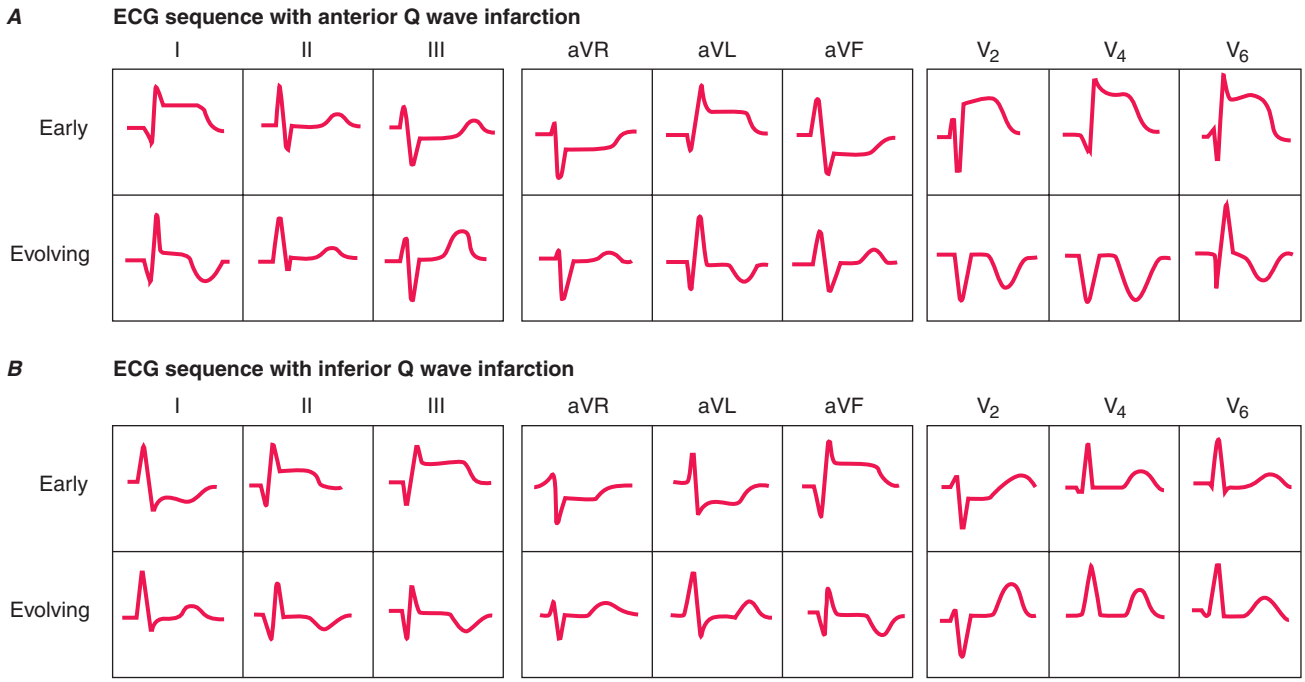

FIGURE 221-13 Sequence of depolarization and repolarization changes with (***A***) acute anterior and (***B***) acute inferior wall Q-wave infarctions. With anterior infarcts, ST elevation in leads I, aVL, and the precordial leads may be accompanied by reciprocal ST depressions in leads II, III, and aVF. Conversely, acute inferior (or posterior) infarcts may be associated with reciprocal ST depressions in leads V_1 to V_3. *(After Goldberger, 2006.)*

the conventional leads. Atrial infarction may be associated with PR-segment deviations due to an atrial current of injury, changes in P-wave morphology, or atrial arrhythmias.

In the weeks and months following infarction, these ECG changes may persist or begin to resolve. Complete normalization of the ECG following Q-wave infarction is uncommon but may occur, particularly with smaller infarcts. In contrast, ST-segment elevations that persist for several weeks or more after a Q-wave infarct usually correlate with a severe underlying wall motion disorder (akinetic or dyskinetic zone), although not necessarily a frank ventricular aneurysm.

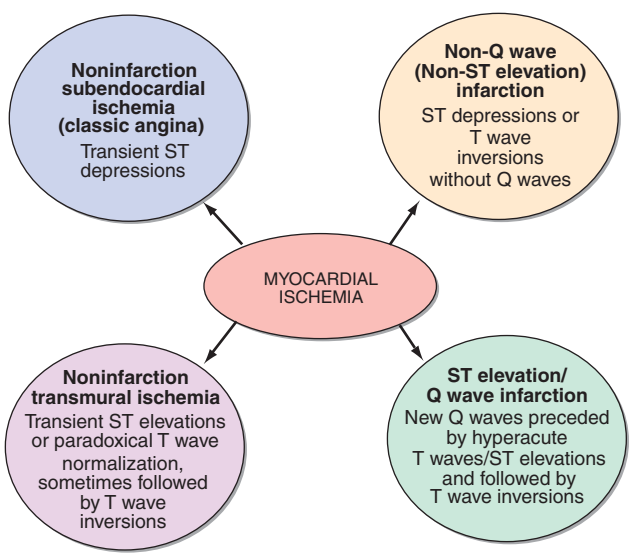

FIGURE 221-14 Variability of ECG patterns with acute myocardial ischemia. The ECG also may be normal or nonspecifically abnormal. Furthermore, these categorizations are not mutually exclusive. For example, a non-ST elevation infarct may evolve into a Q-wave infarct; ST elevations may be followed by a non-Q-wave infarct; or ST depressions and T-wave inversions may be followed by a Q-wave infarct. *(After Goldberger, 2006.)*

ECG changes due to ischemia may occur spontaneously or may be provoked by various exercise protocols (stress electrocardiography) (Chap. 237). In patients with severe ischemic heart disease, exercise testing is most likely to elicit signs of subendocardial ischemia (horizontal or downsloping ST depression in multiple leads). ST-segment elevation during exercise is most often observed after a Q-wave infarct. This repolarization change does not necessarily indicate active ischemia but correlates strongly with the presence of an underlying ventricular wall motion abnormality. However, in patients *without* prior infarction, transient ST-segment elevation with exercise is a reliable sign of transmural ischemia.

The ECG has important limitations in both sensitivity and specificity in the diagnosis of ischemic heart disease. Although a single normal ECG does not exclude ischemia or even acute infarction, a normal ECG *throughout* the course of an acute infarct is distinctly uncommon. Prolonged chest pain without diagnostic ECG changes, therefore, should always prompt a careful search for other noncoronary causes of chest pain (Chap. 13). Furthermore, the diagnostic changes of acute or evolving ischemia are often masked by the presence of left bundle branch block, electronic ventricular pacemaker patterns, and WPW preexcitation. On the other hand, clinicians may overdiagnose ischemia or infarction based on the presence of ST-segment elevations or depressions, T-wave inversions, tall positive T waves, or Q waves *not* related to ischemic heart disease (pseudoinfarct patterns). For example, ST-segment elevations simulating ischemia may occur with acute pericarditis or myocarditis, as a normal variant ("early repolarization" pattern), or in a variety of other conditions (Table 221-1). Similarly, tall, positive T waves do not invariably represent hyperacute ischemic changes but may also be caused by normal variants, hyperkalemia, cerebrovascular injury, and left ventricular volume overload due to mitral or aortic regurgitation, among other causes.

ST-segment elevations and tall, positive T waves are common findings in leads V_1 and V_2 in left bundle branch block or left ventricular hypertrophy in the absence of ischemia. The differential diagnosis of Q waves (Table 221-2) includes physiologic or positional variants, ventricular hypertrophy, acute or chronic noncoronary myocardial injury, hypertrophic cardiomyopathy, and ventricular conduction disorders. Digoxin, ventricular hypertrophy, hypokalemia, and a variety of other

TABLE 221-1 DIFFERENTIAL DIAGNOSIS OF ST SEGMENT ELEVATIONS

- Ischemia/myocardial infarction
  - Noninfarction, transmural ischemia (Prinzmetal's angina, and possibly tako-tsubo syndrome)
  - Acute myocardial infarction
  - Postmyocardial infarction (ventricular aneurysm pattern)
- Acute pericarditis
- Normal variant ("early repolarization" pattern)
- Left ventricular hypertrophy/left bundle branch block[a]
- Other (rarer)
  - Brugada pattern (right bundle branch block-like pattern with ST elevations in right precordial leads)[a]
  - Class 1C antiarrhythmic drugs[a]
  - DC cardioversion
  - Hypercalcemia[a]
  - Hyperkalemia[a]
  - Hypothermia (J wave/Osborn waves)
  - Myocardial injury
    - Myocarditis
    - Tumor invading left ventricle
    - Trauma to ventricles

factors may cause ST-segment depression mimicking subendocardial ischemia. Prominent T-wave inversion may occur with ventricular hypertrophy, cardiomyopathies, myocarditis, and cerebrovascular injury (particularly intracranial bleeds), among many other conditions.

METABOLIC FACTORS AND DRUG EFFECTS

A variety of metabolic and pharmacologic agents alter the ECG and, in particular, cause changes in repolarization (ST-T-U) and sometimes QRS prolongation. Certain life-threatening electrolyte disturbances may be diagnosed initially and monitored from the ECG. *Hyperkalemia* produces a sequence of changes (Fig. 221-15), usually beginning with narrowing and peaking (tenting) of the T waves. Further elevation of extracellular K^+ leads to AV conduction disturbances, diminution in P-wave amplitude, and widening of the QRS interval. Severe hyperkalemia eventually causes cardiac arrest with a slow sinusoidal type of mechanism ("sine-wave" pattern) followed by asystole. *Hypokalemia* (Fig. 221-16) prolongs ventricular repolarization, often with prominent U waves. Prolongation of the QT interval is also seen with drugs that increase the duration of the ventricular action potential—class 1A antiarrhythmic agents and related drugs (e.g., quinidine, disopyramide, procainamide, tricyclic antidepressants, phenothiazines) and class III agents [amiodarone (Fig. 221-16), sotalol, ibutilide]. Marked QT prolongation, sometimes with deep, wide T-wave inversions, may occur with intracranial bleeds, particularly subarachnoid hemorrhage ("CVA T-wave" pattern) (Fig. 221-16). Systemic *hypothermia* also prolongs repolarization, usually with a distinctive convex elevation of the J point (Osborn wave). *Hypocalcemia* typically prolongs the QT interval (ST portion), while *hypercalcemia* shortens it (Fig. 221-17). Digitalis glycosides also shorten the QT interval, often with a characteristic "scooping" of the ST–T-wave complex (*digitalis effect*).

Many other factors are associated with ECG changes, particularly alterations in ventricular repolarization. T-wave flattening, minimal T-wave inversions, or slight ST-segment depression ("nonspecific ST–T-wave changes") may occur with a variety of electrolyte and acid-base disturbances, a variety of infectious processes, central nervous system disorders, endocrine abnormalities, many drugs, ischemia, hypoxia, and virtually any type of cardiopulmonary abnormality. While subtle ST–T-wave changes may be markers of ischemia, transient nonspecific repolariza-

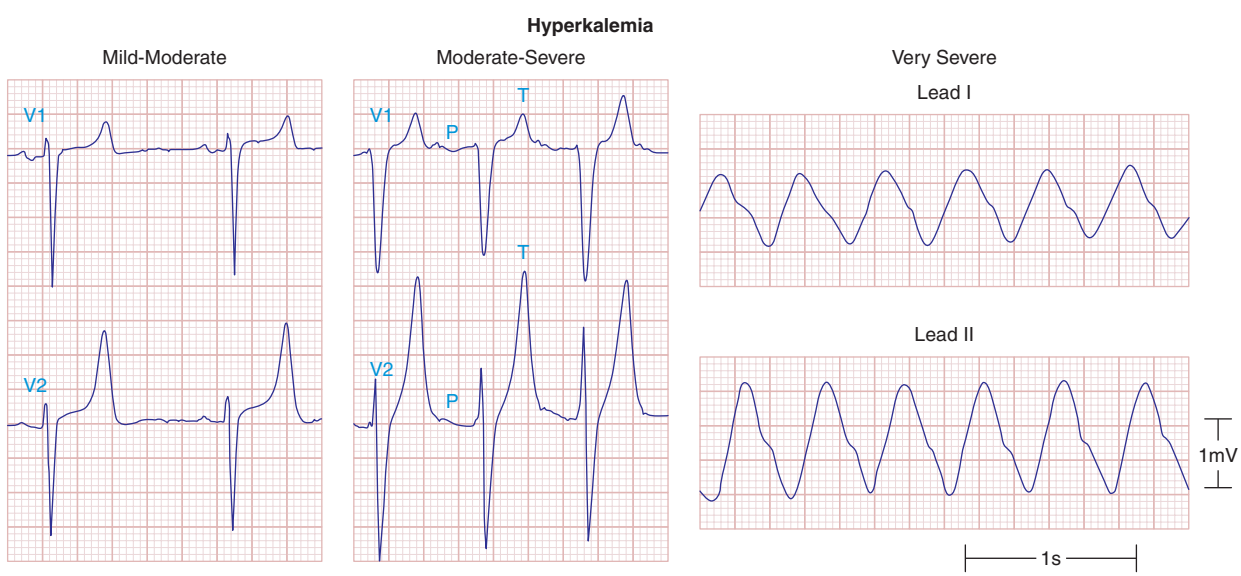

FIGURE 221-15 The earliest ECG change with hyperkalemia is usually peaking ("tenting") of the T waves. With further increases in the serum potassium concentration, the QRS complexes widen, the P waves decrease in amplitude and may disappear, and finally a sine-wave pattern leads to asystole unless emergency therapy is given. *(After Goldberger, 2006.)*

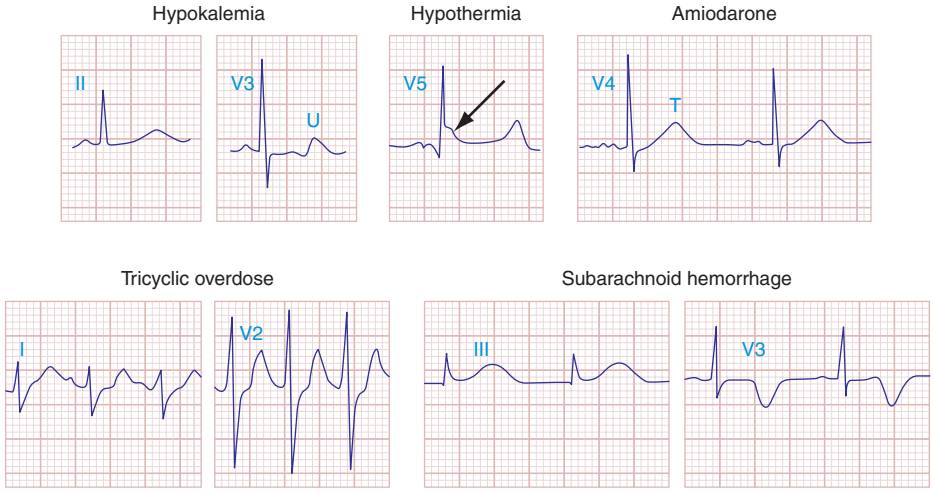

FIGURE 221-16 A variety of metabolic derangements, drug effects, and other factors may prolong ventricular repolarization with QT prolongation or prominent U waves. Prominent repolarization prolongation, particularly if due to hypokalemia, inherited "channelopathies," or certain pharmacologic agents, indicates increased susceptibility to *torsades des pointes*–type ventricular tachycardia (Chap. 226). Marked systemic hypothermia is associated with a distinctive convex "hump" at the J point (Osborn wave, *arrow*) due to altered ventricular action potential characteristics. Note QRS and QT prolongation along with sinus tachycardia in the case of tricyclic antidepressant overdose.

tion changes may also occur following a meal or with postural (orthostatic) change, hyperventilation, or exercise in healthy individuals.

ELECTRICAL ALTERNANS

Electrical alternans—a beat-to-beat alternation in one or more components of the ECG signal—is a common type of nonlinear cardiovascular response to a variety of hemodynamic and electrophysiologic perturbations. Total electrical alternans (P-QRS-T) with sinus tachycardia is a relatively specific sign of pericardial effusion, usually with cardiac tamponade. The mechanism relates to a periodic swinging motion of the heart in the effusion at a frequency exactly one-half the heart rate. Repolarization (ST-T or U wave) alternans is a sign of electrical instability and may precede ventricular tachyarrhythmias.

CLINICAL INTERPRETATION OF THE ECG

Accurate analysis of ECGs requires thoroughness and care. The patient's age, gender, and clinical status should always be taken into account. For example, T-wave inversions in leads V_1–V_3 are more likely to represent a normal variant in a healthy young adult woman ("persistent juvenile T-wave pattern") than in an elderly man with chest discomfort. Similarly, the likelihood that ST-segment depression during exercise testing represents ischemia depends partly on the prior probability of coronary artery disease.

Many mistakes in ECG interpretation are errors of omission. Therefore, a systematic approach is essential. The following 14 points should be analyzed carefully in every ECG: (1) standardization (calibration) and technical features (including lead placement and artifacts); (2) rhythm; (3) heart rate; (4) PR interval/AV conduction; (5) QRS interval; (6) QT/QT_c interval; (7) mean QRS electrical axis; (8) P waves; (9) QRS voltages; (10) precordial R-wave progression; (11) abnormal Q waves; (12) ST segments; (13) T waves; (14) U waves.

Only after analyzing all these points should the interpretation be formulated. Where appropriate, important clinical correlates or inferences should be mentioned. For example, the combination of left atrial abnormality (enlargement) and signs of right ventricular hypertrophy suggests mitral stenosis. Low voltage with sinus tachycardia raises the possibility of pericardial tamponade or chronic obstructive lung disease. Sinus tachycardia with QRS and QT-(U) prolongation, especially in the context of mental status changes, suggests tricyclic antidepressant overdose (Fig. 221-16). The triad of peaked T waves (hyperkalemia), a long QT due to ST segment lengthening (hypocalcemia) and left ventricular hypertrophy (systemic hypertension) suggests chronic renal failure. Comparison with previous ECGs is essential. **The diagnosis and management of specific cardiac arrhythmias and conduction disturbances are discussed in Chaps. 225 and 226.**

COMPUTERIZED ELECTROCARDIOGRAPHY

Computerized ECG systems are widely used. Digital systems provide for convenient storage and immediate retrieval of thousands of ECG records. Despite advances, computer interpretation of ECGs has important limitations. Incomplete or inaccurate readings are most likely with arrhythmias and complex abnormalities. Therefore, computerized interpretation (including measurements of basic ECG intervals) should not be accepted without careful clinician review.

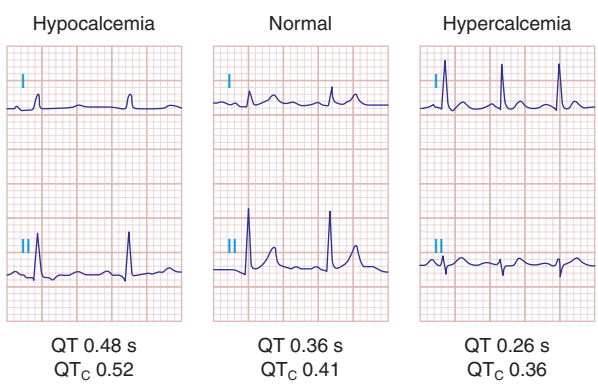

FIGURE 221-17 Prolongation of the Q-T interval (ST-segment portion) is typical of hypocalcemia. Hypercalcemia may cause abbreviation of the ST segment and shortening of the QT interval.

222 Noninvasive Cardiac Imaging: Echocardiography, Nuclear Cardiology, and MRI/CT Imaging

Rick A. Nishimura, Raymond J. Gibbons, James F. Glockner, A. Jamil Tajik

Cardiovascular imaging has significantly enhanced the practice of cardiology over the past few decades. Two-dimensional (2D) echocardiography is able to visualize the heart directly in real time using ultrasound, providing instantaneous assessment of the myocardium, cardiac chambers, valves, pericardium, and great vessels. Doppler echocardiography measures the velocity of moving red blood cells and has become a noninvasive alternative to cardiac catheterization for assessment of hemodynamics. Transesophageal echocardiography (TEE) provides a unique window for high-resolution imaging of posterior structures of the heart, particularly the left atrium, mitral valve, and aorta. Nuclear cardiology uses isotopes to assess myocardial perfusion and ventricular function and has contributed greatly to the evaluation of patients with ischemic heart disease. Cardiac MRI and CT can delineate cardiac structure and function with high resolution. They are particularly useful in the examination of cardiac masses, the pericardium, and the great vessels. MRI stress testing is now possible examining both ventricular function and perfusion. Detection of coronary calcification by CT as well as direct visualization of coronary arteries by CT angiography (CTA) are of growing utility in patients with suspected coronary artery disease (CAD). This chapter provides an overview of the basic concepts of these cardiac imaging modalities, as well as the clinical indications for each procedure. **The illustrations in this chapter are supplemented by "real time" and other static images in Chap. e20, "The Atlas of Noninvasive Cardiac Imaging."**

ECHOCARDIOGRAPHY

TWO-DIMENSIONAL ECHOCARDIOGRAPHY

Basic Principles 2D echocardiography uses the principle of ultrasound reflection off cardiac structures to produce images of the heart (Table 222-1). For a transthoracic echocardiogram (TTE), the imaging is performed with a handheld transducer placed directly on the chest wall. In selected patients, a TEE may be performed, in which an ultrasound transducer is mounted on the tip of an endoscope placed in the esophagus and directed toward the cardiac structures.

TABLE 222-1 CLINICAL USES OF ECHOCARDIOGRAPHY

Two-Dimensional Echocardiography
- Cardiac chambers
  - Chamber size
  - Left ventricular
  - Hypertrophy
  - Regional wall motion abnormalities
- Valve
  - Morphology and motion
- Pericardium
  - Effusion
  - Tamponade

  - Valve disease

Doppler Echocardiography
- Valve stenosis
  - Gradient
  - Valve area
- Valve regurgitation
  - Semiquantitation
- Intracardiac pressures
- Volumetric flow
- Diastolic filling
- Intracardiac shunts

Transesophageal Echocardiography
- Inadequate transthoracic images
- Aortic disease
- Infective endocarditis
- Source of embolism
- Valve prosthesis
- Intraoperative

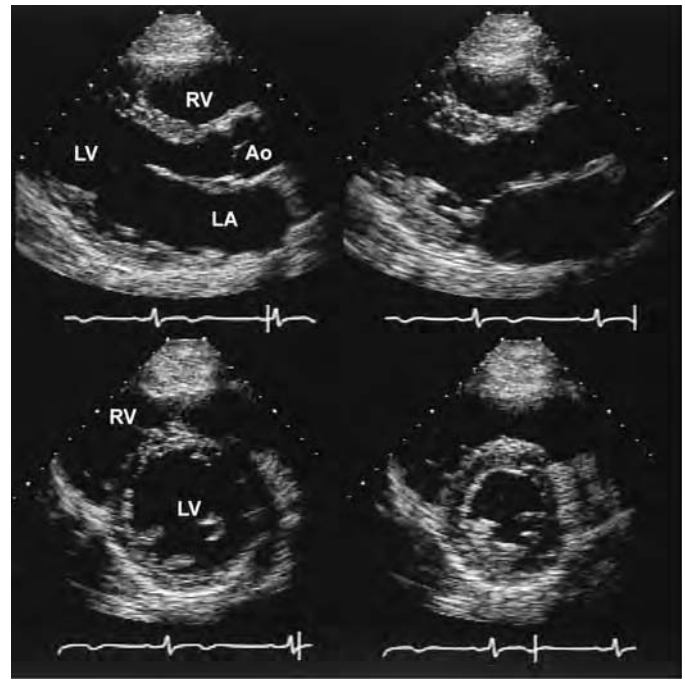

FIGURE 222-1 Two-dimensional echocardiographic still-frame images from a normal patient with a normal heart. ***Top:*** Parasternal long axis view during systole and diastole (*left*) and systole (*right*). During systole, there is thickening of the myocardium and reduction in the size of the left ventricle (LV). The valve leaflets are thin and open widely. ***Bottom:*** Parasternal short axis view during diastole (*left*) and systole (*right*) demonstrating a decrease in the left ventricular cavity size during systole as well as an increase in wall thickening. LA, left atrium; RV, right ventricle; Ao, aorta.

Current echocardiographic machines are portable and can be wheeled directly to the patient's bedside. Thus, a major advantage of echocardiography over other imaging modalities is the ability to obtain instantaneous images of the cardiac structures for immediate interpretation. Handheld echocardiographic units weighing 6 lb (<2.7 kg) have now become available, further enhancing the ease and portability of echocardiography. They are becoming an essential initial diagnostic modality for the critically ill patient in the emergency room and critical care setting.

A limitation of TTE is the inability to obtain high-quality images in all patients, especially those with a thick chest wall or severe lung disease, as ultrasound waves are poorly transmitted through lung parenchyma. New technology such as harmonic imaging and IV contrast agents (which traverse the pulmonary circulation) can now be used to enhance endocardial borders in patients with poor acoustic windows.

Chamber Size and Function 2D echocardiography is an ideal imaging modality for assessing left ventricular (LV) size and function (Fig. 222-1). A qualitative assessment of the cavity sizes of the ventricles and systolic function can be made directly from the 2D image by experienced observers. 2D echocardiography is useful in the diagnosis of LV hypertrophy and is the imaging modality of choice for the diagnosis of hypertrophic cardiomyopathy. Other chamber sizes are assessed by visual analysis, including the left atrium and right-sided chambers.

Valve Abnormalities (See Chap. 230) 2D echocardiography is the "gold standard" for imaging valve morphology and motion. Leaflet thickness and mobility, valve calcification, and the appearance of subvalvular and supravalvular structures can be assessed. Valve stenosis is reliably diagnosed by the thickening and decreased mobility of the valve. 2D echocardiography is also the gold standard for the diagnosis of mitral stenosis, which produces typical tethering and diastolic doming, and the severity of the stenosis can be ascertained from a direct

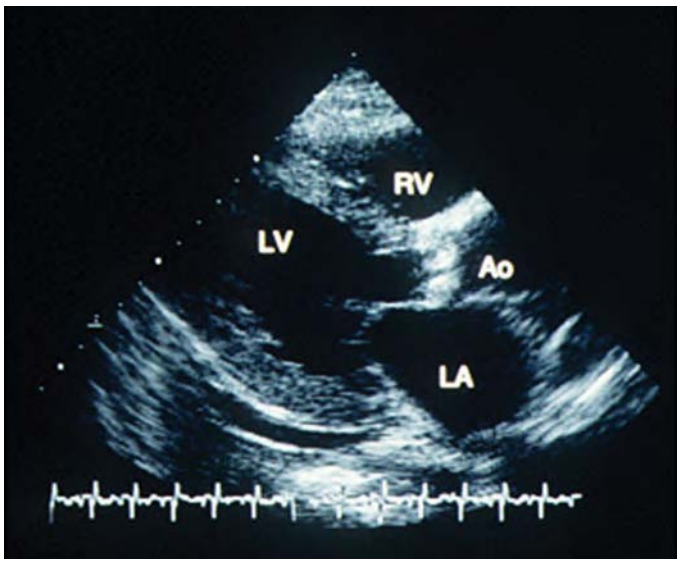

FIGURE 222-2 Still frame two-dimensional echocardiographic image from the parasternal long axis view of a patient with aortic stenosis. The aortic valve is calcified with restricted opening during systole. Ao, aorta; RV, right ventricle; LA, left atrium; LV, left ventricle.

planimeter measurement of the mitral valve orifice. The presence and often the etiology of stenosis of the semilunar valves can be made by 2D echocardiography (Fig. 222-2), but evaluation of the severity of the stenosis requires Doppler echocardiography (see below). The diagnosis of valvular regurgitation must be made by Doppler echocardiography, but 2D echocardiography is valuable for determining the etiology of the regurgitation, as well as its effects on ventricular dimensions, shape, and function.

Pericardial Disease (See Chap. 232) 2D echocardiography is the imaging modality of choice for the detection of pericardial effusion, which is easily visualized as a black echolucent ovoid structure surrounding the heart (Fig. 232-4). In the hemodynamically unstable patient with pericardial tamponade, typical echo findings include a dilated inferior vena cava, right atrial collapse, and then right ventricular collapse, usually at the base of the ventricle. Echocardiographically guided pericardiocentesis has now become a standard of care. A 2D echocardiogram can directly visualize the location of the pericardial fluid to guide the entry point of the needle.

Intracardiac Masses (See Chap. 233) Intracardiac masses can be visualized on 2D echocardiography, provided that image quality is adequate. Solid masses appear as echo-dense structures, which can be located inside the cardiac chambers or infiltrating into the myocardium or pericardium. LV thrombus appears as an echo-dense structure, usually in the apical region associated with regional wall motion abnormalities. The appearance and mobility of the thrombus are predictive of embolic events. Vegetations appear as mobile linear echo densities attached to valve leaflets. Atrial myxoma can be diagnosed by the appearance of a well-circumscribed mobile mass with attachments to the atrial septum (Fig. 233-1). The high-resolution images provided by TEE may be required for further delineation of myocardial masses, especially those <1 cm in diameter.

Aortic Disease (See Chap. 242) 2D echocardiography can provide extremely useful information on diseases of the aorta. The proximal ascending aorta, the arch, and the distal descending aorta can usually be visualized via the transthoracic approach. The definitive diagnosis of a suspected aortic dissection usually requires a TEE, which can rapidly provide high-resolution images of the proximal ascending and descending thoracic aorta (Fig. 222-3).

DOPPLER ECHOCARDIOGRAPHY

Basic Principles Doppler echocardiography uses ultrasound reflecting off moving red blood cells to measure the velocity of blood flow across valves, within cardiac chambers, and through the great vessels. Normal and abnormal blood flow patterns can be assessed noninvasively. *Color-flow Doppler* imaging displays the blood velocities in real time superimposed upon a 2D echocardiographic image. The different colors indicate the direction of blood flow (red toward and blue away from the transducer), with green superimposed when there is turbulent flow. *Pulsed-wave Doppler* measures the blood flow velocity in a specific location on the 2D echocardiographic image. *Continuous-wave Doppler* echocardiography can measure high velocities of blood flow directed along the line of the Doppler beam, such as occur in the presence of valve stenosis, valve regurgitation, or intracardiac shunts. These high velocities can be used to determine intracardiac pressure gradients by a modified Bernoulli equation:

$$\text{Pressure change} = 4 \times (\text{velocity})^2$$

The derived pressure gradient can be used to determine intracardiac pressures and stenosis severity.

Tissue Doppler echocardiography measures the velocity of myocardial motion. The velocity of myocardium is several magnitudes lower than the velocity of moving red blood cells. Myocardial velocities can be used to determine myocardial strain rate, which is a quantitative measure of regional myocardial contraction and relaxation.

Valve Gradients In the presence of valvular stenosis, there is an increase in the velocity of blood flow across the stenotic valve. A continuous-wave Doppler beam is used to determine an instantaneous gradient across the valve.

Valvular Regurgitation Valvular regurgitation is diagnosed by Doppler echocardiography when there is abnormal retrograde flow across the valve. Color-flow imaging is the Doppler method used most frequently to detect valve regurgitation by visualization of a high-velocity turbulent jet in the chamber proximal to the regurgitant valve (Fig. 222-3). The size and extent of the color-flow jet into the receiving cardiac chamber provide a semiquantitative estimate of the severity of regurgitation.

Intracardiac Pressures These can be calculated from the peak continuous-wave Doppler signal of a regurgitant lesion. The Bernoulli equa-

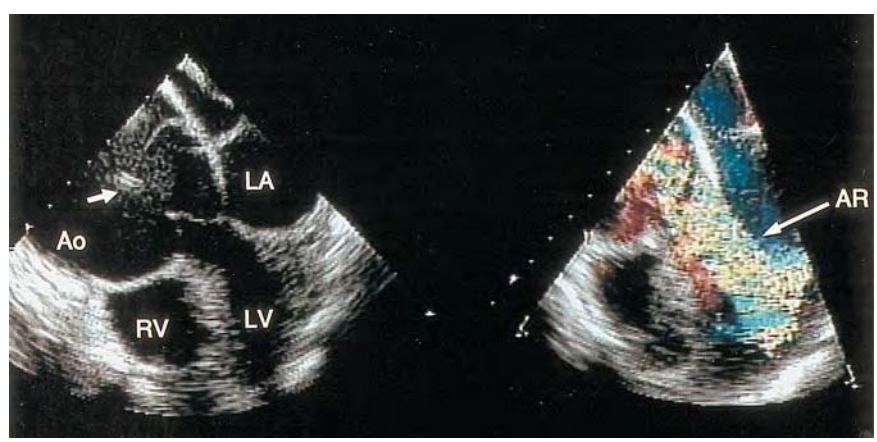

FIGURE 222-3 Transesophageal echocardiographic view of a patient with a dilated aorta, aortic dissection, and severe aortic regurgitation. ***Left:*** The long axis apex-down view of the black and white two-dimensional image in diastole. The arrow points to the intimal flap that is seen in the dilated ascending aorta. ***Right:*** Color-flow imaging that demonstrates a large mosaic jet of aortic regurgitation. Ao, aorta; RV, right ventricle; AR, aortic regurgitation.

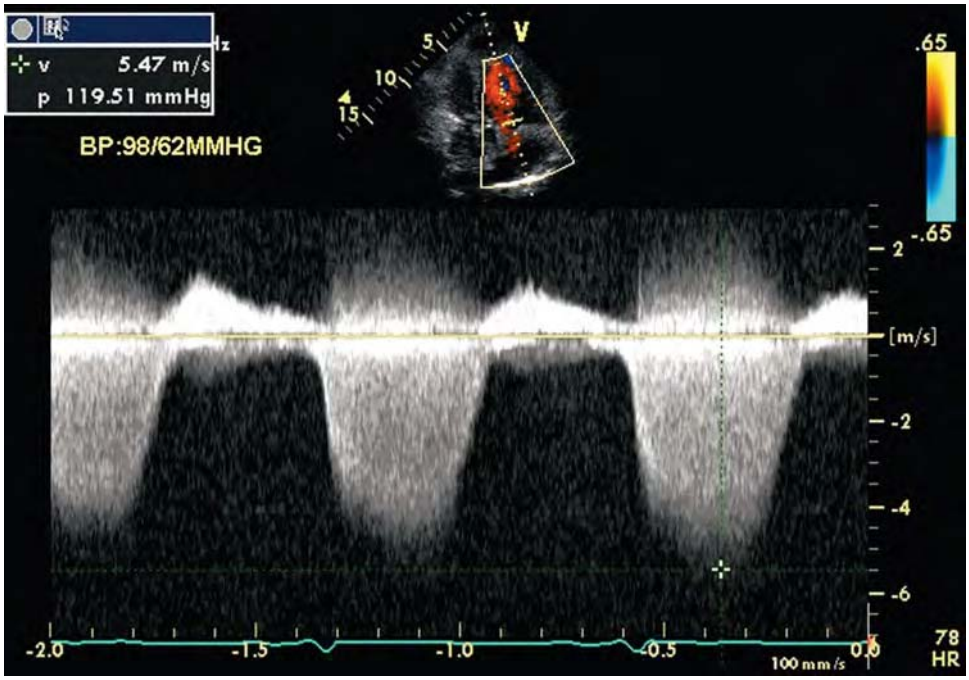

FIGURE 222-4 Continuous-wave Doppler of tricuspid regurgitation in a patient with pulmonary hypertension. There is an increase in the velocity of flow from the right ventricle into the right atrium to 5.4 m/s. Using the modified Bernoulli equation, the peak pressure gradient between the right ventricle and right atrium during systole is 120 mmHg. Assuming a right atrial pressure of 10 mmHg, the right ventricular systolic pressure is 130 mmHg. In the absence of right ventricular outflow tract obstruction, this indicates there is severe pulmonary hypertension with a pulmonary artery systolic pressure of 130 mmHg.

tion is applied to the peak velocity to obtain the pressure gradient between two cardiac chambers. This is commonly applied to a tricuspid regurgitant jet, from which the systolic pressure gradient between the right atrium and right ventricle can be calculated. Adding an assumed right atrial pressure to this gradient will give a derived right ventricular systolic pressure. In the absence of right ventricular outflow tract obstruction, the latter provides the pulmonary artery systolic pressure (Fig. 222-4).

Cardiac Output Volume flow rates (or stroke volume and cardiac output) can be reliably measured noninvasively by Doppler echocardiography. Flow is calculated as the product of the cross-sectional area of the vessel or chamber through which blood moves and the velocity of blood flow as assessed by continuous-wave Doppler determination. The time-velocity integral can be used to calculate pulsatile flow, and that integral multiplied by the cross-sectional area of, for example, the aortic root yields the stroke volume which, when multiplied by the heart rate, provides an estimate of the cardiac output.

Diastolic Filling Doppler echocardiography allows noninvasive evaluation of ventricular diastolic filling. The transmitral velocity curves reflect the relative pressure gradients between the left atrium and ventricle throughout diastole. They are influenced by the rate of ventricular relaxation, the driving force across the valve, and the compliance of the ventricle. There is a progression of diastolic dysfunction, which can be assessed by Doppler flow velocity curves. In the early phase of diastolic dysfunction there is primarily an impairment of LV relaxation, with reduced early transmitral flow and a compensatory increase in flow during atrial contraction (Fig. 222-5). As disease progresses, and ventricular compliance declines, left atrial pressure rises, resulting in a higher early transmitral velocity and shortening of the deceleration of flow in early diastole so that the filling pattern becomes normal, termed *pseudonormalization*. In patients with the most severe diastolic dysfunction and further elevation of left atrial pressure, early diastolic flow velocity rises further, termed the *restrictive filling pattern*. The addition of analysis of Doppler tissue velocities of annular motion provides further information concerning the diastolic properties.

Congenital Heart Disease (See Chap. 229) 2D and Doppler echocardiography have been useful in the evaluation of patients with congenital heart disease. Congenital stenotic or regurgitant valve lesions can be assessed. The detection of intracardiac shunts is possible by 2D and Doppler echocardiography (Fig. 229-1). Patency of surgical shunts and conduits can be determined.

STRESS ECHOCARDIOGRAPHY

2D and Doppler echocardiography are usually performed with the patient in the resting state. Further information can be obtained by reimaging during either exercise or pharmacologic stress. The primary indications for stress echocardiography are to confirm the suspicion of ischemic heart disease and estimate its severity (see below).

A decrease in systolic contraction of an ischemic area of myocardium, termed a *regional wall motion abnormality*, occurs before symptoms or electrocardiographic changes. New regional wall motion abnormalities, a decline in ejection fraction, and an increase in end-systolic volume with stress are all indicators of myocardial ischemia. Exercise stress testing is usually done with exercise protocols using either upright treadmill or bicycle exercise. The echocardiographic imaging is done at baseline and then immediately after exercise. In patients who are not able to exercise, pharmacologic testing can be performed by infusion of dobutamine

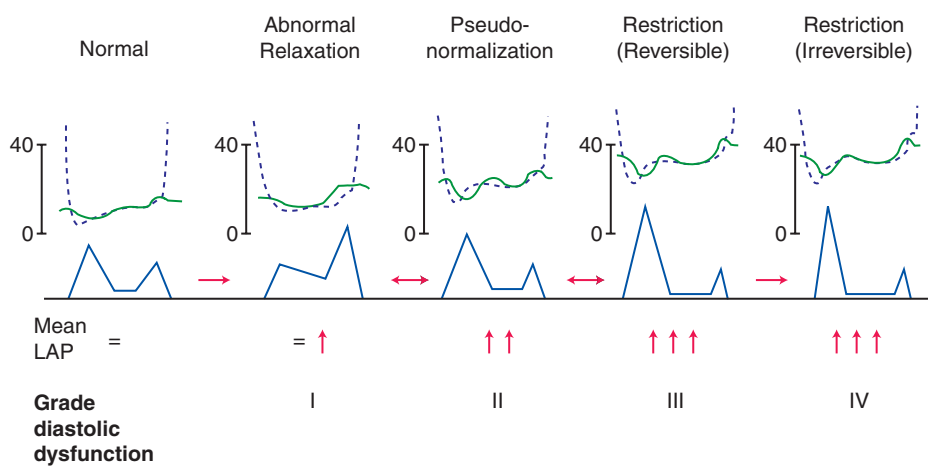

FIGURE 222-5 Diagrammatic illustration indicating the progression of diastolic dysfunction. ***Top,*** left atrial and ventricular pressures; ***Middle,*** transmitral flow velocity as measured by Doppler echocardiography; ***Bottom,*** grade of diastolic dysfunction. LAD, left atrial pressure.

to increase myocardial oxygen demand. Dobutamine echocardiography has also been used to assess myocardial viability in patients with poor systolic function and concomitant CAD.

Doppler echocardiography can be used at rest and during exercise in patients with valvular heart disease to determine the hemodynamic response to stress. In patients with low-output, low-gradient aortic stenosis, the response of the gradient to dobutamine stimulation is of diagnostic and therapeutic value.

TRANSESOPHAGEAL ECHOCARDIOGRAPHY

When limited information is obtained from a TTE due to poor imaging windows, TEE can be useful. Diseases of the aorta, such as aortic dissection, can be readily diagnosed by TEE (Fig. 222-3). Defining the source of embolism is a common indication for TEE, as abnormalities such as atrial thrombi, patent foramen ovale, and aortic plaques can be detected. Other masses, particularly those in the atria, can be visualized. The presence of vegetations for the diagnosis of infective endocarditis and its complications can be assessed by TEE. This technique has been used before cardioversion in patients with atrial fibrillation to detect a thrombus in the left atrium or left atrial appendage. If no thrombus is present, cardioversion can be safely performed, as long as there is full-dose anticoagulation before, during, and after the procedure.

EMERGENCY ECHOCARDIOGRAPHY

A major advantage of echocardiography is the ability to obtain instantaneous images of the cardiac structures for immediate interpretation at the patient's bedside. Thus, echocardiography has become an ideal imaging modality for cardiac emergencies.

Unstable Hemodynamics For the patient with unstable hemodynamics, echocardiography can determine LV size and function, right ventricular size and function, and the presence of acute valvular regurgitation and pericardial tamponade. Echocardiography is especially useful in the hemodynamically unstable patient following myocardial infarction (Chaps. 239 and 266), in whom acute mechanical complications (e.g., papillary muscle rupture, ventricular septal defect, myocardial perforation with tamponade, and right ventricular infarction) that need to be differentiated from severe LV systolic dysfunction can be diagnosed.

Chest Pain Syndromes (See Chap. 13) Echocardiography can be useful in selected patients with chest pain syndromes. For those patients who have an equivocal electrocardiogram, the presence of regional wall motion abnormalities on an echocardiogram can lead to the diagnosis of myocardial ischemia as an etiology for the pain. Other etiologies of chest pain, such as acute dissection or pericarditis with effusion, can also be diagnosed by echocardiography.

NUCLEAR CARDIOLOGY

BASIC PRINCIPLES OF NUCLEAR CARDIOLOGY

All nuclear cardiology studies depend on the injection into the patient of an isotope that emits photons, generally gamma rays generated during radioactive decay when the nucleus of an isotope changes from one energy level to a lower one. Radionuclide imaging uses a special camera that images these photons.

ASSESSMENT OF VENTRICULAR FUNCTION

Equilibrium radionuclide angiography, also known as *multiple-gated blood pool imaging*, involves the imaging of ^{99m}Tc-labeled albumin or red cells that are uniformly distributed throughout the blood volume. Resting images of the blood pool of isotopes within the cardiac chambers are obtained by electrocardiographic gating through multiple cycles, so that sufficient counts can be detected to obtain an image. This requires that the heart rate be reasonably constant. It provides an accurate, reproducible method for assessment of LV function. It is most commonly used when echocardiography is technically difficult or when poor LV function requires accurate quantitation.

Gated single-photon emission computed tomography (SPECT) is the nuclear cardiology technique that is most commonly utilized to assess ejection fraction and regional wall motion. This is usually performed post-stress by gating the acquisition of SPECT myocardial perfusion images using ^{99m}Tc- labeled compounds (see below). An automated technique determines the endocardial borders of the LV cavity, and a geometric model is used to calculate the ejection fraction.

ASSESSMENT OF MYOCARDIAL PERFUSION BY SPECT

(See Chap. 237) Myocardial perfusion imaging by nuclear techniques is now widely applied for the evaluation of ischemic heart disease. Injection of radioisotopes at rest and during stress is performed to produce images of myocardial regional uptake proportional to regional blood flow. With maximal exercise, myocardial blood flow is increased up to fivefold above the resting condition. In the presence of a fixed coronary stenosis, there is an inability to increase myocardial perfusion in the territory supplied by the stenosis, creating a flow differential and inhomogeneous distribution of the isotope. In patients who are unable to exercise, pharmacologic agents are used to increase blood flow and create similar inhomogeneities. The preferred pharmacologic agents are adenosine or dipyridamole, which increase blood flow to a similar degree as exercise. In patients with bronchospastic lung disease, which is a contraindication to the use of adenosine or dipyridamole, dobutamine may be used as an alternative, although it does not increase myocardial blood flow to the same extent.

^{201}Tl (thallium) was the first isotope used for this purpose. It has been largely replaced by ^{99m}Tc, which has a higher photon energy and shorter half-life, permitting the injection of larger doses resulting in scans of higher quality (Fig. 222-6). Two technetium-labeled myocardium perfusion agents are in common use: tetrofosmin and sestamibi. Like thallium, both tetrofosmin and sestamibi distribute to the myocardium in relation to blood flow, and their uptake requires an intact cell membrane and a viable myocardial cell. Both agents are bound within the cell in a nearly irreversible fashion. As a result, these agents must generally be injected twice—once at rest and once during stress.

POSITRON EMISSION TOMOGRAPHY

The underlying physics of positron emission tomography (PET) scanning differs from that involved in the standard radionuclide techniques described above. Positron emission is a type of beta-decay of an unstable isotope. In this unstable isotope, a proton undergoes spontaneous decay into a neutron, a neutrino, and a β^+ particle (positron). The spontaneous release of positrons from these unstable nuclei leads to their interaction with electrons, which cause the release of gamma-radiation (photons) upon collision with tissue. It is this gamma emission that is detected by the gamma camera in the PET scanner. The very high energy of the photons results in far less scatter than with conventional nuclear cardiology techniques. PET cameras are considerably more expensive than conventional nuclear cardiology cameras. Rubidium-82 is the most commonly used positron emitter, as it is available from a generator and does not require a nearby cyclotron. Pharmacologic stress with dipyridamole, adenosine, or dobutamine is preferred for PET scanning.

Positron emitters can be employed to study both myocardial blood flow and myocardial metabolism. Nitrogen-13 ammonia, oxygen-15 water, and rubidium-82 have all been employed to assess myocardial blood flow. They permit measurement of absolute regional blood flows, in contrast to the relative blood flows that are assessed with ^{201}Tl- or ^{99m}Tc-labeled compounds. This advantage has been utilized for research purposes but has generally not been exploited clinically. Myocardial metabolism is most often assessed using fluorine-18 deoxyglucose. This agent permits the detection and quantification of exogenous glucose utilization in areas of hypoperfused myocardium.

The clinical application of PET scanning that has been best studied is the assessment of myocardial viability. The pattern of enhanced fluorodeoxyglucose uptake in regions of decreased perfusion (termed *glucose/blood flow "mismatch"*) indicates the presence of ischemic myocardium that has preferentially shifted its metabolic substrate toward

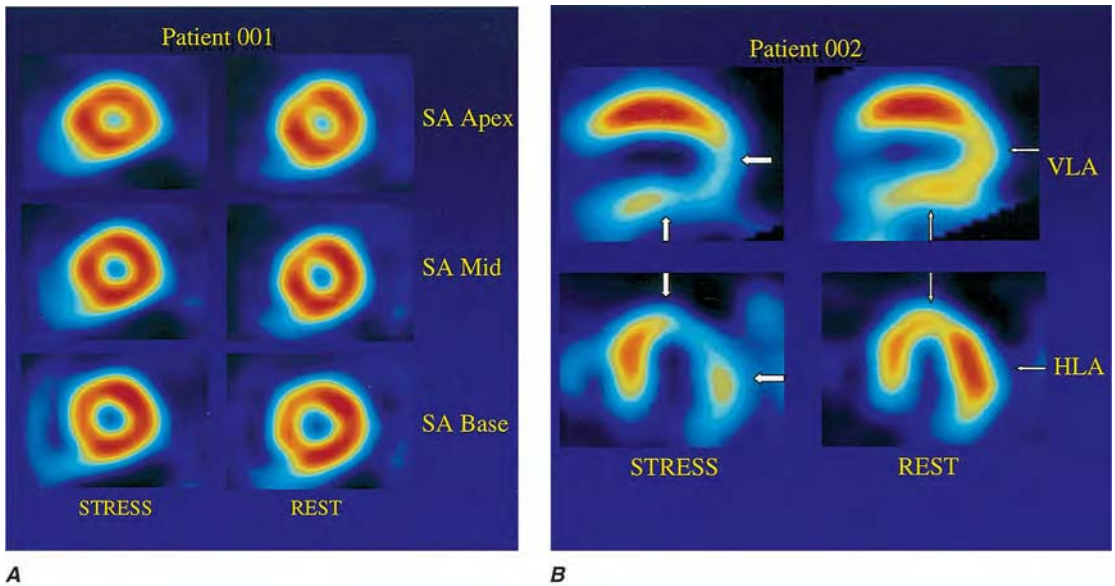

FIGURE 222-6 Exercise studies of atypical and typical angina. ***A.*** Exercise ^{99m}Tc sestamibi study of a 71-year-old white female with atypical angina. ***Left:*** Stress images; ***right:*** rest images. The images are normal. There is uniform sestamibi uptake throughout the myocardium at rest and during stress. ***B.*** Exercise sestamibi study of a 75-year-old male with a history of typical angina. ***Left:*** Stress images; ***right:*** rest images. The stress images show a large defect involving the apex, lateral, and inferior walls (thick arrows), which improves at rest (thin arrows). Subsequent coronary angiography demonstrates severe three-vessel coronary artery disease.

glucose rather than fatty acid or lactate. This pattern identifies regions of ischemic or hibernating myocardium that are likely to improve in function after revascularization (Fig. 222-7).

Comparative studies have consistently shown the ability of PET to identify ischemic or hibernating myocardium in 10–20% of regions that would be classified as fibrotic (infarcted) by ^{201}Tl- or ^{99m}Tc-labeled compounds. For that reason, this technique is generally regarded as the gold standard for the assessment of myocardial viability. When large fixed defects (infarcts) are detected by ^{201}Tl- or ^{99m}Tc labeled compounds in patients who are candidates for coronary revascularization, PET imaging can help in the decision whether the risk of revascularization is justified by the potential benefit.

The technical limitations of both ^{201}Tl- and ^{99m}Tc-labeled compounds in obese patients, and the increasing prevalence of patient obesity, are contributing to the increasing use of PET scanning for the assessment of myocardial perfusion.

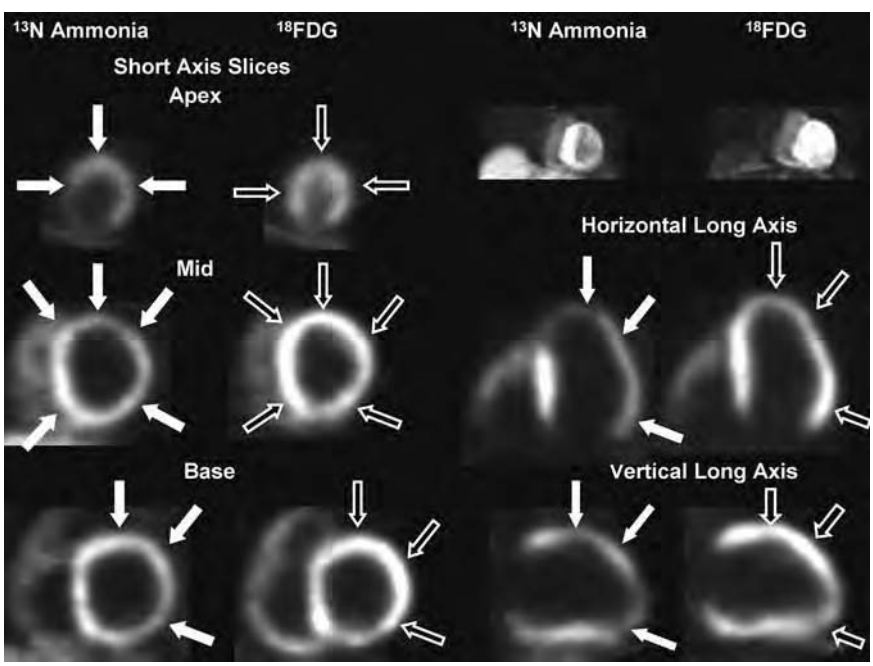

FIGURE 222-7 Positron emission tomography (PET). Short-axis PET resting ammonia image (***left***) and FDG image (***right***) of a 63-year-old diabetic female with dyspnea on exertion, a fixed SPECT defect, severe LV dysfunction, and severe coronary artery disease. The ammonia images show a very large apical, septal, anterior and lateral perfusion defect, which improves on the FDG images. This is consistent with hibernating myocardium. The patient underwent CABG with subsequent dramatic improvement in LV function. FDG, fluorodeoxyglucose; SPECT, single-photon emission CT; CABG, coronary artery bypass grafting; LV, left ventricular.

MRI AND CT IMAGING

MAGNETIC RESONANCE IMAGING

Basic Principles MRI is a technique based on the magnetic properties of hydrogen nuclei. In the presence of a large magnetic field, nuclear spin transitions from the ground state to excited states can be induced, and as the nuclei relax and return to their ground state, they release energy in the form of electromagnetic radiation that is detected and processed into an image. Contrast agents, such as gadolinium, are frequently employed to produce magnetic resonance angiograms (MRAs). These provide enhanced soft tissue contrast as well as the opportunity to obtain rapid angiographic images during the first pass of contrast through the vascular system. Cardiac MRI is particularly challenging because of the rapid motion of the heart and coronary arteries. Both static and cine images can be obtained using electrocardiographic triggering, often within a short breath-hold of 10–15 s. Cine images can be acquired in any plane with excellent blood-myocardial contrast, and these images can be used to quantify ejection fraction, end-systolic and end-diastolic volumes, and cardiac mass with high accuracy, reliability, and reproducibility, without the need for ionizing radiation.

Clinical Utility The multiplanar capabilities of MRI, coupled with excellent contrast and spatial

resolution, are often valuable in defining anatomic relationships in patients with complex congenital heart disease and cardiomyopathies (Fig. 231-2). Cardiac masses can be characterized and their relationship to normal anatomic structures defined. Likewise, MRI is often the examination of choice to determine whether a mediastinal or pulmonary mass has invaded the pericardium or heart. The entire pericardium can be visualized in multiple planes, and MRI has proved useful in characterizing pericardial effusions or pericardial thickening in patients with indeterminate results on echocardiography. Specialized pulse sequences have been designed to measure the velocity of blood in each pixel of the image, so that flow across valves and within blood vessels may be determined with accuracy. These techniques may allow characterization of the severity of valvular disease as well as quantification of shunt volumes.

MRA is a standard technique for imaging the aorta and large vessels of the chest and abdomen, with results essentially identical to conventional catheter-based angiography (Fig. 222-8). MRA of the coronary arteries is a much more difficult challenge, both because of the small size of these vessels and because of their rapid and complex motion during the cardiac cycle. Although promising results have been achieved, coronary MRA is not yet an accurate and reliable clinical technique.

MRI is a promising technology for the evaluation of patients with suspected or known coronary disease. Ventricular function and wall motion can be assessed at rest and during infusion of inotropic agents. Assessment of myocardial perfusion can be performed by injecting a bolus of gadolinium contrast and then continuously scanning the heart as the gadolinium passes through the cardiac chambers and into the myocardium. Relative perfusion deficits are reflected as regions of low signal intensity within the myocardium. Pharmacologic stress (typically achieved with vasodilators) can be applied during perfusion imaging to detect physiologically significant coronary artery lesions. Myocardial perfusion imaging with cardiac MRI is more sensitive then SPECT imaging for detecting subendocardial ischemia due to its enhanced spatial resolution. Myocardial viability may be determined by imaging the heart 10–20 min after gadolinium injection, as infarcted tissue retains contrast by virtue of its larger extracellular volume.

Limitations of MRI Relative contraindications include the presence of pacemakers, internal defibrillators, or cerebral aneurysm clips. A small percentage of patients are claustrophobic and unable to tolerate the examination within the relatively confined quarters of the magnet bore. However, open-bore magnets are now available to deal with this problem. Examination of clinically unstable patients is problematic, since close monitoring is difficult. Image quality in patients with significant arrhythmias is often limited.

FIGURE 222-8 Still frame of an MR angiogram showing a severe coarctation of the descending aorta, with abundant collateral arteries.

FIGURE 222-9 CT scan demonstrating calcium in a thickened pericardium in a patient with constrictive pericarditis. The calcium is shown as white densities.

COMPUTED TOMOGRAPHIC IMAGING

Basic Principles CT is fast, simple, noninvasive, and provides images with excellent spatial resolution and good soft tissue contrast. Cardiac CT has long been technically challenging because image acquisition times for conventional CT were too long to freeze cardiac motion. The development of electron-beam CT and multislice spiral (helical) CT have led to improved temporal resolution and routine imaging of the beating heart.

Clinical Applications Cardiac CT has several clinical applications. Pericardial calcification is an important sign of constrictive pericarditis and is easily detected by CT (Fig. 222-9). CT is useful in characterizing cardiac masses, particularly those containing fat or calcium. The ability to detect small amounts of fat with high spatial resolution makes CT an attractive technique for imaging patients with suspected arrhythmogenic right ventricular dysplasia (Chap. 231). Cine images can be used to evaluate wall motion and to determine ejection fraction, end-diastolic and end-systolic volumes, and cardiac mass.

CT angiography (CTA) has demonstrated accuracy similar to MRA in imaging the aorta and great vessels, and CTA is rapidly becoming the examination of choice in the evaluation of patients with suspected pulmonary embolus. CTA is an excellent imaging modality for the diagnosis of aortic dissection or penetrating ulcers. Visualization of the entire aorta is possible by CTA, so that the initial diagnosis as well as follow-up of patients with aortic aneurysmal disease can be done.

Coronary Calcification Calcium in the coronary arteries occurs in atherosclerosis and is absent in the normal coronary artery. CT is very sensitive for the detection of coronary artery calcification and is being promoted as a noninvasive modality for the screening and diagnosis of CAD. The quantity of coronary calcification (coronary calcium score) is related to the severity of CAD. However, although CT has a very high sensitivity for the detection of CAD, it has a low specificity. The overall predictive accuracy for angiographic obstructive coronary disease in a typical population of patients with CAD is similar to other imaging modalities, such as SPECT. Due to its low specificity, CT should not be used for the diagnosis of obstructive coronary disease.

Contrast-Enhanced CT Angiography With the high temporal and spatial resolution of multislice spiral CT, accurate assessment of luminal

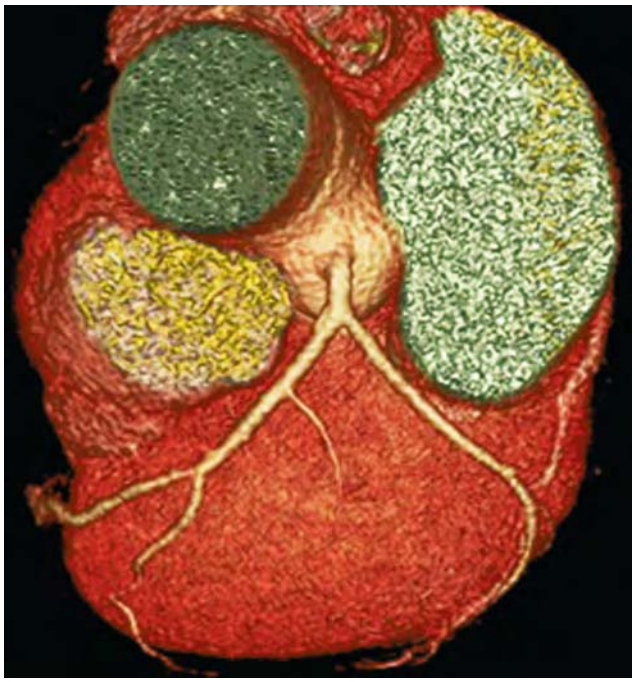

FIGURE 222-10 Three-dimensional reconstruction of a CT angiogram demonstrating a normal main left coronary artery arising from the aorta, and its two branches, the left anterior descending artery (***left***) and the left circumflex artery (***right***).

narrowing in the major branches of the coronary arteries is possible in selected patients. Studies at experienced centers have shown a high sensitivity (>85%), and specificity (>90%) of CTA as compared to cardiac catheterization. The highest accuracy has been noted in the left main and the proximal portions of the left anterior descending and left circumflex arteries (Fig. 222-10), probably due to the rapid motion of the right and circumflex arteries. Fast, irregular heart rates and body motion limit the accuracy of CTA.

The concept of "noninvasive coronary angiography" has generated great interest in the widespread utility of CTA. However, at present, the major well-accepted indication for coronary CTA is in the evaluation of suspected coronary anomalies. CTA may also be of use in patients with chest pain syndromes who have an intermediate pretest probability of CAD who are unable to exercise or have an uninterpretable or equivocal stress test.

Limitations of CT Limitations of CT include its dependence on ionizing radiation (in contrast to MRI) and the need for iodinated contrast, which is problematic in patients with renal insufficiency or contrast allergy. While radiation doses for some applications (such as coronary calcification scoring) are relatively low, doses tend to increase as the spatial resolution improves, and the doses for coronary CTA generally exceed those delivered during standard diagnostic cardiac catheterization.

SELECTION OF IMAGING TESTS

BASIC PREMISE

The choice of the optimal imaging modality for a particular patient should be based upon the major problem being addressed, other concomitant clinical questions, as well as the local expertise and equipment available in an institution. The clinical urgency and costs need to be considered, due to the high costs of some of these modalities (Table 222-2).

Left Ventricular Size and Function 2D echocardiography is the primary imaging modality obtained for assessment of LV cavity size, systolic function, and wall thickness. It is widely available, portable, and provides an instantaneous view of the heart. Echocardiography can also provide concomitant information on valve function, pulmonary artery pressures, and diastolic filling, which are valuable in the patient presenting with possible heart failure. The disadvantage is poor endocardial resolution in some patients and the lack of reproducible quantitative measurements.

Equilibrium radionuclide angiography can provide an accurate quantitative measurement of LV function but is not widely available and cannot be used in patients with irregular rhythms. Gated SPECT can measure ejection fraction as a part of stress imaging. Both MRI and CT scanning provide the highest quality resolution of endocardial border and thus are the most accurate of all modalities. However, they are of higher cost, lack portability, and do not provide concomitant hemodynamic information as echocardiography does.

Valvular Heart Disease 2D and Doppler echocardiography provide both anatomic and hemodynamic information regarding valve disease, thus echocardiography is the first test of choice. MRI can also visualize valve motion and determine abnormal flow velocities across valves, but there is less validation of quantitative hemodynamic measurements in comparison to echocardiography.

Pericardial Disease Echocardiography is the first imaging modality of choice in patients with suspected pericardial effusion and tamponade, due to its rapid image display and portability. For patients with suspected constrictive pericarditis, either MRI or CT scanning is the imaging modality that best delineates pericardial thickness. Hemodynamic analysis of the enhancement of ventricular interaction that occurs in pericardial constriction can be assessed by Doppler echocardiography.

Aortic Disease Both CT scanning and MRI are the imaging modalities of choice for the evaluation of the stable patient with suspected aortic aneurysm or aortic dissection. In the acutely ill patient with suspected aortic dissection, either TEE or CT scanning is a reliable imaging modality.

TABLE 222-2 SELECTION OF IMAGING TESTS

	Echo	Nuclear	CT[a]	MRI[b]
LV Size/ function	Initial modality of choice Low cost, portable Provides ancillary structural and hemodynamic information	Available from gated SPECT stress imaging	Best resolution Highest cost	Best resolution Highest cost
Valve disease	Initial modality of choice Valve motion Doppler hemodynamics			Visualize valve motion Delineate abnormal flow
Pericardial disease	Pericardial effusion Doppler hemodynamics		Pericardial thickening	Pericardial thickening
Aortic disease	TEE rapid diagnosis[c] Acute dissection		Image entire aorta Acute aneurysm Aortic dissection	Image entire aorta Aortic aneurysm Chronic dissection
Cardiac masses	TTE—large intracardiac masses TEE—smaller intracardiac masses[c]		Extracardiac masses Myocardial masses	Extracardiac masses Myocardiac masses

[a]Contrast required.
[b]Relative contraindication: pacemakers, metallic objects, claustrophobic.
[c]When not seen on TTE.
Note: Echo, echocardiography; SPECT, single-photon emission CT; TEE, transesophageal echocardiography; TTE, transthoracic echocardiogram.

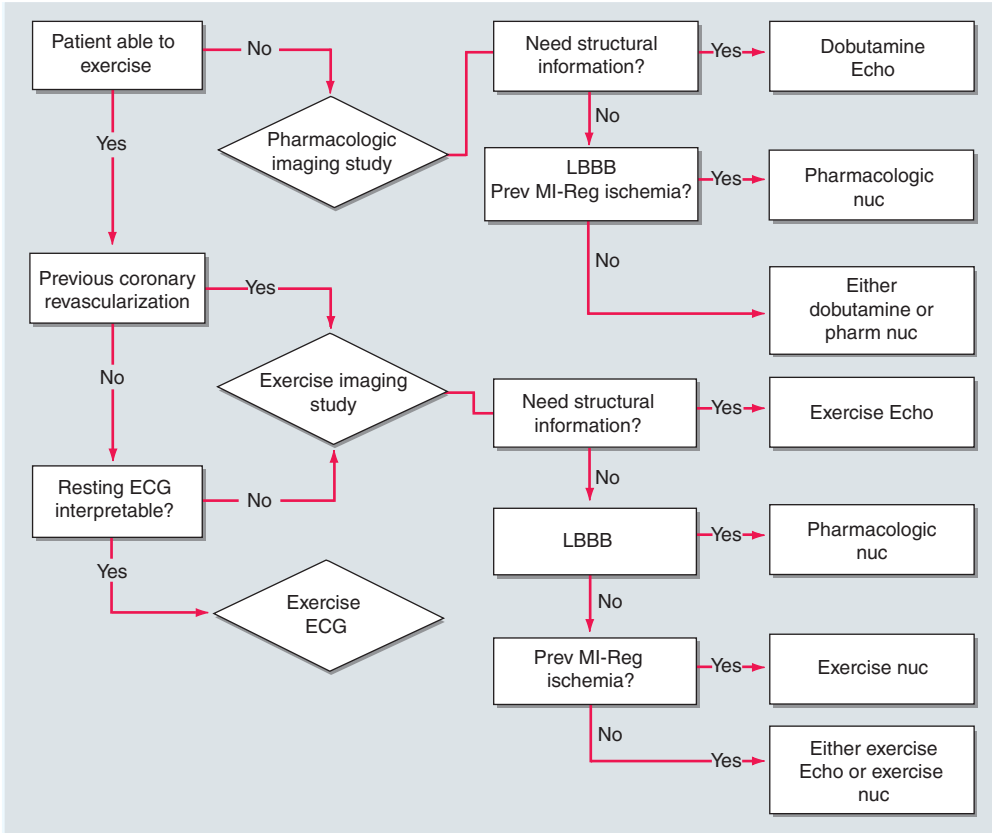

FIGURE 222-11 Flow diagram showing selection of initial stress test in a patient with chest pain. Patients who are able to exercise, without previous revascularization, and with an interpretable resting ECG can be tested with an exercise ECG. The appropriate imaging study for other patients depends on multiple factors (see text). LBBB, left bundle branch block; Prev MI-Reg ischemia, previous MI with a need to detect regional ischemia; Nuc, SPECT nuclear imaging study; Pharm, pharmacologic.

Cardiac Masses 2D TTE is the first test to rule out an intracardiac mass; masses >1.0 cm in diameter are usually well visualized. Intracardiac masses of smaller size may be visualized by TEE. CT scanning and MRI are optimal for evaluating masses extrinsic to the heart or involving the myocardium.

CHOOSING THE APPROPRIATE STRESS TEST

The choice of an initial stress testing modality should be based on the evaluation of the patient's resting electrocardiogram, the ability to perform exercise, and the available local expertise and technology (Fig. 222-11). For the standard assessment of CAD, the exercise electrocardiographic test should be the initial stress test in patients with an interpretable electrocardiogram who are able to exercise. If there are resting electrocardiographic abnormalities (ST depression >1 mm, LV hypertrophy, bundle branch block, paced rhythm, preexcitation), if the patient is taking digoxin, or if the patient has had a prior coronary revascularization, an imaging modality (either nuclear imaging or echocardiography) should be used for initial evaluation. Pharmacologic stress testing with imaging should be used in patients who are unable to exercise.

When an imaging modality is indicated, the decision to use an echocardiographic or a nuclear test depends not only on the clinical features but also on the available local expertise and technology. Both echocardiography and nuclear imaging require expertise in the performance and interpretation of the tests, and the patient is often best evaluated with the imaging modality for which the most expertise and experience are available. There are, however, certain situations in which one imaging modality has an advantage over the other.

Echocardiography provides additional structural information. Therefore, if there is a question of concomitant valve disease, pericardial disease, or aortic disease, echocardiography is able to provide information regarding these issues. The major limitation of echocardiography is the inability to obtain diagnostic images in all patients, especially those with chronic obstructive pulmonary disease or severe obesity. If there is inadequate definition of endocardial motion on the resting echocardiogram, stress echocardiography should not be performed unless contrast enhancement can be used. If the patient has had a previous infarction and one needs to determine whether a specific region of the myocardium is ischemic, nuclear imaging is the preferred modality. Nuclear imaging using ^{99m}Tc-labeled compounds is preferred in obese patients and those with severe lung disease. Nuclear imaging is more sensitive and less specific than echocardiography for the detection of myocardial ischemia.

The imaging tests can add prognostic information, especially when the results of an exercise electrocardiogram fall into an intermediate risk category. For nuclear imaging, a normal stress (exercise or pharmacologic) myocardial perfusion scan is highly predictive of the absence of significant artery disease and a low risk of subsequent cardiac death. Similarly, for stress (exercise or dobutamine) echocardiography, an increase in ejection fraction and a decrease in end-systolic volume at a high workload predict the absence of significant CAD and a low risk of subsequent cardiac death. On the other hand, for nuclear imaging, large or multiple stress-induced defects, or a large fixed defect with LV dilatation or increased ^{201}Tl lung uptake are high-risk findings. For stress echocardiography, patients with a decrease in ejection fraction, multiple new regional wall motion abnormalities, and an increase in end-systolic volume at a low workload are at high risk. Investigations are underway to determine the clinical value of stress MRI.

223 Diagnostic Cardiac Catheterization and Angiography

Donald S. Baim*

Despite progressive improvements in noninvasive techniques, cardiac catheterization remains a key clinical tool for assessing the anatomy and physiology of the heart and its associated vasculature. It involves the insertion of catheters (2-mm diameter hollow plastic tubes) into a peripheral artery or vein under local anesthesia, and their passage into the heart for the purposes of intracardiac pressure measurement or the injection of a liquid radiographic contrast agent. The findings of diagnostic cardiac catheterization characterize the extent and severity of cardiac disease and thereby can help to determine the most appropriate plan for medical, surgical, or catheter-based treatment. While the majority of patients with coronary artery disease (CAD) or valvular disease can be managed medically using only clinical and noninvasive data (e.g., exercise testing, echocardiography, and MRI), >2 million patients each year undergo cardiac catheterization and angiographic procedures for diagnostic or interventional purposes, or both. This chapter focuses on the uses of cardiac catheterization as a diagnostic tool. **For further discussion of catheter-based interventions, see Chap. 240.**

BASIC PRINCIPLES

Given the expense and small but real risks of cardiac catheterization, this procedure is not indicated routinely whenever cardiac disease is diagnosed or suspected. Instead, cardiac catheterization is reserved for situations where there is a need to confirm the presence of a clinically suspected condition, define its anatomic and physiologic severity, and determine the presence or absence of important associated conditions. This situation arises most commonly when a patient experiences limiting or escalating symptoms of cardiac dysfunction (Chap. 227) that may include acute coronary syndromes, such as unstable angina or acute myocardial infarction (Chap. 238), or when objective measures (such as exercise testing or echocardiography) suggest that the patient has findings (such as an early positive exercise test or worsening ventricular function) that signal a high risk of progressing to rapid functional deterioration, myocardial infarction, or other adverse events. Under these circumstances, diagnostic catheterization may not only identify the culprit coronary lesions, but in ~40% of procedures may progress seamlessly into a catheter-based therapeutic procedure [percutaneous coronary intervention (PCI); Chap. 240] that can provide definitive correction. Alternatively, diagnostic catheterization may demonstrate only less critical lesions that can be managed medically or severe lesions poorly suited to PCI that may be referred for treatment by cardiac surgery (e.g., coronary bypass surgery, valve replacement, or valve repair).

While cardiac catheterization was once considered mandatory in *all* patients being considered for cardiac surgery, currently many patients with congenital or valvular heart disease undergo surgical correction based solely on clinical and noninvasive test data [e.g., echocardiography and MRI (Chap. 222)], with diagnostic coronary angiography performed in older patients or those with risk factors for or non-invasive testing suggesting coronary disease, prior to surgery.

When there is a clinical "need to know," there are very few absolute contraindications to diagnostic cardiac catheterization in a patient who understands and accepts the associated risks. The risk of death from elective cardiac catheterization approaches 1 in 10,000 (0.01%), but the procedure does carry a small (~1 in 1000) risk of stroke or myocardial infarction, transient tachy- or bradyarrhythmias, or bruising or bleeding at the catheter insertion site. These complications respond to drug therapy, countershock, or vascular surgical repair, without long-term sequelae. About 1% of patients used to experience *allergic reactions* to iodinated contrast agents, ranging from urticaria to frank anaphylaxis in sensitive patients, but these have become rare events with current nonionic low-osmolar contrast agents.

Other patients (particularly those with baseline renal dysfunction or proteinuria) may develop transient deterioration in renal function, the chance of which may be further reduced by adequate prehydration (50% normal saline, or D_5W with 154 meq/L of sodium bicarbonate added, given at 3 mL/kg for 1 h prior to and 1 mL/kg for 6 h following the procedure, absent congestive heart failure), preprocedure administration of *N*-acetylcysteine (Mucomist, 600 mg orally before and twice a day after the procedure), or the use of an isoosmolar contrast agent (iodixanol). Newer low- or iso-osmolar contrast agents also reduce the chance of myocardial depression and other side effects (hypotension, nausea, bradycardia, or a sensation of marked warmth following injection) that were once common when earlier high-osmolar contrast agents were used.

Cardiac catheterization is generally performed with the patient fasting for the previous 6 h and awake but lightly sedated. The desired level of sedation may be achieved with preprocedure sedatives such as oral diazepam (Valium, 5–10 mg), or with IV conscious sedation using midazolam (Versed, 1 mg) or fentanyl (25–50 μg) following guidelines for conscious sedation. Most elective procedures are performed on an *outpatient* basis, with the patient discharged with instructions regarding maintenance of a liberal oral fluid intake, avoidance of strenuous activity, and self-monitoring for access site complications, following 2–4 h of postprocedure bed rest. If required by associated medical conditions or complications, or if a PCI has been performed, overnight hospitalization may be recommended.

To minimize the risks of bleeding at the local catheter insertion site, patients who have been anticoagulated chronically with warfarin should have this agent discontinued at least 48 h prior to the procedure, so that the INR falls below 2. Oral aspirin (325 mg/d) is routinely administered to patients undergoing diagnostic catheterization for suspected coronary disease, since aspirin pretreatment is desired if a coronary intervention is to be performed. Since cardiac catheterization is a sterile procedure, prophylactic antibiotics are not necessary.

Most (>95%) cardiac catheterizations are performed by the percutaneous femoral technique that begins with needle puncture of the common femoral artery or (for right heart catheterization) the femoral vein. A flexible guidewire is inserted through this needle and supports insertion of a vascular access sheath, through which the desired catheters can be advanced. This percutaneous technique can be adapted to other arterial sites such as (1) the brachial and radial artery in patients with peripheral vascular disease involving the abdominal aorta and iliac or femoral arteries or in whom immediate postprocedure ambulation is desired, or (2) the internal jugular vein for right heart catheterization in patients who may require prolonged hemodynamic monitoring.

Cardiac catheterization may include a variety of different measurements of pressure and flow (hemodynamics) as well as a variety of different contrast injections recorded as x-ray movies (angiography),

*At the time that Dr. Baim prepared this chapter he was a Professor of Medicine at Harvard Medical School and Senior Physician at Brigham and Women's Hospital. Since then, he has assumed the position of Senior Vice-President at Boston Scientific Co.

e20 Atlas of Noninvasive Cardiac Imaging

Rick Nishimura, Raymond J. Gibbons, James F. Glockner, A. Jamil Tajik

Noninvasive cardiac imaging is essential to the diagnosis and management of patients with known or suspected cardiovascular disease. Chapter 222 describes the principles and clinical applications of these important techniques. This atlas supplements Chap. 222. It provides "real time" image clips, as they are viewed in clinical practice, as well as additional static images.

VIDEO e20-1 Real-time echocardiographic images of a patient with a normal heart. ***A.*** (Play video) Parasternal long axis view. ***B.*** (Play video) Parasternal short axis view. ***C.*** (Play video) Apical four-chamber view. There is symmetric contraction of the ventricles, evidenced by a decrease in cavity size and an increase in wall thickness during systole.

Echocardiographic imaging is performed from multiple acoustic windows with different transducer rotations so that the entire heart and great vessels can be displayed in various planes. Most information from a study is obtained from a visual analysis of the two-dimensional images, although objective measurements of cardiac dimensions can be made (see **Fig. e20-1**).

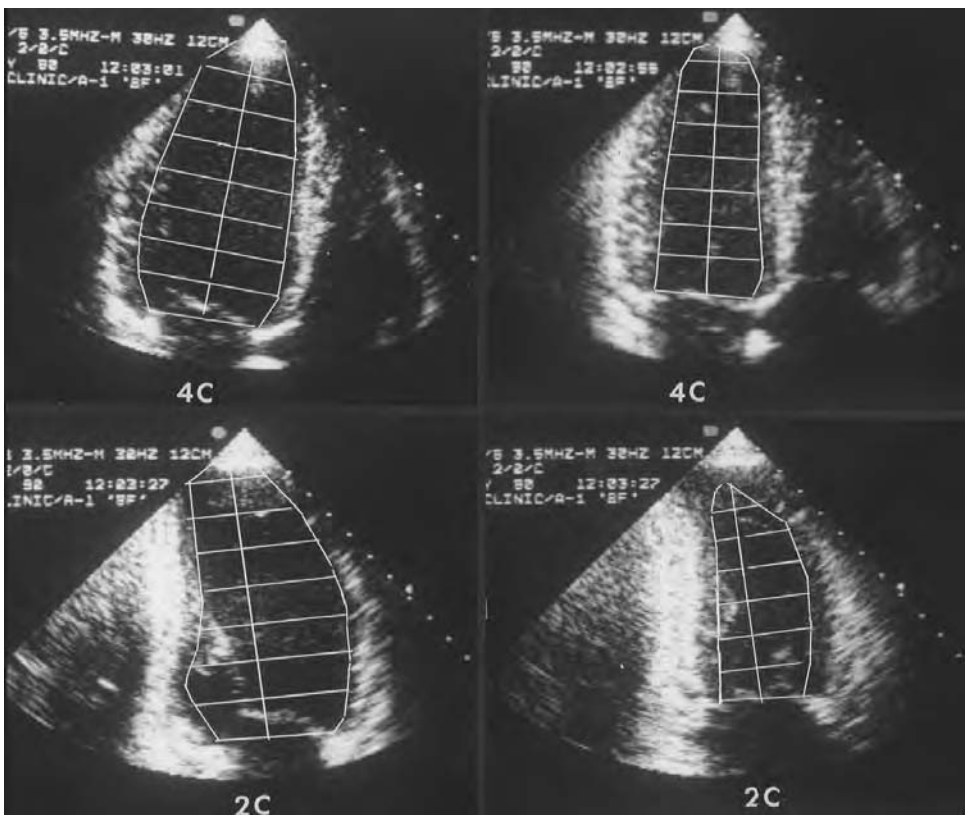

FIGURE e20-1 Still frame images of an echocardiogram in diastole (*left*) and systole (*right*). Apical four-chamber view (***top***) and apical two-chamber view (***bottom***) comprise two orthogonal views. This illustrates the quantitative assessment of ejection fraction. The endocardial area is outlined and is used for calculation of ejection fraction.

With quantitative two-dimensional echocardiography, endocardial outlines of the left ventricle (LV) cavity are traced in systole and diastole and the LV cavity areas are then fitted to computer models of the LV to obtain systolic and diastolic volumes. The presence or absence of regional wall motion abnormalities can be assessed by examining endocardial motion as well as wall thickening.

VIDEO e20-2 Real-time echocardiographic images of a patient with a severe decrease in left ventricular systolic function. The estimated ejection fraction is 20%. ***A.*** (Play video) Parasternal long axis view. ***B.*** (Play video) Parasternal short axis view.

VIDEO e20-3 Real-time echocardiographic images of a patient with hypertrophic cardiomyopathy, demonstrating an increase in wall thickness during systole. ***A.*** (Play video) Parasternal long axis view. ***B.*** (Play video) Parasternal short axis view.

VIDEO e20-4 Real-time echocardiographic images of a patient with mitral stenosis. There is diastolic doming and restricted leaflet opening secondary to fusion of the commissures. ***A.*** (Play video) Parasternal long axis. ***B.*** (Play video) Parasternal short axis.

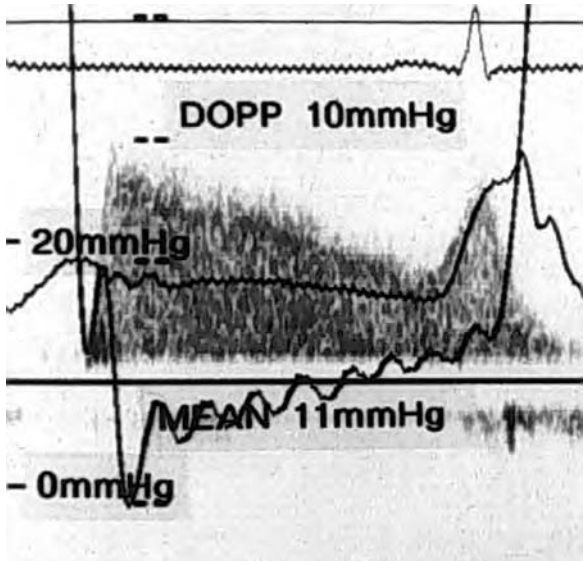

FIGURE e20-2 Continuous wave Doppler (DOPP) echocardiographic tracings across the mitral valve in a patient with mitral stenosis with simultaneous pressures in the left atrium (LA) and left ventricle (LV). The velocity of flow is high in early diastole, followed by a prolonged deceleration of transmitral mitral flow velocity, and a re-acceleration during atrial systole (A). There is a mean gradient of 10 mmHg derived from the Doppler tracing, which corresponds to the simultaneous transmitral gradient of 11 mmHg derived from cardiac catheterization. These are consistent with the diagnosis of moderate mitral stenosis. LA, left atrial pressure; LV, left ventricular pressure; a, atrial contraction wave. *(From RA Nishimura et al: J Am Coll Cardiol 24:152, 1994.)*

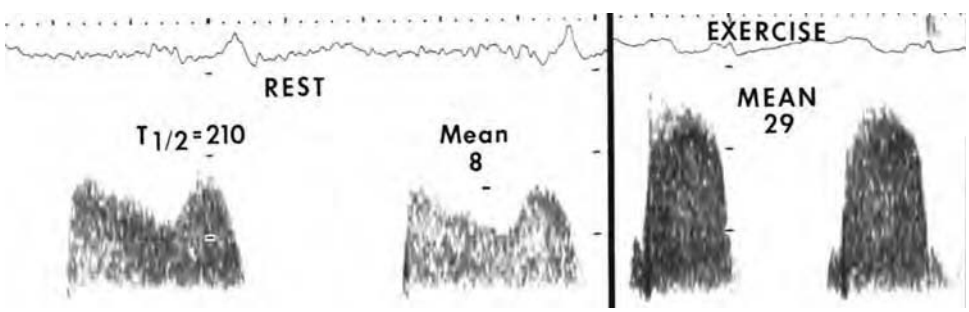

FIGURE e20-3 Continuous-wave Doppler echocardiogram across the mitral valve of a patient with mitral stenosis. In the resting state (***left***) there is a mean gradient of 8 mmHg. During exercise (***right***), the mean gradient rises to 29 mmHg, indicating hemodynamically significant mitral stenosis.

VIDEO e20-5 Real-time images with color-flow Doppler imaging of a patient with mitral regurgitation due to ruptured chordae tendinae. *A.* (Play video) Gray scale image showing a thickened redundant posterior leaflet with loss of coaptation. ***B.*** (Play video) Color-flow imaging showing the regurgitation as a high-velocity turbulence (mosaic pattern) regurgitating into the left atrium during systole. ***C.*** (Play video) Color-flow imaging of a patient with a normal mitral valve showing no regurgitation into the left atrium.

VIDEO e20-6 (Play video) **Real-time transesophageal echocardiographic images of a patient with severe mitral regurgitation** due to a flail posterior leaflet. The posterior mitral valve leaflet is completely unsupported and moves into the left atrium during systole.

VIDEO e20-7 Real-time echocardiographic images from the parasternal long axis view of a patient with mitral valve prolapse. Both leaflets prolapse into the left atrium during systole. ***A.*** (Play video) Black and white images demonstrating leaflet morphology and motion. ***B.*** (Play video) Color-flow imaging demonstrating a late systolic blue-colored jet of mitral regurgitation.

Annular dilatation, prolapse, flail leaflets, vegetation, and rheumatic involvement can all be diagnosed and the LV response to volume overload assessed by two-dimensional echocardiography.

Copyright © 2008 The McGraw-Hill Companies. All rights reserved.

VIDEO e20-8 (Play video) **Real-time two-dimensional echocardiographic images of a patient with a vegetation on the mitral valve.** There is a mobile echo density attached directly to the mitral valve apparatus.

VIDEO e20-9 (Play video) **Real-time two-dimensional parasternal long axis echocardiographic images from a patient with aortic stenosis.** The aortic valve is calcified with restricted opening.

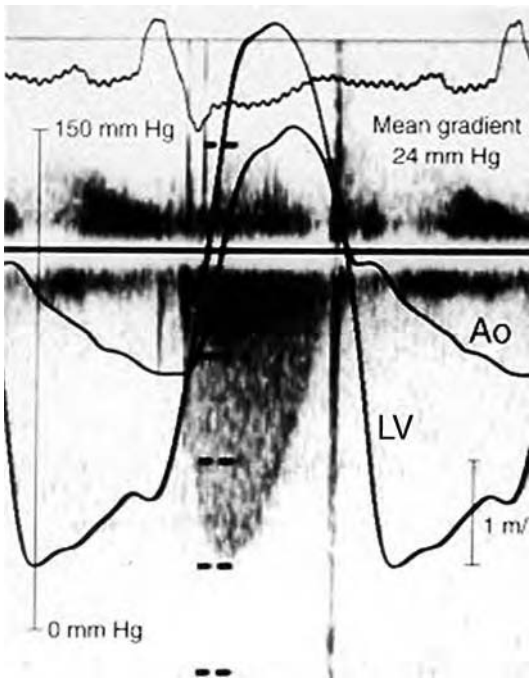

FIGURE e20-4 Continuous-wave Doppler tracings across the aortic valve in a patient with aortic stenosis. There is an increase in velocity to 3 m/s, with a mean transvalvular gradient calculated to be 24 mmHg. This corresponds to the simultaneous catheterization gradient of 24 mmHg between left ventricle (LV) and aorta (Ao).

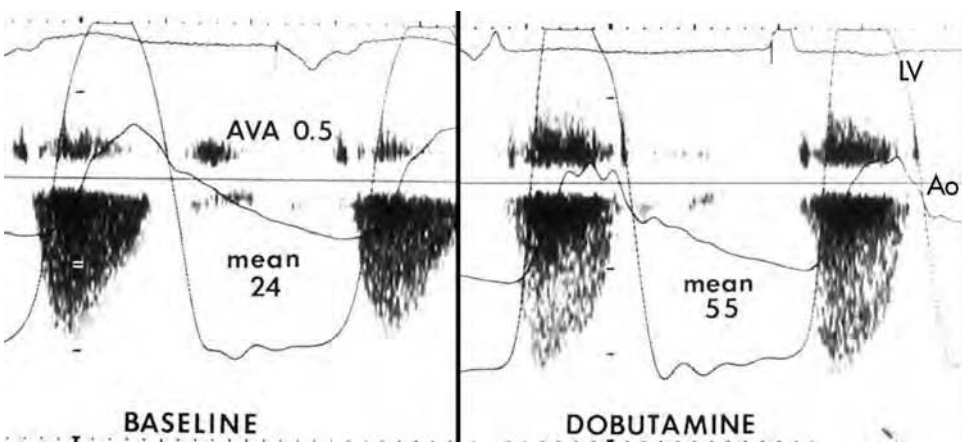

FIGURE e20-5 Continuous-wave Doppler echocardiogram across the aortic valve in a patient with low output–low gradient aortic stenosis and a reduced ejection fraction. ***Left.*** At baseline, there is a mean left ventricular (LV)-aortic (Ao) gradient of 24 mmHg (by Doppler) with a calculated aortic valve area (AVA) of 0.5 cm^2. This presents a diagnostic dilemma as the reduced aortic valve area may be due to either critical aortic stenosis and secondary LV dysfunction or a low-output state, in which there is not enough force to open fully a mildly stenotic aortic valve. ***Right.*** During dobutamine infusion, there is an increase in the transvalvular pressure gradient to 55 mmHg, with normalization of the stroke volume. This indicates the presence of severe aortic stenosis.

VIDEO e20-10 Real-time echocardiographic images showing a close-up view of the atrial septum in a patient with a large secundum atrial septal defect. *A.* (Play video) Gray scale image showing a questionable "drop-out" in the atrial septum. ***B.*** (Play video) Color-flow imaging confirms flow across the atrial septum.

VIDEO e20-11 (Play video) **Real-time transesophageal echocardiographic images of a patient with a left atrial myxoma.** There is a large echo-dense mass in the left atrium that is attached to the atrial septum. The mass moves across the mitral valve in diastole.

Although an echocardiographic examination cannot provide pathologic confirmation of the etiology of a mass, in many instances the diagnosis can be suspected from the appearance, mobility, attachments, and concomitant abnormalities.

Copyright © 2008 The McGraw-Hill Companies. All rights reserved.

VIDEO e20-12 (Play video) **Real-time two-dimensional echocardiographic images of a patient with a pericardial effusion.** The effusion is shown as black echo-free space surrounding the heart.

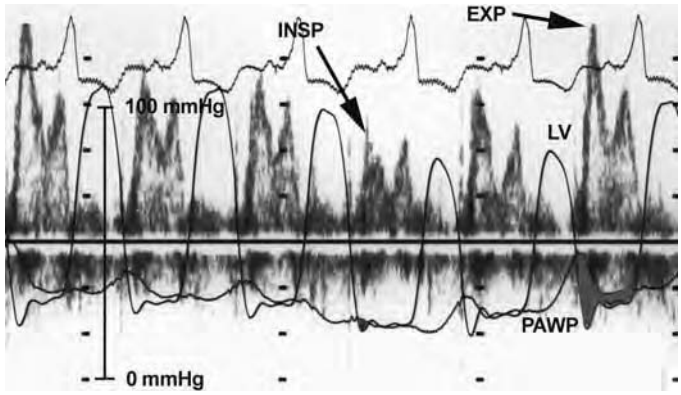

FIGURE e20-6 Pulsed-wave Doppler echocardiogram of transmitral flow recorded simultaneously with pulmonary artery wedge pressure (PAWP) and left ventricular (LV) pressure in a patient with constrictive pericarditis. There is a dissociation of intrathoracic and intracardiac pressures so that the PAWP has a larger inspiratory (INSP) fall than the LV pressure, causing a decrease in the driving force across the mitral valve. This results in a fall in the transmitral flow velocity. The opposite occurs during expiration (EXP).

VIDEO e20-13 (Play video) **Real-time two-dimensional echocardiographic images from the parasternal long axis view of a patient with a large aneurysm of the ascending aorta.**

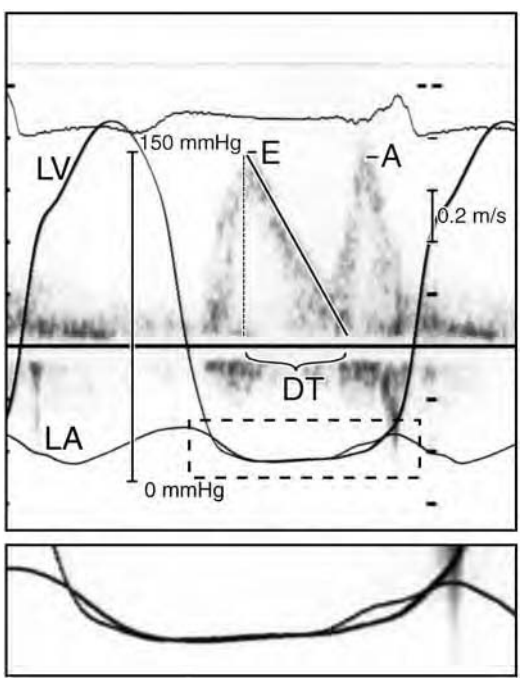

FIGURE e20-7 Pulsed-wave Doppler tracings of the mitral valve inflow velocities superimposed on left atrial (LA) and left ventricular (LV) pressures. The initial (early diastolic) velocity of mitral inflow (E) correlates with the driving pressure across the mitral valve. The deceleration time (DT) indicates the relative change in LA and LV pressures as blood begins to fill the LV. This increases LV pressure, which rises to meet the LA pressure. The A velocity on the mitral flow velocity curve is a reacceleration of flow due to atrial contraction. Normally, the E velocity exceeds the A velocity. In this patient, they are equal, suggestive of mild diastolic dysfunction (see Fig. e20-8).

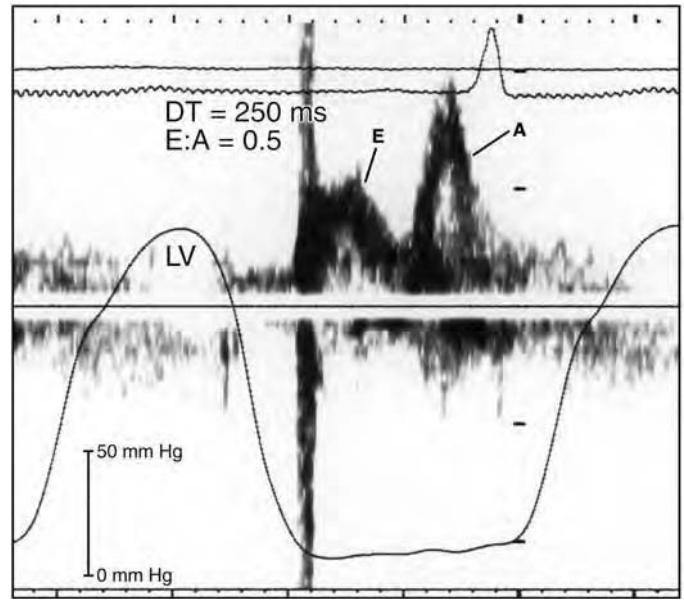

FIGURE e20-8 High-fidelity left ventricular pressure (LV) curve superimposed on a mitral inflow velocity curve obtained by Doppler echocardiography in a patient with stage I diastolic dysfunction. There is a decrease in the early diastolic filling and an increase with filling at atrial contraction, resulting in a low E:A ratio and prolonged deceleration time (DT). The LV diastolic pressure is normal at 12 mmHg.

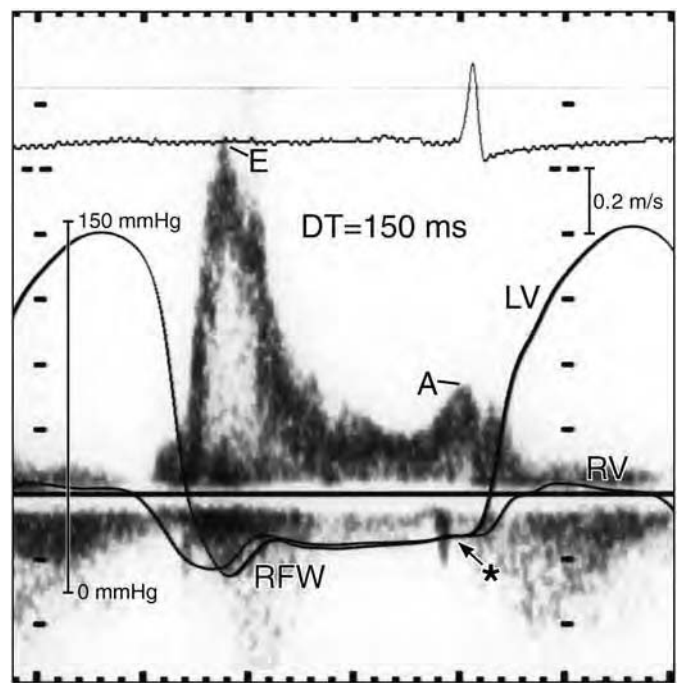

FIGURE e20-9 High-fidelity left ventricular (LV) and right ventricular (RV) pressure tracings superimposed on a Doppler mitral inflow velocity tracing in a patient with stage III diastolic dysfunction. There is a restriction to filling, in which there is a high early diastolic velocity [rapid filling wave (RFW)] and low velocity of atrial contraction resulting in a high E:A ratio with a short (150 ms) deceleration time (DT). Both ventricular diastolic pressures (*) are elevated.

VIDEO e20-14 Real-time two-dimensional stress echocardiogram in a normal subject. The studies at rest are shown on the left and the studies during peak exercise are on the right. ***A.*** (Play video) Parasternal long axis (*top*) and short axis (*bottom*) views. ***B.*** (Play video) Apical four-chamber (*top*) and two-chamber (*bottom*) views. At rest, there is contraction of all segments of the myocardium. During exercise, there are increases in contractility and in the thickening of all segments of the myocardium.

VIDEO e20-15 Real-time two-dimensional stress echocardiogram of a patient with coronary artery disease. The studies at rest are shown on the left and the studies during peak exercise are on the right. ***A.*** (Play video) Parasternal long axis (*top*) and short axis (*bottom*) views. ***B.*** (Play video) Apical four-chamber (*top*) and two-chamber views (*bottom*). The images during peak exercise show regional wall motion abnormalities in the anteroapical distribution indicative of myocardial ischemia.

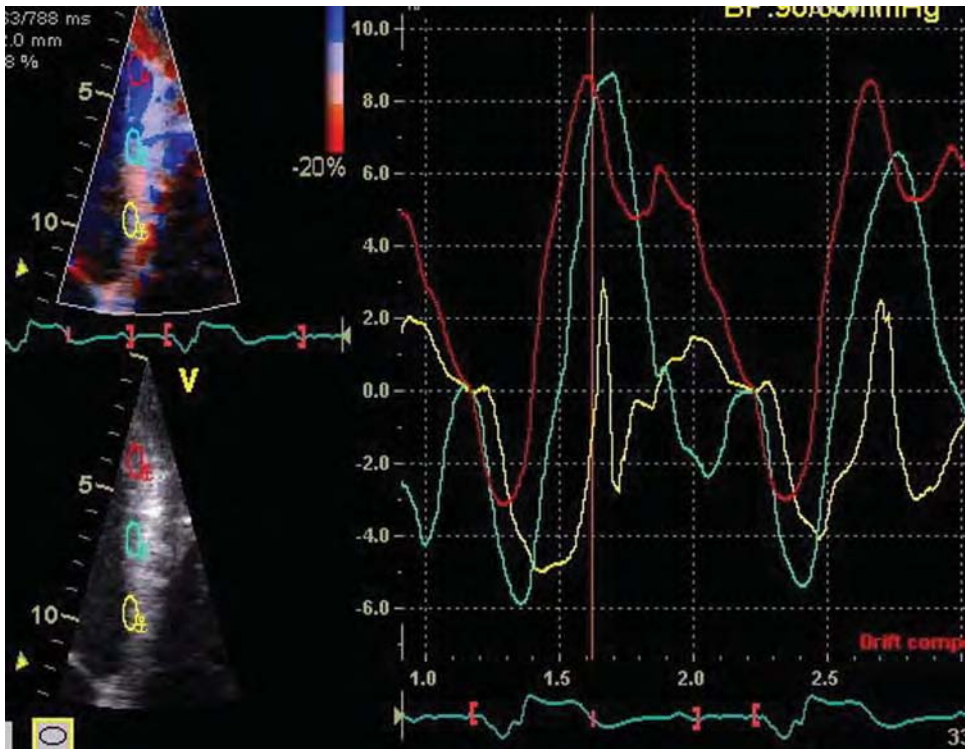

FIGURE e20-10 Strain rate images from a patient with severe left ventricular dysfunction illustrating dyssynchronous contraction.

Strain rate is a measure of regional deformation (or contraction). Strain rates can be used to examine the degree of dyssynchronous contraction of the ventricle, which may help in determining patients who would benefit from biventricular pacing. Shown are the different strain rates over time of the basal septum (yellow line), mid septum (blue line), and apical septum (red line).

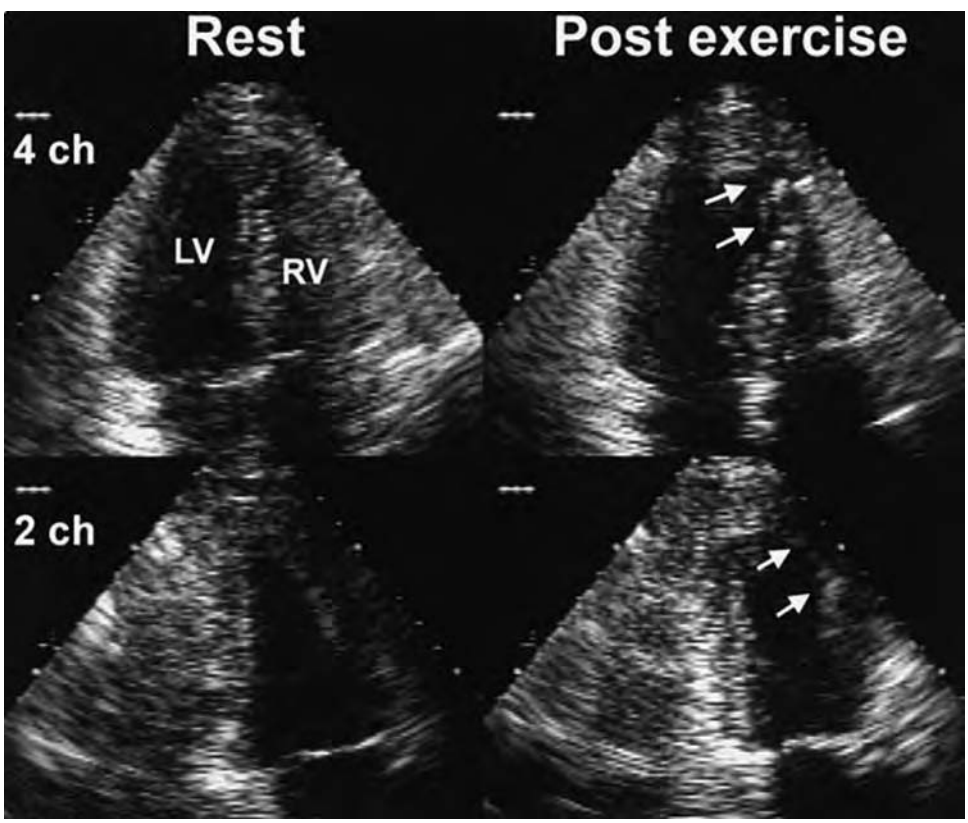

FIGURE e20-11 Still frame images demonstrating regional wall motion abnormalities during an exercise echocardiogram in a patient with known coronary artery disease. ***Left.*** The systolic frames in the resting state show symmetric contraction of all segments of the myocardium. The upper frame is from the apical four-chamber view and the lower frame is from the apical two-chamber view. ***Right.*** The systolic frames immediately after exercise show regional wall motion abnormalities in the anterior and apical segments (*arrows*). LV, left ventricle; RV, right ventricle *(From JK Oh et al: The Echo Manual, 2d ed. Philadelphia, Lippincott Williams & Wilkins, 1999, with permission.)*

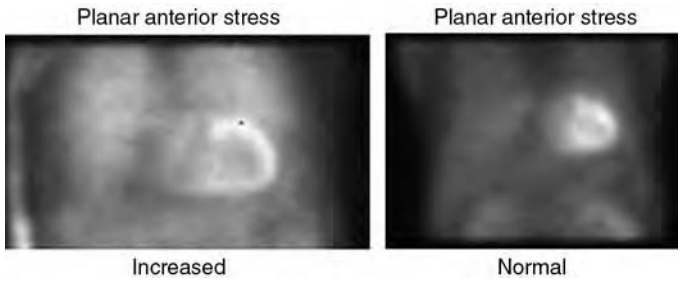

FIGURE e20-12 Anterior planar thallium images following stress, showing increased lung uptake on the left (count intensity in lung >50% of that in myocardium) and normal lung uptake on the right (count intensity in lung <50% of that in myocardium).

Increased lung uptake of thallium may be seen immediately after stress. It reflects increased pulmonary capillary wedge pressure and occurs in the presence of severe coronary artery disease and/or left ventricular dysfunction. It provides important adverse prognostic information that is incremental to other clinical, stress, and coronary angiographic variables.

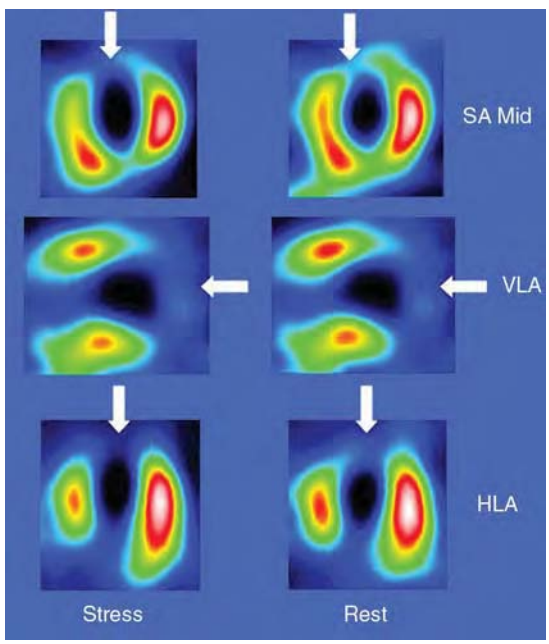

FIGURE e20-13 Adenosine ^{99m}Tc sestamibi scan in a 50-year-old male with a previous anterior infarct. The stress images (***left***) show a large defect involving the apex and anterior walls (*white arrows*) with little change from the rest images (*white arrows*), signifying a fixed defect without further ischemia during stress. SA, short axis in the middle of the left ventricle; VLA, vertical long axis; HLA, horizontal long axis.

The relative advantage of ^{201}Tl and ^{99m}Tc are detailed in **Table e20-1**. The better image quality and assessment of ventricular function permitted by ^{99m}Tc compounds have contributed to their more common use for stress imaging, although both ^{201}Tl- and ^{99m}Tc-labeled compounds provide clinically useful myocardial perfusion images in the majority of patients. A "dual-isotope" protocol is employed in some centers. This uses ^{201}Tl for the initial rest image and a ^{99m}Tc-labeled compound for the subsequent stress image, primarily for patient and scheduling convenience.

TABLE e20-1 RELATIVE ADVANTAGES OF THALLIUM 201 AND TECHNETIUM 99M

Thallium
Lower radiopharmaceutical cost
Measurement of increased pulmonary uptake
Less hepatobiliary and bowel uptake
Detection of resting ischemia (hibernating myocardium)
Technetium
Better image quality (particularly in obese patients)
Ventricular function assessment (gated SPECT)
Shorter imaging time
Shorter imaging protocols (patient/scheduling convenience)
Acute imaging in myocardial infarction and unstable angina
Superior quantification

SPECT, single photon emission computed tomography.

VIDEO e20-16 (Play video) MRI scan in real-time of a patient with a large left ventricular apical aneurysm. The long axis view demonstrates a thin dyskinetic apical aneurysm with preserved systolic function of the basal anterior and basal inferior wall.

TABLE 223-1 NORMAL VALUES FOR HEMODYNAMIC PARAMETERS

Pressures (mmHg)	
Systemic arterial	
Peak systolic/end-diastolic	100–140/60–90
Mean	70–105
Left ventricle	
Peak systolic/end-diastolic	100–140/3–12
Left atrium (or pulmonary capillary wedge)	
Mean	2–10
a wave	3–15
v wave	3–15
Pulmonary artery	
Peak systolic/end-diastolic	15–30/4–12
Mean	9–18
Right ventricle	
Peak systolic/end-diastolic	15–30/2–8
Right atrium	
Mean	2–8
a wave	2–10
v wave	2–10
Resistances [(dyn·s)/cm^5]	
Systemic vascular resistance	700–1600
Pulmonary vascular resistance	20–130
Cardiac index [(L/min)/m^2]	2.6–4.2
Oxygen consumption index [(L/min)/m^2]	110–150
Arteriovenous oxygen difference (mL/L)	30–50

determined by the nature of the clinical problem being evaluated, and the extent of information available from prior noninvasive evaluation of left ventricular and valvular function. Full left and right heart hemodynamic studies are generally reserved for patients in whom the noninvasive data are unclear, or in whom intra- and postprocedural hemodynamic monitoring of unstable circulatory status may be desired.

Right Heart Catheterization This procedure involves measurement of the pressures in the right side of the heart. It was once a routine component of cardiac catheterization but is now used in <25% of procedures, especially when significant left and/or right ventricular dysfunction, valve disease, myopericardial disease, or intracardiac shunting is suspected. The right heart catheterization procedure is similar to the placement of a Swan-Ganz catheter at the bedside (except that it is performed under fluoroscopic guidance). A balloon flotation catheter is inserted percutaneously into a suitable vein (femoral, brachial, subclavian, or internal jugular) and advanced sequentially into the right atrium, right ventricle, pulmonary artery, and pulmonary artery wedge position. Pressure is recorded at each of these locations, and after recording the pulmonary wedge pressure (which approximates left atrial pressure), the balloon is deflated so that blood samples can be obtained for oxygen saturation measurement to screen for intracardiac shunts and to estimate the cardiac output by the Fick principle (Table 223-1). Alternatively, the cardiac output may be estimated by the thermodilution method, using a thermistor on the catheter to analyze the temperature deviations in the pulmonary artery that occur following a 10-mL bolus injection of room-temperature IV solution into the right atrium.

Left Heart Catheterization This procedure may be performed by percutaneous access of the femoral, brachial, or radial arteries. The left heart catheter is advanced under fluoroscopic guidance into the central aorta and then retrograde across the aortic valve into the left ventricle. If a right heart catheter is in place, simultaneous measurement and recording of left heart, right heart, and peripheral arterial pressures, together with a determination of cardiac output by either thermodilution or the Fick method, can capture a comprehensive hemodynamic profile. When valvular stenosis is present, the measurements of the pressures in the upstream and downstream chambers (e.g., in the left ventricle and ascending aorta for aortic stenosis, or the pulmonary capillary wedge pressure and left ventricle in mitral stenosis) can be combined with the measurement of flow from the cardiac output measurement to allow calculation of the stenotic valve orifice area.

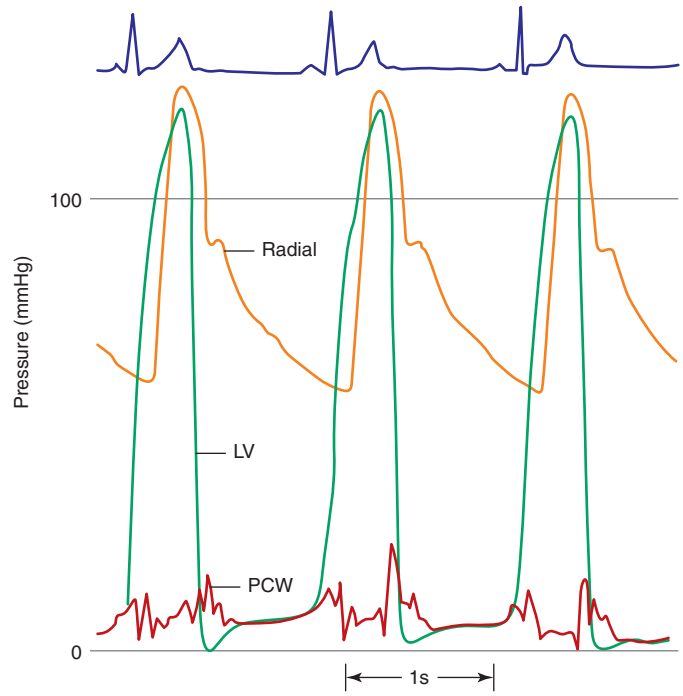

FIGURE 223-1 Left ventricular (LV), radial artery, and pulmonary capillary wedge (PCW) pressures in a patient with normal cardiovascular function. Note the absence of a pressure gradient between the LV and radial artery in systole and between the LV and PCW in diastole.

An example of normal pressure tracings is shown in Fig. 223-1. In contrast, the characteristic hemodynamic tracings of mitral stenosis, with a diastolic pressure gradient between the left atrium (or pulmonary capillary wedge pressure) and the left ventricle, is seen in Fig. 223-2, and the findings of significant mitral regurgitation with a prominent *v* wave in the pulmonary capillary wedge pressure that in-

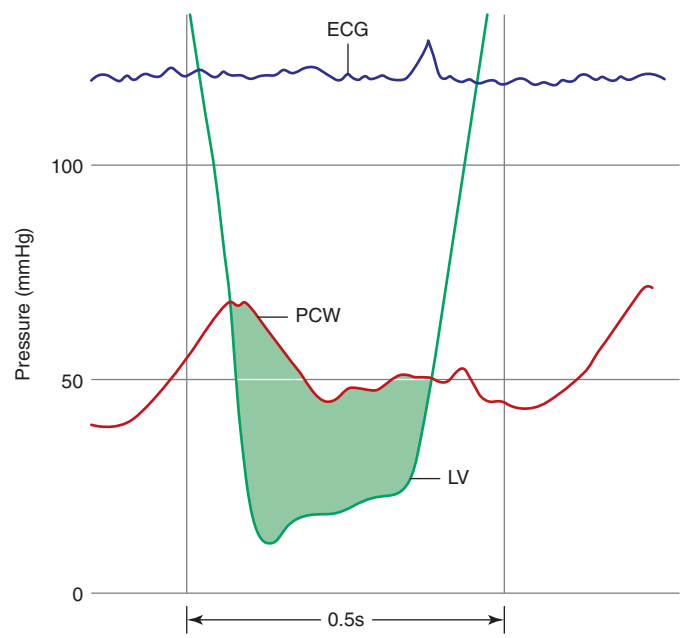

FIGURE 223-2 Pulmonary capillary wedge (PCW) and left ventricular (LV) pressure tracings in a 40-year-old woman with mitral stenosis. This patient also had systemic hypertension and significant elevation of her LV diastolic pressure. *[From BA Carabello, W Grossman, in Grossman's Cardiac Catheterization, Angiography, and Intervention, 7th ed, DS Baim (ed). Baltimore, Lippincott Williams & Wilkins, 2006.]*

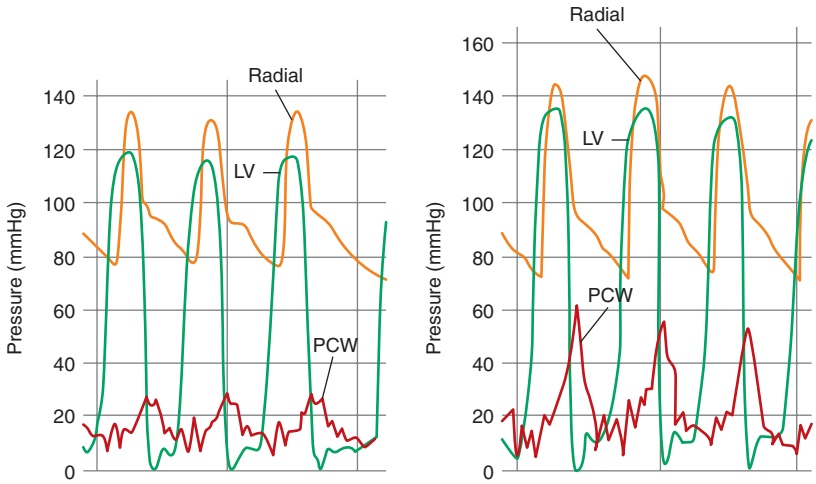

FIGURE 223-3 Hemodynamic findings at rest and during exercise in a patient with mitral regurgitation. Left ventricular (LV), pulmonary capillary wedge (PCW), and radial artery pressure tracings are shown before (*left*) and during (*right*) the sixth minute of supine bicycle exercise. PCW mean pressure and *v* wave increase substantially with exercise. *[From W Grossman, in Grossman's Cardiac Catheterization, Angiography, and Intervention, 7th ed, DS Baim (ed). Baltimore, Lippincott Williams & Wilkins, 2006.]*

creases substantially during modest exercise in Fig. 223-3. Severe *aortic stenosis* results in a systolic gradient between the left ventricular cavity and the ascending aorta, as shown in Fig. 223-4, while severe *aortic regurgitation* produces a widening of the aortic pulse pressure, with equilibration of aortic and left ventricular pressures in diastole as seen in Fig. 223-5. Valvular heart disease affecting the tricuspid or pulmonic valves results in similar deformities of the right-sided pressures, i.e., in patients with severe *tricuspid regurgitation*, the right atrial pressure resembles the right ventricular pressure closely in appearance, while in *tricuspid stenosis*, there is a pressure gradient between the right atrium and ventricle during diastole.

LEFT VENTRICULAR AND AORTIC ANGIOGRAPHY

If left ventricular size and function have not been previously assessed by noninvasive means, left ventriculography may be performed by power injection through a suitable catheter (usually a pigtail shape) of 30 to 45 mL of radiographic contrast material into the left ventricular chamber at a rate of 10–12 mL/s. The resulting radiographic images define the left ventricular cavity silhouette throughout the cardiac cycle, and tracing of that silhouette at end-diastole and end-systole permits calculation of the absolute left ventricular chamber volumes and the ejection fraction (the fraction of end diastolic volume ejected during systole; normally 50–80%), as well as qualitative assessment of regional wall motion abnormalities. Regional abnormalities of wall motion include diminished inward motion of a myocardial segment (*hypokinesis*), absence of inward movement of a myocardial segment (*akinesis*), and paradoxical systolic expansion of a regional myocardial segment (*dyskinesis*) (Fig. 223-6).

Mitral regurgitation is also easily visualized during left ventriculography as the leakage of radiographic contrast material back into the left atrium during left ventricular systole (Fig. 223-7). Its severity can be estimated qualitatively using a grading system of 1+ (mild; radio-

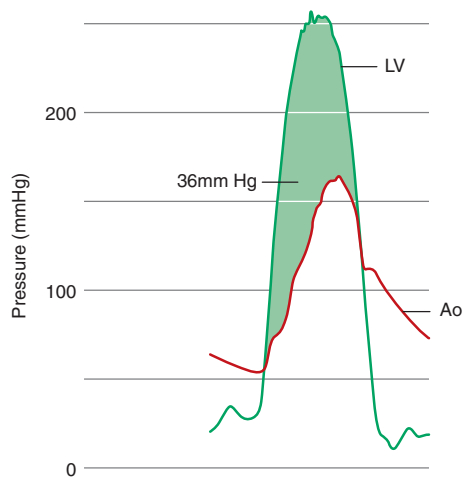

FIGURE 223-4 Severe aortic stenosis. Hemodynamic findings show the left ventricular (LV), and aortic (Ao) pressure with a slow systolic rise and large (96 mmHg) systolic gradient (shaded area) corresponding to critical aortic stenosis (aortic valve area 0.5 cm^2). *[From BA Carabello, W Grossman, in Grossman's Cardiac Catheterization, Angiography, and Intervention, 7th ed, DS Baim (ed). Baltimore, Lippincott Williams & Wilkins, 2006.]*

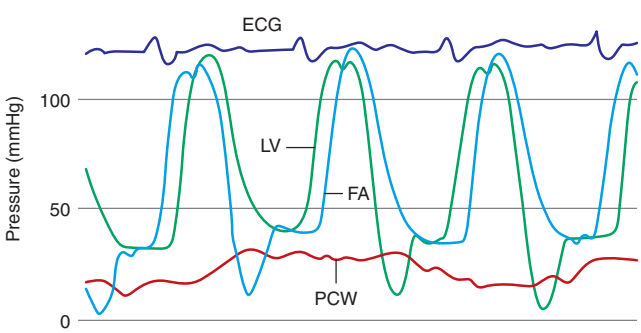

FIGURE 223-5 Severe aortic regurgitation. There is equilibration between the left ventricular (LV) and aortic or femoral artery (FA) pressures in diastole. Also, LV diastolic pressure exceeds pulmonary capillary wedge (PCW) pressure early in diastole, indicating premature closure of the mitral valve (a characteristic feature of severe aortic regurgitation). *[From W Grossman, in Grossman's Cardiac Catheterization, Angiography, and Intervention, 7th ed, DS Baim, W Grossman (eds). Baltimore, Lippincott Williams & Wilkins, 2006.]*

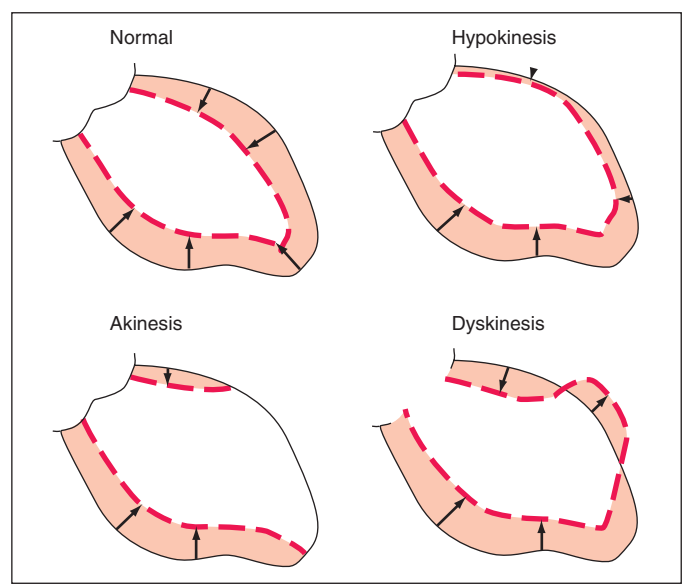

FIGURE 223-6 Diagrammatic representation of end-diastolic (*solid line*) and end-systolic (*dashed line*) silhouettes of left ventricular cineangiograms. These represent various forms of localized wall motion disorder in patients with coronary heart disease. Normal wall motion is symmetric; a patient with *hypokinesis* exhibits reduced contraction, seen here over the anterior and apical surfaces; a patient with *akinesis* exhibits absent wall motion, seen here over the anteroapical surface; a patient with *dyskinesis* exhibits paradoxic bulging of a small portion of the anterior wall with systole.

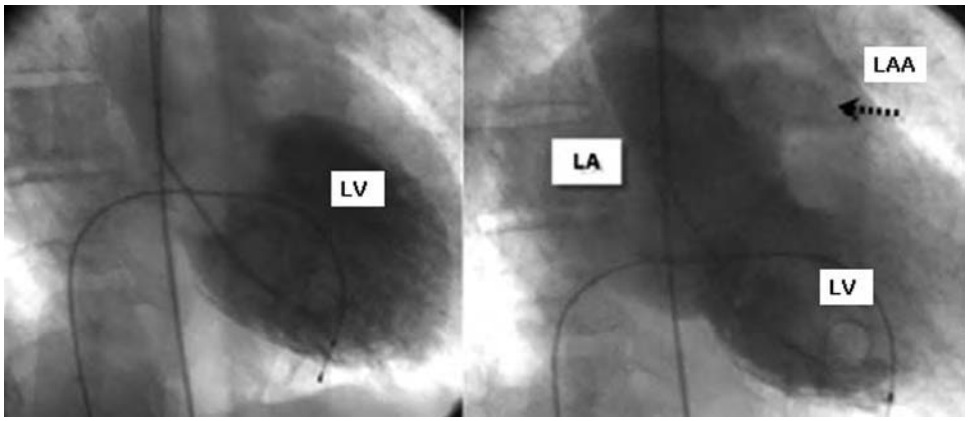

FIGURE 223-7 Left ventricular angiogram showing end-diastole (*left*) and end-systole (*right*). Left ventricular ejection fraction remains normal, but the calculated ventricular volumes are increased, due to severe chronic mitral regurgitation [note dense opacification of the left atrium (LA) and left atrial appendage (*arrow*) on the systolic frame]. *[From D Baim, in Grossman's Cardiac Catheterization, Angiography, and Intervention, 7th ed, DS Baim (ed). Baltimore, Lippincott Williams & Wilkins, 2006.]*

graphic contrast material clears with each beat and never opacifies the entire left atrium) to 4+ (severe; opacification of the entire left atrium occurs within one beat, and contrast material can be seen refluxing into the pulmonary veins).

Aortography involves rapid injection of radiographic contrast material into the ascending aorta, to detect abnormalities of the ascending aorta and aortic valve. It allows qualitative assessment abnormalities such as aortic regurgitation, which is graded using a 1+ to 4+ scale, similar to that used for mitral regurgitation (see above). Aortography can permit identification of aortic aneurysm and/or aortic dissection in which external compression of the aortic true lumen is caused by displacement of an intimal flap separating the true and false aortic lumina (Chap. 242). Aortography may also be used to identify the origin of patent saphenous vein grafts which cannot be cannulated selectively and have not been identified by the cardiac surgeon by placement of a radiopaque marker at the graft origin.

CORONARY ANGIOGRAPHY

While the aspects of cardiac catheterization described above may be performed in specific clinical situations, the essence of modern catheterization is high-quality coronary angiography. The tips of specially shaped catheters are placed into the left and then the right coronary artery, and any surgical bypass grafts, under fluoroscopic guidance. Hand injection of a radiographic contrast agent allows opacification of their lumina, with those images recorded at 15 frames per second on a radiographic image (*cine angiography*). Each coronary artery is usually viewed in several projections to permit assessment of the location and severity of any stenosis relative to the adjacent "normal" vessel segments (Fig. 223-8). In addition to the detection of coronary artery stenoses, coronary angiography evaluates the rapidity of coronary flow, the blush of capillary filling in the myocardium, collateral pathways that perfuse myocardial territories supplied by an occluded vessel, the presence of congenital abnormalities of the coronary circulation (e.g., coronary fistulae), and patency of any previously constructed coronary artery bypass grafts.

The degree of stenosis is typically evaluated by visual estimation of percent diameter stenosis of each lesion relative to the "uninvolved" adjacent reference segment, with 50% diameter stenosis representing the minimal lesion severity that is capable of interfering with maximal increases in perfusion of the related myocardial territory during stress (Fig. 223-9). Borderline lesions (i.e., those between 40 and 70% diameter stenosis) that are not clearly related to the clinical ischemic syndrome may be further assessed by the following: (1) measurement of the pressure gradient between the segments proximal and distal to the stenosis; (2) measurement of the increase in distal coronary blood flow during maximal coronary vasodilatation using adenosine; and (3) use of intravascular ultrasound (IVUS), which has the advantage of imaging the underlying plaque as well as precisely measuring the luminal cross-sectional area at the point of a borderline lesion. Despite recent progress in multidetector computed tomography (MDCT) that suggests this evolving technique (Chap. 222) may ultimately replace screening pre-surgical coronary angiography (Fig. 223-10), coronary arteriography remains the most definitive diagnostic tool for evaluation of the *coronary anatomy* with sufficient precision to inform deci-

sions regarding coronary surgery vs. catheter-based interventions in patients with CAD.

POSTPROCEDURE CARE

The average diagnostic cardiac catheterization procedure takes ~30 min and ~60 mL of contrast (increased to ~90 mL by contrast left ventriculography). No anticoagulant agents are usually administered for a purely diagnostic procedure, and the vascular sheaths are removed at the end of the procedure. Hemostasis may be achieved by applying local pressure over the puncture site for 10–15 min, followed by a 2- to 4-h period of bed rest before ambulation and discharge. Alternatively, a variety of vascular closure devices (sutures or external clips or collagen plugs) are now available to seal the arterial puncture site, allowing a shorter period of bed rest and earlier ambulation. Most patients with suitable anatomy, however, will go on seamlessly to undergo PCI following the diagnostic catheterization procedure before the sheaths are removed, followed by an overnight hospital stay (Chap. 240).

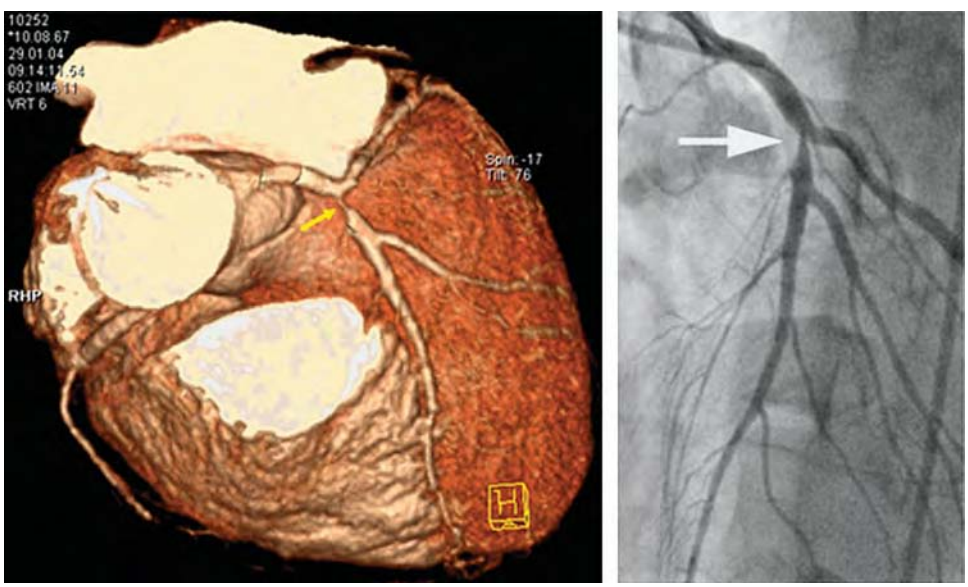

FIGURE 223-10 Comparison of 64-slice multidetector CT imaging to contrast coronary angiography in a patient with severe stenosis of the proximal left anterior descending (*arrow*). This technique may supplant screening coronary angiography in patients who do not have clinical indications for percutaneous coronary intervention. *(Images provided by Thomas J. Brady, M.D.)*

224 Principles of Electrophysiology

Gordon F. Tomaselli

HISTORY AND INTRODUCTION

The field of cardiac electrophysiology was ushered in with the development of the electrocardiogram (ECG) by Einthoven at the turn of the twentieth century. The recording of cellular membrane currents revealed that the body surface ECG is the timed sum of the cellular action potentials in the atria and ventricles. In the late 1960s, the development of intracavitary recording, and in particular the ability to record His bundle electrograms with programmed stimulation of the heart, marked the beginning of contemporary clinical electrophysiology. Adoption of radiofrequency technology to ablate cardiac tissue in the early 1990s heralded the birth of interventional cardiac electrophysiology.

The clinical problem of sudden death caused by ventricular arrhythmias, most commonly in the setting of coronary obstruction, was recognized as early as the late nineteenth century. The problem was vexing and led to the development of pharmacologic and nonpharmacologic therapies, including transthoracic defibrillators, cardiac massage, and, most recently, implantable defibrillators. Over time the limitations of antiarrhythmic drug therapy have been repeatedly highlighted in clinical trials, such that ablation and devices are first-line therapy for a number of cardiac arrhythmias.

In the past decade the genetic basis of a number of heritable arrhythmias has been elucidated, revealing important insights into the mechanisms not only of these rare arrhythmias, but also of similar rhythm disturbances observed in more common forms of heart disease.

DESCRIPTIVE PHYSIOLOGY

The normal cardiac impulse is generated by pacemaker cells in the sinoatrial node located at the junction of the right atrium and superior vena cava (see Fig. 221-1). This impulse is slowly transmitted through nodal tissue to the anatomically complex atria, where it is more rapidly conducted to the atrioventricular node (AVN) inscribing the P wave of the ECG (see Fig. 221-2). There is a perceptible delay in conduction through the anatomically and functionally heterogeneous AVN. The time needed for activation of the atria and the AVN delay is represented as the PR interval of the ECG. The AVN is the only electrical connection between the atria and ventricles in the normal heart. The electrical impulse emerges from the AVN and is transmitted to the His-Purkinje system, specifically the common bundle of His, then the left and right bundle branches, and thence to the Purkinje network, facilitating activation of ventricular muscle. Under normal circumstances, the ventricles are rapidly activated in a well-defined fashion that is determined by the course of the Purkinje network and inscribes the QRS complex (see Fig. 221-2). Recovery of electrical excitability occurs more slowly and is governed by the time of activation and duration of regional action potentials. The relative brevity of epicardial action potentials in the ventricle results in repolarization occurring first on the epicardial surface then proceeding to the endocardium, which inscribes a T wave normally of the same polarity as the QRS complex. The duration of activation and recovery is determined by the action potential duration represented on the body surface ECG by the QT interval (see Fig. 221-2).

The gross anatomic features of the heart—the extracellular matrix and intramural vasculature—create both macro- and microanatomic barriers that are central to both the normal electrophysiology of the heart and clinically important arrhythmias. Cardiac myocytes exhibit a characteristically long action potential (200–400 ms) compared to neurons or skeletal muscle cells (1–5 ms). The action potential profile is sculpted by the orchestrated activity of multiple distinctive time- and voltage-dependent ionic currents (Fig. 224-1*A*). The currents, in turn, are carried by complex transmembrane proteins that passively conduct ions down their electrochemical gradients through selective pores (ion channels), actively transport ions against their electro-

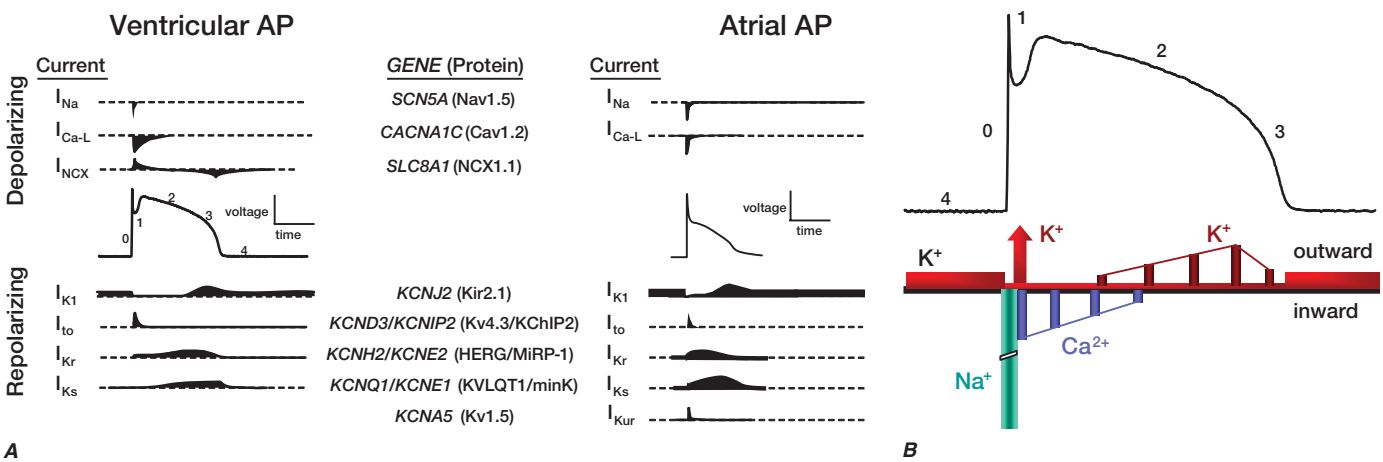

FIGURE 224-1 ***A.*** Cellular atrial and ventricular action potentials. Schematic atrial and ventricular action potentials with the phases are shown in the top portion of the figure. Phases 0–4 are the rapid upstroke, early repolarization, plateau, late repolarization, and diastole respectively. The ionic currents and the genes that generate the currents with schematics of the current trajectories are shown above and below the action potentials. The active currents and their densities vary in atrial and ventricular myocytes. ***B.*** A ventricular action potential with a schematic of the ionic currents flowing during the phases of the action potential. Potassium current (I_{K1}) is the principal current during phase 4 and determines the resting membrane potential of the myocyte. Sodium current generates the upstroke of the action potential (phase 0), activation of I_{to} with inactivation of the Na current inscribes early repolarization (phase 1). The plateau phase (2) is generated by a balance of repolarizing potassium currents and depolarizing calcium current. Inactivation of the calcium current with persistent activation of potassium currents (predominantly I_{Kr} and I_{Ks}) cause phase 3 repolarization.

chemical gradient (pumps, transporters), or electrogenically exchange ionic species (exchangers).

Action potentials in the heart are regionally distinct. The regional variability in cardiac action potentials is the result of differences in the number and types of ion channel proteins expressed by different cell types in the heart. Further, unique sets of ionic currents are active in pacemaking and muscle cells, and the relative contributions of these currents may vary in the same cell type in different regions of the heart (Fig. 224-1*A*).

Ion channels are complex, multisubunit transmembrane glycoproteins that open and close in response to a number of biologic stimuli, including a change in membrane voltage, ligand binding (directly to the channel or to a G protein–coupled receptor), and mechanical deformation (Fig. 224-2). Other ion motive transmembrane proteins, such as exchangers and transporters, contribute importantly to cellular excitability in the heart. Ion pumps establish and maintain the ionic gradients across the cell membrane that serve as the driving force for current flow through ion channels. Transporters or exchangers that do not move ions in an electrically neutral manner (e.g., the sodium-calcium exchanger transports three Na^+ for one Ca^{2+}) are termed *electrogenic*, and contribute directly to the action potential profile.

The most abundant superfamily of ion channels expressed in the heart is voltage-gated. Several structural themes are common to all voltage-dependent ion channels. First, the architecture is modular, consisting either of four homologous subunits (e.g., K^+ channels) or of four internally homologous domains (e.g., Na^+ and Ca^{2+} channels). Second, the proteins fold around a central pore lined by amino acids that exhibit exquisite conservation within a given channel family of like selectivity (e.g., jellyfish, eel, fruit fly, and human Na channels have very similar P segments). Third, the general strategy for activation gating (opening and closing in response to changes in membrane voltage) is highly conserved: the fourth transmembrane segment (S4), studded with positively charged residues, lies within the membrane field and moves in response to depolarization, opening the channel. Fourth, most ion channel complexes include not only the pore-forming proteins (α subunits) but also auxiliary subunits (e.g., β subunits) that modify channel function (Fig. 224-2).

Na^+ and Ca^{2+} channels are the primary carriers of depolarizing current in both the atrium and ventricles; inactivation of these currents and activation of repolarizing K^+ currents hyperpolarize the heart cell, reestablishing the negative resting membrane potential (Fig. 224-1*B*). The *plateau phase* is a time when little current is flowing, and relatively minor changes in depolarizing or repolarizing currents can have profound effects on the action potential shape and duration. Mutations in subunits of these channel proteins produce arrhythmogenic alterations in the action potentials that cause long and short QT syndrome, idiopathic ventricular fibrillation, familial atrial fibrillation, and some forms of conduction system disease.

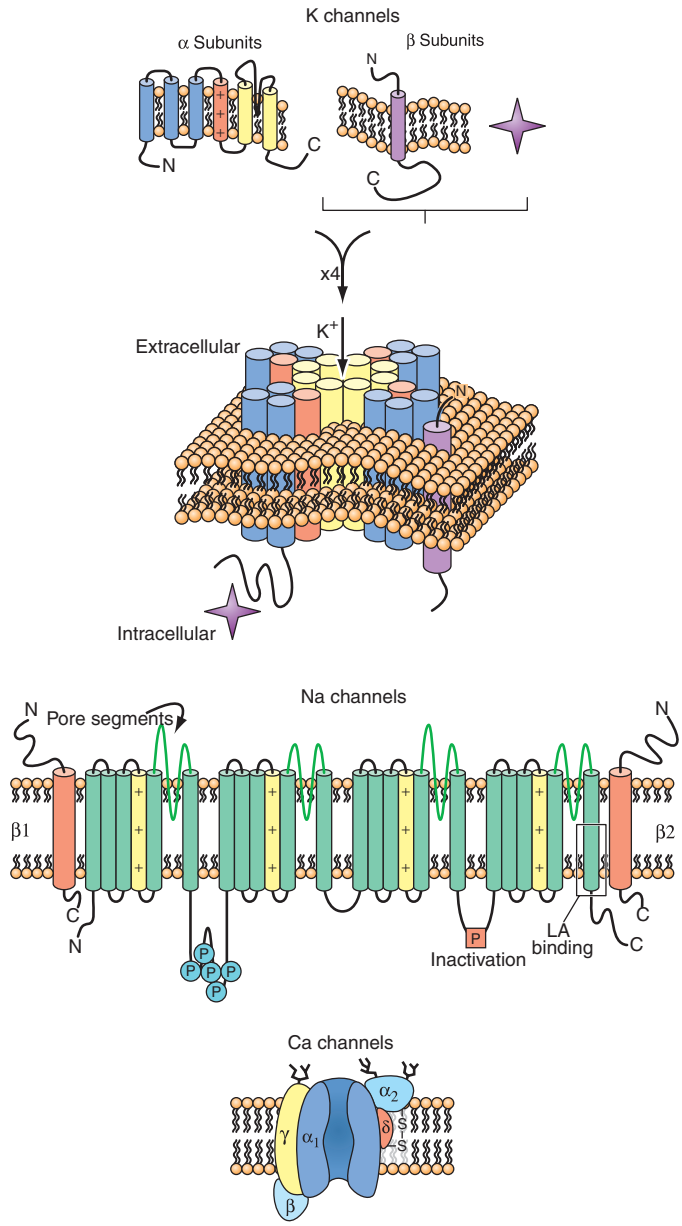

FIGURE 224-2 Topology and subunit composition of the voltage dependent ion channels. (***Top panel***) Potassium channels are formed by the tetramerization of α or pore-forming subunits and one or more β subunits, only single β subunits are shown for clarity. (***Bottom panel***) Sodium and calcium channels are composed of α subunits with four homologous domains and one or more ancillary subunits. In all channel types the loop of protein between the fifth and sixth membrane spanning repeat in each subunit or domain forms the ion-selective pore. In the case of the sodium channel, the channel is a target for phosphorylation, the linker between the third and fourth homologous domain is critical to inactivation, and the sixth membrane-spanning repeat in the fourth domain is important in local anesthetic antiarrhythmic drug binding.

MECHANISMS OF CARDIAC ARRHYTHMIAS

Cardiac arrhythmias result from abnormalities of impulse generation, conduction, or both. It is, however, difficult to establish with certainty an underlying mechanism for many clinical arrhythmias. The response of a tachycardia to pacing (initiation, termination, entrainment) is used in the clinical electrophysiology laboratory to make the diagnosis of reentry. There are even fewer specific tools available to diagnose non-reentrant arrhythmias. It is clear that molecular changes in the heart predispose to the development of abnormalities of cardiac rhythm. However, an exclusively molecular approach to understanding arrhythmia mechanisms is limited by failure to include cellular and network properties of the heart. A summary of the cellular and molecular changes that underlie prototypic arrhythmias and their putative mechanisms is shown in Table 224-1.

Alterations in Impulse Initiation: Automaticity Spontaneous (phase 4) diastolic depolarization underlies the property of automaticity (pacemaking) characteristic of cells in the sinoatrial (SA) and atrioventricular (AV) nodes, His-Purkinje system, coronary sinus, and pulmonary veins. Phase 4 depolarization results from the concerted action of a number of ionic currents including the inward rectifier (I_{K1}) and delayed rectifier (rapid I_{Kr} and slow I_{Ks} components) K^+ currents, Ca^{2+} currents, electrogenic Na^+,K^+-ATPase, the Na^+-Ca^{2+} exchanger, and the so-called funny, or pacemaker, current (I_f); however, the relative importance of these currents remains controversial.

The rate of phase 4 depolarization and, therefore, the firing rate of pacemaker cells are dynamically regulated. Prominent among the factors that modulate phase 4 is autonomic nervous system tone. The

TABLE 224-1 ARRHYTHMIA MECHANISMS

Electrophysiologic Property	Molecular Components	Mechanism	Prototypic Arrhythmias
Cellular			
Impulse Initiation			
Automaticity	I_f, $I_{Ca\text{-}L}$, $I_{Ca\text{-}T}$, I_K, I_{K1}	Suppression/acceleration of phase 4	Sinus bradycardia, sinus tachycardia
Triggered automaticity	Calcium overload, I_{TI}	DADs	Digitalis toxicity, reperfusion VT
	$I_{Ca\text{-}L}$, I_K, I_{Na}	EADs	Torsades des pointes, congenital and acquired
Excitation	I_{Na}	Suppression of phase 0	Ischemic VF
	$I_{K\text{-}ATP}$	AP shortening, inexcitability	
	$I_{Ca\text{-}L}$	Suppression	AV block
Repolarization	I_{Na}, $I_{Ca\text{-}L}$, I_K, I_{K1}, Ca^{2+} homeostasis	AP prolongation, EADS, DADs	Polymorphic VT (HF, LVH)
	$I_{Ca\text{-}L}$, K channels, Ca^{2+} homeostasis	AP shortening	Atrial fibrillation
Multicellular			
Cellular coupling	Connexins (Cx43), I_{Na}, $I_{K\text{-}ATP}$	Decreased coupling	Ischemic VT/VF
Tissue Structure	Extracellular matrix, collagen	Excitable gap and functional reentry	Monomorphic VT, atrial fibrillation

Note: DAD, delayed afterdepolarization; VT, ventricular tachyarrhythmia; IVR, idioventricular rhythm; EAD, early afterdepolarization; VF, ventricular fibrillation; AV, atrioventricular; HF, heart failure; AP, action potential.

negative chronotropic effect of activation of the parasympathetic nervous system is the result of release of acetylcholine that binds to muscarinic receptors, releasing G protein βγ subunits that activate a potassium current (I_{KACh}) in nodal and atrial cells. The resulting increase in K^+ conductance opposes membrane depolarization, slowing the rate of rise of phase 4 of the action potential. Conversely, augmentation of sympathetic nervous system tone increases myocardial catecholamine concentrations, which activate both α and β receptors. The effect of β_1-adrenergic stimulation predominates in pacemaking cells, augmenting both L-type Ca current ($I_{Ca\text{-}L}$) and I_f, thus increasing the slope of phase 4. Enhanced sympathetic nervous system activity can dramatically increase the rate of firing of SA nodal cells, producing sinus tachycardia with rates >200 beats/min. By contrast, the increased rate of firing of Purkinje cells is more limited, rarely producing ventricular tachyarrhythmias >120 beats/min.

Normal automaticity may be affected by a number other factors associated with heart disease. Hypokalemia and ischemia may reduce the activity of the Na^+,K^+-ATPase, thereby reducing the background repolarizing current and enhancing phase 4 diastolic depolarization. The end result would be an increase in the spontaneous firing rate of pacemaking cells. Modest increases in extracellular potassium may render the maximum diastolic potential more positive, thereby also increasing the firing rate of pacemaking cells. A more significant increase in $[K^+]_o$, however, renders the heart inexcitable by depolarizing the membrane potential.

Normal or enhanced automaticity of subsidiary latent pacemakers produces escape rhythms in the setting of failure of more dominant pacemakers. Suppression of a pacemaker cell by a faster rhythm leads to an increased intracellular Na^+ load ($[Na^+]_i$), and extrusion of Na^+ from the cell by the Na^+,K^+-ATPase produces an increased background repolarizing current that slows phase 4 diastolic depolarization. At slower rates, the $[Na^+]_i$ is decreased, as is the activity of the Na^+,K^+-ATPase, resulting in progressively more rapid diastolic depolarization and warm-up of the tachycardia rate. Overdrive suppression and warm-up are characteristic of, but may not be observed in, all automatic tachycardias. Abnormal conduction into tissue with enhanced automaticity (*entrance block*) may blunt or eliminate the phenomena of overdrive suppression and warm-up of automatic tissue.

Abnormal automaticity may underlie atrial tachycardia, accelerated idioventricular rhythms, and ventricular tachycardia, particularly that associated with ischemia and reperfusion. It has also been suggested that injury currents at the borders of ischemic myocardium may depolarize adjacent non-ischemic tissue, predisposing to automatic ventricular tachycardia.

Afterdepolarizations and Triggered Automaticity Triggered automaticity or activity refers to impulse initiation that is dependent on afterdepolarizations (Fig. 224-3). Afterdepolarizations are membrane voltage oscillations that occur during (early afterdepolarizations, EAD) or following (delayed afterdepolarization, DADs) an action potential.

The cellular feature common to the induction of DADs is the presence of increased Ca^{2+} load in the cytosol and sarcoplasmic reticulum. Inhibition of the Na^+,K^+-ATPase by digitalis glycosides facilitates, but is not necessary for creating, the Ca^{2+} overload that predisposes to DADs. Catecholamines and ischemia sufficiently enhance Ca^{2+} loading to produce DADs. Accumulation of lysophospholipids in ischemic myocardium with consequent Na^+ and Ca^{2+} overload has been suggested as a mechanism for DADs and triggered automaticity. Cells from damaged areas or surviving a myocardial infarction may display spontaneous release of calcium from the sarcoplasmic reticulum, and this may generate "waves" of intracellular calcium elevation and arrhythmias.

EADs occur during the action potential and interrupt the orderly repolarization of the myocyte. It has been traditionally held that, unlike DADs, EADs do not depend on a rise in intracellular Ca^{2+}, and that, instead, action potential prolongation and reactivation of depolarizing currents are fundamental to their production. More recent experimental evidence suggests a previously unappreciated interrelationship between intracellular calcium loading and EADs. Cytosolic calcium may increase when action potentials are prolonged. This, in turn, appears to enhance L-type Ca current, further prolonging action potential dura-

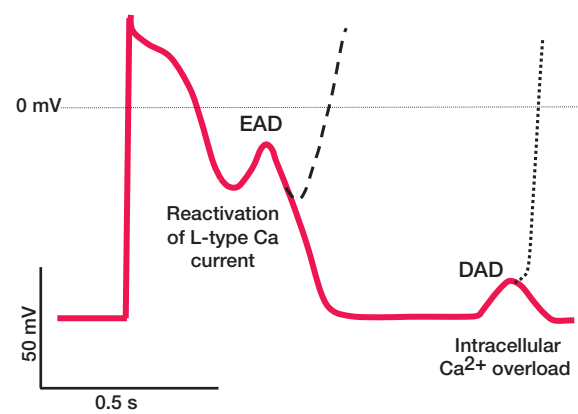

FIGURE 224-3 Schematic action potentials with early (EAD) and delayed afterdepolarizations (DAD). Afterdepolarizations are spontaneous depolarizations in cardiac myocytes. EADs occur before the end of the action potential (phases 2 and 3), interrupting repolarization. DADs occur during phase 4 of the action potential after completion of repolarization. The cellular mechanisms of EADs and DADs differ (see text).

tion as well as providing the inward current driving EADs. Intracellular calcium loading by action potential prolongation may also enhance the likelihood of DADs. The interrelationship among intracellular $[Ca^{2+}]$, EADs, and DADs may be one explanation for the susceptibility of hearts that are calcium loaded (e.g., in ischemia or congestive heart failure) to develop arrhythmias, particularly on exposure to action potential–prolonging drugs.

EAD-triggered arrhythmias exhibit rate dependence. In general, the amplitude of an EAD is augmented at slow rates when action potentials are longer. Rapid pacing will shorten the action potential duration and reduce EAD amplitude, likely due to augmentation of delayed rectifier K^+ currents and, perhaps, hastening of Ca^{2+}-induced inactivation of L-type Ca currents. Similarly, catecholamines increase heart rate and decrease action potential duration and EAD amplitude, despite the well-described effect of β-adrenergic stimulation on increasing L-type Ca current. A fundamental condition that underlies the development of EADs is action potential and QT prolongation. Hypokalemia, hypomagnesemia, bradycardia, and, most commonly, drugs can predispose to the generation of EADs, invariably in the context of prolonging the action potential. Antiarrhythmics with class IA and III action (see below) produce action potential and QT prolongation intended to be therapeutic, but frequently causing arrhythmias. Noncardiac drugs, such as phenothiazines, nonsedating antihistamines, and some antibiotics can also prolong the action potential duration and predispose to EAD-mediated triggered arrhythmias. Decreased $[K^+]_o$ may paradoxically decrease membrane potassium currents (particularly I_{Kr}) in the ventricular myocyte, explaining why hypokalemia causes action potential prolongation and EADs. In fact, potassium infusions in patients with the congenital long QT syndrome (LQTS) and in those with drug-induced acquired QT prolongation shorten the QT interval.

EAD-mediated triggered activity likely underlies initiation of the characteristic polymorphic ventricular tachycardia, *torsades des pointes*, seen in patients with congenital and acquired forms of the LQTS. Structural heart disease, such as cardiac hypertrophy and failure, may also delay ventricular repolarization (so-called electrical remodeling) and predispose to arrhythmias related to abnormalities of repolarization. The abnormalities of repolarization in hypertrophy and failure are often magnified by concomitant drug therapy or electrolyte disturbances.

Abnormal Impulse Conduction: Reentry The most common arrhythmia mechanism is reentry. Reentry is a property of networks of myocytes. Fundamentally, reentry is defined as circulation of an activation wave around an inexcitable obstacle. Thus, the requirements for reentry are two electrophysiologically dissimilar pathways for impulse propagation around an inexcitable region such that unidirectional block occurs in one of the pathways and a region of excitable tissue exists at the head of the propagating wavefront (Fig. 224-4). Structural and electrophysiologic properties of the heart may contribute to the development of the inexcitable obstacle and of unidirectional block. The complex geometry of muscle bundles in the heart and spatial heterogeneity of cellular coupling or other active membrane properties (i.e., ionic currents) appear to be critical.

A key feature in classifying reentrant arrhythmias, particularly for therapy, is the presence and size of an excitable gap. An excitable gap exists when the tachycardia circuit is longer than the tachycardia wavelength (λ = conduction velocity × refractory period, representing the size of the circuit that can sustain reentry), allowing appropriately timed stimuli to reset propagation in the circuit. Reentrant arrhythmias may exist in the heart in the absence of an excitable gap and with a tachycardia wavelength nearly the same size as the path length. In this case, the wavefront propagates through partially refractory tissue with no anatomic obstacle and no fully excitable gap; this is referred to as *leading circle reentry*, a form of functional reentry (reentry that depends on functional properties of the tissue). Unlike excitable gap reentry, there is no fixed anatomic circuit in leading circle reentry, and it may therefore not be possible to disrupt the tachycardia with pacing or destruction of a part of the circuit. Furthermore, the circuit in leading

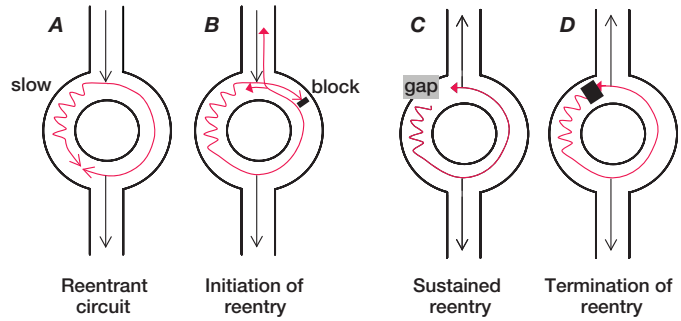

FIGURE 224-4 Schematic diagram of reentry. *A.* The circuit comprises two limbs, one with slow conduction. ***B.*** A premature impulse blocks in the fast pathway and conducts over the slow pathway, allowing the fast pathway to recover so that the activation wave can reenter the fast pathway from the retrograde direction. ***C.*** During sustained reentry utilizing such a circuit, a gap (excitable gap) exists between the activating head of the wave and the recovering tail. ***D.*** One mechanism of termination of reentry is when the conduction and recovery characteristics of the circuit change, and the activating head of the wave collides with the tail, extinguishing the tachycardia.

circle reentry tends to be less stable than that in excitable gap reentrant arrhythmias, with large variations in cycle length and predilection to termination.

Anatomically determined, excitable gap reentry can explain several clinically important tachycardias, such as AV reentry, atrial flutter, bundle branch reentry ventricular tachycardia, and ventricular tachycardia in scarred myocardium. Atrial flutter represents an example of a reentrant tachycardia with a large excitable gap not always due to an anatomic constraint but to functional block (reflecting the special properties of the crista terminalis discussed above). There is strong evidence to suggest that arrhythmias, such as atrial and ventricular fibrillation, are associated with more complex activation of the heart and are due to functional reentry.

Structural heart disease is associated with changes in conduction and refractoriness that increase the risk of reentrant arrhythmias. Chronically ischemic myocardium exhibits a down-regulation of the gap junction channel protein (connexin 43) that carries intercellular ionic current. The border zones of infarcted and failing ventricular myocardium exhibit not only functional alterations of ionic currents but also remodeling of tissue and altered distribution of gap junctions. The changes in gap junction channel expression and distribution, in combination with macroscopic tissue alterations, support a role for slowed conduction in reentrant arrhythmias that complicate chronic coronary artery disease. Aged human atrial myocardium exhibits altered conduction, manifest as highly fractionated atrial electrograms, producing an ideal substrate for the reentry that may underlie the very common development of atrial fibrillation in the elderly.

APPROACH TO THE PATIENT: Cardiac Arrhythmia

The evaluation of patients with suspected cardiac arrhythmias is highly individualized; however, two key features, the history and ECG, are pivotal in directing the diagnostic workup and therapy. Patients with cardiac arrhythmias exhibit a wide spectrum of clinical presentations from asymptomatic ECG abnormalities to survival from cardiac arrest. In general, the more severe the presenting symptoms, the more aggressive are the evaluation and treatment. Loss of consciousness that is believed to be of cardiac origin typically mandates an exhaustive search for the etiology and often requires invasive, device-based therapy. The presence of structural heart disease and prior myocardial infarction dictates a change in the approach to the management of syncope or ventricular arrhythmias. The presence of a family history of serious ventricular

arrhythmias or premature sudden death will influence the evaluation of presumed heritable arrhythmias.

The physical examination is focused on determining if there is cardiopulmonary disease that is associated with specific cardiac arrhythmias. The absence of significant cardiopulmonary disease often, but not always, suggests benignity of the rhythm disturbance. In contrast, palpitations, syncope, or near syncope in the setting of significant heart or lung disease has more ominous implications. In addition, the physical examination may reveal the presence of a persistent arrhythmia such as atrial fibrillation.

The judicious use of noninvasive diagnostic tests is an important element in the evaluation of patients with arrhythmias, and there is none more important that the ECG, particularly if recorded at the time of symptoms. Uncommon but diagnostically important signatures of electrophysiologic disturbances may be unearthed on the resting ECG, such as delta waves in Wolff-Parkinson-White (WPW) syndrome, prolongation or shortening of the QT interval, right precordial ST-segment abnormalities in Brugada syndrome, and epsilon waves in arrhythmogenic right ventricular dysplasia. Variants of body surface ECG recording can provide important information about arrhythmia substrates and triggers. Holter monitoring and event recording, either continuous or intermittent, record the body surface ECG over longer periods of time, enhancing the possibility of observing the cardiac rhythm during symptoms. Implantable long-term monitors and commercial ambulatory ECG monitoring services exist that permit prolonged telemetric monitoring for both diagnosis and to assess the efficacy of therapy.

Long-term recordings permit the assessment of the time-varying behavior of the heart rhythm. Heart rate variability (HRV) and QT interval variability (QTV) provide noninvasive methods to assess autonomic nervous system influence on the heart. HRV arises because of subtle changes in sinus rate due to changes in sympathovagal input to the sinus node. Normal time domain, frequency domain, and geometric methods metrics have been established for HRV; a decrease in HRV and an increase in low-frequency power have been associated with increased sympathetic nervous system tone and increased mortality in patients after myocardial infarction. Signal-averaged electrocardiography (SAECG) uses signal-averaging techniques to amplify small potentials in the body surface ECG that are associated with slow conduction in the myocardium. The presence of these small potentials, referred to as *late potentials* because of their timing with respect to the QRS complex, and prolongation of the filtered (or averaged) QRS duration are indicative of slowed conduction in the ventricle and have been associated with an increased risk of ventricular arrhythmias after myocardial infarction. Exercise electrocardiography is important in determining the presence of myocardial demand ischemia; more recently, analysis of the morphology of the QT interval with exercise has been used to assess the risk of serious ventricular arrhythmias. Microscopic alterations in the T wave (T wave alternans, TWA) at low heart rates identify patients at risk for ventricular arrhythmias. A number of other tests of the variability in the T-wave morphology or duration of the QT interval have been used to assess instability in repolarization of the ventricle and an increased risk of arrhythmias.

Head-up tilt (HUT) testing is a useful in the evaluation of some patients with syncope. The physiologic response to HUT is incompletely understood; however, redistribution of blood volume and increased ventricular contractility occur consistently. Exaggerated activation of a central reflex in response to HUT produces a stereotypic response of an initial increase in heart rate, then a drop in blood pressure followed by a reduction in heart rate characteristic of neurally mediated hypotension. Other responses to HUT may be observed in patients with orthostatic hypotension and autonomic insufficiency. HUT is most often used in patients with recurrent syncope, although it may be useful in patients with single syncopal episodes with associated injury, particularly in the absence of structural heart disease. In patients with structural heart disease, HUT may be indicated in those with syncope, in whom other causes (e.g., asystole, ventricular tachyarrhythmias) have been excluded. HUT has been suggested as a useful tool in the diagnosis and therapy of recurrent idiopathic vertigo, chronic fatigue syndrome, recurrent transient ischemic attacks, and repeated falls of unknown etiology in the elderly. Importantly, HUT is relatively contraindicated in the presence of severe coronary artery disease with proximal coronary stenoses, known severe cerebrovascular disease, severe mitral stenosis, and obstruction to left ventricular outflow (e.g., aortic stenosis). The method of HUT is variable, but the angle of tilt and the duration of upright posture are central to the diagnostic utility of the test. The use of pharmacologic provocation of orthostatic stress with isoproterenol, nitrates, adenosine, and edrophonium have been used to shorten the test and enhance specificity.

Electrophysiologic testing is central to the understanding and treatment of many cardiac arrhythmias. Indeed, most frequently electrophysiologic testing is interventional, providing both diagnosis and therapy. The components of the electrophysiologic test are baseline measurements of conduction under resting and stressed (rate or pharmacologic) conditions and maneuvers, both pacing and pharmacologic, to induce arrhythmias. A number of sophisticated electrical mapping and catheter-guidance techniques have been developed to facilitate catheter-based therapeutics in the electrophysiology laboratory.

Rx CARDIAC ARRHYTHMIAS

ANTIARRHYTHMIC DRUG THERAPY The interaction of antiarrhythmic drugs with cardiac tissues and the resulting electrophysiologic changes are complex. An incomplete understanding of the effects of these drugs has produced serious missteps that have had adverse effects on patient outcomes and the development of newer pharmacologic agents. Currently, antiarrhythmic drugs have been relegated to an ancillary role in the treatment of most cardiac arrhythmias.

There are several explanations for the complexity of antiarrhythmic drug action: the structural similarity of target ion channels; regional differences in the levels of expression of channels and transporters, which change with disease; time and voltage dependence of drug action; and the effect of these drugs on targets other than ion channels. Recognizing the limitations of any scheme to classify antiarrhythmic agents, a shorthand that is useful in describing the major mechanisms of action is of some utility. Such a classification scheme was proposed in 1970 by Vaughan-Williams and later modified by Singh and Harrison. The classes of antiarrhythmic action are: class I; local anesthetic effect due to blockade of Na^+ current; class II, interference with the action of catecholamines at the β-adrenergic receptor; class III, delay of repolarization due to inhibition of K^+ current or activation of depolarizing current; class IV, interference with calcium conductance **(Table 224-2)**. The limitations of the Vaughan-Williams classification scheme include multiple actions of most drugs, overwhelming consideration of antagonism as a mechanism of action, and the fact that several agents have none of the four classes of action in the scheme.

TABLE 224-2 ANTIARRHYTHMIC DRUG ACTIONS

Drug	Class Actions I	II	III	IV	Miscellaneous Action
Quinidine	++		++		α-Adrenergic blockade
Procainamide	++		++		Ganglionic blockade
Flecainide	+++		+		
Propafenone	++	+			
Sotalol		++	+++		
Dofetilide			+++		
Amiodarone	++	++	+++	+	α-Adrenergic blockade
Ibutilide			+++		Na^+ channel activator

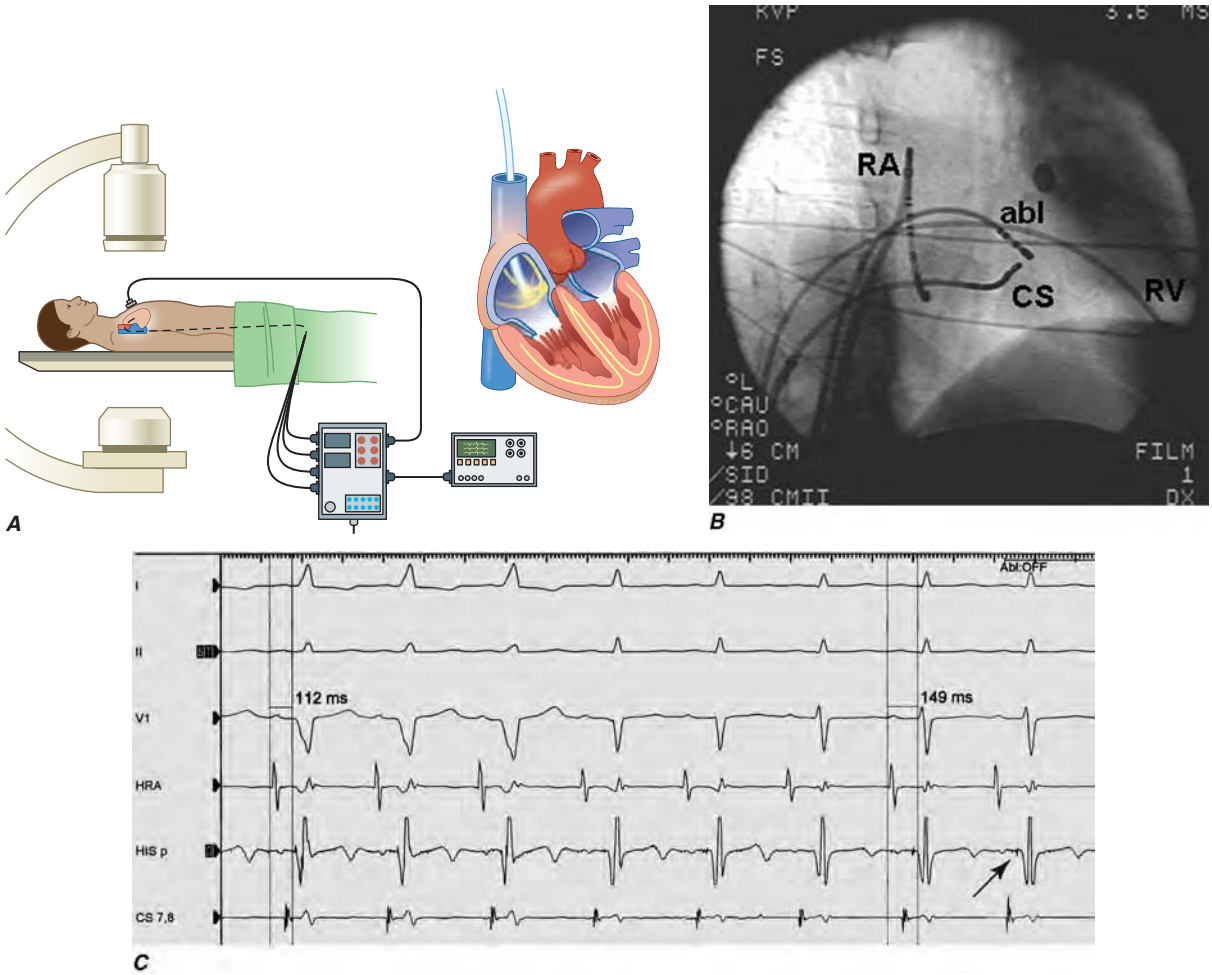

FIGURE 224-5 Catheter ablation of cardiac arrhythmias. *A.* A schematic of the lead system and generator in a patient undergoing radiofrequency catheter ablation (RFA); the circuit involves the lead in the heart and a dispersive patch placed on the body surface (usually the back). The inset shows a diagram of the heart with a catheter located at the AV valve ring for ablation of an accessory pathway. ***B.*** A right anterior oblique fluoroscopic image of the catheter position for ablation of a left-sided accessory pathway. A catheter is placed in the atrial side of the mitral valve ring (abl) via a transseptal puncture, other catheters are placed in the coronary sinus to record intracardiac electrograms around the mitral annulus: a circumferential catheter in the right atrium (RA) and a catheter in the right ventricular apex (RV). ***C.*** Body surface ECG recordings (I, II, V1) and endocardial electrograms (HRA: high right atrium; HISp: proximal His bundle electrogram; CS 7,8 recordings from poles 7 and 8 of a decapolar catheter placed in the coronary sinus) during RFA of a left-sided accessory pathway in a patient with Wolff-Parkinson-White syndrome. The QRS narrows at the 4th complex, the arrow shows the His bundle electrogram, which becomes apparent with elimination of ventricular preexcitation over the accessory pathway.

CATHETER ABLATION The use of catheter ablation is based on the principle that there is a critical anatomic region of impulse generation or propagation required for the initiation and maintenance of cardiac arrhythmias. Destruction of such a critical region results in the elimination of the arrhythmia. The use of radiofrequency (RF) energy in clinical medicine is nearly a century old. The first catheter ablation using a DC energy source was performed in the early 1980s by Scheinman and colleagues. By the early 1990s, RF had been adapted for use in catheter-based ablation in the heart **(Fig. 224-5)**.

The RF frequency band (300–30,000 kHz) is used to generate energy for several biomedical applications, including coagulation and cauterizing tissues. Energy of this frequency will not stimulate skeletal muscle or the heart and heats tissue by a resistive mechanism, with the intensity of heating being proportional to the delivered power. The density of power in the tissue falls off rapidly (with the 4th power of the radius or distance), as does the temperature, allowing for the production of small-volume lesions. The applied power, energy, or current are not good predictors of lesion size; temperature at the electrode-tissue interface is the best predictor, with temperatures >55°C consistently producing tissue necrosis. The temperature rise at the tissue-electrode interface is rapid, but heating is slower in the tissue, and steady-state lesion size may be not achieved for ≥40 s of radiofrequency energy application. Notably, tissue temperature may remain high for many seconds despite cessation of energy delivery, producing undesired ablation of cardiac structures. Alternative, less frequently used energy sources for catheter ablation of cardiac arrhythmias include microwaves (915 MHz or 2450 MHz), lasers, ultrasound, or freezing (cryoablation). In addition to RF energy, cryoablation is being used clinically and is a safe and effective alternative to RF, especially with ablation in the region of the AV node. At temperatures just below 32°C, membrane ion transport is disrupted, producing depolarization of cells, decreased action potential amplitude and duration, and slowed conduction velocity (resulting in local conduction block)—all of which are reversible, if the tissue is rewarmed in a timely fashion. Tissue cooling can be used for mapping and ablation. Cryomapping can be used to confirm the location of a desired ablation target, such as an accessory pathway in WPW syndrome, or can be used to determine the safety of ablation around the AV node by monitoring AV conduction during cooling. Another advantage of cryoablation is that once the catheter tip cools below freezing, it adheres to the tissue, increasing catheter stability independent of the rhythm or pacing.

225 The Bradyarrhythmias

Gordon F. Tomaselli

Electrical activation of the heart normally originates in the sinoatrial (SA) node, the predominant pacemaker. Other subsidiary pacemakers in the atrioventricular (AV) node, specialized conducting system, and muscle may initiate electrical activation if the SA node is dysfunctional or suppressed. Typically subsidiary pacemakers discharge at a slower rate and, in the absence of an appropriate increase in stroke volume, may result in tissue hypoperfusion.

Spontaneous activation and contraction of the heart are the consequence of the specialized pacemaking tissue found within these anatomic locales. As described in Chap. 224, action potentials in the heart are regionally heterogeneous. The action potentials in cells isolated from nodal tissue are distinct from those recorded from atrial and ventricular myocytes (Fig. 225-1). The complement of ionic currents present in nodal cells results in a less negative resting membrane potential compared with atrial or ventricular myocytes. Electrical diastole in nodal cells is characterized by slow diastolic depolarization (phase 4), which generates an action potential as the membrane voltage reaches threshold. The action potential upstrokes (phase 0) are slow compared with atrial or ventricular myocytes, being mediated by calcium rather than sodium current. Cells with properties of SA and AV nodal tissue are electrically connected to the remainder of the myocardium by cells with an electrophysiologic phenotype between that of nodal cells and atrial or ventricular myocytes. Cells in the SA node exhibit the most rapid phase 4 depolarization and thus are the dominant pacemakers in the normal heart.

Bradycardia results from either a failure of impulse initiation or impulse conduction. Failure of impulse initiation may be caused by depressed automaticity resulting from a slowing or failure of phase 4 diastolic depolarization (Fig. 225-2), which may result from disease or exposure to drugs. Prominently, the autonomic nervous system modulates the rate of phase 4 diastolic depolarization and, thus, the firing rate of both primary (SA node) and subsidiary pacemakers. Failure of conduction of an impulse from nodal tissue to atrial or ventricular myocardium may produce bradycardia as a result of exit block. Conditions that alter activation and connectivity of cells (e.g., fibrosis) in the heart may result in failure of impulse conduction.

SA node dysfunction and AV conduction block are the most common causes of pathologic bradycardia. SA node dysfunction may be difficult to distinguish from physiologic sinus bradycardia, particularly in the young. SA node dysfunction increases in frequency between the fifth and sixth decades of life and should be considered in patients with fatigue, exercise intolerance, or syncope and sinus bradycardia. Transient AV block is common in the young and likely the result of the high vagal tone found in up to 10% of young adults. Acquired and persistent failure of AV conduction is decidedly rare in healthy adult populations, with an estimated incidence of ~200/million population per year.

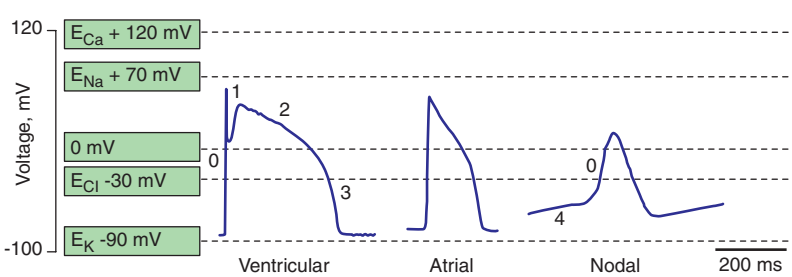

FIGURE 225-1 Action potential profiles recorded in cells isolated from SA or AV nodal tissue compared to that of cells from atrial or ventricular myocardium. Nodal cell action potentials exhibit more depolarized resting membrane potentials, slower phase 0 upstrokes, and phase 4 diastolic depolarization.

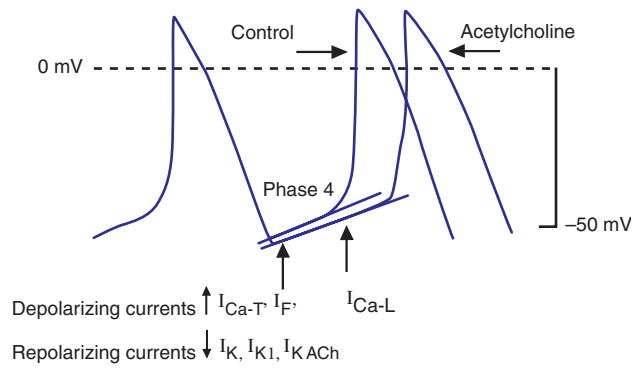

FIGURE 225-2 Schematics of nodal action potentials and the currents that contribute to phase 4 depolarization. Relative increases in depolarizing L- ($I_{Ca\text{-}L}$) and T- ($I_{Ca\text{-}T}$) type calcium and pacemaker currents (I_f) along with a reduction in repolarizing inward rectifier (I_{K1}) and delayed rectifier (I_K) potassium currents result in depolarization. Activation of ACh-gated (I_{KACh}) potassium current and beta blockade slows the rate of phase 4 and decreases the pacing rate. *(Modified from J Jalife et al: Basic Cardiac Electrophysiology for the Clinician, Blackwell Publishing, 1999.)*

Permanent pacemaking is the only reliable therapy for symptomatic bradycardia in the absence of extrinsic and reversible etiologies such as increased vagal tone, hypoxia, hypothermia, and drugs (Table 225-1). Approximately 50% of the 150,000 permanent pacemakers implanted in the United States and 20–30% of the 150,000 of those implanted in Europe were implanted for SA node disease.

SA NODE DISEASE

Structure and Physiology of the SA Node

The SA node is composed of a cluster of small fusiform cells located in the sulcus terminalis on the epicardial surface of the heart at the right atrial–superior vena caval junction, where they envelop the SA nodal artery. The SA node is structurally heterogeneous, but the central prototypic nodal cells have fewer distinct myofibrils than the surrounding atrial myocardium, no intercalated disks visible on light microscopy, a poorly developed sarcoplasmic reticulum, and no T-tubules. Cells in the peripheral regions of the SA node are transitional in both structure and function. The SA nodal artery arises from the right coronary artery in 55–60% and left circumflex artery in 40–45% of persons. The SA node is richly innervated by sympathetic and parasympathetic nerves and ganglia.

Irregular and slow propagation of impulses from the SA node can be explained by the electrophysiology of nodal cells and the structure of the SA node itself. The action potentials of SA nodal cells are characterized by a relatively depolarized membrane potential (Fig. 225-1) of –40 to –60 mV, slow phase 0 upstroke, and relatively rapid phase 4 diastolic depolarization compared to the action potentials recorded in cardiac muscle cells. The relative absence of inward rectifier potassium current (I_{K1}) accounts for the depolarized membrane potential;

TABLE 225-1 ETIOLOGIES OF SA NODE DYSFUNCTION

Extrinsic	Intrinsic
Autonomic	Sick sinus syndrome (SSS)
Carotid sinus hypersensitivity	Coronary artery disease (chronic and acute MI)
Vasovagal (cardioinhibitory) stimulation	Inflammatory
Drugs	Pericarditis
Beta blockers	Myocarditis (including viral)
Calcium channel blockers	Rheumatic heart disease
Digoxin	Collagen vascular diseases
Antiarrhythmics (class I and III)	Lyme disease
Adenosine	Senile amyloidosis
Clonidine (other sympatholytics)	Congenital heart disease
Lithium carbonate	TGA/Mustard and Fontan repairs
Cimetidine	Iatrogenic
Amitriptyline	Radiation therapy
Phenothiazines	Post surgical
Narcotics (methadone)	Chest trauma
Pentamidine	Familial
Hypothyroidism	AD SSS, OMIM #163800 (15q24-25)
Sleep apnea	AR SSS, OMIM #608567 (3p21)
Hypoxia	SA node disease with myopia, OMIM 182190
Endotracheal suctioning (vagal maneuvers)	Kearns-Sayre syndrome, OMIM #530000
Hypothermia	Myotonic dystrophy
Increased intracranial pressure	Type 1, OMIM #160900 (19q13.2-13.3)
	Type 2, OMIM #602668 (3q13.3-q24)
	Friedreich's ataxia, OMIM #229300 (9q13, 9p23-p11)

Note: MI, myocardial infarction; TGA, transposition of the great arteries; AD, autosomal dominant; AR, autosomal recessive; OMIM, Online Mendelian Inheritance in Man (database).

the slow upstroke of phase 0 is the result of the absence of available fast sodium current (I_{Na}) and is mediated by L-type calcium current ($I_{Ca\text{-}L}$); and phase 4 depolarization is the result of the aggregate activity of a number of ionic currents. Prominently, both L- and T-type ($I_{Ca\text{-}T}$) calcium currents, the pacemaker current (so-called funny current, or I_f) formed by the tetramerization of hyperpolarization-activated cyclic nucleotide-gated channels, and the electrogenic sodium-calcium exchanger provide depolarizing current that is antagonized by delayed rectifier (I_{Kr}) and acetylcholine-gated (I_{KACh}) potassium currents. $I_{Ca\text{-}L}$, $I_{Ca\text{-}T}$, and I_f are modulated by β-adrenergic stimulation and I_{KACh} by vagal stimulation, explaining the exquisite sensitivity of diastolic depolarization to autonomic nervous system activity. The slow conduction within the SA node is explained by the absence of I_{Na} and poor electrical coupling of cells in the node, resulting from sizeable amounts of interstitial tissue and a low abundance of gap junctions. The poor coupling allows for graded electrophysiological properties within the node, with the peripheral transitional cells being silenced by electrotonic coupling to atrial myocardium.

Etiology of SA Nodal Disease SA nodal dysfunction has been classified as intrinsic or extrinsic. The distinction is important because extrinsic dysfunction is often reversible and should generally be corrected before considering pacemaker therapy (Table 225-1). The most common causes of extrinsic SA node dysfunction are drugs and autonomic nervous system influences that suppress automaticity and/or compromise conduction. Other extrinsic causes include hypothyroidism, sleep apnea, and conditions likely to occur in critically ill patients such as hypothermia, hypoxia, increased intracranial pressure (Cushing's response), and endotracheal suctioning via activation of the vagus nerve.

Intrinsic sinus node dysfunction is degenerative and often characterized pathologically by fibrous replacement of the SA node or its connections to the atrium. Acute and chronic coronary artery disease (CAD) may be associated with SA node dysfunction, although in the setting of acute myocardial infarction (MI; typically inferior), the abnormalities are transient. Inflammatory processes may alter SA node function, ultimately producing replacement fibrosis. Pericarditis, myocarditis, and rheumatic heart disease have been associated with SA nodal disease with sinus bradycardia, sinus arrest, and exit block. Carditis associated with systemic lupus erythematosus (SLE), rheumatoid arthritis (RA), and mixed connective tissue disorders (MCTDs) may also affect SA node structure and function. Senile amyloidosis is an infiltrative disorder in patients typically in their ninth decade of life; deposition of amyloid protein in the atrial myocardium can impair SA node function. Some SA node disease is iatrogenic and the result of surgical correction of congenital heart disease, particularly palliative repair of corrected transposition of the great arteries by the Mustard procedure.

Rare heritable forms of sinus node disease have been described, and several have been genetically characterized. Autosomal dominant sinus node dysfunction in conjunction with supraventricular tachycardia (i.e., tachycardia-bradycardia variant of sick-sinus syndrome, SSS) has been linked to mutations in the pacemaker current (I_f) subunit gene *HCN4* on chromosome 15. An autosomal recessive form of SSS with the prominent feature of atrial inexcitability and absence of P waves on the electrocardiogram (ECG) is caused by mutations in the cardiac sodium channel gene, *SCN5A*, on chromosome 3. SSS associated with myopia has been described but not genetically characterized. There are several neuromuscular diseases including Kearns-Sayre syndrome (ophthalmoplegia, pigmentary degeneration of the retina, and cardiomyopathy) and myotonic dystrophy that have a predilection for the conducting system and SA node.

SSS in both the young and the elderly is associated with an increase in fibrous tissue in the SA node. The onset of SSS may be hastened by coexisting disease, such as CAD, diabetes mellitus, hypertension, and valvular diseases and cardiomyopathies.

Clinical Features of SA Node Disease SA node dysfunction may be completely asymptomatic and manifest as an ECG anomaly such as sinus bradycardia; sinus arrest and exit block; or alternating supraventricular tachycardia, usually atrial fibrillation, and bradycardia. Symptoms associated with SA node dysfunction, and in particular tachycardia-bradycardia syndrome, may be related to both bradycardia and tachycardia. For example, tachycardia may be associated with palpitations, angina pectoris, and heart failure; and bradycardia may be associated with hypotension syncope, presyncope, fatigue, and weakness. In the setting of SSS, overdrive suppression of the SA node may result in prolonged pauses and syncope upon termination of the tachycardia. In many cases, symptoms associated with SA node dysfunction are the result of concomitant cardiovascular disease. A significant minority of patients with SSS will develop signs and symptoms of heart failure that may be related to slow or fast heart rates.

One-third to one-half of patients with SA node dysfunction will develop supraventricular tachycardia, usually atrial fibrillation or atrial flutter. The incidence of chronic atrial fibrillation in patients with SA node dysfunction increases with advanced age, hypertension, diabetes mellitus, left ventricular dilation, valvular heart disease, and ventricular pacing. Remarkably, some symptomatic patients may experience an improvement in symptoms with the development of atrial fibrillation, presumably from an increase in their average heart rate. Patients with the tachycardia-bradycardia variant of SSS, similar to patients with atrial fibrillation, are at risk for thromboembolism, and *those at greatest risk*, including patients ≥65 years, or patients with a prior history of stroke, valvular heart disease, left ventricular dysfunction, or atrial enlargement, should be treated with anticoagulants. Up to one-quarter of patients with SA node disease will have concurrent AV conduction disease; although only a minority will require specific therapy for high-grade AV block.

The natural history of SA node dysfunction is one of varying intensity of symptoms even in patients who present with syncope. Symptoms related to SA node dysfunction may be significant, but overall mortality is usually not compromised in the absence of other significant comorbid conditions. These features of the natural history need to be taken into account when considering therapy in these patients.

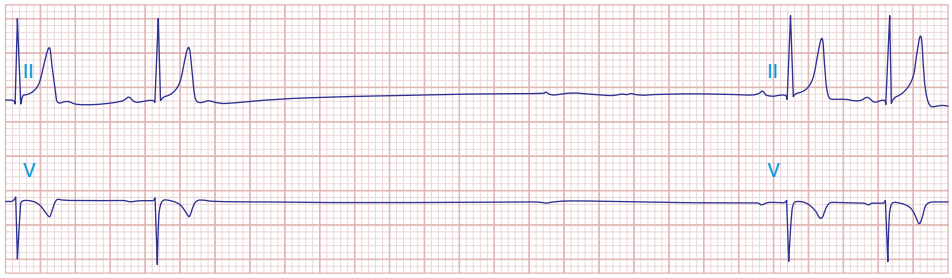

FIGURE 225-3 Sinus slowing and pauses on the ECG. The ECG is recorded during sleep in a young patient without heart disease. The heart rate before the pause is slow, and the PR interval is prolonged consistent with a physiologic response to an increase in vagal tone. The P waves have a morphology consistent with sinus rhythm.

Electrocardiography of SA Node Disease The electrocardiographic manifestations of SA node dysfunction include sinus bradycardia, sinus pauses, sinus arrest, sinus exit block, tachycardia (in SSS), and chronotropic incompetence. It is often difficult to distinguish pathologic from physiologic sinus bradycardia. By definition sinus bradycardia is a rhythm driven by the SA node with a rate of <60 beats/min; sinus bradycardia is very common and typically benign. Resting heart rates of <60 beats/min are very common in young healthy individuals and physically conditioned subjects. A sinus rate of <40 beats/min in the awake state in the absence of physical conditioning is generally considered abnormal. Sinus pauses and sinus arrest result from the failure of the SA node to discharge, producing a pause without P waves visible on the ECG (Fig. 225-3). Sinus pauses of up to 3 s are common in the awake athlete, and pauses of this duration or longer may be observed in asymptomatic elderly subjects. Intermittent failure of conduction from the SA node produces sinus exit block. The severity of sinus exit block may vary in a manner similar to that of AV block (see below). Prolongation of conduction from the sinus node will not be apparent on the ECG; second-degree SA block will produce intermittent conduction from the SA node and a regularly irregular atrial rhythm.

Type I second-degree SA block results from progressive prolongation of SA node conduction and appears on the ECG as a progressive lengthening of the P-R interval and progressive shortening of the R-R interval, followed by a pause (Fig. 225-4). In type II second-degree SA block there is no change in the P-R interval before the pause. Complete or third-degree SA block results in no P waves on the ECG. Tachycardia-bradycardia syndrome is manifest as alternating sinus bradycardia and atrial tachyarrhythmias. Although atrial tachycardia, atrial flutter, and atrial fibrillation may be observed, the latter is the most common tachycardia. Chronotropic incompetence is the inability to increase the heart rate in response to exercise or other stress appropriately and is defined in greater detail below.

Diagnostic Testing SA node dysfunction is most commonly a clinical or electrocardiographic diagnosis. Sinus bradycardia or pauses on the resting ECG are rarely sufficient to diagnose SA node disease, and longer-term recording and symptom correlation are generally required. Symptoms in the absence of sinus bradyarrhythmias may be sufficient to exclude a diagnosis of SA node dysfunction.

Electrocardiographic recording plays a central role in the diagnosis and management of SA node dysfunction. Despite the limitations of the resting ECG, longer-term recording employing Holter or event monitors may permit correlation of symptoms with the cardiac rhythm. Many contemporary event monitors may be automatically triggered to record the ECG when certain programmed heart rate criteria are met. Implantable ECG monitors permit long-term recording (12–18 months) in particularly challenging patients.

Failure to increase the heart rate with exercise is referred to as *chronotropic incompetence*. This is alternatively defined as a failure to reach 85% of predicted maximal heart rate at peak exercise, or failure to achieve a heart rate > 100 beats/min with exercise or a maximal heart rate with exercise less than two standard deviations below that of an age-matched control population. Exercise testing may be useful in discriminating chronotropic incompetence from resting bradycardia and may aid in the identification of the mechanism of exercise intolerance.

Autonomic nervous system testing is useful in diagnosing carotid sinus hypersensitivity; pauses >3 s are consistent with the diagnosis but may be present in asymptomatic elderly subjects. Determining the intrinsic heart rate (IHR) may distinguish SA node dysfunction from slow heart rates resulting from high vagal tone. The normal IHR after administration of 0.2 mg/kg propranolol and 0.04 mg/kg atropine is 117.2 – (0.53 × age) in beats/min; a low IHR is indicative of SA disease.

Electrophysiologic testing may play a role in the assessment of patients with presumed SA node dysfunction and in the evaluation of syncope, particularly in the setting of structural heart disease. In this circumstance, electrophysiologic testing is used to rule out more malignant etiologies of syncope such as ventricular tachyarrhythmias and AV conduction block. There are several ways to assess SA node function invasively. These include the sinus node recovery time (SNRT), defined as the longest pause after cessation of overdrive pacing of the right atrium near the SA node (normal: <1500 ms or, corrected for sinus cycle length, <550 ms); and the sinoatrial conduction time (SACT), defined as one-half the difference between the intrinsic sinus cycle length and a noncompensatory pause after a premature atrial stimulus (normal < 125 ms). The combination of an abnormal SNRT, an abnormal SACT, and a low IHR is a sensitive and specific indicator of intrinsic SA node disease.

SINOATRIAL NODE DYSFUNCTION

Since SA node dysfunction is not associated with increased mortality, the aim of therapy is alleviation of symptoms. Exclusion of extrinsic causes of SA node dysfunction and correlation of the cardiac rhythm with symptoms is an essential part of patient management. Pacemaker implantation is the primary therapeutic intervention in patients with symptomatic SA node dysfunction. Pharmacologic considerations are important in the evaluation and management of patients with SA nodal disease. A number of drugs modulate SA node function and are extrinsic causes of dysfunction (Table 225-1). Beta blockers and calcium channel blockers increase SNRT in patients with SA node dysfunction, and antiarrhythmic drugs with class I and III action may promote SA node exit block. In general such agents should be discontinued prior to making decisions regarding the need for permanent pacing in patients with SA node disease. Chronic pharmacologic therapy for sinus bradyarrhythmias is limited. Some pharmacologic agents may improve SA node function; digitalis, for example, has been shown to shorten SNRT in patients with SA node

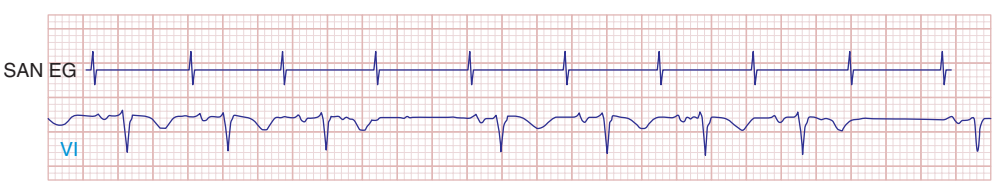

FIGURE 225-4 Mobitz type I SA nodal exit block. A theoretical SA node electrogram (SAN EG) is shown. Note that there is grouped beating producing a regularly irregular heart rhythm. The SA node EG rate is constant with progressive delay in exit from the node, and activation of the atria, inscribing the P wave. This produces subtly decreasing P-P intervals prior to the pause, and the pause is less that twice the cycle length of the last sinus interval.

dysfunction. Isoproterenol or atropine administered IV may increase the sinus rate acutely. Theophylline has been used both acutely and chronically to increase heart rate but has liabilities when used in patients with tachycardia-bradycardia syndrome, increasing the frequency of supraventricular tachyarrhythmias; and in patients with structural heart disease, increasing the risk of potentially serious ventricular arrhythmias. At the current time, there is only a single randomized study of therapy for SA node dysfunction. In patients with resting heart rates <50 and >30 beats/min on a Holter monitor, patients who received dual-chamber pacemakers experienced significantly fewer syncopal episodes and had symptomatic improvement compared to patients randomized to theophylline or no treatment.

In certain circumstances, sinus bradycardia requires no specific treatment or only temporary rate support. Sinus bradycardia is common in patients with acute inferior or posterior MI and can be exacerbated by vagal activation induced by pain or the use of drugs such as morphine. Ischemia of the SA nodal artery probably occurs in acute coronary syndromes more typically with involvement with the right coronary artery, and even with infarction, the effect on SA node function is most often transient.

Sinus bradycardia is a prominent feature of carotid sinus hypersensitivity and neurally mediated hypotension associated with vasovagal syncope that responds to pacemaker therapy. Carotid hypersensitivity with recurrent syncope or presyncope associated with a predominant cardioinhibitory component responds to pacemaker implantation. Several randomized trials have demonstrated that patients with drug-refractory vasovagal syncope have fewer recurrences and longer time to recurrence of symptoms with permanent pacing.

The details of pacing modes and indications for pacing in SA node dysfunction are discussed below.

ATRIOVENTRICULAR CONDUCTION DISEASE

Structure and Physiology of the AV Node

The AV conduction axis is structurally complex, involving the atria and ventricles as well as the AV node. Unlike the SA node, the AV node is a subendocardial structure originating in the transitional zone, which is composed of aggregates of cells in the posterior-inferior right atrium. Superior, medial, and posterior transitional atrionodal bundles converge on the compact AV node. The compact AV node (~1 × 3 × 5 mm) is located at the apex of the triangle of Koch, which is defined by the coronary sinus ostium posteriorly, the septal tricuspid valve annulus anteriorly, and the tendon of Todaro superiorly. The compact AV node continues as the penetrating AV bundle where it immediately traverses the central fibrous body and is in close proximity to the aortic, mitral, and tricuspid valve annuli; thus, it is subject to injury in the setting of valvular heart disease or its surgical treatment. The penetrating AV bundle continues through the annulus fibrosis and emerges along the ventricular septum adjacent to the membranous septum as the bundle of His. The right bundle branch (RBB) emerges from the distal AV bundle in a band that traverses the right ventricle (moderator band). In contrast, the left bundle branch (LBB) is a broad subendocardial sheet of tissue on the septal left ventricle. The Purkinje fiber network emerges from the RBB and LBB and extensively ramifies on the endocardial surfaces of the right and left ventricles, respectively.

The blood supply to the penetrating AV bundle is from the AV nodal artery and first septal perforator of the left anterior descending coronary artery. The bundle branches also have a dual blood supply from the septal perforators of the left anterior descending coronary artery and branches of the posterior descending coronary artery. The AV node is highly innervated with postganglionic sympathetic and parasympathetic nerves. The bundle of His and distal conducting system are minimally influenced by autonomic tone.

The cells that comprise the AV node complex are heterogeneous with a range of action potential profiles. In the transitional zones, the cells have an electrical phenotype between atrial myocytes and cells of the compact node (Fig. 225-1). Atrionodal transitional connections may exhibit *decremental conduction*, defined as slowing of conduction with increasingly rapid rates of stimulation. Fast and slow AV nodal pathways have been described, but controversy remains as to whether these two types of pathway are anatomically distinct or represent functional heterogeneities in different regions of the AV nodal complex. Myocytes that comprise the compact node are depolarized (resting membrane potential ~ –60 mV); exhibit action potentials with low amplitudes, slow upstrokes of phase 0 (<10 V/s), and phase 4 diastolic depolarization; high-input resistance; and relative insensitivity to external $[K^+]$. The action potential phenotype is explained by the complement of ionic currents expressed. AV nodal cells lack I_{K1} and I_{Na}; $I_{Ca\text{-}L}$ is responsible for phase 0; and phase 4 depolarization reflects the composite activity of the depolarizing currents I_f, $I_{Ca\text{-}L}$, $I_{Ca\text{-}T}$, and I_{NCX} and the repolarizing currents I_{Kr} and I_{KACh}. Electrical coupling between cells in the AV node is tenuous due to the relatively sparse expression of gap junction channels (predominantly connexin-40) and increased extracellular volume.

The His bundle and bundle branches are insulated from ventricular myocardium. The most rapid conduction in the heart is observed in these tissues. The action potentials exhibit very rapid upstrokes (phase 0), prolonged plateaus (phase 2), and modest automaticity (phase 4 depolarization). Gap junctions, composed largely of connexin-40, are abundant but bundles are poorly connected transversely to ventricular myocardium.

Etiology of AV Conduction Disease

Conduction block from the atrium to the ventricle can occur for a variety of reasons in a number of clinical situations, and AV conduction block may be classified in a number of ways. The etiologies may be functional or structural, in part analogous to extrinsic and intrinsic causes of SA nodal dysfunction. The block may be classified by its severity from first to third degree or complete AV block, or by the location of block within the AV conduction system. Table 225-2 summarizes the etiologies of AV conduction

TABLE 225-2 ETIOLOGIES OF ATRIOVENTRICULAR BLOCK

Autonomic	
Carotid sinus hypersensitivity	Vasovagal
Metabolic/endocrine	
Hyperkalemia	Hypothyroidism
Hypermagnesemia	Adrenal insufficiency
Drug-related	
Beta blockers	Adenosine
Calcium channel blockers	Antiarrhythmics (class I & III)
Digitalis	Lithium
Infectious	
Endocarditis	Tuberculosis
Lyme disease	Diphtheria
Chagas disease	Toxoplasmosis
Syphilis	
Heritable/congenital	
Congenital heart disease	Facioscapulohumeral MD, OMIM #158900 (4q35)
Maternal SLE	Emery-Dreifuss MD, OMIM #310300 (Xq28)
Kearns-Sayre syndrome, OMIM #530000	Progressive familial heart block, OMIM #113900 (19q13.2-q13.3, 3p21)
Myotonic dystrophy	
Type 1, OMIM #160900 (19q13.2-13.3)	
Type 2, OMIM #602668 (3q13.3-q24)	
Inflammatory	
SLE	MCTD
Rheumatoid arthritis	Scleroderma
Infiltrative	
Amyloidosis	Hemochromatosis
Sarcoidosis	
Neoplastic/traumatic	
Lymphoma	Radiation
Mesothelioma	Catheter ablation
Melanoma	
Degenerative	
Lev disease	Lenègre disease
Coronary artery disease	
Acute MI	

Note: SLE, systemic lupus erythematosus; OMIM, Online Mendelian Inheritance in Man (database); MCTD, mixed connective tissue disease; MI, myocardial infarction.

block, those that are functional (autonomic, metabolic/endocrine, and drug-related) tend to be reversible. Most other etiologies produce structural changes, typically fibrosis, in segments of the AV conduction axis that are generally permanent. Heightened vagal tone during sleep or in well-conditioned individuals can be associated with all grades of AV block. Carotid sinus hypersensitivity, vasovagal syncope, and cough and micturition syncope may be associated with SA node slowing and AV conduction block. Transient metabolic and endocrinologic disturbances as well as a number of pharmacologic agents may also produce reversible AV conduction block.

Several infectious diseases have a predilection for the conducting system. Lyme disease may involve the heart in up to 50% of cases; 10% of patients with Lyme carditis develop AV conduction block, which is generally reversible but may require temporary pacing support. Chagas disease, common in Latin America, and syphilis may produce more persistent AV conduction disturbances. Some autoimmune and infiltrative diseases may produce AV conduction block including SLE, RA, MCTD, scleroderma, amyloidosis (primary and secondary), sarcoidosis, and hemochromatosis; rare malignancies may also impair AV conduction.

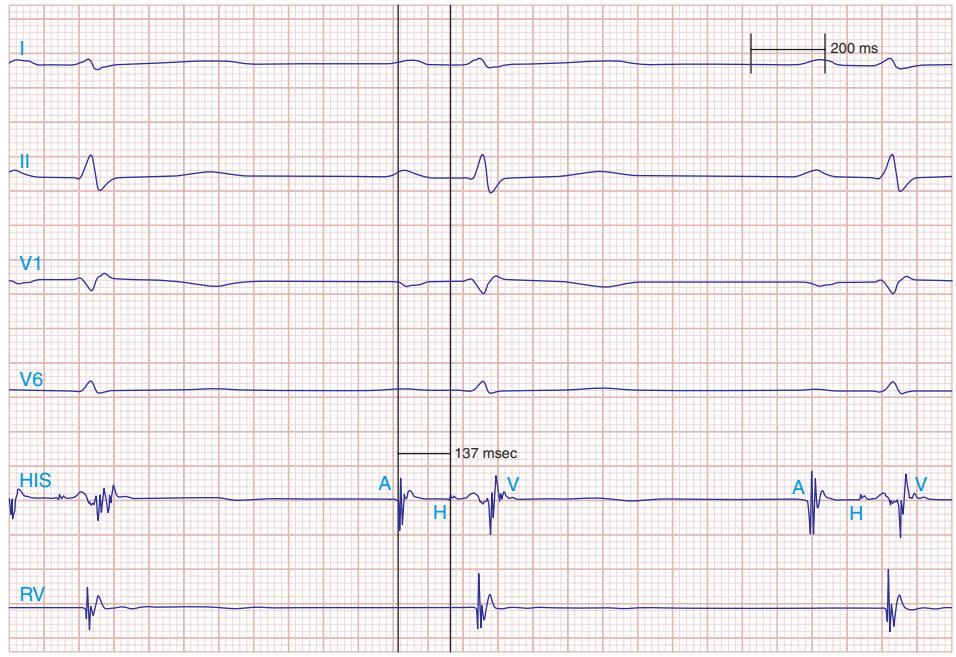

FIGURE 225-5 First-degree AV block with slowing of conduction in the AV node as indicated by the prolonged atrial-to-His bundle electrogram (AH) interval, in this case 157 ms. The His bundle-to-earliest ventricular activation on the surface ECG (HV) interval is normal. The normal HV interval suggests normal conduction below the AV node to the ventricle. I and V1 are surface ECG leads, HIS is the recording of the endocavitary electrogram at the His bundle position. A, H, and V are labels for the atrial, His bundle, and right ventricular electrograms respectively.

Idiopathic progressive fibrosis of the conduction system is one of the more common and degenerative causes of AV conduction block. Aging is associated with degenerative changes in the summit of the ventricular septum, central fibrous body, and aortic and mitral annuli and has been described as "sclerosis of the left cardiac skeleton." The process typically begins in the fourth decade of life and may be accelerated by atherosclerosis, hypertension with arteriosclerosis, and diabetes mellitus. Accelerated forms of progressive familial heart block have been identified in families with mutations in the cardiac sodium channel gene (*SCN5A*) and a second locus that has been mapped to chromosome 19.

AV conduction block has been associated with heritable neuromuscular diseases, including the nucleotide repeat disease myotonic dystrophy, the mitochondrial myopathy Kearns-Sayre syndrome (Chap. 382), and several of the monogenic muscular dystrophies. Congenital AV block may be observed in complex congenital cardiac anomalies (Chap. 229), such as transposition of the great arteries, ostium primum atrial septal defects (ASD), ventricular septal defects (VSD), endocardial cushion defects, and some single ventricle defects. Congenital AV block in the setting of a structurally normal heart has been seen in children born to mothers with SLE. Iatrogenic AV block may occur during mitral or aortic valve surgery, rarely in the setting of thoracic radiation, and as a consequence catheter ablation. AV block is a decidedly rare complication of the surgical repair of VSDs or ASDs but may complicate Fontan or Mustard repairs of transposition of the great arteries.

CAD may produce transient or persistent AV block. In the setting of coronary spasm, ischemia, particularly in the right coronary artery distribution, may produce transient AV block. In acute MI, AV block transiently develops in 10–25% of patients; most commonly this is first- or second-degree AV block but complete heart block (CHB) may also occur. Second-degree and higher grade AV block tends to occur more often in inferior rather than anterior acute MI; however, the level of block in inferior MI tends to be in the AV node with more stable, narrow escape rhythms. In contrast, acute anterior MI is associated with block in the distal AV nodal complex, His bundle, or bundle branches and results in wide complex, unstable escape rhythms and a worse prognosis with high mortality.

Electrocardiography and Electrophysiology of AV Conduction Block

Atrioventricular conduction block is typically diagnosed electrocardiographically which characterizes the severity of the conduction disturbance and allows one to draw inferences about the location of block. AV conduction block manifests as slow conduction in its mildest forms and failure to conduct, either intermittent or persistently, in more severe varieties. First-degree AV block (PR interval > 200 ms) is a slowing of conduction through the AV junction (Fig. 225-5). The site of delay is typically in the AV node but may be in the atria, AV node bundle of His, or His-Purkinje system; a wide QRS complex favors distal conduction and narrow QRS complex delay in the node proper or, less commonly, in the bundle of His. In second-degree AV block there is an intermittent failure of electrical impulse conduction from atrium to ventricle. Second-degree AV block is subclassified as Mobitz type 1 or Wenckebach and Mobitz type 2. The periodic failure of conduction in Mobitz type 1 block is characterized by a progressively lengthening PR interval, shortening of the RR interval, and a pause that is less than two times the immediately preceding RR interval on the ECG. The ECG complex after the pause exhibits a shorter PR interval that that immediately preceding the pause (Fig. 225-6). This ECG pattern most often arises because of decremental conduction of electrical impulses in the AV node.

It is important to distinguish type 1 from type 2 second-degree AV nodal block because the latter has more serious prognostic implications. Type 2 second-degree AV block is characterized by intermittent failure of conduction of the P wave without changes in the preceding PR or RR intervals. When AV block is 2:1 it may be difficult to distinguish type 1 from type 2 block. Type 2 second-degree AV block typically occurs in the distal or infra-His conduction system, is often associated with intraventricular conduction delays (e.g., bundle branch block), and is more likely to proceed to higher grades of AV block than is type 1 second-degree AV block. Second-degree AV block (particularly type 2) may be associated with a series of nonconducted P waves, referred to as *paroxysmal AV block* (Fig. 225-7), and implies significant

FIGURE 225-6 Mobitz type I second-degree AV block. The PR interval prolongs prior to the pause as shown in the ladder diagram. The ECG pattern results from slowing of conduction in the AV node.

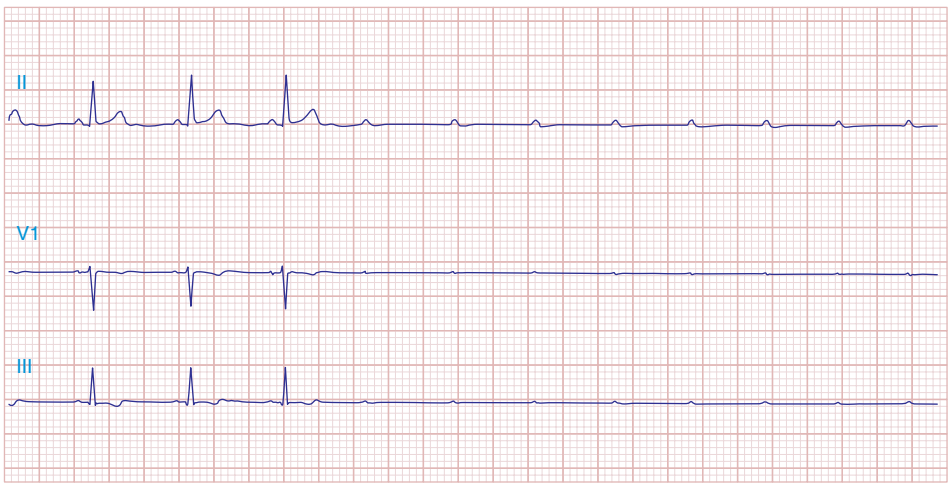

FIGURE 225-7 Paroxysmal AV block. Multiple nonconducted P waves following a period of sinus bradycardia with a normal PR interval. This implies significant conduction system disease, requiring permanent pacemaker implantation.

conduction system disease and an indication for permanent pacing. Complete failure of conduction from atrium to ventricle is referred to as complete or third-degree AV block. AV block that is intermediate between second and third degree is referred to as high-grade AV block, and, as with CHB, implies advanced AV conduction system disease. In both cases, block is most often distal to the AV node, and the duration of the QRS complex can be helpful in determining the level of block. In the absence of a preexisting bundle branch block, a wide QRS escape rhythm (Fig. 225-8*B*) implies block in the distal His or bundle branches; in contrast, a narrow QRS rhythm implies block in the AV node or proximal His and an escape rhythm originating in the AV junction (Fig. 225-8*A*). Narrow QRS escape rhythms are typically faster and more stable than wide QRS escape rhythms and originate more proximally in the AV conduction system.

Diagnostic Testing Diagnostic testing in the evaluation of AV block is aimed at determining the level of conduction block, particularly in asymptomatic patients, since the prognosis and therapy depend upon whether block is in or below the AV node. Vagal maneuvers, carotid sinus massage, exercise, and administration of drugs such as atropine or isoproterenol may be diagnostically informative. Owing to the differences in innervation of the AV node and infranodal conduction system, vagal stimulation and carotid sinus massage slow conduction in the AV node but have less of an effect on infranodal tissue and may even improve conduction due to a reduced rate of activation of distal tissues. Conversely, atropine, isoproterenol, and exercise improve conduction through the AV node and impair infranodal conduction. In patients with congenital CHB and a narrow QRS complex, exercise typically increases heart rate; by contrast, those with acquired CHB, particularly with wide QRS, do not respond to exercise with an increase in heart rate.

Additional diagnostic evaluation, including electrophysiologic testing, may be indicated in patients with syncope and suspected high-grade AV block. This is particularly relevant if noninvasive testing does not reveal the cause of syncope or if the patient has structural heart disease with ventricular tachyarrhythmias as a cause of symptoms. Electrophysiologic testing provides more precise information regarding the location of AV conduction block and permits studies of AV conduction under conditions of pharmacologic stress and exercise. Recording of the His bundle electrogram by a catheter positioned at the superior margin of the tricuspid valve annulus provides information about conduction at all levels of the AV conduction axis. A properly recorded His bundle electrogram reveals local atrial activity, the His electrogram, and local ventricular activation; when monitored simultaneously with recorded body surface electrocardiographic traces, intraatrial, AV nodal, and infranodal conduction times can be assessed (Fig. 225-5).

The *PA interval*, the time from the earliest onset of the P wave on the surface ECG to the onset of the atrial deflection on the His bundle catheter, is an index of intraatrial conduction time and should be ≤50 ms. The time from the most rapid deflection of the atrial electrogram in the His bundle recording to the His electrogram (*AH interval*) represents conduction through the AV node and is normally <130 ms. Finally, the time from the His electrogram to the earliest onset of the QRS on the surface ECG (*HV interval*) represents the conduction time through the His-Purkinje system and is normally ≤55 ms. Rate stress produced by pacing can unveil abnormal AV conduction. Mobitz I second-degree AV block at short atrial paced cycle lengths is a normal response; however, when it occurs at atrial cycle lengths > 500 ms

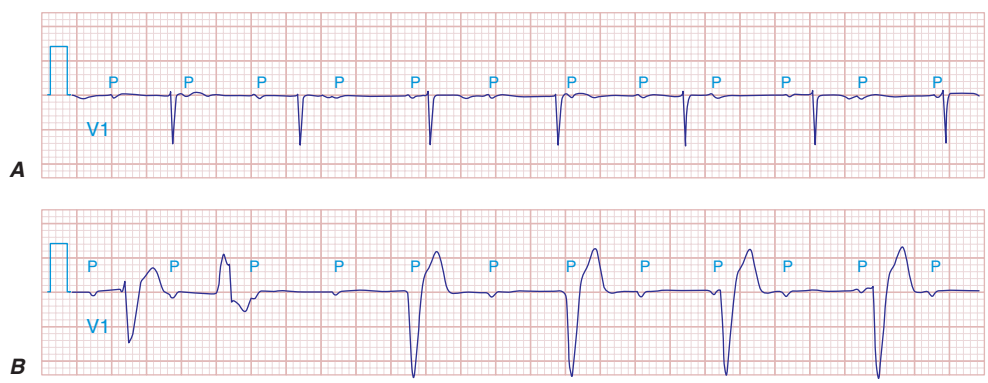

FIGURE 225-8 High-grade AV block. *A.* Multiple nonconducted P waves with a regular narrow complex QRS escape rhythm likely emanating from the AV junction. ***B.*** A wide complex QRS escape and a single PVC. In both cases there is no consistent temporal relationship between the P waves and QRS complexes.

(<120 beats/min) in the absence of high vagal tone, it is abnormal. Typically type I second-degree AV block is associated with prolongation of the AH interval representing conduction slowing and block in the AV node. Block below the node with prolongation of the HV interval or a His bundle electrogram with no ventricular activation (Fig. 225-9) is abnormal unless it is elicited at fast pacing rates or short coupling intervals with extra stimulation.

First-degree AV block is classically intranodal and is associated with a prolonged AH interval. Often, AH prolongation is due to the effect of drugs (beta blockers, calcium channel blockers, digitalis), or increased vagal tone. Atropine can be used to reverse high vagal tone; however, if AH prolongation and AV block at long pacing cycle lengths persist, intrinsic AV node disease is likely. Mobitz type 1 second-degree AV block is usually intranodal and type 2 second-degree block is infranodal, frequently in the His-Purkinje system. It is often difficult to determine the type of second-degree AV block when 2:1 conduction is present; however, the finding of a His bundle electrogram after every atrial electrogram indicates that block is occurring in the distal conduction system.

Intracardiac recording at electrophysiologic study that reveals the presence of His-Purkinje conduction block is associated with an increased risk of progression to higher grades of block and is generally an indication for pacing. In the setting of bundle branch block, the HV interval may reveal the condition of the unblocked bundle and the prognosis for developing more advanced AV conduction block. Prolongation of the HV interval in patients with asymptomatic bundle branch block is associated with an increased risk of developing higher-grade AV block. The risk increases with greater prolongation of the HV interval such that in patients with an HV interval > 100 ms, the annual incidence of complete AV block approaches 10%, indicating a need for pacing. In patients with acquired CHB, even if intermittent, there is little role for electrophysiologic testing, and pacemaker implantation is almost always indicated.

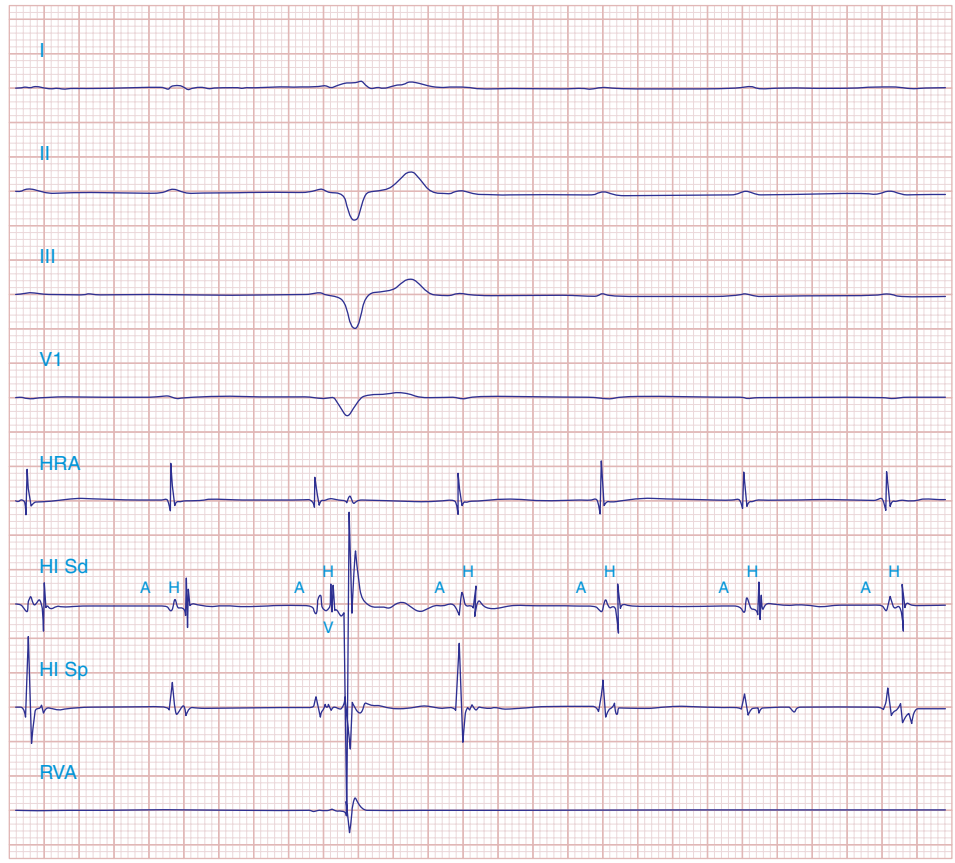

FIGURE 225-9 High-grade AV block below the His. The AH interval is normal and is not changing prior to block. Atrial and His bundle electrograms are recorded consistent with block below the distal AV junction. I, II, III, and V1 are surface ECG leads. HISp, HISd, RVA are the proximal HIS, distal HIS, and right ventricular apical electrical recordings. A, H, and V represent the atrial, His, and ventricular electrograms on the His bundle recording. *(Tracing courtesy of Dr. Joseph Marine; with permission.)*

℞ ATRIOVENTRICULAR CONDUCTION BLOCK

Temporary or permanent artificial pacing is the most reliable treatment for patients with symptomatic AV conduction system disease. However, exclusion of reversible causes of AV block and the need for temporary heart rate support based on the hemodynamic condition of the patient are essential considerations in each patient. Correction of electrolyte derangements and ischemia, inhibition of excessive vagal tone, and withholding drugs with AV nodal blocking properties may increase the heart rate. Adjunctive pharmacologic treatment with atropine or isoproterenol may be useful if block is in the AV node. Since most pharmacologic treatment may take some time to initiate and become effective, temporary pacing may be necessary. The most expeditious technique is the use of transcutaneous pacing, where pacing patches are placed anteriorly over the cardiac apex (cathode) and posteriorly between the spine and scapula or above the right nipple (anode). Acutely, transcutaneous pacing is highly effective, but its duration is limited by patient discomfort and longer-term failure to capture the ventricle owing to changes in lead impedance. If a patient requires more than a few minutes of pacemaker support, transvenous temporary pacing should be instituted. Temporary pacing leads can be placed from the jugular or subclavian venous system and advanced to the right ventricle, permitting stable temporary pacing for many days, if necessary. In most circumstances, in the absence of prompt resolution, conduction block distal to the AV node requires permanent pacemaking.

PERMANENT PACEMAKERS

Nomenclature and Complications

The main therapeutic intervention in SA node dysfunction and AV conduction block is permanent pacing. Since the first implementation of permanent pacing in the 1950s, many advances in technology have resulted in miniaturization, increased longevity of pulse generators, improvement in leads, and increased functionality. In order to better understand pacemaker therapy of bradycardias, it is important to be familiar with fundamentals of pacemaking. Pacemaker modes and function are named using a five-letter code. The first letter indicates the chamber(s) that is paced (O, none; A, atrium; V, ventricle; D, dual; S, single), the second is the chamber(s) in which sensing occurs (O, none; A, atrium; V, ventricle; D, dual; S, single), the third is the response to a sensed event (O, none; I, inhibition; T, triggered; D, inhibition + triggered), the fourth letter refers to the programmability or rate response (R, rate responsive), and the fifth refers to the existence of antitachycardia functions if present (O, none; P, antitachycardia pacing; S, shock; D, pace + shock). Almost all modern pacemakers are multiprogrammable and have the capability for rate responsiveness using one of several rate sensors: activity or motion, minute ventilation, or QT interval. The most commonly programmed modes of implanted single- and dual-chamber pacemakers are VVIR and DDDR, respectively, although multiple modes can be programmed in modern pacemakers.

Although pacemakers are highly reliable, they are subject to a number of complications related to implantation and electronic function. In adults, permanent pacemakers are most commonly implanted with

access to the heart by way of the subclavian–superior vena cava venous system. Rare, but possible, acute complications of transvenous pacemaker implantation include infection, hematoma, pneumothorax, cardiac perforation, diaphragmatic/phrenic nerve stimulation, and lead dislodgment. Limitations of chronic pacemaker therapy include infection, erosion, lead failure, and abnormalities resulting from inappropriate programming or interaction with the patient's native electrical cardiac function. Rotation of the pacemaker pulse generator in its subcutaneous pocket, either intentionally or inadvertently, often referred to as "twiddler's syndrome," can wrap the leads around the generator and produce dislodgment with failure to sense or pace the heart. The small size and light weight of contemporary pacemakers makes this a rare complication.

A common problem is pacemaker syndrome; a constellation of signs and symptoms associated with any mode of pacing that does not maintain or restore AV synchrony. The symptoms include neck pulsation, fatigue, palpitations, cough, confusion, exertional dyspnea, dizziness, and syncope, and they may be associated with an elevation in jugular venous pressure, canon A waves, and stigmata of congestive heart failure, including edema, rales, and a third heart sound. Often, there is a substantial drop in blood pressure with ventricular pacing. The management of pacemaker syndrome involves changing the pacing mode to restore AV synchrony.

Pacemaker Therapy in SA Node Dysfunction Pacing in SA nodal disease is indicated to alleviate symptoms of bradycardia. Consensus guidelines published by the AHA/ACC/HRS outline the indications for the use of pacemakers, and categorize them by class based on levels of evidence. Class I conditions are those for which there is evidence or consensus of opinion that therapy is useful and effective. In class II conditions there is conflicting evidence or a divergence of opinion about the efficacy of a procedure or treatment; in class IIa conditions the weight of evidence or opinion favors treatment, and in class IIb conditions, efficacy is less well established by the evidence or opinion of experts. In class III conditions, the evidence or weight of opinion indicates that the therapy is not efficacious or useful, and may be harmful.

Class I indications for pacing in SA node dysfunction include documented symptomatic bradycardia, sinus node dysfunction–associated long-term drug therapy for which there is no alternative, or symptomatic chronotropic incompetence. Class IIa indications include those outlined previously in which sinus node dysfunction is suspected but not documented and for syncope of unexplained origin in the presence of major abnormalities of SA node dysfunction. Mildly symptomatic individuals with heart rates consistently <40 beats/min comprise a class IIb indication for pacing. Pacing is not indicated in patients with SA node dysfunction who do not have symptoms and in those in whom bradycardia is associated with the use of nonessential drugs (Table 225-3).

There is some controversy regarding the mode of pacing that should be employed in SA node disease. A number of randomized, single-blind trials of pacing mode have been performed. There are no trials that demonstrate an improvement in mortality with AV synchronous compared with single-chamber pacing in SA node disease. In some of these studies, the incidence of atrial fibrillation and thromboembolic events was reduced with AV synchronous pacing. In trials of patients with dual-chamber pacemakers designed to compare single-chamber with dual-chamber pacing by crossover design, the need for AV synchronous pacing due to pacemaker syndrome was common. Pacing modes that preserve AV synchrony appear to be associated with a reduction in the incidence of atrial fibrillation and improved quality of life. Because of the low but finite incidence of AV conduction disease, patients with SA node dysfunction will usually undergo dual-chamber pacemaker implantation.

Pacemaker Therapy in Carotid Sinus Hypersensitivity and Vasovagal Syncope Carotid sinus hypersensitivity, if accompanied by a significant cardioinhibitory component, responds well to pacing. In this circumstance, pacing is only required intermittently and single-chamber ventricular pacing is often sufficient. The mechanism of vasovagal syncope is incompletely understood but appears to involve activation of cardiac mechanoreceptors with consequent activation of neural centers that mediate vagal activation and withdrawal of sympathetic nervous system tone. Several randomized clinical trials have been performed in patients with drug-refractory vasovagal syncope, with a reduction in the frequency and the time to recurrent syncope in patients who were paced compared to those who were not.

TABLE 225-3 SUMMARY OF GUIDELINES FOR PACEMAKER IMPLANTATION IN SA NODE DYSFUNCTION

Class I
1. SA node dysfunction with symptomatic bradycardia or sinus pauses
2. Symptomatic SA node dysfunction as a result of essential long-term drug therapy with no acceptable alternatives
3. Symptomatic chronotropic incompetence

Class IIa
1. SA node dysfunction with heart rates < 40 beats/min without a clear and consistent relationship between bradycardia and symptoms
2. SA node dysfunction with heart rates < 40 beats/min on an essential long-term drug therapy with no acceptable alternatives, without a clear and consistent relationship between bradycardia and symptoms
3. Syncope of unknown origin when major abnormalities of SA node dysfunction are discovered or provoked by electrophysiologic testing

Class IIb
1. Mildly symptomatic patients with waking chronic heart rates < 40 beats/min

Class III
1. SA node dysfunction in asymptomatic patients even those with heart rates < 40 beats/min
2. SA node dysfunction in which symptoms suggestive of bradycardia are not associated with a slow heart rate
3. SA node dysfunction with symptomatic bradycardia due to nonessential drug therapy

Pacemakers in AV Conduction Disease There are no randomized trials that evaluate the efficacy of pacing in patients with AV block as there are no reliable therapeutic alternatives for AV block and untreated high-grade AV block is potentially lethal. The consensus guidelines for pacing in acquired AV conduction block in adults provide a general outline for situations in which pacing is indicated (Table 225-4). Pacemaker implantation should be performed in any patient with symptomatic bradycardia and irreversible second- or third-degree AV block, regardless of the cause or level of block in the conducting system. Symptoms may include those directly related to bradycardia and low cardiac output or to worsening heart failure, angina, or intolerance to an essential medication. Pacing in patients with asymptomatic AV block should be individualized; situations in which pacing should be considered are in those patients with acquired CHB, particularly in the setting of cardiac enlargement; left ventricular dysfunction; and waking heart rates of ≤40 beats/min. Patients who have asymptomatic second-degree AV block of either type should be considered for pacing if the block is demonstrated to be intra- or infraHis, or is associated with a wide QRS complex. Pacing may be indicated in asymptomatic patients under special circumstances; in patients with profound first-degree AV block and left ventricular dysfunction in whom a shorter AV interval produces hemodynamic improvement, and in the setting of milder forms of AV conduction delay (first-degree AV block, intraventricular conduction delay) in patients with neuromuscular diseases that have a predilection for the conduction system, such as myotonic dystrophy and other muscular dystrophies, and Kearns-Sayre syndrome.

Pacemaker Therapy in Myocardial Infarction Atrioventricular block in acute MI is often transient, particularly in inferior infarction. The circumstances under which pacing is indicated in acute MI are persistent second- or third-degree AV block, particularly if symptomatic, and transient second- or third-degree AV block associated with bundle branch block (Table 225-5). Pacing is generally not indicated in the setting of transient AV block in the absence of intraventricular con-

TABLE 225-4 GUIDELINE SUMMARY FOR PACEMAKER IMPLANTATION IN ACQUIRED AV BLOCK

Class I
1. Third-degree or high-grade AV block at any anatomic level associated with:
   a. Symptomatic bradycardia
   b. Essential drug therapy that produces symptomatic bradycardia
   c. Periods of asystole > 3 s or any escape rate < 40 beats/min while awake
   d. Postoperative AV block not expected to resolve
   e. Catheter ablation of the AV junction
   f. Neuromuscular diseases such as myotonic dystrophy, Kearns-Sayre syndrome, Erb dystrophy, and peroneal muscular atrophy, regardless of the presence of symptoms
2. Second-degree AV block with symptomatic bradycardia
3. Type II second-degree AV block with a wide QRS complex with or without symptoms

Class IIa
1. Asymptomatic third-degree AV block regardless of level
2. Asymptomatic type II second-degree AV block with a narrow QRS complex
3. Asymptomatic type II second-degree AV block with block within or below the His at electrophysiologic study
4. First- or second-degree AV block with symptoms similar to pacemaker syndrome

Class IIb
1. Marked first-degree AV block (PR interval > 300 ms) in patients with LV dysfunction in whom shortening the AV delay would improve hemodynamics
2. Neuromuscular diseases, such as myotonic dystrophy, Kearns-Sayre syndrome, Erb dystrophy, and peroneal muscular atrophy, with any degree of AV block regardless of the presence of symptoms

Class III
1. Asymptomatic first-degree AV block
2. Asymptomatic type I second-degree AV block at the AV node level
3. AV block that is expected to resolve or is unlikely to recur (Lyme disease, drug toxicity)

Source: Modified from Gregoratos et al, 1997, and Gregoratos et al, 2002.

duction delays, or in the presence of fascicular block or first-degree AV block that develops in the setting of preexisting bundle branch block. Fascicular blocks that develop in acute MI in the absence of other forms of AV block also do not require pacing (Table 225-5 and Table 225-6).

Distal forms of AV conduction block may require pacemaker implantation in certain clinical settings. In patients with bifascicular or trifascicular block and symptoms, particularly syncope that is not attributable to other causes, should undergo pacemaker implantation.

TABLE 225-5 GUIDELINE SUMMARY FOR PACEMAKER IMPLANTATION IN AV CONDUCTION BLOCK IN ACUTE MYOCARDIAL INFARCTION (AMI)

Class I
1. Persistent second-degree AV block in the His-Purkinje system with bilateral bundle branch block or third-degree block within or below the His after AMI
2. Transient advanced (second- or third-degree) infranodal AV block and associated bundle branch block. If the site of block is uncertain, an electrophysiologic study may be necessary
3. Persistent and symptomatic second- or third-degree AV block

Class IIb
1. Persistent second- or third-degree AV block at the AV node level

Class III
1. Transient AV block in the absence of intraventricular conduction defects
2. Transient AV block in the presence of isolated left anterior fascicular block
3. Acquired left anterior fascicular block in the absence of AV block
4. Persistent first-degree AV block in the presence of bundle branch block that is old or age-indeterminate

Source: Modified from Gregoratos et al, 1997.

TABLE 225-6 INDICATIONS FOR PACEMAKER IMPLANTATION IN CHRONIC BIFASCICULAR AND TRIFASCICULAR BLOCK

Class I
1. Intermittent third-degree AV block
2. Type II second-degree AV block
3. Alternating bundle branch block

Class IIa
1. Syncope not demonstrated to be due to AV block when other likely causes (e.g., ventricular tachycardia) have been excluded
2. Incidental finding at electrophysiologic study of a markedly prolonged HV interval (>100 ms) in asymptomatic patients
3. Incidental finding at electrophysiologic study of pacing-induced infra-His block that is not physiologic

Class IIb
1. Neuromuscular diseases, such as myotonic dystrophy, Kearns-Sayre syndrome, Erb dystrophy, and peroneal muscular atrophy, with any degree of fascicular block regardless of the presence of symptoms, because there may be unpredictable progression of AV conduction disease

Class III
1. Fascicular block without AV block or symptoms
2. Fascicular block with first-degree AV block without symptoms

Source: Modified from Gregoratos et al, 1997, and Gregoratos et al, 2002.

Pacemaking is indicated in asymptomatic patients with bifascicular or trifascicular block who experience intermittent third-degree, type II second-degree AV block, or alternating bundle branch block. In patients with fascicular block who are undergoing electrophysiologic study, a markedly prolonged HV interval or block below the His at long cycle lengths may also constitute an indication for permanent pacing. In patients with fascicular block and the neuromuscular diseases previously described should also undergo pacemaker implantation (Table 225-6).

Selection of Pacing Mode In general, a pacing mode that maintains AV synchrony reduces complications of pacing such as pacemaker syndrome and pacemaker-mediated tachycardia. This is particularly true in younger patients, but the importance of dual-chamber pacing, especially in the elderly, is not well established. Several studies have failed to demonstrate a difference in mortality in older patients with AV block treated with a single- (VVI) compared to a dual- (DDD) chamber pacing mode. In some of these studies that randomized pacing mode, the risk of chronic atrial fibrillation and stroke risk decreased with physiologic pacing. In patients with sinus rhythm and AV block, the very modest increase in risk with dual-chamber pacemaker implantation appears to be justified to avoid the possible complications of single-chamber pacing.

226 The Tachyarrhythmias

Francis Marchlinski

Tachyarrhythmias typically refer to isolated premature complexes (depolarizations) or to nonsustained and sustained forms of tachycardia originating from myocardial foci or reentrant circuits. The standard definition of tachycardia is rhythm that produces a ventricular rate >100 beats/min. This definition has some limitations in that atrial rates can exceed 100 beats/min despite a slow ventricular rate. Furthermore, ventricular rates may exceed the baseline sinus rate and be <100 beats/min but still represent an important "tachycardia" response, such as is observed with accelerated ventricular rhythms.

SYMPTOMS DUE TO TACHYARRHYTHMIAS

Tachyarrhythmias classically produce symptoms of palpitations or racing of the pulse. For premature beats, skipping of the pulse or a pause may be experienced, and patients may even sense slowing of the heart rate. A more dramatic irregularity of the pulse will be experienced with chaotic rapid rhythms or tachyarrhythmias that originate in the atrium and conduct variably to the ventricles. For very rapid tachyarrhythmias, hemodynamic compromise can occur, as can dizziness or syncope due to a decrease in cardiac output or breathlessness due to a marked increase in cardiac filling pressures. Occasionally, chest discomfort may be experienced that mimics symptoms of myocardial ischemia. The underlying cardiac condition typically dictates the severity of symptoms at any specific heart rate. Even patients with normal systolic left ventricular (LV) function may experience severe symptoms if diastolic compliance due to hypertrophy or valvular obstruction is present. Hemodynamic collapse with the development of ventricular fibrillation (VF) can lead to sudden cardiac death (SCD) (Chap. 267). SCD remains one of the principal causes of death in the adult population, thus emphasizing the importance of appropriate tachyarrhythmia prevention as well as management.

DIAGNOSTIC TESTS IN EVALUATING TACHYARRHYTHMIAS

In patients who present with non-life-threatening symptoms, such as palpitations or dizziness, electrocardiogram (ECG) confirmation of an arrhythmia with the development of recurrent symptoms is essential. A 24-h Holter monitor should be considered only for patients with daily symptoms. For intermittent symptoms that are of a prolonged duration, a patient-activated event monitor can be used to obtain the ECG information without the need for continuous ECG lead attachment and recordings. A patient-activated monitor with a continuously recorded memory loop ("loop recorder") can be used to document short-lived episodes and the onset of the arrhythmia. This is the preferred monitoring technique for symptomatic patients with less frequent arrhythmia events but it requires continuous ECG recording. Patients with infrequent, severe symptoms that cannot be identified by intermittent ECG monitoring may receive an implanted loop ECG monitor that provides more extended periods of monitoring and automatic arrhythmia detection (Fig. 226-1).

In patients who present with more severe symptoms, such as syncope, outpatient monitoring may be insufficient. In patients with structural heart disease and syncope in whom there is suspicion of ventricular tachycardia (VT), hospitalization and diagnostic electrophysiologic testing are warranted, with strong consideration for an implantable cardioverter/defibrillator (ICD) device. The 12-lead ECG recorded in sinus rhythm should be carefully assessed in patients without structural heart disease for evidence of ST-segment elevation in leads V_1 and V_2 consistent with the Brugada syndrome, QT interval changes consistent with long or short QT syndromes, or a short PR interval and delta wave consistent with Wolff-Parkinson-White (WPW) syndrome. These ECG patterns identify an arrhythmogenic substrate that may cause intermittent life-threatening symptoms and warrant further evaluation and therapy. The individual syndromes are discussed in detail later in this chapter.

Monitoring for asymptomatic tachyarrhythmias is indicated in several specific situations. In patients with a suspected tachycardia-induced cardiomyopathy marked by chamber dilatation and depression in systolic function, the demonstration of arrhythmia control is essential. Monitoring for asymptomatic ventricular premature complexes (VPCs) and nonsustained VT can be helpful in stratifying the risk of SCD in patients with depressed LV function after myocardial infarction. Finally, in patients with asymptomatic atrial fibrillation (AF), anticoagulation treatment strategies depend on an accurate assessment of the presence of this arrhythmia. The duration of monitoring for asymptomatic arrhythmias may vary. The transition from 24-h Holter monitoring to more extended periods of monitoring with technology capable of automatic arrhythmia detection improves the reliability of the monitoring information used in decision-making.

A 12-lead ECG recording during the tachycardia can be an important diagnostic tool in identifying the mechanism and the origin of a tachycardia not afforded by one- or two-lead ECG recordings. A 12-lead ECG of the tachyarrhythmia should be recorded and incorporated as a permanent part of the medical record whenever possible. For patients whose arrhythmias are provoked by exercise, an exercise test may provide the opportunity to obtain 12-lead ECG recordings of the arrhythmia and may obviate the need for more extended periods of monitoring.

Many paroxysmal supraventricular tachyarrhythmias are not associated with a significant risk of structural heart disease, and an evaluation for the presence of ischemic heart disease and cardiac function is uncommonly required unless dictated by the severity or characteristics of the symptoms. However in patients with focal or macroreentrant atrial tachycardias (ATs), atrial flutter (AFL), or AF, an evaluation of cardiac chamber size and function and of valve function is warranted. In patients with VT, an echocardiographic assessment of LV and right ventricular (RV) size and function should be the norm. VT occurring in the setting of depressed LV function should raise the suspicion of advanced coronary artery disease. Polymorphic VT in the absence of QT prolongation should always raise the concern for a potentially unstable ischemic process that may need to be corrected to effect VT control.

MECHANISMS OF TACHYARRHYTHMIAS

Tachycardias are due to abnormalities of impulse formation and/or abnormalities of impulse propagation (Fig. 226-2).

Abnormalities in Impulse Formation An increase in automaticity normally causes an increase in sinus rate and sinus tachycardia (Fig. 226-2*A*). Abnormal automaticity is due to an increase in the slope of phase 4 depolarization or a reduced threshold for action potential depolarization in myocardium other than the sinus node. Abnormal automaticity is thought to be responsible for most atrial premature complexes (APCs) and VPCs and some ATs. Pacing does not provoke automatic rhythms. Less commonly, abnormal impulse formation is

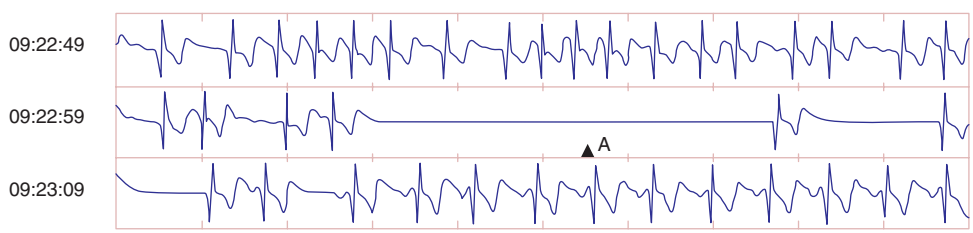

FIGURE 226-1 Spontaneous termination of atrial fibrillation at the time of a syncopal episode identified from implantable loop ECG recording.

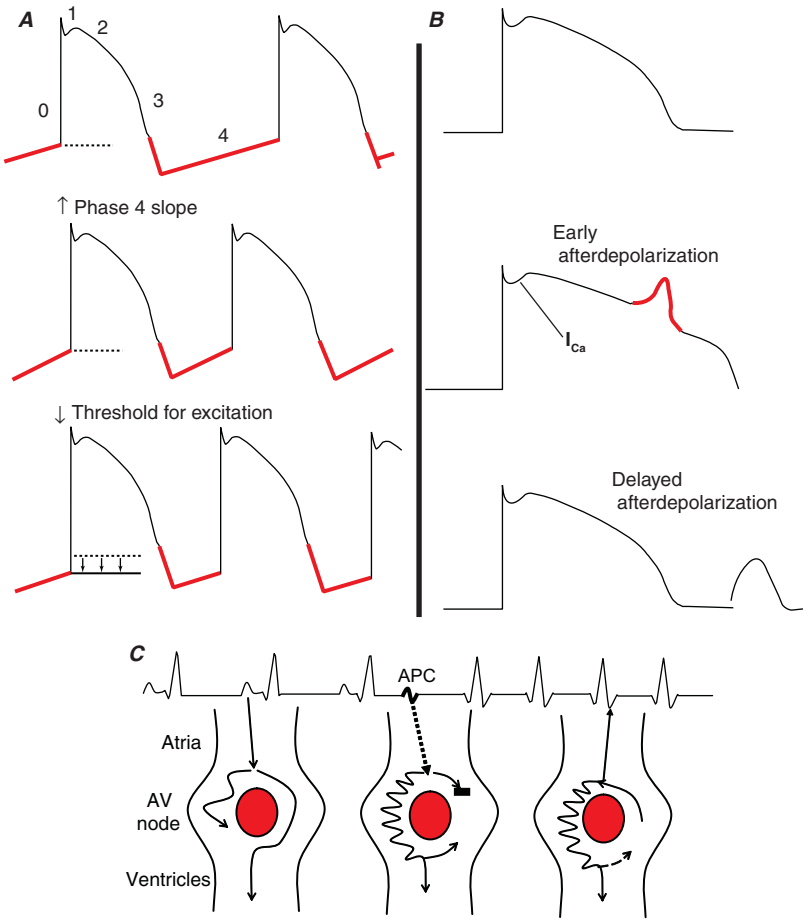

FIGURE 226-2 Schematic representation of the different mechanisms for arrhythmias. *A.* Abnormal automaticity due to an increased slope of phase 4 of the action potential or a decrease in the threshold for phase 0. ***B.*** Triggered activity due to early afterdepolarizations (EADs) during phase 3 of the action potential due to alteration of plateau currents, or delayed afterdepolarizations (DADs) during phase 4 of the action potential due to intracellular calcium accumulation. ***C.*** Reentry with basic requirements of two pathways that have heterogeneous electrophysiologic properties which allows conduction to block in one pathway and to propagate slowly in the other, allowing for sufficient delay so that the blocked site has time for recovery to allow for reentry or circus movement tachycardia. Shown is typical schema for reentry in the AV node. (AV, atrioventricular; APC, atrial premature complex.)

due to the development of triggered activity. Triggered activity is related to cellular afterdepolarizations that occur at the end of the action potential, during phase 3, and are referred to as *early afterdepolarizations*, or they occur after the action potential, during phase 4, and are referred to as *late afterdepolarizations*. Afterdepolarizations are attributable to an increase in intracellular calcium accumulation. If sufficient afterdepolarization amplitude is achieved, repeated myocardial depolarization and a tachycardic response can occur. Early afterdepolarizations may be responsible for the VPCs that trigger the polymorphic ventricular arrhythmia known as *torsades des pointes* (TDP) (p. 1436). Late afterdepolarizations are thought to be responsible for atrial, junctional, and fascicular tachyarrhythmias caused by digoxin toxicity and also appear to be the basis for catecholamine-sensitive VT originating in the outflow tract. In contrast to automatic tachycardias, tachycardias due to triggered activity (Fig. 226-2*B*) can frequently be provoked with pacing maneuvers.

Abnormalities in Impulse Propagation Reentry is due to inhomogeneities in myocardial conduction and/or recovery properties. The presence of unidirectional block with slow conduction to allow for retrograde recovery of the blocked myocardium allows for a circuit to form that, if perpetuated, can sustain a tachycardia (Fig. 226-2*C*). These inhomogeneities are somewhat inherent but minimized in normal myocardial activation/recovery. The inhomogeneities can be exaggerated by the presence of extra pathways, such as occurs with the WPW syndrome; generalized genetically determined myocardial ion channel abnormalities, such as occurs with long QT syndrome (LQTS); or by the interruption of normal myocardial patterns of activation due to the development of fibrosis.

Reentry appears to be the basis for most abnormal sustained supraventricular tachycardias (SVTs) and VTs. In general, reentry can be anatomically driven (fixed) based on the presence of "extra" pathways, natural anatomic barriers of conduction such as the crista terminalis, the vertical crest on the interior wall of the right atrium that separates the sinus of the vena cava and nontrabeculated posterior right atrium from the rest of the trabeculated right atrium located lateral to the structure, and/or extensive fibrosis created by underlying myocardial disease. This form of reentry seems to be more stable and results in a tachycardia that has a uniform (often monomorphic), repetitive appearance. Other forms of reentry appear to be more functional and are more dependent on dynamic changes in electrophysiologic properties of the myocardium. These tachycardias tend to be more unstable and may result in tachycardias that have a polymorphic appearance. Two classic examples of reentry that is primarily functional include VF due to acute myocardial ischemia and polymorphic VT in patients with genetically determined ion channel abnormalities, such as the Brugada syndrome, LQTS, or catecholaminergic polymorphic VT (p. 1441).

SUPRAVENTRICULAR TACHYARRHYTHMIAS

ATRIAL PREMATURE COMPLEXES

APCs are the most common arrhythmia identified during extended ECG monitoring. The incidence of APCs frequently increases with age and with the presence of structural heart diseases. APCs typically are asymptomatic, although some patients experience palpitations or an irregularity of the pulse.

ECG Diagnosis of APCs The ECG diagnosis of premature atrial complexes is based on the identification of a P wave that occurs prior to the anticipated sinus beat (Figs. 226-3*A* and 226-3*B*). The source of the APC appears to parallel the typical sites of origin for ATs. The orifices of the superior vena cava and pulmonary veins, the coronary sinus, the crista terminalis, mitral and tricuspid valve annuli, and left and right atrial appendages are common sites of origin of APCs. The P wave contour differs from that noted during sinus rhythm, although APCs from the right atrial appendage, superior vena cava (SVC), and superior aspect of the crista terminalis in the region of the sinus node may mimic the sinus P wave morphology. In response to an APC, the PR interval lengthens, although APCs that originate near the atrioventricular (AV) nodal region may actually have a shorter PR interval because the atrial conduction time to the junction is shortened. A very early APC may not conduct to the ventricle and can create a pulse irregularity that may be perceived as a pause or "dropped beat." If the APC conducts rapidly through the AV node, a partially recovered His-Purkinje system will be encountered and a QRS pattern consistent with a right or left bundle branch block may occur. This wide QRS pattern and the failure to recognize the preceding P wave may result in the misdiagnosis of VPCs. APCs characteristically reset the sinus node. The resulting sum of the pre- and post-APC RR interval is less than two sinus PP intervals.

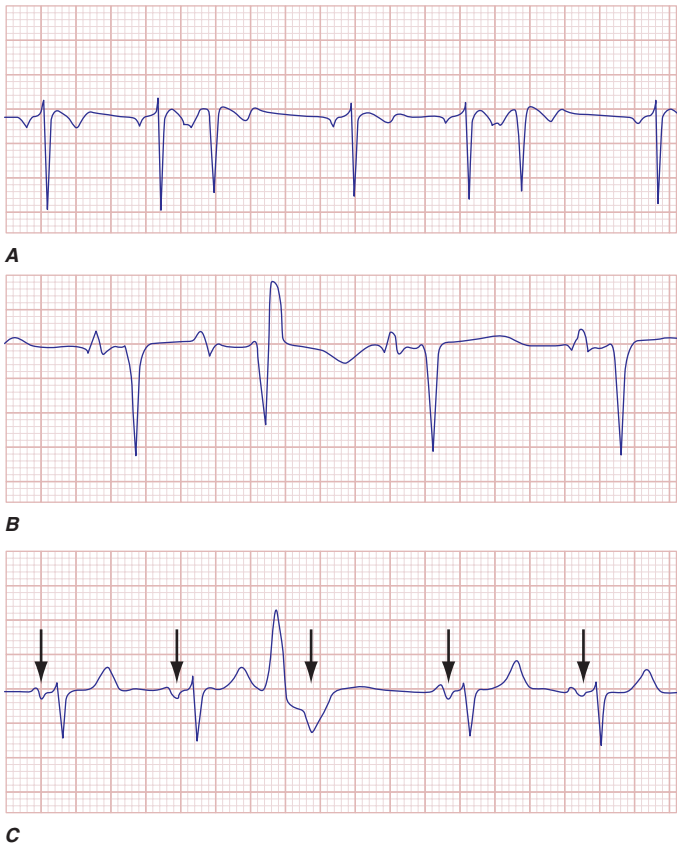

FIGURE 226-3 Atrial and ventricular premature complexes (APCs, VPCs). The APC resets the sinus node and no compensatory pause is present (***A***) even when conducted aberrantly in the ventricles with a bundle branch block type QRS pattern (***B***). VPCs tend not to reset the sinus activity (*arrows*) and will demonstrate a full compensatory pause (***C***).

℞ ATRIAL PREMATURE COMPLEXES

APCs uncommonly require intervention. For extremely symptomatic patients who do not respond to explanation and reassurance, an attempt can be made to suppress the APCs with pharmacologic agents. The repetitive focus can even be targeted for catheter ablation. Beta blockers are typical first-line therapy, but they may exacerbate symptoms if AV block occurs with the APC and irregularity of the pulse consequently becomes more profound. The use of class IC antiarrhythmic agents may eliminate the APCs but should be avoided if structural heart disease is present.

JUNCTIONAL PREMATURE COMPLEXES

Junctional premature complexes are extremely uncommon. The complexes originate from the AV node and His bundle region and may produce retrograde atrial activation with the P wave distorting the initial or terminal portions of the QRS complex producing pseudo Q or S waves in leads II, III, and aVF. Extrasystoles originating in the bundle of His that do not conduct to the ventricle and also block the atria can produce unexplained surface ECG PR prolongation that does not follow a typical Wenckebach periodicity, i.e., gradual PR prolongation culminating in atrial activity that fails to conduct to the ventricles. Intracardiac recordings can frequently identify a His depolarization, thus identifying the origin of the complex to the AV junction. Symptomatic patients may be typically treated with beta blockers or, if there is no structural heart disease, class IC antiarrhythmic agents.

SINUS TACHYCARDIA

Physiologic sinus tachycardia represents a normal or appropriate response to physiologic stress, such as occurs with exercise, anxiety, or fever. Pathologic conditions, such as thyrotoxicosis, anemia, or hypotension, may also produce sinus tachycardia. It is important to distinguish sinus tachycardia from other SVTs. Sinus tachycardia will produce a P wave contour consistent with its origin from the sinus node located in the superior-lateral and posterior aspect of the right atrium. The P wave is upright in leads II, III and aVF, and negative in lead aVR. The P wave morphology in lead V_1 characteristically has a biphasic, positive/negative contour. Onset of sinus tachycardia is gradual, and in response to carotid sinus pressure there may be some modest and transient slowing but no abrupt termination. Importantly, the diagnosis should not be based on the PR interval or the presence of a P wave before every QRS complex. The PR interval and the presence of 1:1 AV conduction properties are entirely determined by AV nodal and His-Purkinje conduction and, therefore, the PR interval can be dramatically prolonged while sinus tachycardia remains the mechanism of the atrial activity.

℞ PHYSIOLOGIC SINUS TACHYCARDIA

Treatment of physiologic sinus tachycardia is directed at the underlying condition causing the tachycardia response. Uncommonly, beta blockers are used to minimize the tachycardia response if it is determined to be potentially harmful, as may occur in a patient with ischemic heart disease and rate-related anginal symptoms.

Inappropriate sinus tachycardia represents an uncommon but important medical condition in which the heart rate increases either spontaneously or out of proportion to the degree of physiologic stress/exercise. Dizziness and even frank syncope can often accompany the sinus tachycardia and symptoms of palpitations. The syndrome can be quite disabling. Associated symptoms of chest pain, headaches, and gastrointestinal upset are common. In many patients, the syndrome occurs after a viral illness and may resolve spontaneously over the course of 3–12 months, suggesting a postviral dysautonomia.

Excluding the diagnosis of an automatic AT that originates in the region of the sinus node can be difficult and may require invasive electrophysiologic evaluation. Frequently, patients are misdiagnosed as having an anxiety disorder with physiologic sinus tachycardia.

℞ INAPPROPRIATE SINUS TACHYCARDIA

For symptomatic patients, maintaining an increased state of hydration, salt loading, and careful titration of beta blockers to the maximum tolerated dose, administered in divided doses, frequently minimizes symptoms. For severely symptomatic patients who are intolerant of or unresponsive to beta blockers, catheter ablation directed at modifying the sinus node may be effective. Because of the high recurrence rate after ablation and the frequent need for atrial pacing therapy, this intervention remains second-line treatment.

ATRIAL FIBRILLATION

(Fig. 226-4) AF is the most common sustained arrhythmia. It is marked by disorganized, rapid, and irregular atrial activation. The ventricular response to the rapid atrial activation is also irregular. In the untreated patient, the ventricular rate also tends to be rapid and is entirely dependent on the conduction properties of the AV junction. Although typically the rate will vary between 120 and 160 beats/min, in some patients it can be >200 beats/min. In other patients, because of heightened vagal tone or intrinsic AV nodal conduction properties, the ventricular response is <100 beats/min and occasionally even profoundly slow. The mechanism for AF initiation and maintenance, although still debated, appears to represent a complex interaction between drivers responsible for the initiation and the complex anatomic atrial substrate that promotes the maintenance of multiple wavelets of (micro)reentry. The drivers appears to originate predominantly from the atrialized musculature that enters the pulmonary veins and either represent focal abnormal automaticity or triggered firing that is somewhat modulated by autonomic influences. Sustained

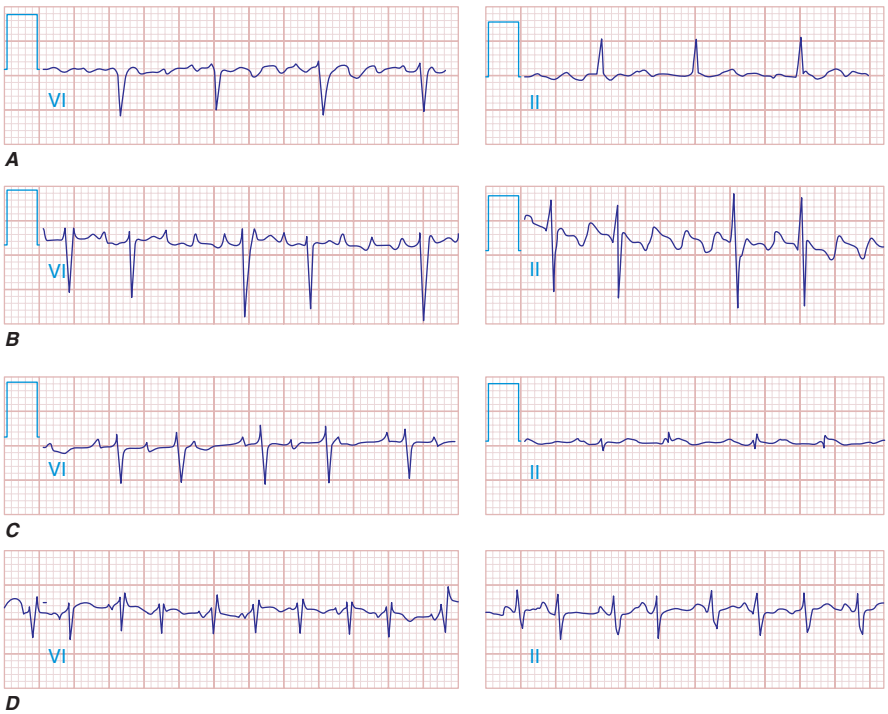

FIGURE 226-4 Supraventricular tachycardias with irregular ventricular rates. Atrial fibrillation (***A***), atrial flutter (***B***), atrial tachycardia (***C***), and multifocal atrial tachycardia (MAT; ***D***) are shown. The characteristics of the atrial activity with respect to the morphology and rate provide the clues to the diagnosis.

forms of microreentry as drivers have also been documented around the orifice of pulmonary veins; nonpulmonary vein drivers have also been demonstrated. The role these drivers play in maintaining the tachycardias may also be significant and may explain the success of pulmonary vein isolation procedures in eliminating more chronic or persistent forms of AF.

Although AF is common in the adult population, it is extremely unusual in children unless structural heart disease is present or there is another arrhythmia that precipitates the AF, such as paroxysmal SVT in patients with WPW syndrome. The incidence of AF increases with age such that >5% of the adult population over 70 will experience the arrhythmia. As many patients are asymptomatic with AF, it is anticipated that the overall incidence, particularly that noted in the elderly, may be more than double previously reported rates. Occasionally AF appears to have a well-defined etiology, such as acute hyperthyroidism, an acute vagotonic episode, or acute alcohol intoxication. Acute AF is particularly common during the acute or early recovery phase of major vascular, abdominal, and thoracic surgery where autonomic fluxes and/or direct mechanical irritation potentiate the arrhythmia. AF may also be triggered by other supraventricular tachycardias (p. 1433), such as AV nodal reentrant tachycardia (AVNRT), and elimination of these arrhythmias may prevent AF recurrence.

AF has clinical importance related to (1) the loss of atrial contractility, (2) the inappropriate fast ventricular response, and (3) the loss of atrial appendage contractility and emptying leading to the risk of clot formation and subsequent thromboembolic events.

Symptoms from AF vary dramatically. Many patients are asymptomatic and have no apparent hemodynamic consequences to the development of AF. Other patients experience only minor palpitations or sense irregularity of their pulse. Many patients, however, experience severe palpitations. The hemodynamic effect in patients can be quite dramatic, depending on the need for normal atrial contractility and the ventricular response. Hypotension, pulmonary congestion, and anginal symptoms may be severe in some patients. In patients with the LV diastolic dysfunction that occurs with hypertension, hypertrophic cardiomyopathy, or obstructive aortic valvular disease, symptoms may be even more dramatic, especially if the ventricular rate does not permit adequate ventricular filling. Exercise intolerance and easy fatigability are the hallmarks of poor rate control with exertion. Occasionally, the only manifestation of AF is severe dizziness or syncope associated with the pause that occurs upon termination of AF before sinus rhythm resumes (Fig. 226-1).

The ECG in AF is characterized by the lack of organized atrial activity and the irregularly irregular ventricular response. Occasionally, one needs to record from multiple ECG leads simultaneously to identify the chaotic continuous atrial activation. Lead V_1 may frequently show the appearance of organized atrial activity that mimics AFL. This occurs because the crista terminalis serves as an effective anatomic barrier to electrical conduction, and the activation of the lateral right atrium may be represented by a more uniform activation wavefront that originates over the roof of the right atrium. ECG assessment of the PP interval (<200 ms) and the chaotic P wave morphology in the remaining ECG leads will confirm the presence of AF.

Evaluation of the patient with AF should include a search for reversible causes of the arrhythmia, such as hyperthyroidism or anemia. An echocardiogram should be performed to determine if there is structural heart disease. Persistent or labile hypertension should be identified and treated, and heart failure treatment should be optimized.

℞ ATRIAL FIBRILLATION

Treatment for AF must take into account the clinical situation in which the arrhythmia is encountered, the chronicity of the AF, the status of the patient's level of anticoagulation, risk factors for stroke, the patient's symptoms, the hemodynamic impact of the AF, and the ventricular rate.

ACUTE RATE CONTROL In the absence of hemodynamic compromise that might warrant emergent cardioversion to terminate the AF, the initial goals of therapy are (1) to establish control of the ventricular rate, and (2) to address anticoagulation status and begin IV heparin treatment if the duration of AF is >12 h and risk factors for stroke with AF are present **(Table 226-1)**. Ventricular rate control for acute AF is best established with beta blockers and/or calcium channel blocking agents, verapamil or diltiazem. The route of administration and dose will be dictated by the ventricular rate and clinical status. Digoxin may add to the rate-controlling benefit of the other agents but is uncommonly used as a stand-alone agent, especially in acute AF.

Anticoagulation is of particular importance in patients who have known risk factors for stroke associated with AF. Factors associated with the highest risk of stroke include a history of stroke, transient ischemic attack or systemic embolism, or the presence of rheumatic mitral stenosis. Other identified risk factors include age >65 years, history of congestive heart failure, diabetes mellitus, hypertension, LV dysfunction, and evidence of marked left atrial enlargement (>5.0 cm). Chronic anticoagulation with warfarin targeting an INR between 2.0 and 3.0 is recommended in patients with persistent or frequent and long-lived paroxysmal AF and risk factors. If patients have not been adequately anticoagulated and the AF is more

TABLE 226-1 RISK FACTORS FOR STROKE IN ATRIAL FIBRILLATION

History of stroke or transient ischemic attack	Age > 75 years
Mitral stenosis	Congestive heart failure
Hypertension	Left ventricular dysfunction
Diabetes mellitus	Marked left atrial enlargement (>5.0 cm)
	Spontaneous echo contrast

TABLE 226-2 COMMONLY USED ANTIARRHYTHMIC AGENTS—INTRAVENOUS DOSE RANGE/PRIMARY INDICATION

Drug	Loading	Maintenance	Primary Indication	Class[a]
Adenosine	6–18 mg (rapid bolus)	N/A	Terminate reentrant SVT involving AV node	—
Amiodarone	15 mg/min for 10 min, 1 mg/min for 6 h	0.5–1 mg/min	AF, AFL, SVT, VT/VF	III
Digoxin	0.25 mg q2h until 1.0 mg total	0.125–0.25 mg/d	AF/AFL rate control	—
Diltiazem	0.25 mg/kg over 3–5 min (max 20 mg)	5–15 mg/h	SVT, AF/AFL rate control	IV
Esmolol	500 μg/kg over 1 min	50 μg/kg per min	AF/AFL rate control	II
Ibutilide	1 mg over 10 min if over 60 kg	N/A	Terminate AF/AFL	III
Lidocaine	1–3 mg/kg at 20–50 mg/min	1–4 mg/min	VT	IB
Metoprolol	5 mg over 3–5 min times 3 doses	1.25–5 mg q6h	SVT, AF rate control; exercise-induced VT; long QT	II
Procainamide	15 mg/kg over 60 min	1–4 mg/min	Convert/prevent AF/VT	IA
Quinidine	6–10 mg/kg at 0.3–0.5 mg/kg per min	N/A	Convert/prevent AF/VT	IA
Verapamil	5–10 mg over 3–5 min	2.5–10 mg/h	SVT, AF rate control	IV

[a]Classification of antiarrhythmic drugs: Class I—agents that primarily block inward sodium current; class IA agents also prolong action potential duration; class II—antisympathetic agents; class III—agents that primarily prolong action potential duration; class IV—calcium channel-blocking agents.

Note: SVT, supraventricular tachycardia; AV, atrioventricular; AF, atrial fibrillation; AFL, atrial flutter; VT, ventricular tachycardia; VF, ventricular fibrillation.

than 24–48 h in duration, a transesophageal echocardiogram (TEE) can be performed to exclude the presence of a left atrial thrombus that might dislodge with the attempted restoration of sinus rhythm using either nonpharmacologic or pharmacologic therapy. Anticoagulation must be instituted coincident with the TEE and maintained for at least 1 month following restoration of sinus rhythm if the duration of AF has been prolonged or is unknown. Heparin is maintained routinely until the INR is 1.8 with the administration of warfarin after the TEE. For patients who do not warrant early cardioversion of AF, anticoagulation should be maintained for at least 3 weeks with the INR confirmed to be >1.8 on at least two separate occasions prior to attempts at cardioversion.

Termination of AF acutely may be warranted based on clinical parameters and/or hemodynamic status. Confirmation of appropriate anticoagulation status as described above must be documented unless symptoms and clinical status warrant emergent intervention. Direct current transthoracic cardioversion during short-acting anesthesia is a reliable way to terminate AF. Conversion rates using a 200-J biphasic shock delivered synchronously with the QRS complex typically are >90%. Pharmacologic therapy to terminate AF is less reliable. Oral and/or IV administration of amiodarone or procainamide have only modest success. The acute IV administration of ibutilide appears to be somewhat more effective and may be used in selected patients to facilitate termination with direct current (DC) cardioversion **(Tables 226-2** and **226-3)**.

Pharmacologic therapy to maintain sinus rhythm can be instituted once sinus rhythm has been established or in anticipation of cardioversion to attempt to maintain sinus rhythm (Table 226-3). A single episode of AF may not warrant any intervention or only a short course of beta blocker therapy. To prevent recurrent AF unresponsive to beta blockade, a trial of antiarrhythmic therapy may be warranted, particularly if the AF is associated with rapid rates and/or significant symptoms. The selection of antiarrhythmic agents should be dictated primarily by the presence or absence of coronary artery disease, depressed LV function not attributable to a reversible tachycardia-induced cardiomyopathy, and/or severe hypertension with evidence of marked LV hypertrophy. The presence of any significant structural heart disease typically narrows treatment to the use of sotalol, amiodarone, or dofetilide. Severely depressed LV function may preclude sotalol therapy or require only low-dose therapy be considered. Owing to the risk of QT prolongation and polymorphic VT, sotalol and dofetilide need to be initiated in hospital in most cases.

In patients without evidence of structural heart disease or hypertensive heart disease without evidence of severe hypertrophy, the use of the class IC antiarrhythmic agents flecainide or propafenone appears to be well tolerated and does not have significant proarrhythmia risk. It is important to recognize that no drug is uniformly effective, and arrhythmia recurrence should be anticipated in over half the patients during long-term follow-up regardless of type and number of agents tried. It is also important to recognize that although the maintenance of sinus rhythm has been associated with improved long-term survival, the survival outcome of patients randomized to the pharmacologic maintenance of sinus rhythm was not superior to those treated with rate control and anticoagulation in the

TABLE 226-3 COMMONLY USED ANTIARRHYTHMIC AGENTS—CHRONIC ORAL DOSING/PRIMARY INDICATIONS

Drug	Dosing Oral, mg, Maintenance	Half-Life, h	Primary Route(s) of Metabolism/Elimination	Most Common Indication	Class[a]
Acebutolol	200–400 mg q12h	6–7	Renal/hepatic	AF rate control/SVT Long QT/RVOT VT	II
Amiodarone	100–400 qd	40–55 d	Hepatic	AF/VT prevention	III
Atenolol	25–100 mg/d	6–9	Renal	AF rate control/SVT Long QT/RVOT VT	II
Digoxin	0.125–0.5 qd	38–48	Renal	AF rate control	—
Diltiazem	30–60 q6h	3–4.5	Hepatic	AF rate control/SVT	IV
Disopyramide	100–300 q6–8h	4–10	Renal 50%/hepatic	AF/SVT prevention	Ia
Dofetilide	125–500 q12h	10	Renal	AF prevention	III
Flecainide	50–200 q12h	7–22	Hepatic 75%/renal	AF/SVT/VT prevention	Ic
Metoprolol	25–100 q6h	3–8	Hepatic	AF rate control/SVT Long QT/RVOT VT	II
Mexiletine	150–300 q8–12h	10–14	Hepatic	VT prevention	Ib
Moricizine	100–400 q8h	3–13	Hepatic 60%/renal	AF prevention	Ic
Nadolol	40–240 mg/d	10–24	Renal	Same as metoprolol	II
Procainamide	250–500 q3–6h	3–5	Hepatic/renal	AF/SVT/VT prevention	Ia
Propafenone	150–300 q8h	2–8	Hepatic	AF/SVT/VT prevention	Ic
Quinidine	300–600 q6h	6–8	Hepatic 75%/renal	AF/SVT/VT prevention	Ia
Sotalol	80–160 q12h	12	Renal	AF/VT prevention	III
Verapamil	80–120 q6–8h	4.5–12	Hepatic/renal	AF rate control/RVOT VT Idiopathic LV VT	IV

[a]Classification of antiarrhythmic drugs: Class I—agents that primarily block inward sodium current; class II—antisympathetic agents; class III—agents that primarily prolong action potential duration; class IV—calcium channel-blocking agents.

Note: AF, atrial fibrillation; SVT, supraventricular tachycardia; RVOT, right ventricular outflow tract; VT, ventricular tachycardia; LV, left ventriclar.

TABLE 226-4 COMMON NONARRHYTHMIC TOXICITY OF MOST FREQUENTLY USED ANTIARRHYTHMIC AGENTS

Drug	Common Nonarrhythmic Toxicity
Amiodarone	Tremor, peripheral neuropathy, pulmonary inflammation, hypothyroidism and hyperthyroidism, photosensitivity
Adenosine	Cough, flushing
Digoxin	Anorexia, nausea, vomiting, visual changes
Disopyramide	Anticholinergic effects, decreased myocardial contractility
Dofetilide	Nausea
Flecainide	Dizziness, nausea, headache, decreased myocardial contractility
Ibutilide	Nausea
Lidocaine	Dizziness, confusion, delirium, seizures, coma
Mexiletine	Ataxia, tremor, gait disturbances, rash, nausea
Moricizine	Mood changes, tremor, loss of mental clarity, nausea,
Procainamide	Lupus erythematosus–like syndrome (more common in slow acetylators), anorexia, nausea, neutropenia
Propafenone	Taste disturbance, dyspepsia, nausea, vomiting
Quinidine	Diarrhea, nausea, vomiting, cinchonism, thrombocytopenia
Sotalol	Hypotension, bronchospasm

TABLE 226-5 PROARRHYTHMIC MANIFESTATIONS OF MOST FREQUENTLY USED ANTIARRHYTHMIC AGENTS

Drug	Common Proarrhythmic Toxicity
Amiodarone	Sinus bradycardia, AV block, increase in defibrillation threshold Rare: long QT and torsades des pointes, 1:1 ventricular conduction with atrial flutter
Adenosine	All arrhythmias potentiated by profound pauses, atrial fibrillation
Digoxin	High-grade AV block, fascicular tachycardia, accelerated junctional rhythm, atrial tachycardia
Disopyramide	Long QT and torsades des pointes, 1:1 ventricular response to atrial flutter; increased risk of some ventricular tachycardias in patients with structural heart disease
Dofetilide	Long QT and torsades des pointes
Flecainide	1:1 Ventricular response to atrial flutter; increased risk of some ventricular tachycardias in patients with structural heart disease; sinus bradycardia
Ibutilide	Long QT and torsades des pointes
Procainamide	Long QT and torsades des pointes, 1:1 ventricular response to atrial flutter; increased risk of some ventricular tachycardias in patients with structural heart disease
Propafenone	1:1 Ventricular response to atrial flutter; increased risk of some ventricular tachycardias in patients with structural heart disease; sinus bradycardia
Quinidine	Long QT and torsades des pointes, 1:1 ventricular response to atrial flutter; increased risk of some ventricular tachycardias in patients with structural heart disease
Sotalol	Long QT and torsades des pointes, sinus bradycardia

Note: AV, atrioventricular.

AFFIRM and RACE trials. The AFFIRM and RACE trials compared outcome with respect to survival and thromboembolic events in patients with AF and risk factors for stroke using the two treatment strategies. It is believed that the poor outcome related to pharmacologic therapy used to maintain sinus rhythm was primarily due to frequent inefficacy of such drug therapy and an increased incidence of asymptomatic AF. Many of the drugs used for rhythm control, including sotalol, amiodarone, propafenone, and flecainide, enhance slowing of AV nodal conduction. The absence of symptoms frequently leads to stopping anticoagulant therapy, and asymptomatic AF without anticoagulation increases stroke risk. Any consideration for stopping anticoagulation must, therefore, be accompanied by a prolonged period of ECG monitoring to document asymptomatic AF. It is also recommended that patients participate in monitoring by learning to take their pulse on a twice-daily basis and to reliably identify its regularity if discontinuing anticoagulant therapy is seriously contemplated.

It is clear that to reduce the risk of drug-induced complications when treating AF, a thorough understanding of the drug planned to be used is critical—its dosing, metabolism, and common side effects and important drug-drug interactions. This information has been summarized in Tables 226-2, 226-3, **226-4**, and **226-5** and serves as a starting point for a more complete review. When using antiarrhythmic agents that slow atrial conduction, strong consideration should be given to adding a beta blocker or a calcium channel blocker (verapamil or diltiazem) to the treatment regimen. This should help to avoid a rapid ventricular response if AF is converted to "slow" AF with the drug therapy **(Fig. 226-5)**.

CHRONIC RATE CONTROL This is an option in patients who are asymptomatic or symptomatic due to the resulting tachycardia. Rate control is frequently difficult to achieve in patients who have paroxysmal AF. In patients with more persistent forms of AF, rate control with beta blockers, calcium channel blockers, diltiazem or verapamil, and/or digoxin can frequently be achieved. Using the drugs in combination may avoid some of the common side effects seen with high-dose monotherapy. An effort should be made to document the adequacy of rate control to reduce the risk of a tachycardia-induced cardiomyopathy. Heart rates >80 beats/min at rest or 100 beats/min with very modest physical activity are indications that rate control is inadequate in persistent AF. Extended periods of ECG monitoring and assessment of heart rate with exercise should be considered.

In patients with symptoms resulting from inadequate rate control with pharmacologic therapy or worsening LV function due to the persistent tachycardia, a His bundle/AV junction ablation can be performed. The ablation must be coupled with the implantation of an activity sensor pacemaker to maintain a physiologic range of heart rates. Recent evidence that RV pacing can occasionally modestly depress LV function should be taken into consideration in identifying which patients are appropriate candidates for the "ablate and pace" treatment strategy. Occasionally, biventricular pacing may be used to minimize the degree of dyssynchronization that can occur with RV apical pacing alone. Rate control treatment options must be coupled with chronic anticoagulation therapy in all cases. Trials evaluating the elimination of embolic risk by surgical elimination or isolation of the left atrial appendage or by endovascular insertion of a left atrial appendage–occluding device are ongoing and may provide other treatment options that can eliminate the need for chronic anticoagulation.

CATHETER AND SURGICAL ABLATIVE THERAPY TO PREVENT RECURRENT AF Although the optimum ablation strategy has not been defined, most ablation strategies incorporate techniques that isolate the atrial muscle sleeves entering the pulmonary veins; these muscle sleeves have been identified as the source of the majority of triggers responsible for the initiation of AF. Ablation therapy is currently considered an alternative to pharmacologic therapy in patients with recurrent symptomatic AF. Elimination of AF in 50–80% of patients with a catheter-based ablation procedure should be anticipated, depending on the chronicity of the AF, with additional patients becoming responsive to previously ineffective medications.

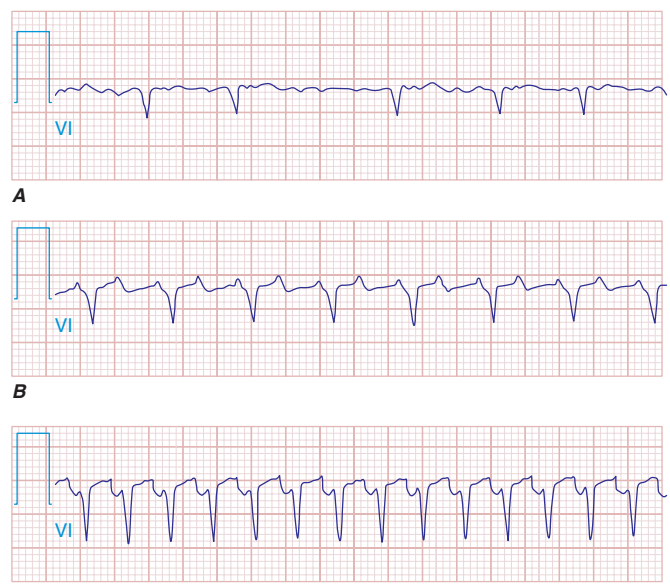

FIGURE 226-5 Atrial fibrillation (***A***) transitions to "slow" atrial flutter during antiarrhythmic drug therapy. ***B.*** A rapid ventricular response with 1:1 atrioventricular conduction occurred with exercise, leading to (***C***) symptoms of dizziness.

Catheter ablative therapy also holds promise in patients with more persistent forms of AF and even those with severe atrial dilatation. If its efficacy is confirmed with additional study, it may also afford an important alternative to His bundle ablation and pacemaker insertion. Risks related to the left atrial ablation procedure, albeit low (overall 2–4%), include pulmonary vein stenosis, atrioesophageal fistula, systemic embolic events, and perforation/tamponade.

Surgical ablation of AF is typically performed at the time of other cardiac valve or coronary artery surgery and, less commonly, as a stand-alone procedure. The Cox surgical Maze procedure is designed to interrupt all macroreentrant circuits that might potentially develop in the atria, thereby precluding the ability of the atria to fibrillate. In an attempt to simplify the operation, the multiple incisions of the traditional Cox-Maze procedure have been replaced with linear lines of ablation and pulmonary vein isolation using a variety of energy sources.

Severity of AF symptoms and difficulties in rate and/or rhythm control with pharmacologic therapy will frequently dictate the optimum AF treatment strategy. Similar to the approach with pharmacologic rhythm control, a cautious approach to eliminating anticoagulant therapy is recommended after catheter or surgical ablation. Careful ECG monitoring for asymptomatic AF, particularly in patients with multiple risk factors for stroke, should be considered until guidelines are firmly established. If the left atrial appendage has been removed surgically, then the threshold for stopping anticoagulation should be lowered. Antiarrhythmic therapy typically can be discontinued after catheter or surgical ablation of AF. However, in selected patients, satisfactory AF control may require maintenance of previously ineffective drug therapy after the ablation intervention.

ATRIAL FLUTTER AND MACROREENTRANT ATRIAL TACHYCARDIAS

Macroreentrant arrhythmias involving the atrial myocardium are collectively referred to as AFL. The terms *AFL* and *macroreentrant AT* are frequently used interchangeably, with both denoting a nonfocal source of an atrial arrhythmia. The typical or most common AFL circuit rotates in a clockwise or counterclockwise direction in the right atrium around the tricuspid valve annulus. The posterior boundary of the right AFL circuit is defined by the crista terminalis, the Eustachian ridge, and the inferior and superior vena cavae. Counterclockwise right AFL represents ~80% of all AFL with superiorly directed activation of the interatrial septum, which produces the saw-toothed appearance of the P waves in ECG leads II, III, and aVF. Clockwise rotation of the same right atrial circuit produces predominantly positive P waves in leads II, III, and aVF (Fig. 226-4). Macroreentrant left AFL may also develop, albeit much less commonly. This type of arrhythmia may be the sequelae of surgical or catheter-based ablation procedures that create large anatomic barriers or promote slowing of conduction in the left atrium, especially around the mitral valve annulus. Atypical AFL or macroreentrant AT can also develop around incisions created during surgery for valvular or congenital heart disease or in and/or around large areas of atrial fibrosis.

Classic or typical right AFL has an atrial rate of 260–300 beats/min with a ventricular response that tends to be 2:1, or typically 130–150 beats/min. In the setting of severe atrial conduction disease and or antiarrhythmic drug therapy, the atrial rate can slow to <200 beats/min. In this setting, a 1:1 rapid ventricular response may occur, particularly with exertion, and produce adverse hemodynamic effects (Fig. 226-5). Atypical AFL or macroreentrant AT related to prior surgical incisions and atrial fibrosis demonstrates less predictability in terms of the atrial rate and is more likely to demonstrate slower rates that overlap with those identified with focal atrial tachycardias (p. 1432).

Because lead V_1 is frequently monitored in a hospitalized patient, coarse AF may be misdiagnosed as AFL. This occurs because in both typical right AFL and coarse AF the crista terminalis in the right atrium may serve as an effective anatomic barrier. The free wall of the right atrium, whose electrical depolarization is best reflected on the body surface by lead V_1, may demonstrate a uniform wavefront of atrial activation under both conditions. The timing of atrial activation is much more rapid in AF and always demonstrates variable atrial intervals with some intervals between defined P waves <200 ms (Fig. 226-6). A review of the other ECG leads demonstrates the disorganized atrial depolarization that is characteristic of AF. Frequently, an individual patient may alternate between AF and AFL or, less commonly, may manifest AF in one atria and AFL in the other, making the distinction more difficult.

℞ ATRIAL FLUTTER

Because of the anticipated rapid regular ventricular rate associated with AFL and the failure to respond to pharmacologic therapy directed at slowing the ventricular rate, patients are frequently treated with DC cardioversion. The organized atrial flutter activity can frequently be terminated with low-energy external cardioversion of 50–100 J. The risk of thromboembolic events associated with typical AFL is high, and anticoagulation must be managed similarly to that described for patients with AF (p. 1428).

Asymptomatic patients with AFL may develop heart failure symptoms with tachycardia-induced severe LV dysfunction. In all patients, an effort should be made to control the ventricular rate pharmacologically or restore sinus rhythm. Rate control with calcium antagonists (diltiazem or verapamil), beta blockers, and/or digoxin may be difficult. Even higher grade AV slowing, such as a 4:1 AV response, may only be transient and is easily overcome with activity or emotional stress. Owing to the typically faster ventricular rate, AFL tends to be poorly tolerated in comparison to AF.

In selected patients with high anesthetic risk, an attempt at pharmacologic cardioversion with procainamide, amiodarone, or ibultilide is appropriate. Antiarrhythmic drug therapy may also enhance the efficacy of direct current cardioversion and the maintenance of sinus rhythm after cardioversion. Recurrence rates of AFL with pharmacologic attempts at rhythm control exceed 80% by 1 year.

Patients who manifest recurrent AFL appear to be effectively treated with catheter ablative therapy. For typical right AFL, an isthmus ablation line from the tricuspid annulus to the opening of the inferior vena cava can permanently eliminate flutter, with an anticipated success rate of >90% in most experienced centers. In patients with macroreentrant atrial tachycardia or AFL involving prior surgical incisions or in areas of atrial fibrosis, detailed mapping of the arrhythmia circuit is required to design the best ablation strategy to interrupt the circuit. In selected patient with AF and typical right AFL, pharmacologic therapy may help to prevent the AF but not the AFL. In this type of patient, hybrid therapy with antiarrhythmic agents coupled with a right atrial isthmus ablation may produce AF and AFL control.

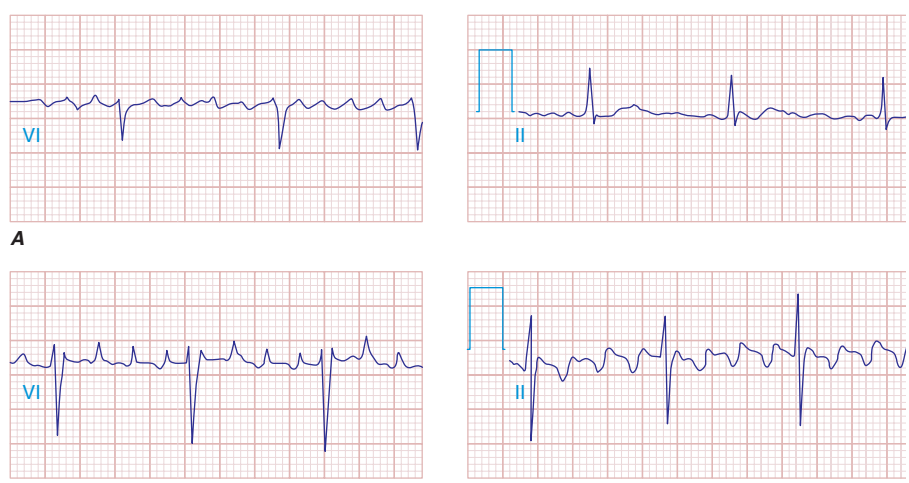

FIGURE 226-6 Atrial flutter/atrial fibrillation. Coarse atrial fibrillation (***A***) contrasted with organized atrial flutter (***B***).

MULTIFOCAL ATRIAL TACHYCARDIA

Multifocal AT (MAT) is the signature tachycardia of patients with significant pulmonary disease. The atrial rhythm is characterized by at least three distinct P wave morphologies and often at least three different PR intervals, and the associated atrial and ventricular rates are typically between 100 and 150 beats/min. The presence of an isoelectric baseline distinguishes this arrhythmia from AF (Fig. 226-4). The absence of any intervening sinus rhythm distinguishes MAT from normal sinus rhythm with frequent multifocal APCs, although this distinction may be moot as these processes define an electrophysiologic continuum.

℞ MULTIFOCAL ATRIAL TACHYCARDIA

Therapy for MAT should be directed at improving the underlying medical condition, which is typically, although not invariably, chronic obstructive or restrictive lung disease. Treatment with the calcium channel blocker, verapamil, may also provide some benefit. The judicious use of flecainide or propafenone may also decrease atrial arrhythmias. Patients should be screened for the presence of significant ventricular dysfunction or coronary artery disease before starting these agents. Low-dose amiodarone therapy may also control the arrhythmia and minimize the risk of pulmonary toxicity noted with the drug.

FOCAL ATRIAL TACHYCARDIAS

The two general mechanisms for focal ATs can be distinguished by observations made at AT initiation and in response to adenosine. *Automatic ATs* start with a "warm-up" period over the first 3–10 complexes and, similarly, slow in rate prior to termination. They may respond to adenosine not only with evidence of AV block but also with gradual slowing of the atrial rhythm and termination. The initiation of automatic ATs can frequently be provoked by isoproterenol infusion. The first P wave of the tachycardia has the same morphology as the remaining waves. Some of the ATs may be triggered or provoked by burst atrial pacing but are not reliably initiated by programmed atrial stimulation.

In contrast, evidence supporting a focal reentrant AT includes the initiation of the tachycardia with programmed atrial stimulation or spontaneous premature beats. The P wave initiating the tachycardia will characteristically have a different morphology than the P wave during the sustained AT. In response to adenosine, reentrant ATs will demonstrate AV block but typically do not slow and/or terminate. Most focal ATs in the absence of structural heart disease originate from specific anatomic locations. These anatomic locations appear to be associated with anatomic ridges, such as the crista terminalis, the valve annuli, or the limbus of the fossa ovalis. ATs also appear to originate from the muscular sleeves associated with the cardiac thoracic veins, i.e., the SVC, the coronary sinus, and the pulmonary veins. As indicated, repetitive firing of these foci appears to serve as the triggering mechanism for AF in most patients.

It is important to distinguish focal ATs from reentrant tachycardias that incorporate the AV node in the circuit (Fig. 226-7). The primary distinction is related to the persistence of the AT in the presence of AV block that occurs spontaneously or is created by carotid sinus massage or the administration of adenosine (Fig. 226-4). Atrial activity drives the ventricles in AT and all changes in the PP interval accompanied by correlative changes in the RR intervals; in addition, the V–A relationship changes when the atrial rate changes. The P wave in AT is characteristically distinct from the sinus P wave morphology, and, unless there is significant AV nodal conduction delay, the PR interval is shorter than the measured RP interval when there is a 1:1 relationship between atria and ventricles (Fig. 226-7).

The P wave for ATs depends on the anatomic site of origin. In addition to attempting to create AV block to establish the diagnosis of AT, analysis of the P wave morphology on the 12-lead ECG may help to exclude AV nodal reentry, AV bypass tract–mediated reentrant tachycardias, and physiologic or inappropriate sinus tachycardia (Fig. 226-7).

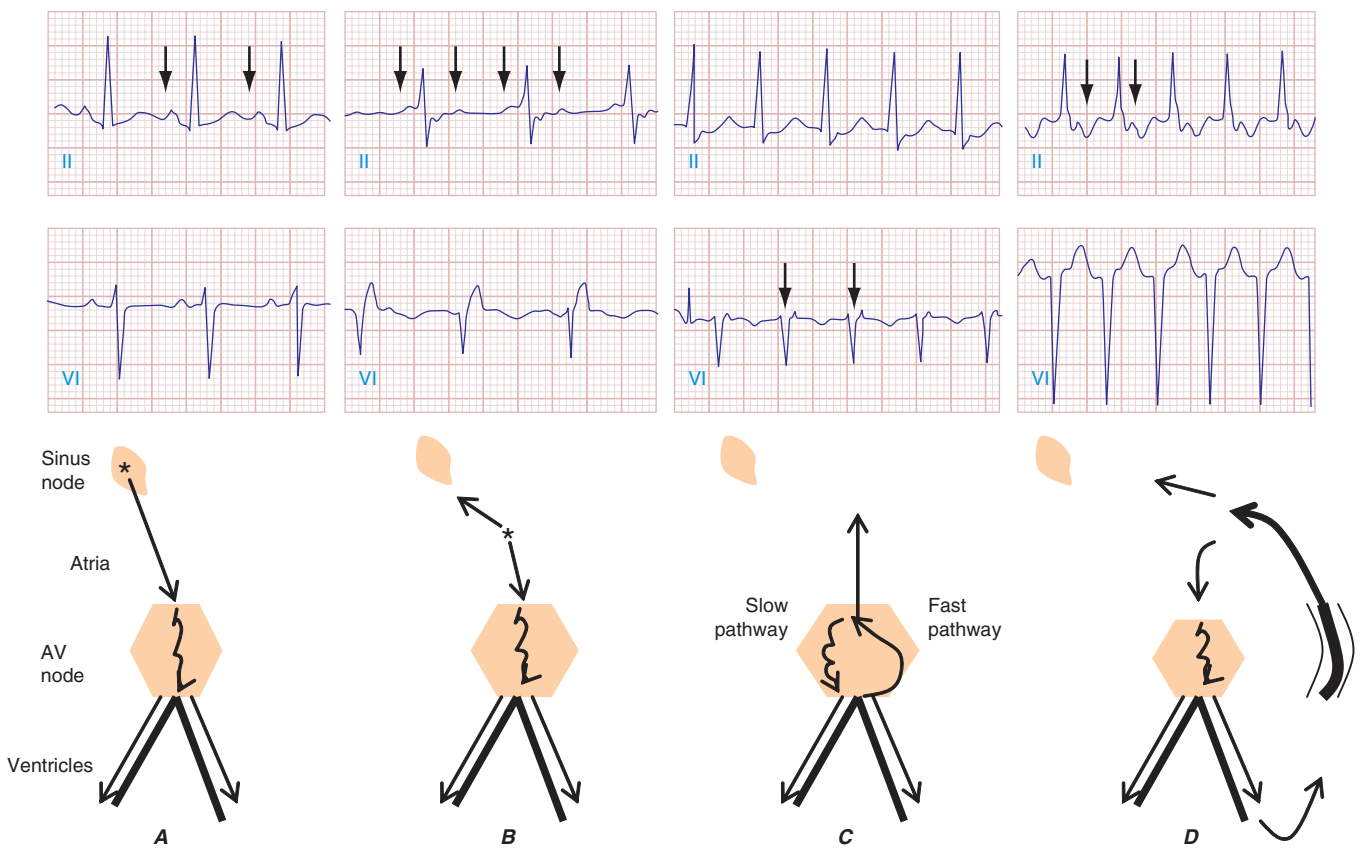

FIGURE 226-7 Pattern of atrial and ventricular activation and characteristic relationship of P wave and QRS complex as recorded in leads II and V_1 during regular supraventricular tachycardias. ***A.*** Sinus tachycardia. ***B.*** Atrial tachycardia from top of the atria. ***C.*** Atrioventricular nodal reentry. ***D.*** Accessory pathway–mediated orthodromic supraventricular tachycardia.

The ECG distinction between focal automatic or microreentrant AT and macroreentrant AT or atypical AFL is not always possible. Although sustained focal ATs tend to be slower, the atrial rates will frequently overlap. Focal ATs, which are more common in the absence of structural heart disease, will tend to demonstrate an isolectric baseline between P waves, whereas macroreentrant ATs represent atrial activation that is continuous and an isoelectric baseline between P waves may be frequently absent. In patients with a history of prior atrial surgery, one must suspect a macroreentrant mechanism. These distinctions are less important with respect to acute management but have importance related to ablation strategies and anticipated outcome (p. 1431).

℞ ATRIAL TACHYCARDIA

Pharmacologic treatment of AT is generally approached in a similar fashion to that of AF and AFL. AV nodal blocking agents are administered in the setting of rapid ventricular rates. Acute IV administration of procainamide or amiodarone may terminate the tachycardia. Tachycardias not responding to pharmacologic therapy may be terminated with electrical cardioversion. Typically, anticoagulation prior to treatment is not needed unless there is evidence of severe atrial dilatation, >5 cm left atrial diameter with a high risk of AF, and/or a history of coincident paroxysmal AF. Most focal ATs are readily amenable to catheter ablative therapy. In patients who fail to respond to medical therapy or who are reluctant to take chronic drug therapy, this option should be considered, with an anticipated 90% cure rate. A para-Hisian location for the AT and/or focus that is located in the left atrium may modestly increase the risk related to the procedure, and, for this reason, every effort should be made to determine the likely origin of the AT based on an analysis of the P wave morphology on 12-lead ECG prior to the procedure.

AV NODAL TACHYCARDIAS

AV Nodal Reentrant Tachycardia AVNRT is the most common paroxysmal regular SVT. It is more commonly observed in women than men and is typically manifest in the second to fourth decades of life. In general, because AVNRT tends to occur in the absence of structural heart disease, it is usually well tolerated. In the presence of hypertension or other forms of structural heart disease that limit ventricular filing, hypotension or syncope may occur.

AVNRT develops because of the presence of two electrophysiologically distinct pathways for conduction in the complex syncytium of muscle fibers that make up the AV node. The fast pathway located in the more superior part of the node has a longer refractory period, while the pathway lower in the AV node region conducts more slowly but has a shorter refractory period. As a result of the inhomogeneities of conduction and refractoriness, a reentrant circuit can develop in response to premature stimulation. Although conduction occurs over both pathways during sinus rhythm, only the conduction over the fast pathway is manifest and, as a result, the PR interval is normal. APCs occurring at a critical coupling interval are blocked in the fast pathway because of the longer refractory period and are conducted slowly over the slow pathway. When sufficient conduction slowing occurs, the blocked fast pathway can recover excitability and atrial activation can occur over the fast pathway to complete the circuit. Repetitive activation down the slow and up the fast pathway results in typical AV nodal reentrant tachycardia (Fig. 226-7).

ECG FINDINGS IN AVNRT The APC initiating AVNRT is characteristically followed by a long PR interval consistent with conduction via the slow pathway. AVNRT is manifest typically as a narrow QRS complex tachycardia at rates that range from 120 to 250 beats/min. The QRS-P wave pattern associated with typical AVNRT is quite characteristic, with simultaneous activation of the atria and ventricles from the reentrant AV nodal circuit. The P wave will frequently be buried inside the QRS complex and either not be visible or will distort the initial or terminal portion of the QRS complex (Fig. 226-7). Because atrial activation originates in the region of the AV node, a negative deflection will be generated by retrograde atrial depolarization.

Occasionally, AVNRT occurs with activation in the reverse direction, conducting down the fast pathway and returning up the slow pathway. This form of AVNRT occurs much less commonly and produces a prolonged RP interval during the tachycardia with a negative P wave in leads 2, 3, and aVF. This atypical form of AVNRT is more easily precipitated by ventricular stimulation.

℞ ATRIOVENTRICULAR NODAL REENTRANT TACHYCARDIA

ACUTE TREATMENT Treatment is directed at altering conduction within the AV node. Vagal stimulation, such as occurs with the Valsalva maneuver or carotid sinus massage, can slow conduction in the AV node sufficiently to terminate AVNRT. In patients in whom physical maneuvers do not terminate the tachyarrhythmia, the administration of adenosine, 6–12 mg IV, frequently does so. Intravenous beta blockade or calcium channel therapy should be considered second-line agents. If hemodynamic compromise is present, R wave synchronous DC cardioversion using 100–200 J can terminate the tachyarrhythmia.

PREVENTION Prevention may be achieved with drugs that slow conduction in the antegrade slow pathway, such as digitalis, beta blockers, or calcium channel blockers. In patients who have a history of exercise-precipitated AVNRT, the use of beta blockers frequently eliminates symptoms. In patients who do not respond to drug therapy directed at the antegrade slow pathway, treatment with class IA or IC agents directed at altering conduction of the fast pathway may be considered.

Catheter ablation, directed at elimination or modification of slow pathway conduction, is very effective in permanently eliminating AVNRT. Patients with recurrent AVNRT that produces significant symptoms or heart rates >200 beats/min and patients reluctant to take chronic drug therapy should be considered for ablative therapy. Catheter ablation can cure AV nodal reentry in >95% of patients. The risk of AV block requiring a permanent pacemaker is ~1% with the ablation procedure. This risk may be further minimized with the use of cryoablation techniques when the slow pathway is in close proximity to the compact AV node.

AV Junctional Tachycardias These can also occur in the setting of enhanced normal automaticity, abnormal automaticity, or triggered activity. These tachycardias may or may not be associated with retrograde conduction to the atria, and the P waves may appear dissociated or produce intermittent conduction and early activation of the junction. These arrhythmias may occur as a manifestation of increased adrenergic tone or drug effect in patients with sinus node dysfunction or following surgical or catheter ablation. The arrhythmia may also be a manifestation of digoxin toxicity. The most common manifestation of digoxin intoxication is the sudden regularization of the response to AF. A junctional tachycardia due to digoxin toxicity typically does not manifest retrograde conduction. Sinus activity may appear dissociated or result in intermittent capture beats with a long PR interval. If the rate is >50 beats/min and <100 beats/min, the term *accelerated junctional rhythm* applies. Occasionally, automatic rhythms are mimicked by AVNRT that fails to conduct to the atrium. The triggering events associated with the onset of the tachycardia may provide a clue to the appropriate diagnosis. Initiation of the tachycardia without an atrial premature beat with a gradual acceleration in rate suggests an automatic focus.

℞ ATRIOVENTRICULAR JUNCTIONAL TACHYCARDIAS

Treatment of automatic/triggered junctional tachycardias is directed at decreasing adrenergic stimulation and reversing digoxin toxicity, if present. Digoxin therapy can be withheld if toxicity is suspected, and the administration of digoxin-specific antibody fragments can rapidly reverse digoxin toxicity if the tachycardia is producing significant symptoms and rapid termination is indicated. Junctional tachycardia due to abnormal automaticity can be treated pharmacologically with beta blockers. A trial of class IA or IC drugs may also be attempted. For incessant automatic junctional tachycardia, focal catheter ablation can be performed but is associated with an increased risk of AV block.

Tachycardias that involve accessory pathways (APs) between atria and ventricles commonly manifest a normal QRS complex with a short or long RP interval. They must be considered in the differential diagnosis of other narrow-complex tachycardias. Importantly, most tachycardias associated with APs involve a large macroreentrant circuit that includes the ventricles (Fig. 226-7). Thus, identifying these arrhythmias as "supraventricular" is actually a misnomer, and they deserve separate consideration.

APs are typically capable of conducting rapidly both in an antegrade and retrograde direction. In the absence of an AP, the sinus impulse normally activates the ventricles via the AV node and His-Purkinje system, resulting in a PR interval of 120–200 ms. When an antegradely conducting AP is present, the sinus impulse bypasses the AV node and can rapidly activate the ventricles, resulting in ventricular preexcitation. The resulting PR interval is shorter than anticipated. In addition, because the initial ventricular activation is due to muscle-to-muscle conduction, as opposed to rapid spread of activation via the His-Purkinje system, the initial portion of the QRS complex is slurred, creating the characteristic "delta wave." The remaining portion of the QRS complex in sinus rhythm is created by a fusion of the ventricular activation wavefront originating from the Purkinje network and the continued spread of activation from the site of insertion of the AP (Fig. 226-8). Evidence of ventricular preexcitation includes evidence in sinus rhythm of a short PR interval and a delta wave.

The most common AP connects the left atrium to the left ventricle, followed by posterior septal, right free wall, and anterior septal APs. APs typically insert from the atrium into the adjacent ventricular myocardium. However, occasionally pathways, particularly those originating from the right atrium, can have a ventricular insertion at a site distant from the AV groove in the fascicles. These pathways tend to be long, conduct more slowly, and are referred to as *atriofascicular accessory pathways*. Atriofascicular APs are unique in their tendency to demonstrate decremental antegrade conduction.

Other accessory pathway connections from the AV node to the fascicles may also exist. These pathways are referred to as *Mahaim fibers* and typically manifest a normal PR interval with a delta wave.

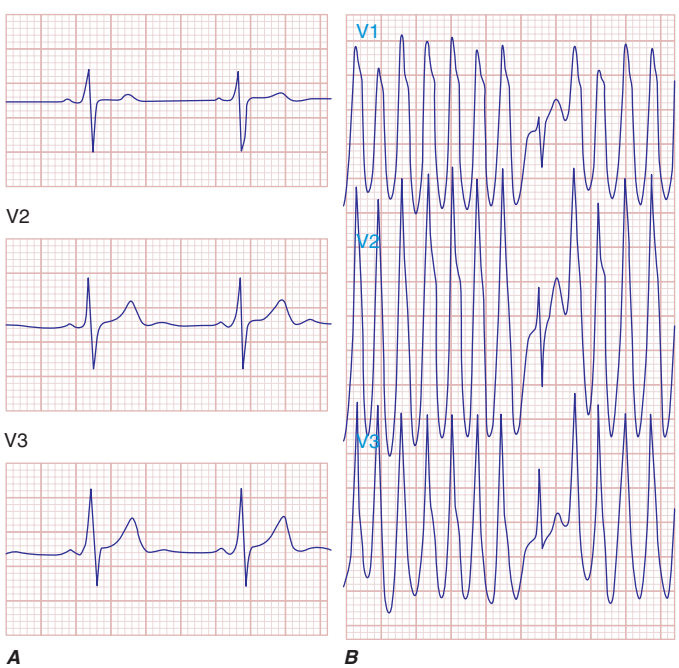

FIGURE 226-8 ***A.*** Sinus rhythm tracing of leads V_1–V_3 showing evidence of Wolff-Parkinson-White syndrome with short PR interval and delta wave. ***B.*** During atrial fibrillation, rapid conduction to the ventricles is observed producing a wide QRS complex tachycardia with marked irregularity of the ventricular response and morphology of the QRS complex.

Patients with manifest preexcitation and WPW syndrome are typically subject to both macroreentrant tachycardias and a rapid response to AF (Fig. 226-8). The most common macroreentrant tachycardia associated with the WPW syndrome is referred to as *orthodromic AV reentry*. Ventricular activation occurs via the AV node and the His-Purkinje system. Conduction then returns or reenters the atria via retrograde conduction over the AP. The reentrant circuit develops because of the inhomogeneity in conduction and refractoriness in the AP and normal AV node.

Characteristically, the AP has more rapid conduction but a longer refractory period when compared to that of the AV node. Typical APs do not show evidence of antegrade decremental conduction. An APC can block in the AP and conduct sufficiently slowly or with decrement via the AV node to allow for retrograde recovery of activation of the AP and, in turn, of the atria (Fig. 226-7). This retrograde activation of the atria via the AP is referred to as an *echo beat*. If the pattern repeats itself, a tachycardia develops. Uncommonly, the reentrant circuit can be reversed so that the impulse reaches the ventricle via the AP and conducts retrogradely through to the atria via the His-Purkinje system and the AV node; this is referred to as *antidromic AV reentry* and/or *preexcitated macroreentry*, with the entire activation of the ventricle originating from the site of insertion of the AP. Although uncommon, it is important to recognize antidromic SVT. The ECG pattern during the tachycardia mimics VT originating from the site of ventricular insertion of the AP. The presence of a similar or lesser degree of manifest preexcitation in sinus rhythm provides a valuable clue to the diagnosis.

The second most common and potentially more serious arrhythmia associated with the WPW syndrome is rapidly conducting AF. Nearly 50% of patients with evidence of APs are predisposed to episodes of AF. In patients who have rapid antegrade conduction from the atria to the ventricles over the AP, the AP can conduct rapidly in response to AF, resulting in a faster ventricular rate than would occur normally via the AV node. The rapid ventricular rates can result in hemodynamic compromise and even precipitate VF. The QRS pattern during AF in patients with manifest preexcitation can appear quite bizarre and change on a beat-to-beat basis due to the variability in the degree of fusion from activation over the AV node (Fig. 226-8).

Concealed APs In ~50% of patients with APs, there is no antegrade conduction over the AP; however, retrograde conduction is preserved. As a result, the AP is not manifest in sinus rhythm and is only manifest during the sustained tachycardia. The presence of a concealed AP is suggested by the timing and pattern of atrial activation during the tachycardia: the P wave typically follows ventricular activation with a short RP wave interval (Fig. 226-7). Because many APs connect the left ventricle to the left atrium, the pattern of atrial activation during the tachycardia frequently produces negative P waves in leads I and aVL. The tachycardia circuit, and, therefore, its ECG manifestation during orthodromic tachycardia, are identical both in patients with overt preexcitation in sinus rhythm and in those with concealed APs. Patients with concealed APs, although prone to episodes of AF, are not at risk for developing a rapid ventricular response to the AF.

Occasionally, APs conduct extremely slowly in a retrograde fashion, resulting in longer retrograde conduction and the development of a long RP interval during the tachycardia (*long RP tachycardia*). Because of the presence of this dramatically slowed conduction, additional conduction slowing created by premature atrial complexes is not required for tachycardia to ensue. These patients are more prone to frequent episodes of tachycardia and can present with "incessant" tachycardias and tachycardia-induced LV cardiomyopathy. The correct diagnosis of a long RP tachycardia may be suggested by the pattern of initiation and the P wave morphology. Frequently, however, an electrophysiologic evaluation is required to establish the diagnosis.

℞ ACCESSORY PATHWAY–MEDIATED TACHYCARDIAS

Acute treatment of AP-mediated macroreentrant orthodromic tachycardias is similar to that for AV nodal reentry and is directed at altering con-

duction in the AV node. Vagal stimulation with the Valsalva maneuver and carotid sinus pressure may create sufficient AV nodal slowing to terminate the AVRT. Intravenous administration of adenosine, 6–12 mg, is first-line pharmacologic therapy; IV calcium channel blockers, verapamil or diltiazem, or beta blockers may also be effective. In patients who demonstrate manifest preexcitation and AF, therapy should be aimed at preventing a rapid ventricular response. In life-threatening situations, DC cardioversion should be used to terminate the AF. In non-life-threatening situations, procainamide at a dose of 15 mg/kg administered IV over 20–30 min will slow the ventricular response and may organize and terminate AF. Ibutilide can also be used to facilitate termination of AF. During AF there may be rapid conduction over the AV node as well as the AP. Caution should be used in attempting to slow AV nodal conduction with the use of digoxin or verapamil; when administered IV, these drugs may actually result in an acute increase in rate over the AP, placing the patient at risk for development of VF. Digoxin appears to shorten the refractory period of the AP directly and thus increases the ventricular rate. Verapamil appears to shorten the refractory period indirectly by causing vasodilatation and a reflex increase in sympathetic tone.

Chronic oral administration of beta blockers and/or verapamil or diltiazem may be used to prevent recurrent supraventricular reentrant tachycardias associated with APs. In patients with evidence of AF and a rapid ventricular response and in those with recurrences of SVT on AV nodal blocking drugs, strong consideration should be given to the administration of either a class IA or IC antiarrhythmic drug, such as quinidine, flecainide, or propafenone, that slow conduction and increase refractoriness in the AP.

Patients with a history of recurrent symptomatic SVT episodes, incessant SVT, and heart rates >200 beats/min with SVT should be given strong consideration for undergoing catheter ablation. Patients who have demonstrated rapid antegrade conduction over their AP or the potential for rapid conduction should also be considered for catheter ablation. Catheter ablation therapy has been demonstrated to be successful in >95% of patients with documented WPW syndrome and appears effective regardless of age. The risk of catheter ablative therapy is low and is dictated primarily by the location of the AP. Ablation of para-Hisian APs is associated with a risk of heart block, and ablation in the left atrium is associated with a small but definite risk of thromboembolic phenomenon. These risks must be weighed against the potential serious complications associated with hemodynamic compromise, the risk of VF, and the severity of the patient's symptoms with AP-mediated tachycardias.

Patients who demonstrate evidence of ventricular preexcitation in the absence of any prior arrhythmia history deserve special consideration. The first arrhythmia manifestation can be a rapid SVT or, albeit of low risk (<1%), of a life-threatening rapid response to AF. Patients who demonstrate intermittent preexcitation during ECG monitoring or an abrupt loss of AP conduction during exercise testing are at low risk of a life-threatening rapid response to AF. All other patients should be advised of their risks and therapeutic options in advance of a documented arrhythmia event.

VENTRICULAR TACHYARRHYTHMIAS

VENTRICULAR PREMATURE COMPLEXES (VPCs)

The origin of premature beats in the ventricle at sites remote from the Purkinje network produces slow ventricular activation and a wide QRS complex that is typically >140 ms in duration. VPCs are common and increase with age and the presence of structural heart disease. VPCs can occur with a certain degree of periodicity that has become incorporated into the lexicon of electrocardiography. VPCs may occur in patterns of *bigeminy*, in which every sinus beat is followed by a VPC, or *trigeminy*, in which two sinus beats are followed by a VPC. VPCs may have different morphologies and are thus referred to as *multiformed*. Two successive VPCs are termed *pairs* or *couplets*. Three or more consecutive VPCs are termed *VT* when the rate is >100 beats/min. If the repetitive VPCs terminate spontaneously and are more than three beats in duration, the arrhythmia is referred to as *nonsustained VT*.

APCs with aberrant ventricular conduction may also create a wide and early QRS complex. The premature P wave can occasionally be difficult to discern when it falls on the preceding T wave, and other clues must be used to make the diagnosis. The QRS pattern for a VPC does not appear to follow a typical right or left bundle branch block pattern as the QRS morphology is associated with aberrant atrial conduction and can be quite bizarre. On occasion, VPCs can arise from the Purkinje network of the ventricles, in which case the QRS pattern mimics aberration. The 12-lead ECG recording of the VPC may be required to identify subtle morphologic clues regarding the QRS complex to confirm its ventricular origin. Most commonly, VPCs are associated with a "fully compensatory pause"; i.e., the duration between the last QRS before the PVC and the next QRS complex is equal to twice the sinus rate (Fig. 226-3). The VPC typically does not conduct to the atrium. If the VPC does conduct to the atrium, it may not be sufficiently early to reset the sinus node. As a result, sinus activity will occur and the antegrade wavefront from the sinus node may encounter some delay in the AV node or His-Purkinje system from the blocked VPC wavefront, or it may collide with the retrograde atrial wavefront. Sinus activity will continue undisturbed, resulting in a delay to the next QRS complex (Fig. 226-3). Occasionally the VPC can occur early enough and conduct retrograde to the atrium to reset the sinus node; the pause that results will be less than compensatory. VPCs that fail to influence the oncoming sinus impulse are termed *interpolated VPCs*. A ventricular focus that fires repetitively at a fixed interval may produce variably coupled VPCs, depending on the sinus rate. This type of focus is referred to as a *parasystolic focus* because its firing does not appear to be modulated by sinus activity and the conducted QRS complex. The ventricular ectopy will occur at a characteristic fixed integer or multiple of these intervals. The variability in coupling relative to the underlying QRS complex and a fixed interval between complexes of ventricular origin provide the diagnostic information necessary to identify a parasystolic focus.

Rx VENTRICULAR PREMATURE COMPLEXES

The threshold for treatment of VPCs is high, and the treatment is primarily directed at eliminating severe symptoms associated with palpitations. VPCs of sufficient frequency can cause a reversible cardiomyopathy. Depressed LV function in the setting of ventricular bigeminy and/or frequent nonsustained VT should raise the possibility of a cardiomyopathy that is reversible with control of the ventricular arrhythmia. In the absence of structural heart disease, VPCs do not appear to have prognostic significance. In patients with structural heart disease, frequent VPCs and runs of nonsustained VT have prognostic significance and may portend an increased risk of SCD. However, no study has documented that elimination of VPCs with antiarrhythmic drug therapy reduces the risk of arrhythmic death in patients with severe structural heart disease. In fact, drug therapies that slow myocardial conduction and/or enhance dispersion of refractoriness can actually increase the risk of life-threatening arrhythmias (drug-induced QT prolongation and TDP) despite being effective at eliminating VPCs.

ACCELERATED IDIOVENTRICULAR RHYTHM (AIVR)

AIVR refers to a ventricular rhythm that is characterized by three or more complexes at a rate >40 beats/min and <120 beats/min. The arrhythmia mechanism causing AIVR is thought to be due to abnormal automaticity. By definition there is an overlap between AIVR and "slow" VT; both rhythms can manifest rates between 90 and 120 beats/min. Because AIVR tends to be a benign rhythm with different therapeutic implications, it is worthwhile to attempt to distinguish it from "slow" VT. AIVR has a characteristic gradual onset and offset and more variability in cycle length. It is typically a brief, self-limiting arrhythmia. AIVR can be seen in the absence of any structural heart disease, but it is frequently present in the setting of acute myocardial infarction, cocaine intoxication, acute myocarditis, digoxin intoxication, and postoperative cardiac surgery. Sustained forms of AIVR can exist, particularly in the setting of acute myocardial infarction and postoperatively. In the setting of sustained AIVR, hemodynamic compromise can occur because of the loss of AV synchrony. Patients with RV infarction associated with proximal right coronary artery occlusion are most susceptible to associated bradyarrhythmias and the he-

modynamic consequences of AIVR. In these patients, acceleration of the atrial rate, either by the cautious administration of atropine or by atrial pacing, may be an important treatment consideration.

VENTRICULAR TACHYCARDIA

VT originates below the bundle of His at a rate >100 beats/min; most have rates >120 beats/min. Sustained VT at rates <120 beats/min and even <100 beats/min can be observed, particularly in association with the administration of antiarrhythmic agents that can slow the rate. Because of the overlap in rates with AIVR, the arrhythmia ECG characteristics and the clinical circumstance can sometimes be used to distinguish the two forms of tachycardia. Slow sustained VT is less likely to show a marked warm-up in rate and the marked cycle-length oscillations seen with AIVR, and it is more likely to occur in the setting of chronic infarction or cardiomyopathy and less likely with acute infarction or myocarditis. Obviously, significant overlap may exist. Typically, slow VT will be initiated with programmed stimulation and is found to represent a large macroreentrant circuit in chronically diseased myocardium capable of supporting markedly slow conduction.

The QRS complex during VT may be uniform (monomorphic) or may vary from beat to beat (polymorphic). Polymorphic VT in patients who demonstrate a long QT interval during their baseline rhythm is typically referred to as *TDP*. The polymorphic VT associated with QT prolongation dramatically oscillates around the baseline on most of the monitored ECG leads, mimicking the "turning of the points" stitching pattern **(Fig. 226-9)**.

Monomorphic VT suggests a stable tachycardia focus in the absence of structural heart disease or a fixed anatomic substrate that can create the substrate for a stable reentrant VT circuit when structural disease is present. Monomorphic VT tends to be a reproducible and recurrent phenomenon and may be initiated with pacing and programmed ventricular stimulation. In contrast, polymorphic VT suggests a more dynamic and/or unstable process and, by its very nature, is less reproducible. Polymorphic VT may be produced by acute ischemia, myocarditis, or dynamic changes in the QT interval and enhanced dispersion of ventricular refractoriness. Polymorphic VTs are not reliably initiated with pacing or programmed stimulation.

A time duration of 30 s is frequently used to distinguish sustained from nonsustained VT. Hemodynamically unstable VT that requires termination before 30 s or VT that is terminated by therapy from an implantable defibrillator is also typically classified as sustained. Ventricular flutter appears as a sine wave on the ECG and has a rate of >250 beats/min. A rapid rate coupled with the sine wave nature of the arrhythmia makes it impossible to identify a discrete QRS morphology. When antiarrhythmic drugs are being administered, a sine wave appearance of the QRS complex can be observed, even at rates of 200 beats/min. VF is characterized by completely disorganized ventricular activation on the surface ECG. Polymorphic ventricular arrhythmias, ventricular flutter, and VF always produce hemodynamic collapse if allowed to continue. The hemodynamic stability of a unimorphic VT depends on the presence and severity of the underlying structural heart disease, the location of the site of origin of the arrhythmia, and the heart rate.

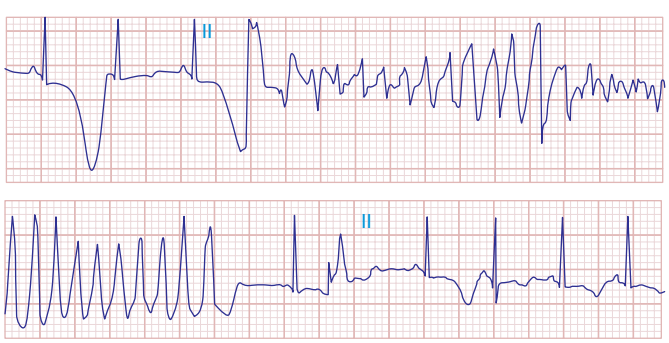

FIGURE 226-9 Sinus rhythm with long QT interval and the polymorphic ventricular arrhythmia torsades des pointes. Dramatic T wave alternans is present in sinus rhythm.

It is important to distinguish monomorphic VT from SVT with aberrant ventricular conduction due to right or left bundle branch block.

Importantly, the sinus or baseline 12-lead ECG tracing can provide important clues that help establish the correct diagnosis of a wide complex tachycardia. The presence of an aberrant QRS pattern that matches exactly that of the wide complex rhythm strongly supports the diagnosis of SVT. A right or left bundle branch block QRS pattern that does not match the QRS and/or that is wider in duration than the QRS during the wide complex tachycardia supports the diagnosis of VT. Most patients with VT have structural heart disease and show evidence of a prior Q wave myocardial infarction during sinus rhythm. Important exceptions to this rule are discussed (p. 1438). Finally, the presence of a preexcited QRS pattern on the 12-lead ECG in sinus rhythm suggests that the wide complex rhythm represents an atrial arrhythmia, such as AFL or a focal AT, with rapid conduction over an AP or antidromic macroreentrant tachycardia (Fig. 226-8). If the arrhythmia is irregular with changing QRS complexes, then the diagnosis of AF with ventricular preexcitation should be considered.

With the exception of some idiopathic outflow tract tachycardias, most VTs do not respond to vagal stimulation provoked by carotid sinus massage, the Valsalva maneuver, or adenosine administration. The IV administration of verapamil and/or adenosine is not recommended as a diagnostic test. Verapamil has been associated with hemodynamic collapse when administered to patients with structural heart disease and VT.

Patients with VT frequently demonstrate AV disassociation. Findings on physical examination of intermittent cannon *a* waves and variability of the first heart sound are consistent with AV dissociation. The presence of AV dissociation is characteristically marked by the presence of sinus capture or fusion beats. The presence of 1:1 ventriculoatrial conduction does not preclude a diagnosis of VT.

Additional characteristics of the 12-lead ECG during the tachycardia that suggest VT include (1) the presence of a QRS duration >140 ms in the absence of drug therapy, (2) a superior and rightward QRS frontal plane axis, (3) a bizarre QRS complex that does not mimic the characteristic QRS pattern associated with left or right bundle branch block, and (4) slurring of the initial portion of the QRS **(Fig. 226-10)**. **Table 226-6** provides a useful summary of ECG criteria that have evolved based on the described characteristics of VT.

Rx VENTRICULAR TACHYCARDIA/FIBRILLATION

Sustained polymorphic VT, ventricular flutter, and VF all lead to immediate hemodynamic collapse. Emergency asynchronous defibrillation is therefore required, with at least 200-J monophasic or 100-J biphasic shock. The shock should be delivered asynchronously to avoid delays related to sensing of the QRS complex. If the arrhythmia persists, repeated shocks with the maximum energy output of the defibrillator are essential to optimize the chance of successful resuscitation. Intravenous lidocaine and/or amiodarone should be administered but should not delay repeated attempts at defibrillation.

For any monomorphic wide complex rhythm that results in hemodynamic compromise, a prompt R wave synchronous shock is required. Conscious sedation should be provided if the hemodynamic status permits. For patients with a well-tolerated wide complex tachycardia, the appropriate diagnosis should be established based on strict ECG criteria (Table 226-6). Pharmacologic treatment to terminate monomorphic VT is not typically successful (<30%). Intravenous procainamide, lidocaine, or amiodarone can be utilized. If the arrhythmia persists, synchronous R wave cardioversion after the administration of conscious sedation is appropriate. Selected patients with focal outflow tract tachycardias (p. 1438) who demonstrate triggered or automatic VT may respond to IV beta blocker administration. Idiopathic LV septal VT (see p. 1438) appears to respond uniquely to IV verapamil administration.

VT in patients with structural heart disease is now almost always treated with the implantation of an ICD to manage anticipated VT recurrence. The ICD can provide rapid pacing and shock therapy to treat most VTs effectively **(Fig. 226-11)**.

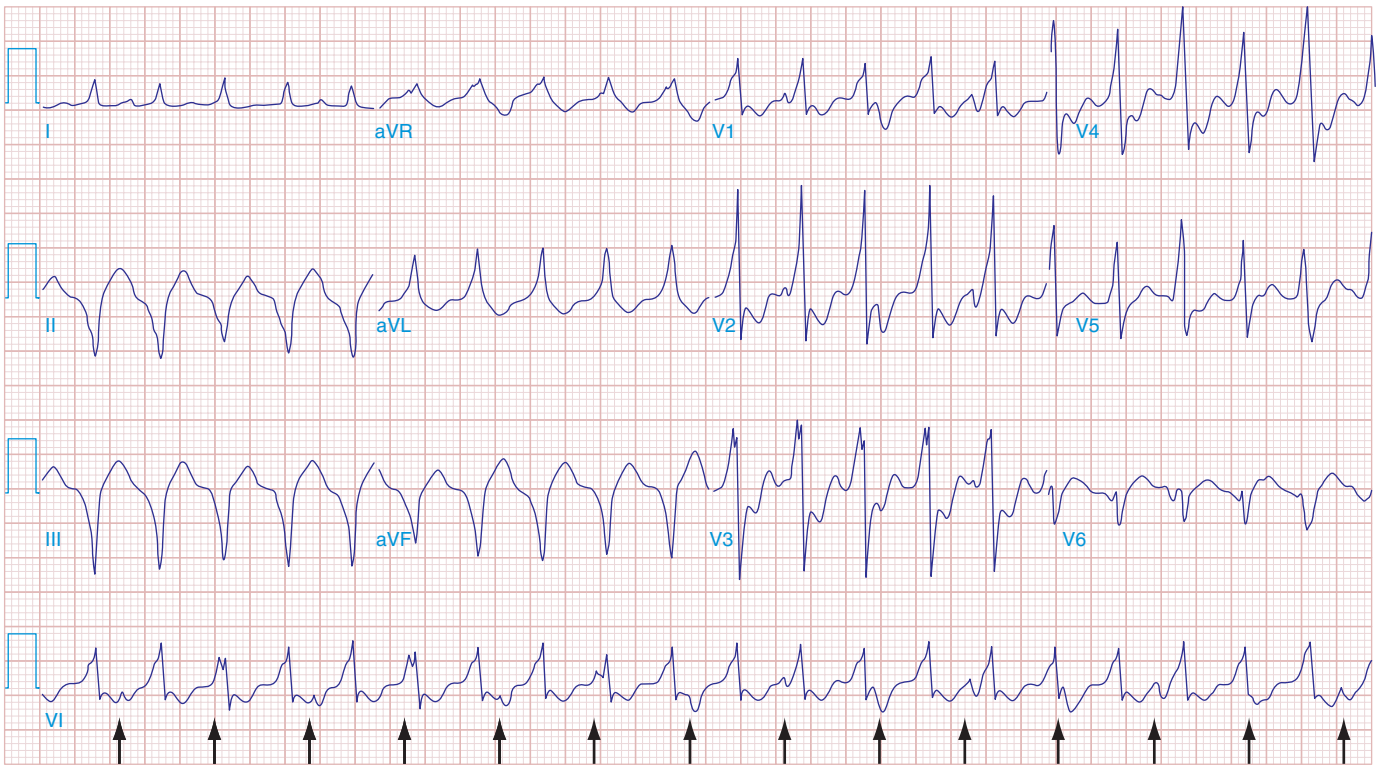

FIGURE 226-10 Ventricular tachycardia. ECG showing AV dissociation (arrows mark P waves), wide QRS > 200 ms, superior frontal plane axis, slurring of the initial portion of the QRS, and large S wave in V_6—all clues to the diagnosis of ventricular tachycardia.

Prevention of VT remains important, and >50% of patients with a history of VT and an ICD may need to be treated with adjunctive antiarrhythmic drug therapy to prevent VT recurrences or to manage atrial arrhythmias. Because of the presence of an ICD, there is more flexibility with respect to antiarrhythmic drug therapy selection. The use of sotalol or amiodarone represents first-line therapy for patients with a history of structural heart disease and life-threatening monomorphic or polymorphic VT not due to long QT syndrome. Importantly, sotalol has been associated with a decrease in the defibrillation threshold, which reflects the amount of energy necessary to terminate VF. Amiodarone may be better tolerated in patients with a more marginal hemodynamic status and systolic blood pressure. The risk of end organ toxicity from amiodarone must be weighed against the ease of use and general efficacy. Antiarrhythmic drug therapy with agents such as quinidine, procainamide, or propafenone, which might not normally be used in patients with structural heart disease because of the risk of proarrhythmia, may be considered in patients with an ICD and recurrent VT.

Catheter ablative therapy for VT in patients without structural heart disease results in cure rates >90%. In patients with structural heart disease, catheter ablation that includes a strategy for eliminating unmappable/rapid VT and one that incorporates endocardial as well as epicardial mapping and ablation should be employed. In most patients, catheter ablation can reduce or eliminate the requirement for toxic drug therapy and should be considered in any patient with recurrent VT. The utilization of ablative therapy to reduce the incidence of ICD shocks for VT in patients who receive the ICD as part of primary prevention for VT is being actively investigated.

TABLE 226-6 ECG CLUES SUPPORTING THE DIAGNOSIS OF VENTRICULAR TACHYCARDIA

AV dissociation (atrial capture, fusion beats)
QRS duration > 140 ms for RBBB type V_1 morphology; V_1 > 160 ms for LBBB type V1 morphology
Frontal plane axis –90° to 180°
Delayed activation during initial phase of the QRS complex
LBBB pattern—R wave in V_1, V2 >40 ms
RBBB pattern—onset of R wave to nadir of S > 100 ms
Bizarre QRS pattern that does not mimic typical RBBB or LBBB QRS complex
Concordance of QRS complex in all precordial leads
RS or dominant S in V_6 for RBBB VT
Q wave in V_6 with LBBB QRS pattern
Monophasic R or biphasic qR or R/S in V_1 with RBBB pattern

Note: AV, atrioventricular; RBBB/LBBB, right/left bundle branch block.

MANAGEMENT OF VT STORM Repeated VT episodes requiring external cardioversion/defibrillation or repeated appropriate ICD shock therapy is referred to as *VT storm*. While a definition of more than two episodes in 24 h is used, most patients with VT storm will experience many more episodes. In the extreme form of VT storm, the tachycardia becomes incessant and the baseline rhythm is unable to be restored for any extended period. In patients with recurrent polymorphic VT in the absence of the long QT interval, one should have a high suspicion of active ischemic disease or fulminant myocarditis. Intravenous lidocaine or amiodarone administration should be coupled with prompt assessment of the status of the coronary anatomy. Endomyocardial biopsy, if indicated by clinical circumstance, may be used to confirm the diagnosis of myocarditis, although the diagnostic yield is low. In patients who demonstrate QT prolongation and recurrent pause-dependent polymorphic VT (TDP), removal of an offending QT-prolonging drug, correction of potassium or magnesium deficiencies, and emergency pacing to prevent pauses should be considered. Intravenous beta blockade therapy should be considered for polymorphic VT storm. A targeted treatment strategy should be employed if the diagnosis of the polymorphic VT syndrome can be established. For example, quinidine or isoproterenol can be used in the treatment of Brugada's syndrome (p. 1442). Intraaortic balloon counterpulsation or acute coronary angioplasty may be needed to stop recurrent polymorphic VT precipitated by acute ischemia. In selected patients with a repeating VPC trigger for their polymorphic VT, the VPC can be targeted for ablation to prevent recurrent VT.

In patients with recurrent monomorphic VT, acute IV administration of lidocaine, procainamide, or amiodarone can prevent recurrences. The use of such therapy is empirical, and a clinical response is not certain. Procainamide and amiodarone are more likely to slow the tachycardia and make it hemodynamically tolerated. Unfortunately, antiarrhythmic drugs, especially those that slow conduction (e.g., amiodarone, procainamide), can also facilitate recurrent VT or even result in incessant VT. VT catheter ablation can eliminate frequent recurrent or incessant VT and frequent ICD shocks.

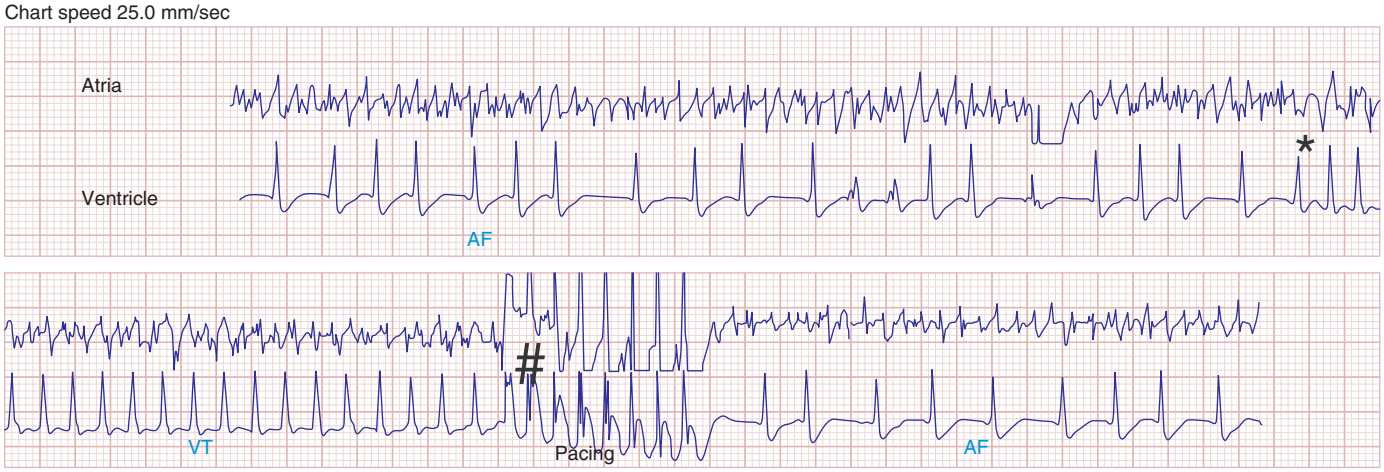

FIGURE 226-11 Ventricular tachycardia (VT) (*) during atrial fibrillation stopped by pacing (#) from an implantable cardioverter defibrillator (ICD) from recording stored by ICD. The atrial electrogram shows characteristic fibrillatory waves through the tracing. The ventricular electrogram shows an irregularly irregular response consistent with atrial fibrillation at the beginning of the tracing. The ventricular electrogram suddenly changes in morphology (*) and becomes regular, consistent with the diagnosis of VT. Pacing transiently accelerates the rate and interrupts the rapid VT. The patient was unaware of the life-threatening event.

Such therapy should be deployed earlier in the course of arrhythmia events to prevent adverse consequences of recurrent VT episodes and adverse effects from antiarrhythmic drugs.

UNIQUE VT SYNDROMES

Although most ventricular arrhythmias occur in the setting of coronary artery disease with prior myocardial infarction, a significant number of patients develop VT in other settings. A brief discussion of each unique VT syndrome is warranted. Information that illustrates a unique pathogenesis and enhances the ability to make the correct diagnosis and institute appropriate therapy will be highlighted.

Idiopathic Outflow Tract VT VT in the absence of structural heart disease is referred to as *idiopathic VT*. There are two major varieties of these VTs. Outflow tachycardias originate in the RV and LV outflow tract regions. Approximately 80% of outflow tract VTs originate in the RV and ~20% in the LV outflow tract regions. Outflow tract VTs appear to originate from anatomic sites that form an arc beginning just above the tricuspid valve and extending along the roof of the outflow tract region to include the free wall and septal aspect of the right ventricle just beneath the pulmonic valve, the aortic valve region, and then the anterior/superior margin of the mitral valve annulus. These arrhythmias appear more commonly in women. Importantly, these ventricular arrhythmias are *not* associated with SCD. Patients manifest symptoms of palpitations with exercise, stress, and caffeine ingestion. In women, the arrhythmia is more commonly associated with hormonal triggers and can frequently be timed to the premenstrual period, gestation, and menopause. Uncommonly, the VPCs and VTs can be of sufficient frequency and duration to cause a tachycardia-induced cardiomyopathy.

The pathogenesis of outflow tract VT remains unknown, and there is no definite anatomic abnormality identified with these VTs. Vagal maneuvers, adenosine, and beta blockers tend to terminate the VTs, whereas catecholamine infusion, exercise, and stress tend to potentiate the outflow tract VTs. Based on these observations, the mechanism of the arrhythmia is most likely calcium-dependent triggered activity. Preliminary data suggest that at least in some patients, a somatic mutation of the inhibitory G protein (Gα I2) may serve as the genetic basis for the VT. In contrast to VT in patients with coronary artery disease, outflow tract VTs are uncommonly initiated with programmed stimulation but are able to be initiated by rapid-burst atrial or ventricular pacing, particularly when coupled with the infusion of isoproterenol.

Outflow tract VT typically produces large monophasic R waves in the inferior frontal plane leads II, III, and aVF, and typically occurs as nonsustained bursts of VT and/or frequent premature beats. Cycle length oscillations during the tachycardia are common. Since most VT originates in the RV outflow tract, the VT typically has a left bundle branch block pattern in lead V_1 (negative QRS vector) (Fig. 226-12). Outflow tract VT, originating in the left ventricle, particularly those associated with an origin from the mitral valve annulus, have a right bundle branch block pattern in lead V_1 (positive QRS vector).

Rx IDIOPATHIC OUTFLOW TRACT VENTRICULAR TACHYCARDIA

Acute medical therapy for idiopathic outflow tract VT is rarely required because the VT is hemodynamically tolerated and is typically nonsustained. Intravenous beta blockers frequently terminate the tachycardia. Chronic therapy with beta or calcium channel blockers frequently prevents recurrent episodes of the tachycardia. The arrhythmia also appears to respond to treatment with class IA or IC agents or with sotalol. In patients who are reluctant to take long-term drug therapy or who have persistent symptoms despite drug therapy, catheter ablative therapy has been utilized successfully to eliminate the tachycardia with success rates >90%. Because of the absence of structural heart disease and the focal nature of these arrhythmias, the 12-lead ECG pattern during VT can help localize the site of origin of the arrhythmia and help facilitate catheter ablation. Efficacy of therapy is assessed with treadmill testing and/or ECG monitoring, and electrophysiologic study is performed only when the diagnosis is in question or to perform catheter ablation.

Idiopathic LV Septal/Fascicular VT The second most common idiopathic VT is linked anatomically to the Purkinje system in the left ventricle. The arrhythmia mechanism appears to be macroreentry involving calcium-dependent slow response fibers that are part of the Purkinje network, although automatic tachycardias have also been observed. A 12-lead ECG morphology of the VT shows a narrow right bundle branch block pattern and a superior leftward axis or an inferior rightward axis, depending upon whether the VT originates from the posterior or anterior fascicles (Fig. 226-12). Idiopathic LV septal VT is unique in its suppression with verapamil. Beta blockers have also been used with some success as primary or effective adjunctive therapy. Catheter ablation is very effective therapy for VT resistant to drug therapy or in patients reluctant to take daily therapy, with anticipated successful elimination of VT in >90% of patients.

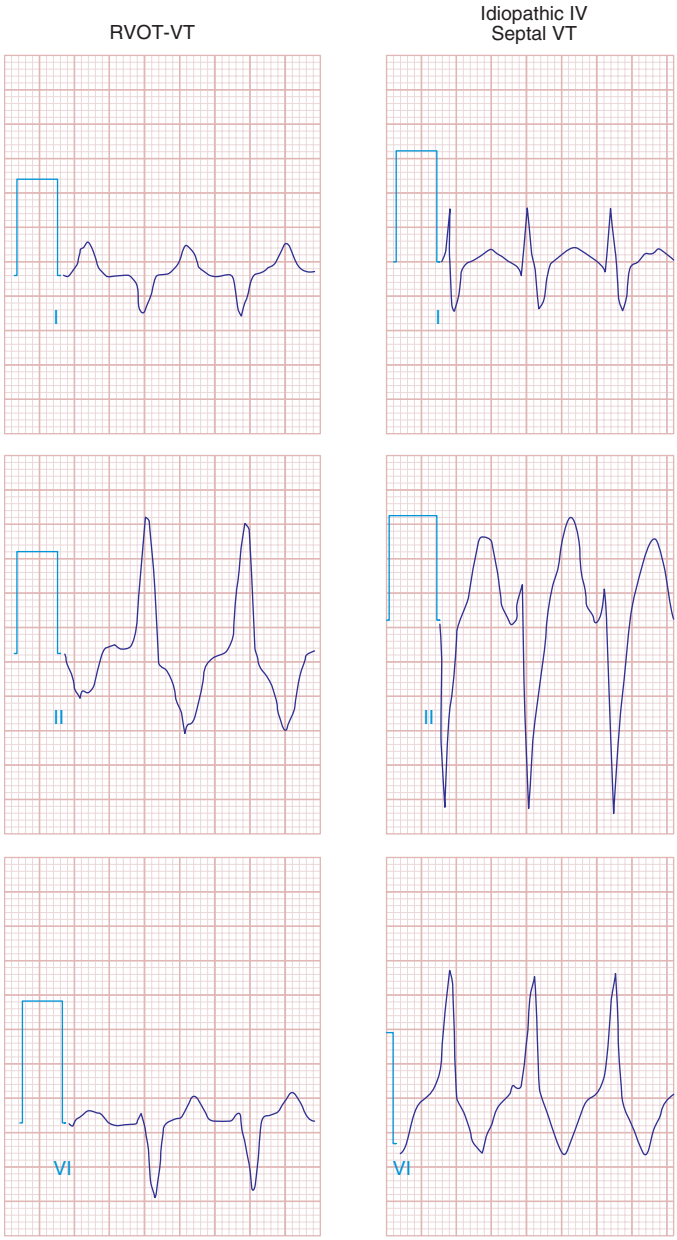

FIGURE 226-12 Common idiopathic ventricular tachycardia (VT) ECG patterns. Right ventricular outflow tract (RVOT) VT with typical left bundle QRS pattern in V_1 and inferiorly directed frontal plane axis, and left ventricular septal VT from the inferior septum with a narrow QRS right bundle branch block pattern in V_1 and superior and leftward front plane QRS axis.

VT Associated with LV Dilated Cardiomyopathy Monomorphic and polymorphic VTs may occur in patients with nonischemic dilated cardiomyopathy (Chap. 231). Although the myopathic process may be diffuse, there appears to be a predilection for the development of fibrosis around the mitral and aortic valvular regions. Most uniform sustained VT can be mapped to these regions of fibrosis. Drug therapy is usually ineffective in preventing VT, and empirical trials of sotalol or amiodarone are usually initiated only for recurrent VT episodes after ICD implantation. VT associated with nonischemic dilated cardiomyopathy appears to be less amenable to catheter ablative therapy from the endocardium; frequently, the VT originates from epicardial areas of fibrosis and catheter access to the epicardium can be gained via a percutaneous pericardial puncture to improve the outcome of ablation techniques. In patients with a history of depressed myocardial dysfunction due to a nonischemic cardiomyopathy with an LV ejection fraction

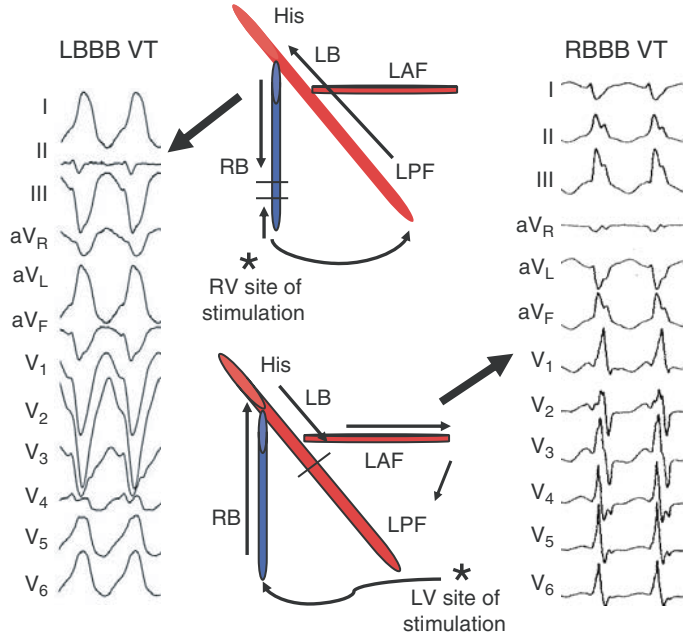

FIGURE 226-13 Bundle branch reentrant ventricular tachycardia (VT) showing typical QRS morphologies when ventricular tachycardia (VT) is initiated with stimulation from the right ventricle [left bundle branch block (LBBB) VT pattern] or left ventricle [right bundle branch block (RBBB) VT pattern] and schema for circuit involving the His-Purkinje network.

< 30%, data now support the implantation of a prophylactic ICD device to reduce the risk of SCD from the first VT/VF episode effectively.

Bundle Branch Reentrant VT Monomorphic VT in patients with idiopathic nonischemic cardiomyopathy or valvular cardiomyopathy is frequently due to a large macroreentrant circuit involving the various elements of the His-Purkinje network. The arrhythmia usually occurs in the presence of underlying His-Purkinje system disease. In sinus rhythm, an incomplete left bundle block is typically present and the time that it takes to traverse the His-Purkinje network is delayed; this slow conduction serves as the substrate for reentry. Characteristically, the VT circuit rotates in an antegrade direction down the right bundle and retrograde up the left posterior or anterior fascicles and left bundle branch. As a result, bundle branch reentrant VT typically has a QRS morphology that mimics RV apical pacing with a left bundle branch block type pattern and a leftward superior axis (Fig. 226-13). The circuit for bundle branch reentrant VT can occasionally rotate in the opposite direction, antegrade through the left bundle and retrograde through the right bundle, in which case a right bundle branch block pattern during VT will be manifest.

It is important to recognize bundle branch reentrant VT because it is readily amenable to ablative therapy that targets a component of the His-Purkinje system, typically the right bundle, to block the VT circuit. In most patients, because of the presence of severely depressed LV function and a high risk of SCD, ablative therapy is coupled with an ICD. Less commonly, bundle branch reentry may occur in the absence of structural heart disease or in the setting of coronary artery disease. The use of adjunctive ICD therapy is dictated by the ability to eliminate the VT successfully and the severity of the LV dysfunction.

VT Associated with Hypertrophic Cardiomyopathy (See also Chap. 231) VT/VF have also been associated with hypertrophic cardiomyopathy. In patients with hypertrophic cardiomyopathy and a history of sustained VT/VF, unexplained syncope, a strong family history of SCD, LV septal thickness > 30 mm, or nonsustained spontaneous VT, the risk of SCD is high and ICD implantation is usually indicated. Amiodarone, sotalol, and beta blockers have been used to control recurrent VT. Experience with ablative therapy is limited because of the infre-

TABLE 226-7 INFILTRATIVE/INFLAMMATORY AND NEUROMUSCULAR DISORDERS ASSOCIATED WITH AN INCREASED VENTRICULAR ARRHYTHMIA RISK

quency with which the VT is tolerated hemodynamically. Ablation procedures that target the substrate for VT/VF and ablate areas of low voltage consistent with fibrosis appear to have promise in this setting. The WPW syndrome has been observed in patients with hypertrophic cardiomyopathy associated with *PRKAG2* mutations.

VT Associated with Other Infiltrative Cardiomyopathies and Neuromuscular Disorders An increased arrhythmia risk has been identified when cardiac involvement occurs in a variety of infiltrative diseases and neuromuscular disorders (Table 226-7). Many patients manifest AV conduction disturbances and may require permanent pacemaker insertion. The decision to implant an ICD device should follow current established guidelines for patients with nonischemic cardiomyopathy, which include a history of syncope with depressed LV function, a history of severely depressed LV function, and LV ejection fraction < 35% with class 2 or 3 heart failure symptoms. Additional study will be required to determine if patients with lesser degrees of LV dysfunction may also warrant primary ICD implantation. A potential proarrhythmic risk of antiarrhythmic drug therapy should be acknowledged, and drug therapy should be reserved for symptomatic arrhythmias and limited to amiodarone or sotalol if an ICD is not present.

Arrhythmogenic RV Cardiomyopathy/Dysplasia (ARVCM/D) (See also Chap. 231) ARVCM/D, due to a genetically determined dysplastic process or after a suspected viral myocarditis, is also associated with VT/VF. The sporadic nonfamilial/nondysplastic form of RV cardiomyopathy appears to be more common; however, this may vary based on ethnicity. In patients predisposed to VT, there appears to be a predominance of perivalvular fibrosis involving mostly the free wall of the right ventricle in proximity to the tricuspid and pulmonic valves. The surface ECG leads that reflect RV activation, including V_1–V_3, may show terminal notching of the QRS complex and inverted T waves in sinus rhythm. When the terminal notching is distinct and appears separated from the QRS complex, it is referred to as an *epsilon wave* (Fig. 226-14). Epsilon waves are consistent with markedly delayed ventricular activation in the region of the RV free wall near the base of the tricuspid and pulmonic valves in areas of extensive fibrosis.

In patients with ARVCM/D, echocardiography demonstrates RV enlargement with RV wall motion abnormalities and RV apical aneurysm formation. MRI may show fatty replacement of the ventricle, thinning of the RV free wall with increased fibrosis, and associated wall motion abnormalities. Because of the presence of extensive amounts of fat normally covering the epicardium in the region of the RV, caution must be used to not overinterpret the MRI in trying to determine the appropriate diagnosis. Patients tend to have multiple VT morphologies. The VT will typically have a left bundle branch block type QRS pattern in V_1 and tend to have poor R wave progression in V_1 through V_6, consistent with an RV free-wall origin. Areas of low electrogram voltage, identified during RV catheter endocardial sinus rhythm voltage mapping, may be helpful in confirming the diagnosis. Importantly, endocardial biopsy may not identify the presence of fatty replacement or fibrosis unless directed to the basal RV free wall. The familial forms of this syndrome have been linked to a number of desmosomal protein mutations. A distinct genetic form of this syndrome, Naxos disease, consists of arrhythmogenic RV dysplasia coupled with palmar-plantar keratosis and woolly hair and is associated with a high risk of SCD in adolescents and young adults.

℞ ARRHYTHMOGENIC RIGHT VENTRICULAR CARDIOMYOPATHY/DYSPLASIA

The threshold for ICD implantation in patients with an established diagnosis of ARVCM/D is low. An ICD will typically be implanted in patients deemed to have a persistent VT risk, those who have had spontaneous or inducible rapid VTs, and those patients who show concomitant LV cardiomyopathy. Treatment options for recurrent VT in patients with ARVCM/D include the use of the antiarrhythmic agent sotalol. Beta blockers serve as useful adjunctive therapy when coupled with other antiarrhythmic agents. Catheter ablative therapy directed at mappable sustained ventricular arrhythmias is also highly successful in controlling recurrent VT. In selected patients with multiple VT morphologies and unstable VT, linear ablation le-

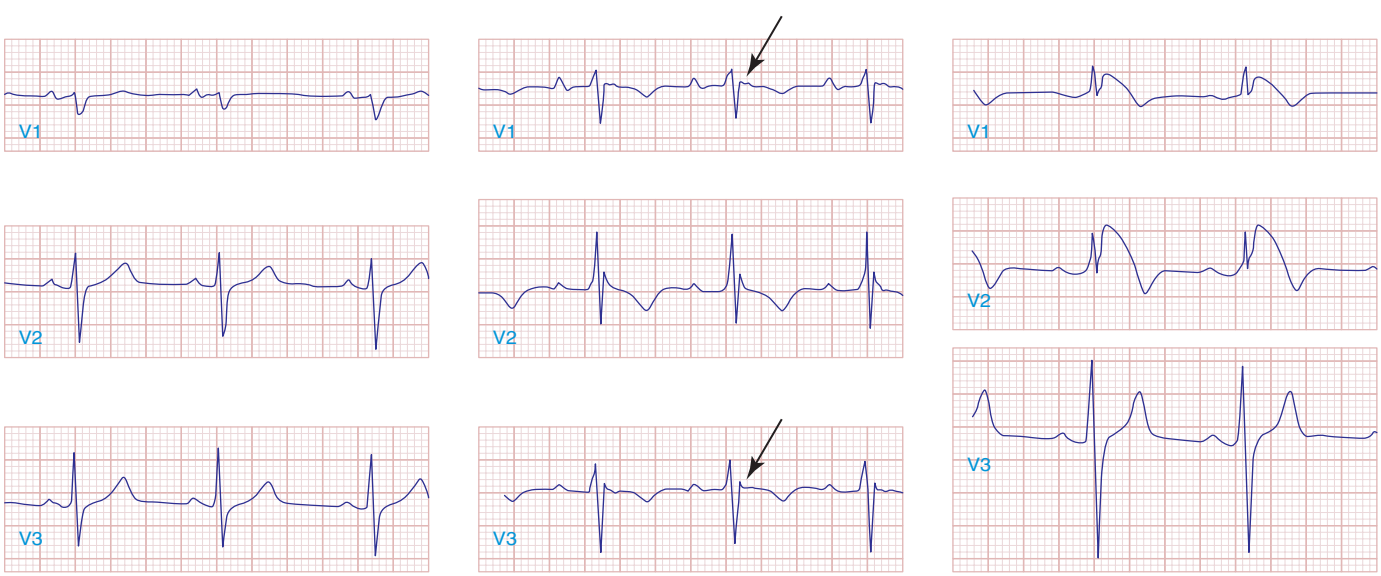

FIGURE 226-14 Leads V_1 to V_3 in sinus rhythm from a normal subject (***A***); from a patient with arrhythmogenic right ventricular cardiomyopathy showing epsilon waves (*arrow*) and T wave inversion (***B***); and from a patient with Brugada syndrome with ST-segment elevation in V_1 and V_2 (***C***).

sions directed at endocardial and, if required, epicardial scarring, defined by catheter-based bipolar voltage mapping, provide significant amelioration of the recurrent VT episodes.

VT After Operative Tetralogy of Fallot Repair VT may also occur after surgical repair of tetralogy of Fallot. Patients typically develop VT many years after the surgery. VT tends to occur in patients with evidence of RV systolic dysfunction. The VT mechanism and location are typically a macroreentrant circuit around the right ventriculotomy scar to the valve annuli. Catheter ablation creating linear lesions that extend from either the pulmonic or tricuspid annuli to the ventriculotomy scar is typically effective in preventing arrhythmia recurrences. An ICD is usually implanted in patients who manifest rapid VT, have persistent inducible VT after ablation, or have concomitant LV dysfunction.

Fascicular Tachycardia Caused by Digoxin Toxicity Digoxin toxicity can produce increased ventricular ectopy and, when coupled with bradyarrhythmias caused by digoxin toxicity, may predispose to sustained polymorphic ventricular arrhythmias and VF. The signature VT associated with digoxin toxicity is bidirectional VT (Fig. 226-15). This unique VT is due to triggered activity associated with calcium overload resulting from the inhibition of sodium/potassium ATPase by digoxin. Bidirectional VT originates from the left anterior and posterior fascicles, creating a relatively narrow QRS right bundle branch configuration with beat-to-beat alternating right and left frontal plane QRS axis. This VT is uncommonly observed in the absence of digoxin toxicity. Treatment for bidirectional VT or other hemodynamically significant arrhythmias due to digoxin excess includes correction of electrolyte disorders and the IV infusion of digoxin-specific Fab fragments. The antibody fragments will, over the course of 1 h, bind digoxin and eliminate toxic effects. In the setting of normal renal function, the bound complex is secreted.

FIGURE 226-15 Digoxin toxic bidirectional fascicular tachycardia.

TABLE 226-8 INHERITED ARRHYTHMIA DISORDERS—"CHANNELOPATHIES" WITH HIGH RISK OF VENTRICULAR ARRHYTHMIAS

Disorder	Gene	Protein/Channel Affected

Note: LQT, long QT (interval); SQT, short QT (interval).

GENETICALLY DETERMINED ABNORMALITIES THAT PREDISPOSE TO POLYMORPHIC VENTRICULAR ARRHYTHMIAS

Ion channel defects that affect cardiac depolarization and repolarization may predispose to life-threatening polymorphic VT and SCD. These defects frequently produce unique ECG characteristics during sinus rhythm that facilitate the diagnosis.

Long QT Syndrome (LQTS) The congenital form of the LQTS consists of defects in cardiac ion channels that are responsible for cardiac repolarization. Defects that enhance sodium or calcium inward currents or inhibit outward potassium currents during the plateau phase of the action potential lengthen action potential duration and, hence, the QT interval. Of the eight genetic mutations identified to date, five affect the α or β subunits of the three different potassium channels involved with repolarization (Table 226-8). Since many patients with QT prolongation do not have one of the defined mutations, it is anticipated that other genetic abnormalities affecting repolarization channel function will be identified.

The triggers for the ventricular arrhythmias are thought to be due to early afterdepolarizations potentiated by intracellular calcium accumulation from a prolonged action potential plateau. Heterogeneity of myocardial repolarization indexed by a longer QT interval predisposes to polymorphic ventricular arrhythmias in response to the triggers (Fig. 226-9).

In most patients with LQTS, the QT interval corrected for heart rate using Bazette's formula is 4 to 460 ms in men and 4 to 480 ms in women. Marked lengthening of the QT interval to > 500 ms is clearly associated with a greater arrhythmia risk in patients with the LQTS. Many affected individuals may have QT intervals that intermittently measure within a normal range or that fail to shorten appropriately with exercise. Some individuals will only manifest the syndrome when exposed to a drug, such as sotalol, that alters channel function.

The genotype associated with the LQTS appears to influence prognosis, and identification of the genotype appears to help to optimize clinical management. The first three genotypic designations of the mutations identified, LQT1, LQT2, and LQT3, appear to account for >99% of patients with clinically relevant LQTSs. Surface ECG characteristics may be helpful in distinguishing the three most common genotypes, with genetic testing being definitive.

LQT1 represents the most common genotypic abnormality. Patients with LQT1 fail to shorten or actually prolong their QT interval with exercise. The T wave in patients with LQT1 tends to be broad and

comprises the majority of the prolonged QT interval. The most common triggers for potentiating cardiac arrhythmias in patients with LQT1 are exercise followed by emotional stress.

More than 80% of male patients have their first cardiac event by age 20, so competitive exercise should be restricted and swimming avoided for these patients. Patients tend to respond to beta blocker therapy. Patients with two LQT1 alleles have the Jervell and Lange-Neilsen syndrome, with more dramatic QT prolongation and deafness and a worse arrhythmia prognosis.

LQT2 is the second most common genotypic abnormality. The T wave tends to be notched and bifid. In LQT2 patients, the most frequent precipitant is emotional stress, followed by sleep or auditory stimulation. Despite the occurrence during sleep, patients typically respond to beta blocker therapy.

LQT3 is due to a mutation in the gene that encodes the cardiac sodium channel located on chromosome 3. Prolongation of the action potential duration occurs because of failure to inactivate this channel. LQT3 patients either have late-onset peaked biphasic T waves or asymmetric peaked T waves. The arrhythmia events tend to be more life-threatening, and thus the prognosis for LQT3 is the poorest of all the LQTs. Male patients appear to have the worst prognosis in patients with LQT3. Most events in LQT3 patients occur during sleep, suggesting that they are at higher risk during slow heart rates. Beta blockers are not recommended, and exercise is not restricted in LQT3.

Rx LONG QT SYNDROME

The institution of ICD therapy should be strongly considered in any patient with LQTS who has demonstrated any life-threatening arrhythmia. Patients with syncope with a confirmed diagnosis based on unequivocal ECG criteria or positive genetic testing should also be given the same strong consideration. Primary prevention with prophylactic ICD implantation should be considered in male patients with LQT3 and in all patients with marked QT prolongation (>500 ms), particularly when coupled with an immediate family history of SCD. Future epidemiologic investigation may provide firmer guidelines to sort patients further based on risks such as age, gender, arrhythmia history, and genetic characteristics. In all patients with documented or suspected LQTS, drugs that prolong the QT interval must be avoided. For an updated list of drugs, see *www.qtdrug.org*.

Acquired LQTS Patients with a genetic predisposition related to what appear to be sporadic mutations and/or single nucleotide polymorphisms can develop marked QT prolongation in response to drugs that alter repolarization currents. The QT prolongation and associated polymorphic ventricular tachycardia (TDP) are more frequently seen in women and may be a manifestation of subclinical LQTS. Drug-induced long QT and TDP are frequently potentiated by the development of hypokalemia and bradycardia. The offending drugs typically block the potassium I_{Kr} channel (Table 226-5). Since most drug effects are dose-dependent, important drug-drug interactions that alter metabolism and/or alterations in elimination kinetics because of hepatic or renal dysfunction frequently contribute to the arrhythmias.

Rx ACQUIRED LONG QT SYNDROME

Acute therapy for acquired LQTS is directed at eliminating the offending drug therapy, reversing metabolic abnormalities by the infusion of magnesium and/or potassium, and preventing pause-dependent arrhythmias by temporary pacing or the cautious infusion of isoproterenol. Class IB antiarrhythmic agents (e.g., lidocaine), which do not cause QT prolongation, may also be used, though they are frequently ineffective. Supportive therapy to allay anxiety and prevent pain with required DC shock therapy for sustained arrhythmias as well as efforts to facilitate drug elimination are important.

Short QT Syndrome A gain in function of repolarization currents can result in a shortening of atrial and ventricular refractoriness and marked QT shortening on the surface ECG (Table 226-8). The T wave tends to be tall and peaked. A QT interval < 320 ms is required to establish the diagnosis of this uncommon syndrome. Mutations in the *HERG*, *KvLQT1*, and *KCNJ2* genes have been identified. Patients with the syndrome are predisposed to both AF and VF. ICD implantation is recommended. Double counting of QRS and T waves may lead to inappropriate ICD shocks. Drug therapy with quinidine has been used to lengthen the QT interval and reduce the amplitude of the T wave. This therapy is currently being evaluated to determine long-term efficacy in preventing arrhythmias in this syndrome.

Brugada Syndrome Mutations of *SCN5A* genes resulting in diminished inward sodium current in the region of the RV outflow tract epicardium appear responsible for the Brugada syndrome (Table 226-8). A loss of the action potential dome in the RV epicardium due to unopposed I_{To} potassium outward current results in dramatic action potential shortening. The large potential difference between the normal endocardium and rapidly depolarized RV outflow epicardium gives rise to ST-segment elevation in V_1-V_3 in sinus rhythm and predisposes to local reentry and life-threatening ventricular arrhythmias in the absence of structural heart disease (Fig. 226-14). Although identified in both genders and all races, the arrhythmia syndrome is most common in young Asian male patients and is thought to be responsible for the sudden and unexpected nocturnal death syndrome (SUDS) previously described in Southeast Asian men.

Rx BRUGADA SYNDROME

Patients do not benefit from beta blocker therapy. Sodium channel-blocking drugs, such as procainamide and flecainide, can exacerbate the syndrome and are used as a provocative test to identify the presence of the abnormality in family members with a more limited expression of the genetic abnormality. This drug challenge may also be important to establish more firmly the diagnosis and the probable cause of unexplained syncope when the surface ECG is equivocal. Acute management of recurrent VT has been reported to respond to isoproterenol administration or quinidine, although the efficacy of this treatment requires more extensive study. ICD treatment to manage recurrences is recommended for all patients who have had documented arrhythmia episodes. Family members should be screened for the presence of the abnormality. A history of syncope, spontaneous ST-segment elevation, and inducibility of VT with programmed stimulation may identify family members also at risk for SCD who warrant prophylactic ICD therapy.

Catecholaminergic Polymorphic VT A mutation of the myocardial ryanodine release channel, which effectively creates a "leak" in calcium from the sarcoplasmic reticulum, has been identified in patients with catecholaminergic VT (Table 226-8). The accumulation of intracellular calcium potentiates delayed afterdepolarizations and triggered activity. Patients can manifest bidirectional VT, nonsustained polymorphic VT, or recurrent VF. Both an autosomal dominant familial and sporadic forms of the disease have been described. More recently, an autosomal recessive variant associated with a mutation in the sarcoplasmic reticulum calcium-buffering protein, calsequestrin, has also been identified. The arrhythmias are precipitated by exercise and emotional stress (Fig. 226-16).

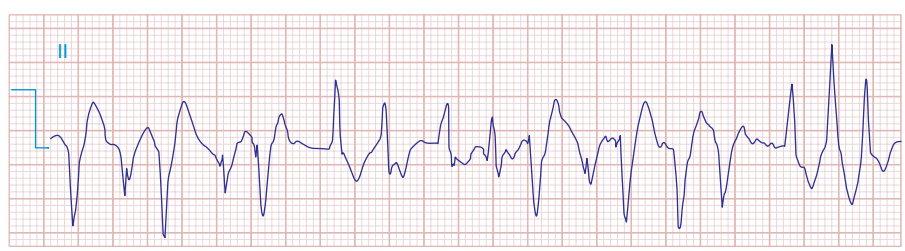

FIGURE 226-16 Catecholaminergic polymorphic ventricular tachycardia noted during an exercise stress test.

Exercise restriction is warranted. Treatment with beta blockers and ICD implantation has been recommended. Prevention of inappropriate or easily triggered ICD shocks by proper ICD programming are essential to prevent VT storm from endogenous catecholamine release.

SECTION 4 DISORDERS OF THE HEART

227 Heart Failure and Cor Pulmonale

Douglas L. Mann

HEART FAILURE

DEFINITION

Heart failure (HF) is a clinical syndrome that occurs in patients who, because of an inherited or acquired abnormality of cardiac structure and/or function, develop a constellation of clinical symptoms (dyspnea and fatigue) and signs (edema and rales) that lead to frequent hospitalizations, a poor quality of life, and a shortened life expectancy.

EPIDEMIOLOGY

HF is a burgeoning problem worldwide, with more than 20 million people affected. The overall prevalence of HF in the adult population in developed countries is 2%. HF prevalence follows an exponential pattern, rising with age, and affects 6–10% of people over the age of 65. Although the relative incidence of HF is lower in women than in men, women constitute at least half of the cases of HF because of their longer life expectancy. In North America and Europe, the lifetime risk of developing HF is approximately one in five for a 40-year-old. The overall prevalence of HF is thought to be increasing, in part because current therapies of cardiac disorders, such as myocardial infarction (MI), valvular heart disease, and arrhythmias, are allowing patients to survive longer. Very little is known with respect to the prevalence or risk of developing HF in emerging nations because of the lack of population-based studies in these countries. Although HF was once thought to arise primarily in the setting of a depressed left ventricular (LV) ejection fraction (EF), epidemiological studies have shown that approximately one-half of patients who develop HF have a normal or preserved EF (EF ≥40–50%). Accordingly, HF patients are now broadly categorized into one of two groups: (1) HF with a depressed EF (commonly referred to as *systolic failure*) or (2) HF with a preserved EF (commonly referred to as *diastolic failure*).

ETIOLOGY

As shown in Table 227-1, any condition that leads to an alteration in LV structure or function can predispose a patient to developing HF. Although the etiology of HF in patients with a preserved EF differs from that of those with depressed EF, there is considerable overlap between the etiologies of these two conditions. In industrialized countries, coronary artery disease (CAD) has become the predominant cause in men and women and is responsible for 60–75% of cases of HF. Hypertension contributes to the development of HF in 75% of patients, including most patients with CAD. Both CAD and hypertension interact to augment the risk of HF, as does diabetes mellitus.

In 20–30% of the cases of HF with a depressed EF, the exact etiologic basis is not known. These patients are referred to as having nonischemic, dilated, or idiopathic cardiomyopathy if the cause is unknown (Chap. 231). Prior viral infection or toxin exposure (e.g., alcoholic or chemotherapeutic) may also lead to a dilated cardiomyopathy. Moreover, it is becoming increasingly clear that a large number of the cases of dilated cardiomyopathy are secondary to specific genetic defects, most notably those in the cytoskeleton. Most of the forms of familial dilated cardiomyopathy are inherited in an autosomal dominant fashion. Mutations of genes encoding cytoskeletal proteins (desmin, cardiac myosin, vinculin) and nuclear membrane proteins (lamin) have been identified thus far. Dilated cardiomyopathy is also associated with Duchenne's, Becker's, and limb girdle muscular dystrophies. Conditions that lead to a high cardiac output (e.g., arteriovenous fistula, anemia) are seldom responsible for the development of HF in a normal heart. However, in the presence of underlying structural heart disease, these conditions can lead to overt HF.

e21 Atlas of Cardiac Arrhythmias

Ary L. Goldberger

The electrocardiograms in this Atlas supplement those illustrated in Chaps. 225 and 226. The interpretations emphasize findings of specific teaching value.

All of the figures are from ECG Wave-Maven, Copyright 2003, Beth Israel Deaconess Medical Center, *http://ecg.bidmc.harvard.edu*.

The abbreviations used in this chapter are as follows:

AF—atrial fibrillation
AV—atrioventricular
AVRT—atrioventricular reentrant tachycardia
LBBB—left bundle branch block
LV—left ventricular
LVH—left ventricular hypertrophy
MI—myocardial infarction
NSR—normal sinus rhythm
RBBB—right bundle branch block
VT—ventricular tachycardia
WPW—Wolff-Parkinson-White

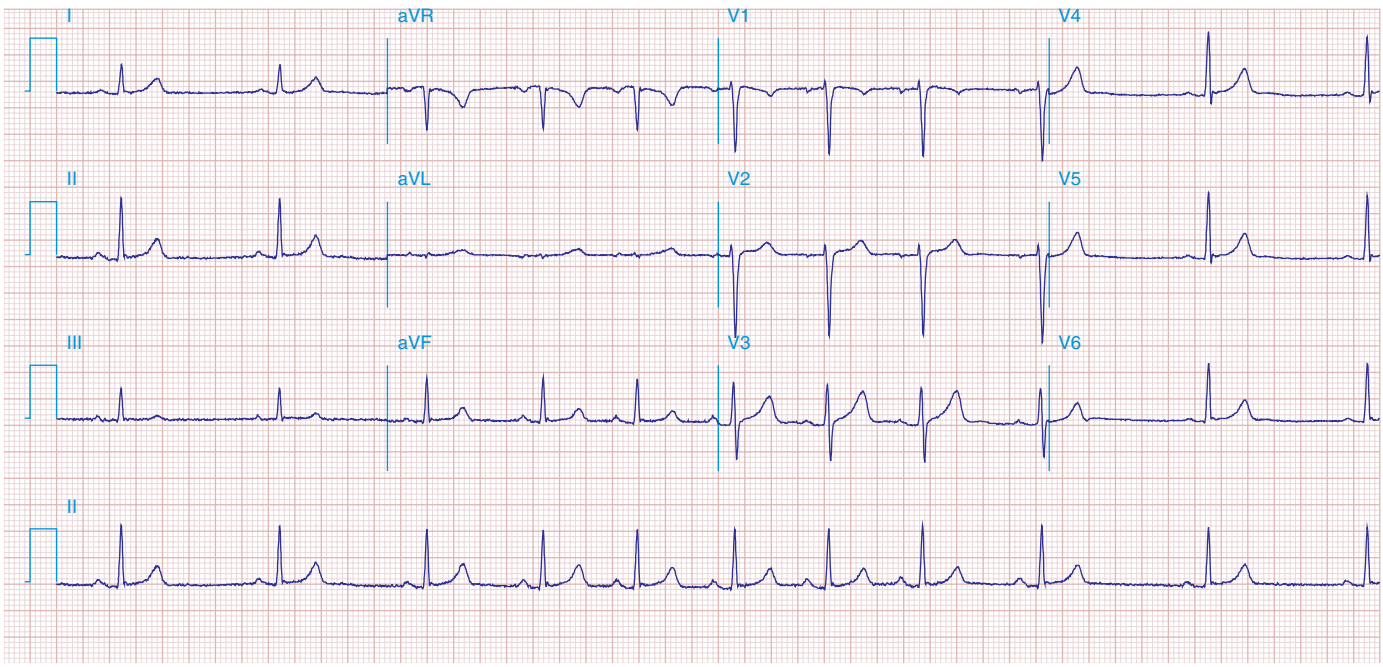

FIGURE e21-1 Respiratory sinus arrhythmias, a physiologic finding in a healthy young woman. The rate of the sinus pacemaker is slow at the beginning of the strip during expiration, then accelerates during inspiration and slows again with expiration.

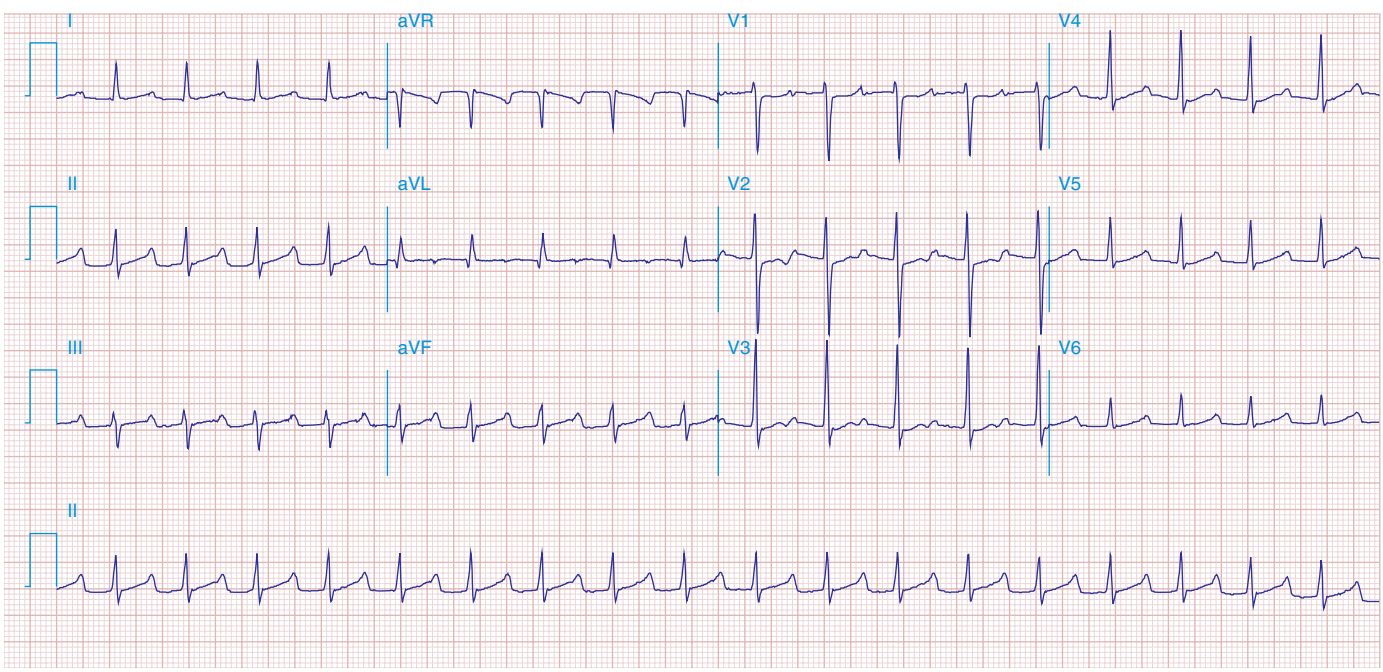

FIGURE e21-2 Sinus tachycardia (110/min) with first-degree AV block (PR interval = 0.28 s). The P wave is visible after the ST-T wave in V_1–V_3. Atrial tachycardia may produce a similar pattern.

TABLE 227-1 ETIOLOGIES OF HEART FAILURE

Depressed Ejection Fraction (<40%)	
Coronary artery disease	Nonischemic dilated cardiomyopathy
Myocardial infarction[a]	Familial/genetic disorders
Myocardial ischemia[a]	Infiltrative disorders[a]
Chronic pressure overload	Toxic/drug-induced damage
Hypertension[a]	Metabolic disorder[a]
Obstructive valvular disease[a]	Viral
Chronic volume overload	Chagas' disease
Regurgitant valvular disease	Disorders of rate and rhythm
Intracardiac (left-to-right) shunting	Chronic bradyarrhythmias
Extracardiac shunting	Chronic tachyarrhythmias
Preserved Ejection Fraction (>40–50%)	
Pathological hypertrophy	Restrictive cardiomyopathy
Primary (hypertrophic cardiomyopathies)	Infiltrative disorders (amyloidosis, sarcoidosis)
Secondary (hypertension)	Storage diseases (hemochromatosis)
Aging	Fibrosis
	Endomyocardial disorders
Pulmonary Heart Disease	
Cor pulmonale	
Pulmonary vascular disorders	
High-Output States	
Metabolic disorders	Excessive blood-flow requirements
Thyrotoxicosis	Systemic arteriovenous shunting
Nutritional disorders (beriberi)	Chronic anemia

[a]***Note:*** Indicates conditions that can also lead to heart failure with a preserved injection fraction.

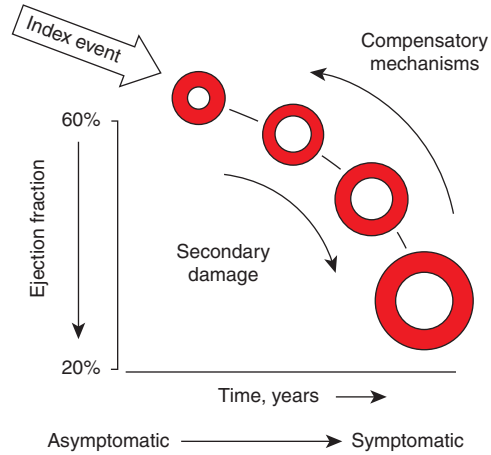

FIGURE 227-1 Pathogenesis of heart failure with a depressed ejection fraction. Heart failure begins after an index event produces an initial decline in the heart's pumping capacity. Following this initial decline in pumping capacity, a variety of compensatory mechanisms are activated, including the adrenergic nervous system, the renin-angiotensin-aldosterone system and the cytokine system. In the short term, these systems are able to restore cardiovascular function to a normal homeostatic range with the result that the patient remains asymptomatic. However, with time the sustained activation of these systems can lead to secondary end-organ damage within the ventricle, with worsening left-ventricular remodeling and subsequent cardiac decompensation. *(From D Mann: Circulation 100:999, 1999.)*

GLOBAL CONSIDERATIONS

Rheumatic heart disease remains a major cause of HF in Africa and Asia, especially in the young. Hypertension is an important cause of HF in the African and African-American populations. Chagas' disease is still a major cause of HF in South America. Not surprisingly, anemia is a frequent concomitant factor in HF in many developing nations. As developing nations undergo socioeconomic development, the epidemiology of HF is becoming similar to that of Western Europe and North America, with CAD emerging as the single most common cause of HF. Although the contribution of diabetes mellitus to HF is not well understood, diabetes accelerates atherosclerosis and is often associated with hypertension.

PROGNOSIS

Despite many recent advances in the evaluation and management of HF, the development of symptomatic HF still carries a poor prognosis. Community-based studies indicate that 30–40% of patients die within 1 year of diagnosis and 60–70% die within 5 years, mainly from worsening HF or as a sudden event (probably because of a ventricular arrhythmia). Although it is difficult to predict prognosis in an individual, patients with symptoms at rest [New York Heart Association (NYHA) class IV] have a 30–70% annual mortality rate, whereas patients with symptoms with moderate activity (NYHA class II) have an annual mortality rate of 5–10%. Thus, functional status is an important predictor of patient outcome (see Table 272-2).

PATHOGENESIS

Figure 227-1 provides a general conceptual framework for considering the development and progression of HF with a depressed EF. As shown, HF may be viewed as a progressive disorder that is initiated after an *index event* either damages the heart muscle, with a resultant loss of functioning cardiac myocytes, or alternatively disrupts the ability of the myocardium to generate force, thereby preventing the heart from contracting normally. This index event may have an abrupt onset, as in the case of a MI; it may have a gradual or insidious onset, as in the case of hemodynamic pressure or volume overloading; or it may be hereditary, as in the case of many of the genetic cardiomyopathies. Regardless of the nature of the inciting event, the feature that is common to each of these index events is that they all, in some manner, produce a decline in the pumping capacity of the heart. In most instances patients remain asymptomatic or minimally symptomatic following the initial decline in pumping capacity of the heart, or develop symptoms only after the dysfunction has been present for some time. Thus, when viewed within this conceptual framework, LV dysfunction is necessary, but not sufficient, for the development of the syndrome of HF.

Although the precise reasons why patients with LV dysfunction may remain asymptomatic is not certain, one potential explanation is that a number of compensatory mechanisms become activated in the presence of cardiac injury and/or LV dysfunction, and they appear to be able to sustain and modulate LV function for a period of months to years. The list of compensatory mechanisms that have been described thus far include (1) activation of the renin-angiotensin-aldosterone (RAA) and adrenergic nervous systems, which are responsible for maintaining cardiac output through increased retention of salt and water (Fig. 227-2), and (2) increased myocardial contractility. In addition, there is activation of a family of countervailing vasodilatory molecules, including the atrial and brain natriuretic peptides (ANP and BNP), prostaglandins (PGE_2 and PGI_2), and nitric oxide (NO), that offset the excessive peripheral vascular vasoconstriction. Genetic background, gender, age, or environment may influence these compensatory mechanisms, which are able to modulate LV function within a physiologic/homeostatic range, such that the functional capacity of the patient is preserved or is depressed only minimally. Thus, patients may remain asymptomatic or minimally symptomatic for a period of years. However, at some point patients become overtly symptomatic, with a resultant striking increase in morbidity and mortality. Although the exact mechanisms that are responsible for this transition are not known, as will be discussed below, the transition to symptomatic HF is accompanied by increasing activation of neurohormonal, adrenergic, and cytokine systems that lead to a series of adaptive changes within the myocardium, collectively referred to as *LV remodeling*.

In contrast to our understanding of the pathogenesis of HF with a depressed EF, our understanding of the mechanisms that contribute to the development of HF with a preserved EF is still evolving. That is, al-

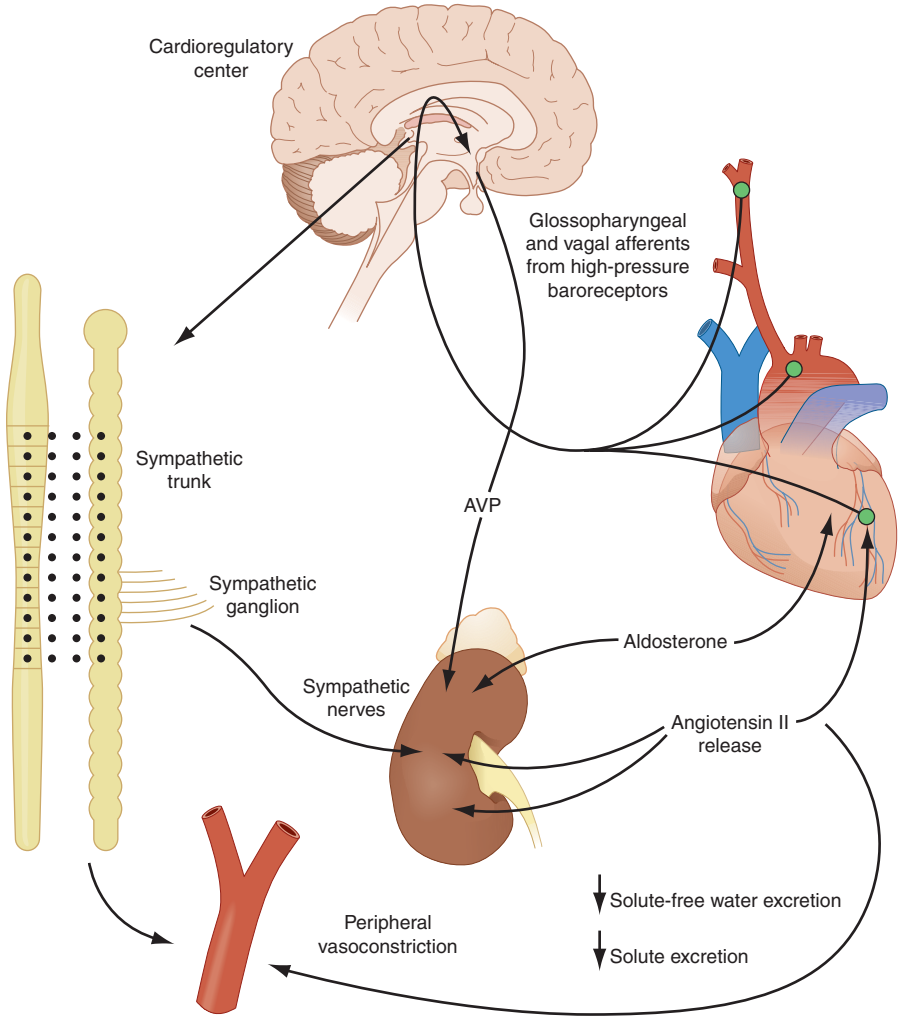

FIGURE 227-2 Activation of neurohormonal systems in heart failure. The decreased cardiac output in HF patients results in an "unloading" of high-pressure baroceptors (circles) in the left ventricle, carotid sinus, and aortic arch. This unloading leads to the generation of afferent signals to the central nervous system (CNS) that stimulate cardioregulatory centers in the brain which stimulate the release of arginine vasopression (AVP) from the posterior pituitary. AVP [or antidiuretic hormone (ADH)] is a powerful vasoconstrictor that increases the permeability of the renal collecting ducts, leading to the reabsorption of free water. These afferent signals to the CNS also activate efferent sympathetic nervous system pathways that innervate the heart, kidney, peripheral vasculature, and skeletal muscles.

Sympathetic stimulation of the kidney leads to the release of renin, with a resultant increase in the circulating levels of angiotensin II and aldosterone. The activation of the renin-angiotensin-aldosterone system promotes salt and water retention and leads to vasoconstriction of the peripheral vasculature, myocyte hypertrophy, myocyte cell death, and myocardial fibrosis. While these neurohormonal mechanisms facilitate short-term adaptation by maintaining blood pressure, and hence perfusion to vital organs, these same neurohormonal mechanisms are believed to contribute to end-organ changes in the heart and the circulation, and to the excessive salt and water retention in advanced HF. *[From E Braunwald: Pathophysiology of heart failure, in Braunwald's Heart Disease, 7th ed, D Zipes et al (eds). Philadelphia, Elsevier Saunders, pp 509–538, 2005; and adapted from Schrier RW, Abraham WT: N Engl J Med 341:577, 1999.]*

though diastolic dysfunction (see below) was thought to be the only mechanism responsible for the development of HF with a preserved EF, community-based studies suggest that additional mechanisms, such as increased vascular and ventricular (*ventricular-vascular*) stiffness, may also be important.

BASIC MECHANISMS OF HEART FAILURE

LV remodeling develops in response to a series of complex events that occur at the cellular and molecular levels. These changes include: (1) myocyte hypertrophy; (2) alterations in the contractile properties of the myocyte; (3) progressive loss of myocytes through necrosis, apoptosis, and autophagic cell death; (4) β-adrenergic desensitization; (5) abnormal myocardial energetics and metabolism; and (6) reorganization of the extracellular matrix with dissolution of the organized structural collagen weave surrounding myocytes and subsequent replacement by an interstitial collagen matrix that does not provide structural support to the myocytes. The biological stimuli for these profound changes include mechanical stretch of the myocyte, circulating neurohormones (e.g., norepinephrine, angiotensin II), inflammatory cytokines [e.g., tumor necrosis factor (TNF)], other peptides and growth factors (e.g., endothelin), and reactive oxygen species (e.g., superoxide, NO). Although these molecules are collectively referred to as *neurohormones*, this historical terminology is somewhat misleading insofar as the classical neurohormones, such as norepinephrine and angiotensin II, may also be synthesized directly within the myocardium and thus may also act in an autocrine and paracrine manner. Nonetheless, the overarching concept is that the sustained overexpression of these biologically active molecules contributes to the progression of HF by virtue of the deleterious effects that they exert on the heart and the circulation. Indeed, this insight forms the clinical rationale for using pharmacologic agents that antagonize these systems [e.g., angiotensin-converting enzyme (ACE) inhibitors and beta blockers] in treating patients with HF.

Systolic Dysfunction In order to understand how the changes that occur in the failing cardiac myocyte contribute to depressed LV systolic function in HF, it is instructive first to review the biology of the cardiac muscle cell (Chap. 217). Sustained neurohormonal activation results in transcriptional and posttranscriptional changes in the genes and proteins that regulate excitation-contraction coupling and cross-bridge interaction (see Fig. 217-7). Collectively, these changes impair the ability of the myocyte to contract and, therefore, contribute to the depressed LV systolic function observed in patients with HF.

Diastolic Dysfunction Myocardial relaxation is an ATP-dependent process that is regulated by uptake of cytoplasmic calcium into the sarcoplasmic reticulum (SR) by sarcoplasmic reticulum Ca^{2+} adenosine triphosphatase (SERCA2A) and extrusion of calcium by sarcolemmal pumps (see Fig. 217-7). Accordingly, reductions in ATP concentration, as occurs in ischemia, may interfere with these processes and lead to slowed myocardial relaxation. Alternatively, if LV filling is delayed because LV compliance is reduced (e.g., from hypertrophy or fibrosis), LV filling pressures will similarly remain elevated at end diastole (see Fig. 217-11). An increase in heart rate disproportionately shortens the time for diastolic filling, which may lead to elevated LV filling pressures, particularly in noncompliant ventricles. Elevated LV end-diastolic filling pressures result in increases in pulmonary capillary pressures, which can contribute to the dyspnea experienced by patients with diastolic dysfunction. Importantly, diastolic dysfunction can occur alone or in combination with systolic dysfunction in patients with HF.

Left Ventricular Remodeling *Ventricular remodeling* refers to the changes in LV mass, volume, shape, and composition of the heart that occur following cardiac injury and/or abnormal hemodynamic loading conditions. LV remodeling may contribute independently to the progression of HF by virtue of the mechanical burdens that are engendered by the changes in the geometry of the remodeled LV. For example, the change in LV shape from a prolate ellipsoid of revolution to a more spherical shape during LV remodeling results in an increase in meridional wall stress of the LV, which creates a de novo mechanical burden for the failing heart. In addition to the increase in LV end-diastolic volume, LV wall thinning also occurs as the left ventricle begins to dilate. The increase in wall thinning along with the increase in afterload created by LV dilation leads to a functional *afterload mismatch* that may contribute further to a decrease in stroke volume. Moreover, the high end-diastolic wall stress might be expected to lead to: (1) hypoperfusion of the subendocardium, with resultant worsening of LV function; (2) increased oxidative stress, with the resultant activation of families of genes that are sensitive to free radical generation (e.g., TNF and interleukin 1β); and (3) sustained expression of stretch-activated genes (angiotensin II, endothelin, and TNF) and/or stretch activation of hypertrophic signaling pathways.

A second important problem that results from increased sphericity of the ventricle is that the papillary muscles are pulled apart, resulting in incompetence of the mitral valve and the development of functional mitral regurgitation. In addition to the loss of forward blood flow, mitral regurgitation also results in further hemodynamic overloading of the ventricle. Taken together, the mechanical burdens that are engendered by LV remodeling can be expected to lead to decreased forward cardiac output, increased LV dilation (stretch), and increased hemodynamic overloading, all of which are sufficient to contribute to the progression of HF.

CLINICAL MANIFESTATIONS

Symptoms The cardinal symptoms of HF are fatigue and shortness of breath. Although fatigue has been traditionally ascribed to the low cardiac output in HF, it is likely that skeletal-muscle abnormalities and other noncardiac comorbidities (e.g., anemia) also contribute to this symptom. In the early stages of HF, dyspnea is observed only during exertion; however, as the disease progresses, dyspnea occurs with less strenuous activity, and ultimately may occur even at rest. The origin of dyspnea in HF is likely multifactorial (Chap. 33). The most important mechanism is pulmonary congestion with accumulation of interstitial or intra-alveolar fluid, which activates juxtacapillary J receptors, which in turn stimulate rapid, shallow breathing characteristic of cardiac dyspnea. Other factors that contribute to dyspnea on exertion include reductions in pulmonary compliance, increased airway resistance, respiratory muscle and/or diaphragm fatigue, and anemia. Dyspnea may become less frequent with the onset of right ventricular (RV) failure and tricuspid regurgitation.

ORTHOPNEA Orthopnea, which is defined as dyspnea occurring in the recumbent position, is usually a later manifestation of HF than is exertional dyspnea. It results from the redistribution of fluid from the splanchnic circulation and lower extremities into the central circulation during recumbency, with a resultant increase in pulmonary capillary pressure. Nocturnal cough is a frequent manifestation of this process and a frequently overlooked symptom of HF. Orthopnea is generally relieved by sitting upright or by sleeping with additional pillows. Although orthopnea is a relatively specific symptom of HF, it may occur in patients with abdominal obesity or ascites and in patients with pulmonary disease whose lung mechanics favor an upright posture.

PAROXYSMAL NOCTURNAL DYSPNEA (PND) This term refers to acute episodes of severe shortness of breath and coughing that generally occur at night and awaken the patient from sleep, usually 1–3 h after the patient retires. PND may be manifest by coughing or wheezing, possibly because of increased pressure in the bronchial arteries leading to airway compression, along with interstitial pulmonary edema leading to increased airway resistance. Whereas orthopnea may be relieved by sitting upright at the side of the bed with the legs in a dependent position, patients with PND often have persistent coughing and wheezing even after they have assumed the upright position. *Cardiac asthma* is closely related to PND, is characterized by wheezing secondary to bronchospasm, and must be differentiated from primary asthma and pulmonary causes of wheezing.

CHEYNE-STOKES RESPIRATION Also referred to as periodic respiration or cyclic respiration, Cheyne-Stokes respiration is common in advanced HF and is usually associated with low cardiac output. Cheyne-Stokes respiration is caused by a diminished sensitivity of the respiratory center to arterial P_{CO_2}. There is an apneic phase, during which the arterial P_{O_2} falls and the arterial P_{CO_2} rises. These changes in the arterial blood gas content stimulate the depressed respiratory center, resulting in hyperventilation and hypocapnia, followed in turn by recurrence of apnea. Cheyne-Stokes respirations may be perceived by the patient or the patient's family as severe dyspnea or as a transient cessation of breathing.

ACUTE PULMONARY EDEMA See Chap. 266.

Other Symptoms Patients with HF may also present with gastrointestinal symptoms. Anorexia, nausea, and early satiety associated with abdominal pain and fullness are frequent complaints and may be related to edema of the bowel wall and/or a congested liver. Congestion of the liver and stretching of its capsule may lead to right-upper-quadrant pain. Cerebral symptoms, such as confusion, disorientation, and sleep and mood disturbances, may be observed in patients with severe HF, particularly elderly patients with cerebral arteriosclerosis and reduced cerebral perfusion. Nocturia is common in HF and may contribute to insomnia.

PHYSICAL EXAMINATION

A careful physical examination is always warranted in the evaluation of patients with HF. The purpose of the examination is to help determine the cause of HF, as well as to assess the severity of the syndrome. Obtaining additional information about the hemodynamic profile and the response to therapy and determining the prognosis are important additional goals of the physical examination.

General Appearance and Vital Signs In mild or moderately severe HF, the patient appears in no distress at rest, except for feeling uncomfortable when lying flat for more than a few minutes. In more severe HF, the patient must sit upright, may have labored breathing, and may not be able to finish a sentence because of shortness of breath. Systolic blood pressure may be normal or high in early HF, but it is generally reduced in advanced HF because of severe LV dysfunction. The pulse pressure may be diminished, reflecting a reduction in stroke volume. Sinus tachycardia is a nonspecific sign caused by increased adrenergic activity. Peripheral vasoconstriction leading to cool peripheral extremities and cyanosis of the lips and nail beds is also caused by excessive adrenergic activity.

Jugular Veins (See also Chap. 220) Examination of the jugular veins provides an estimation of right atrial pressure. The jugular venous pressure is best appreciated with the patient lying recumbent, with the head tilted at 45°. The jugular venous pressure should be quantified in centimeters of water (normal ≤8 cm) by estimating the height of the venous column of blood above the sternal angle in cm and then adding 5 cm. In the early stages of HF, the venous pressure may be normal at rest but may become abnormally elevated with sustained (~1 min) pressure on the abdomen (positive abdominojugular reflux). Giant *v* waves indicate the presence of tricuspid regurgitation.

Pulmonary Examination Pulmonary crackles (rales or crepitations) result from the transudation of fluid from the intravascular space into the alveoli. In patients with pulmonary edema, rales may be heard widely over both lung fields and may be accompanied by expiratory wheezing (cardiac asthma). When present in patients without concomitant lung disease, rales are specific for HF. Importantly, rales are

frequently absent in patients with chronic HF, even when LV filling pressures are elevated, because of increased lymphatic drainage of alveolar fluid. Pleural effusions result from the elevation of pleural capillary pressure and the resulting transudation of fluid into the pleural cavities. Since the pleural veins drain into both the systemic and pulmonary veins, pleural effusions occur most commonly with biventricular failure. Although pleural effusions are often bilateral in HF, when unilateral they occur more frequently in the right pleural space.

Cardiac Examination Examination of the heart, although essential, frequently does not provide useful information about the severity of HF. If cardiomegaly is present, the point of maximal impulse (PMI) is usually displaced below the fifth intercostal space and/or lateral to the midclavicular line, and the impulse is palpable over two interspaces. Severe LV hypertrophy leads to a sustained PMI. In some patients, a third heart sound (S_3) is audible and palpable at the apex. Patients with enlarged or hypertrophied right ventricles may have a sustained and prolonged left parasternal impulse extending throughout systole. An S_3 (or *protodiastolic gallop*) is most commonly present in patients with volume overload who have tachycardia and tachypnea, and it often signifies severe hemodynamic compromise. A fourth heart sound (S_4) is not a specific indicator of HF but is usually present in patients with diastolic dysfunction. The murmurs of mitral and tricuspid regurgitation are frequently present in patients with advanced HF.

Abdomen and Extremities Hepatomegaly is an important sign in patients with HF. When present, the enlarged liver is frequently tender and may pulsate during systole if tricuspid regurgitation is present. Ascites, a late sign, occurs as a consequence of increased pressure in the hepatic veins and the veins draining the peritoneum. Jaundice, also a late finding in HF, results from impairment of hepatic function secondary to hepatic congestion and hepatocellular hypoxia, and is associated with elevations of both direct and indirect bilirubin.

Peripheral edema is a cardinal manifestation of HF, but it is nonspecific and usually absent in patients who have been treated adequately with diuretics. Peripheral edema is usually symmetric and dependent in HF and occurs predominantly in the ankles and pretibial region in ambulatory patients. In bedridden patients, edema may be found in the sacral area (*presacral edema*) and the scrotum. Long-standing edema may be associated with indurated and pigmented skin.

Cardiac Cachexia With severe chronic HF, there may be marked weight loss and cachexia. Although the mechanism of cachexia is not entirely understood, it is likely multifactorial and includes elevation of the resting metabolic rate; anorexia, nausea, and vomiting due to congestive hepatomegaly and abdominal fullness; elevation of circulating concentrations of cytokines such as TNF; and impairment of intestinal absorption due to congestion of the intestinal veins. When present, cachexia augers a poor overall prognosis.

DIAGNOSIS

The diagnosis of HF is relatively straightforward when the patient presents with classic signs and symptoms of HF; however, the signs and symptoms of HF are neither specific nor sensitive. Accordingly, the key to making the diagnosis is to have a high index of suspicion, particularly for high-risk patients. When these patients present with signs or symptoms of HF, additional laboratory testing should be performed.

Routine Laboratory Testing Patients with new-onset HF and those with chronic HF and acute decompensation should have a complete blood count, a panel of electrolytes, blood urea nitrogen, serum creatinine, hepatic enzymes, and a urinalysis. Selected patients should have assessment for diabetes mellitus (fasting serum glucose or oral glucose tolerance test), dyslipidemia (fasting lipid panel), and thyroid abnormalities (thyroid-stimulating hormone level).

Electrocardiogram (ECG) A routine 12-lead ECG is recommended. The major importance of the ECG is to assess cardiac rhythm, determine the presence of LV hypertrophy or a prior MI (presence or absence of Q waves), as well as to determine QRS width to ascertain whether the patient may benefit from resychronization therapy (see below). A normal ECG virtually excludes LV systolic dysfunction.

Chest X-ray This provides useful information about cardiac size and shape, as well as the state of the pulmonary vasculature, and may identify noncardiac causes of the patient's symptoms. Although patients with acute HF have evidence of pulmonary hypertension, interstitial edema, and/or pulmonary edema, the majority of patients with chronic HF do not. The absence of these findings in patients with chronic HF reflects the increased capacity of the lymphatics to remove interstitial and/or pulmonary fluid.

Assessment of LV Function Noninvasive cardiac imaging (Chap. 222) is essential for the diagnosis, evaluation, and management of HF. The most useful test is the 2-D echocardiogram/Doppler, which can provide a semiquantitative assessment of LV size and function as well as the presence or absence of valvular and/or regional wall motion abnormalities (indicative of a prior MI). The presence of left atrial dilation and LV hypertrophy, together with abnormalities of LV diastolic filling provided by pulse-wave and tissue Doppler, are useful for the assessment of HF with a preserved EF. The 2-D echocardiogram/Doppler is also invaluable in assessing RV size and pulmonary pressures, which are critical in the evaluation and management of cor pulmonale (see below). MRI also provides a comprehensive analysis of cardiac anatomy and function and is now the gold standard for assessing LV mass and volumes.

The most useful index of LV function is the EF (stroke volume divided by end-diastolic volume). Because the EF is easy to measure by noninvasive testing and easy to conceptualize, it has gained wide acceptance among clinicians. Unfortunately, the EF has a number of limitations as a true measure of contractility, since it is influenced by alterations in afterload and/or preload. For example, the LV EF is increased in mitral regurgitation as a result of ejection of the blood into the low-pressure left atrium. Nonetheless, with the exceptions indicated above, when the EF is normal (≥50%), systolic function is usually adequate, and when the EF is significantly depressed (<30–40%), contractility is usually also depressed.

Biomarkers Circulating levels of natriuretic peptides are useful adjunctive tools in the diagnosis of patients with HF. Both B-type natriuretic peptide (BNP) and N-terminal pro-BNP, which are released from the failing heart, are relatively sensitive markers for the presence of HF with depressed EF; they are also elevated in HF patients with a preserved HF, albeit to a lesser degree. However, it is important to recognize that natriuretic peptide levels increase with age and renal impairment, are more elevated in women, and can be elevated in right HF from any cause. Levels can be falsely low in obese patients and may normalize in some patients following appropriate treatment. A normal concentration of natriuretic peptides in an untreated patient is extremely useful for excluding the diagnosis of HF. Other biomarkers, such as troponin T and I, C-reactive protein, TNF receptors, and uric acid, may be elevated in HF and provide important prognostic information. Serial measurements of one or more biomarkers may ultimately help to guide therapy in HF, but they are not currently recommended for this purpose.

Exercise Testing Treadmill or bicycle exercise testing is not routinely advocated for patients with HF, but either is useful for assessing the need for cardiac transplantation in patients with advanced HF (Chap. 228). A peak oxygen uptake (V_{O_2}) <14 mL/kg per min is associated with a relatively poor prognosis. Patients with a V_{O_2} <14 mL/kg per min have been shown, in general, to have better survival when transplanted than when treated medically.

DIFFERENTIAL DIAGNOSIS

HF resembles but should be distinguished from (1) conditions in which there is circulatory congestion secondary to abnormal salt and

water retention but in which there is no disturbance of cardiac structure or function (e.g., renal failure) and (2) noncardiac causes of pulmonary edema (e.g., acute respiratory distress syndrome). In most patients who present with classic signs and symptoms of HF, the diagnosis is relatively straightforward. However, even experienced clinicians have difficulty in differentiating the dyspnea that arises from cardiac and pulmonary causes (Chap. 33). In this regard, noninvasive cardiac imaging, biomarkers, pulmonary function testing, and chest x-ray may be useful. A very low BNP or N-terminal pro-BNP may be helpful in excluding a cardiac cause of dyspnea in this setting. Ankle edema may arise secondary to varicose veins, obesity, renal disease, or gravitational effects. When HF develops in patients with a preserved EF, it may be difficult to determine the relative contribution of HF to the dyspnea that occurs in chronic lung disease and/or obesity.

℞ HEART FAILURE

HF should be viewed as a continuum that is comprised of four interrelated stages. *Stage A* includes patients who are at high risk for developing HF but without structural heart disease or symptoms of HF (e.g., patients with diabetes mellitus or hypertension). *Stage B* includes patients who have structural heart disease but without symptoms of HF (e.g., patients with a previous MI and asymptomatic LV dysfunction). *Stage C* includes patients who have structural heart disease and have developed symptoms of HF (e.g., patients with a previous MI with dyspnea and fatigue). *Stage D* includes patients with refractory HF requiring special interventions (e.g., patients with refractory HF who are awaiting cardiac transplantation). In this continuum, every effort should be made to prevent HF, not only by treating the preventable causes of HF (e.g., hypertension) but by treating the patient in Stages B and C with drugs that prevent disease progression (e.g., ACE inhibitors and beta blockers) and by symptomatic management of patients in stage D.

DEFINING AN APPROPRIATE THERAPEUTIC STRATEGY FOR CHRONIC HF Once patients have developed structural heart disease, their therapy depends on their NYHA functional classification **(Table 227-2)**. Although this classification system is notoriously subjective and has large interobserver variability, it has withstood the test of time and continues to be widely applied to patients with HF. For patients who have developed LV systolic dysfunction but remain asymptomatic (class I), the goal should be to slow disease progression by blocking neurohormonal systems that lead to cardiac remodeling (see below). For patients who have developed symptoms (class II–IV), the primary goal should be to alleviate fluid retention, lessen disability, and reduce the risk of further disease progression and death. These goals generally require a strategy that combines diuretics (to control salt and water retention) with neurohormonal interventions (to minimize cardiac remodeling).

TABLE 227-2 NEW YORK HEART ASSOCIATION CLASSIFICATION

Functional Capacity	Objective Assessment
Class I	Patients with cardiac disease but without resulting limitation of physical activity. Ordinary physical activity does not cause undue fatigue, palpitations, dyspnea, or anginal pain.
Class II	Patients with cardiac disease resulting in slight limitation of physical activity. They are comfortable at rest. Ordinary physical activity results in fatigue, palpitation, dyspnea, or anginal pain.
Class III	Patients with cardiac disease resulting in marked limitation of physical activity. They are comfortable at rest. Less than ordinary activity causes fatigue, palpitation, dyspnea, or anginal pain.
Class IV	Patients with cardiac disease resulting in inability to carry on any physical activity without discomfort. Symptoms of heart failure or the anginal syndrome may be present even at rest. If any physical activity is undertaken, discomfort is increased.

Source: Adapted from New York Heart Association, Inc., *Diseases of the Heart and Blood Vessels: Nomenclature and Criteria for Diagnosis*, 6th ed. Boston, Little Brown, 1964, p. 114.

MANAGEMENT OF HF WITH DEPRESSED EJECTION FRACTION (<40%) **General Measures** Clinicians should aim to screen for and treat comorbidities such as hypertension, CAD, diabetes mellitus, anemia, and sleep-disordered breathing, as these conditions tend to exacerbate HF. HF patients should be advised to stop smoking and to limit alcohol consumption to two standard drinks per day in men or one per day in women. Patients suspected of having an alcohol-induced cardiomyopathy should be urged to abstain from alcohol consumption indefinitely. Extremes of temperature and heavy physical exertion should be avoided. Certain drugs are known to make HF worse and should also be avoided **(Table 227-3)**. For example, nonsteroidal anti-inflammatory drugs, including cyclooxygenase 2 inhibitors, are not recommended in patients with chronic HF because the risk of renal failure and fluid retention is markedly increased in the presence of reduced renal function or ACE inhibitor therapy. Patients should receive immunization with influenza and pneumococcal vaccines to prevent respiratory infections. It is equally important to educate the patient and family about HF, the importance of proper diet, as well the importance of compliance with the medical regimen. Supervision of outpatient care by a specially trained nurse or physician assistant and/or in specialized HF clinics have all been found to be helpful, particularly in patients with advanced disease.

Activity Although heavy physical labor is not recommended in HF, routine modest exercise has been shown to be beneficial in patients with NYHA class I–III HF. For euvolemic patients, regular isotonic exercise such as walking or riding a stationary-bicycle ergometer, as tolerated, should be encouraged. Some trials of exercise training have led to encouraging results with reduced symptoms, increased exercise capacity, and improved quality and duration of life. The benefits of weight loss by restriction of caloric intake have not been clearly established.

Diet Dietary restriction of sodium (2–3 g daily) is recommended in all patients with HF and preserved or depressed EF. Further restriction (<2 g daily) may be considered in moderate to severe HF. Fluid restriction is generally unnecessary unless the patient develops hyponatremia (<130 meq/L), which may develop because of activation of the renin-angiotensin system, excessive secretion of antidiuretic hormone, or loss of salt in excess of water from diuretic use. Fluid restriction (<2 L/day) should be considered in hyponatremic patients or for those whose fluid retention is difficult to control despite high doses of diuretics and sodium restriction. Caloric supplementation is recommended for patients with advanced HF and unintentional weight loss or muscle wasting (cardiac cachexia); however, anabolic steroids are not recommended for these patients because of the potential problems with volume retention. The use of dietary supplements ("nutriceuticals") should be avoided in the management of symptomatic HF because of the lack of proven benefit and the potential for significant (adverse) interactions with proven HF therapies.

Diuretics Many of the clinical manifestations of moderate to severe HF result from excessive salt and water retention that leads to volume expansion and congestive symptoms. Diuretics **(Table 227-4)** are the only pharmacologic agents that can adequately control fluid retention in advanced

TABLE 227-3 FACTORS THAT MAY PRECIPITATE ACUTE DECOMPENSATION IN PATIENTS WITH CHRONIC HEART FAILURE

- Dietary indiscretion
- Myocardial ischemia/infarction
- Arrhythmias (tachycardia or bradycardia)
- Discontinuation of HF therapy
- Infection
- Anemia
- Initiation of medications that worsen HF
  - Calcium antagonists (verapamil, diltiazem)
  - Beta blockers
  - Nonsteroidal anti-inflammatory drugs
  - Antiarrhythmic agents [all class I agents, sotalol (class III)]
  - Anti-TNF antibodies
- Alcohol consumption
- Pregnancy
- Worsening hypertension
- Acute valvular insufficiency

Note: HF, heart failure; TNF, tumor necrosis factor.

TABLE 227-4 DRUGS FOR THE TREATMENT OF CHRONIC HEART FAILURE (EF <40%)

	Initiating Dose	Maximal Dose
Diuretics		
Furosemide	20–40 mg qd or bid	400 mg/d[a]
Torsemide	10–20 mg qd bid	200 mg/d[a]
Bumetanide	0.5–1.0 mg qd or bid	10 mg/d[a]
Hydrochlorthiazide	25 mg qd	100 mg/d[a]
Metolazone	2.5–5.0 mg qd or bid	20 mg/d[a]
Angiotensin-Converting Enzyme Inhibitors		
Captopril	6.25 mg tid	50 mg tid
Enalapril	2.5 mg bid	10 mg bid
Lisinopril	2.5–5.0 mg qd	20–35 mg qd
Ramipril	1.25–2.5 mg bid	2.5–5 mg bid
Trandolapril	0.5 mg qd	4 mg qd
Angiotensin Receptor Blockers		
Valsartan	40 mg bid	160 mg bid
Candesartan	4 mg qd	32 mg qd
Irbesartan	75 mg qd	300 mg qd[b]
Losartan	12.5 mg qd	50 mg qd
β Receptor Blockers		
Carvedilol	3.125 mg bid	25–50 mg bid
Bisoprolol	1.25 mg qd	10 mg qd
Metoprolol succinate CR	12.5–25 mg qd	Target dose 200 mg qd
Additional Therapies		
Spironolactone	12.5–25 mg qd	25–50 mg qd
Eplerenone	25 mg qd	50 mg qd
Combination of hydralazine/isosorbide dinitrate	10–25 mg/10 mg tid	75 mg/40 mg tid
Fixed dose of hydralazine/isosorbide dinitrate	37.5 mg/20 mg (one tablet) tid	75 mg/40 mg (two tablets) tid
Digoxin	0.125 mg qd	≤0.375 mg/d[b]

[a]Dose must be titrated to reduce the patient's congestive symptoms.
[b]Target dose not established.

HF, and they should be used to restore and maintain normal volume status in patients with congestive symptoms (dyspnea, orthopnea, edema) or signs of elevated filling pressures (rales, jugular venous distention, or peripheral edema). Furosemide, torsemide, and bumetanide act at the loop of Henle (*loop diuretics*) by reversibly inhibiting the reabsorption of Na^+, K^+, and Cl^- in the thick ascending limb of Henle's loop; thiazides and metolazone reduce the reabsorption of Na^+ and Cl^- in the first half of the distal convoluted tubule; and potassium-sparing diuretics such as spironolactone act at the level of the collecting duct.

Although all diuretics increase sodium excretion and urinary volume, they differ in their potency and pharmacologic properties. Whereas loop diuretics increase the fractional excretion of sodium by 20–25%, thiazide diuretics increase it by only 5–10% and tend to lose their effectiveness in patients with moderate or severe renal insufficiency (creatinine >2.5 mg/dL). Hence, loop diuretics are generally required to restore normal volume status in patients with HF. Diuretics should be initiated in low doses (Table 227-4) and then carefully titrated upward to relieve signs and symptoms of fluid overload in an attempt to obtain the patient's "dry weight." This typically requires multiple dose adjustments over many days and occasionally weeks in patients with severe fluid overload. Intravenous administration of diuretics may be necessary to relieve congestion acutely and can be done safely in the outpatient setting. Once the congestion has been relieved, treatment with diuretics should be continued to prevent the recurrence of salt and water retention.

Refractoriness to diuretic therapy may represent patient noncompliance, a direct effect of chronic diuretic use on the kidney or progression of underlying HF. The addition of thiazides or metolazone, once or twice daily, to loop diuretics may be considered in patients with persistent fluid retention despite high-dose loop diuretic therapy. Metolazone is generally more potent and much longer-acting than the thiazides in this setting as well as in patients with chronic renal insufficiency. However, chronic daily use, especially of metolazone, should be avoided if possible because of the potential for electrolyte shifts and volume depletion. Ultrafiltration and dialysis may be used in cases of refractory fluid retention that are unresponsive to high doses of diuretics and have been shown to be helpful in the short term.

Adverse Effects Diuretics have the potential to produce electrolyte and volume depletion, as well as worsening azotemia. In addition, they may lead to worsening neurohormonal activation and disease progression. One of the most important adverse consequences of diuresis is alterations in potassium homeostasis (hypokalemia or hyperkalemia), which increases the risk of life-threatening arrhythmias. In general, both loop- and thiazide-type diuretics lead to hypokalemia, whereas spironolactone, eplerenone, and triamterene lead to hyperkalemia.

PREVENTING DISEASE PROGRESSION (TABLE 227-4) Drugs that interfere with the excessive activation of the RAA system and the adrenergic nervous system can relieve the symptoms of HF with a depressed EF by stabilizing and/or reversing cardiac remodeling. In this regard, ACE inhibitors and beta blockers have emerged as the cornerstones of modern therapy for HF with a depressed EF.

ACE Inhibitors There is overwhelming evidence that ACE inhibitors should be used in symptomatic and asymptomatic patients **(Figs. 227-3** and **227-4)** with a depressed EF (<40%). ACE inhibitors interfere with the renin-angiotensin system by inhibiting the enzyme that is responsible for the conversion of angiotensin I to angiotensin II. However, because ACE inhibitors also inhibit kininase II, they may lead to the upregulation of bradykinin, which may further enhance the beneficial effects of angiotensin suppression. ACE inhibitors stabilize LV remodeling, improve symptoms, reduce hospitalization, and prolong life. Because fluid retention can attenuate the effects of ACE inhibitors, it is preferable to optimize the dose of

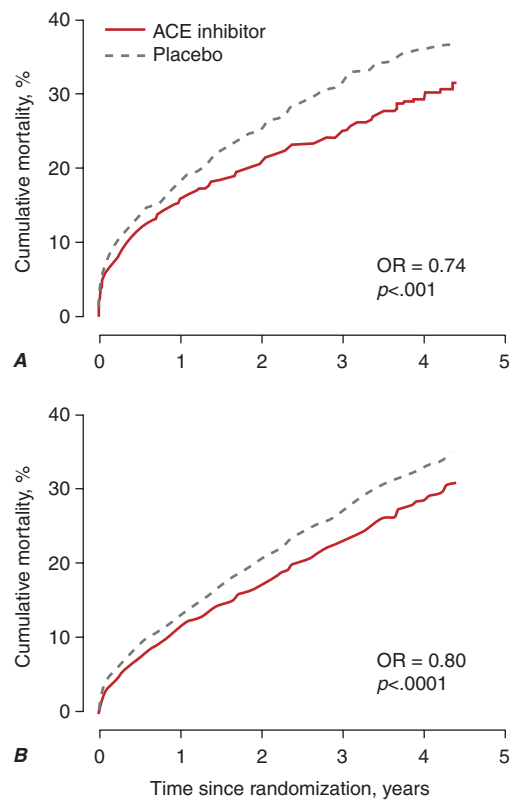

FIGURE 227-3 Meta-analysis of angiotensin-converting enzyme (ACE) inhibitors in heart failure patients with a depressed ejection fraction. *A.* The Kaplan-Meier curves for mortality for 5966 HF patients with a depressed EF treated with an ACE inhibitor following acute myocardial infarction (three trials). ***B.*** The Kaplan-Meier curves for mortality for 12,763 HF patients with a depressed EF treated with an ACE inhibitor in five clinical trials, including postinfarction trials. The benefits of ACE inhibitors were observed early and persisted long-term. *(Modified from Flather et al: Lancet 355:1575, 2000.)*

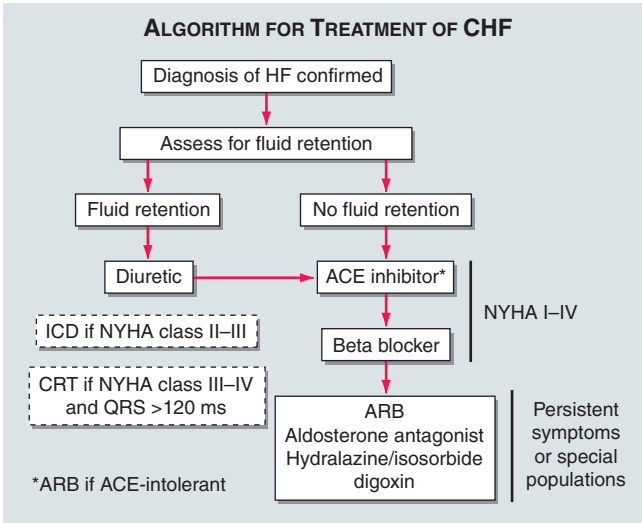

FIGURE 227-4 Treatment algorithm for chronic heart failure patients with a depressed ejection fraction. After the clinical diagnosis of HF is made, it is important to treat the patient's fluid retention before starting an ACE inhibitor (or an ARB if the patient is ACE-intolerant). Beta blockers should be started after the fluid retention has been treated and/or the ACE inhibitor has been uptitrated. If the patient remains symptomatic, an ARB, aldosterone antagonist, or digoxin can be added as "triple therapy." The fixed-dose combination of hydralazine/isosorbide dinitrate should be added to an ACE inhibitor and beta blocker in African-American patients with NYHA class II–IV HF. Device therapy should be considered in addition to pharmacological therapy in appropriate patients. HF, heart failure; ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; NYHA, New York Heart Association; CRT, cardiac resynchronization therapy; ICD, implantable cardiac defibrillator.

diuretic before starting the ACE inhibitor. However, it may be necessary to reduce the dose of diuretic during the initiation of ACE inhibition in order to prevent symptomatic hypotension. ACE inhibitors should be initiated in low doses, followed by gradual increments if the lower doses have been well tolerated. The doses of ACE inhibitors should be increased until they are similar to those that have been shown to be effective in clinical trials (Table 227-4). Higher doses are more effective than lower doses in preventing hospitalization.

Adverse Effects The majority of adverse effects are related to suppression of the renin-angiotensin system. The decreases in blood pressure and mild azotemia that may occur during the initiation of therapy are generally well tolerated and do not require a decrease in the dose of the ACE inhibitor. However, if hypotension is accompanied by dizziness or if the renal dysfunction becomes severe, it may be necessary to reduce the dose of the inhibitor. Potassium retention may also become problematic if the patient is receiving potassium supplements or a potassium-sparing diuretic. Potassium retention that is not responsive to these measures may require a reduction in the dose of ACE inhibitor.

The side effects of ACE inhibitors related to kinin potentiation include a nonproductive cough (10–15% of patients) and angioedema (1% of patients). In patients who cannot tolerate ACE inhibitors because of cough or angioedema, angiotensin receptor blockers (ARBs) are the recommended first line of therapy (see below). Patients intolerant of ACE inhibitors because of hyperkalemia or renal insufficiency are likely to experience the same side effects with ARBs. In these cases, the combination of hydralazine and an oral nitrate should be considered (Table 227-4).

Angiotensin Receptor Blockers These drugs are well tolerated in patients who are intolerant of ACE inhibitors because of cough, skin rash, and angioedema. ARBs should be used in symptomatic and asymptomatic patients with an EF <40% who are ACE-intolerant for reasons other than hyperkalemia or renal insufficiency (Table 227-4). Although ACE inhibitors and ARBs inhibit the renin-angiotensin system, they do so by different mechanisms. Whereas ACE inhibitors block the enzyme responsible for converting angiotensin I to angiotensin II, ARBs block the effects of angiotensin II on the angiotensin type 1 receptor. Some clinical trials have demonstrated a therapeutic benefit for the addition of ARB to an ACE inhibitor in patients with chronic HF. When given in concert with beta blockers, ARBs reverse the process of LV remodeling, improve patient symptoms, prevent hospitalization, and prolong life.

Adverse Effects Both ACE inhibitors and ARBs have similar effects on blood pressure, renal function, and potassium. Therefore the problems of symptomatic hypotension, azotemia, and hyperkalemia are similar for both of these agents.

β-Adrenergic Receptor Blockers Beta-blocker therapy represents a major advance in the treatment of patients with a depressed EF **(Fig. 227-5)**. These drugs interfere with the harmful effects of sustained activation of the adrenergic nervous system by competitively antagonizing one or more adrenergic receptors (α_1, β_1, and β_2). Although there are a number of potential benefits to blocking all three receptors, most of the deleterious effects of adrenergic activation are mediated by the β_1 receptor. When given in concert with ACE inhibitors, beta blockers reverse the process of LV remodeling, improve patient symptoms, prevent hospitalization, and prolong life. Therefore beta blockers are indicated for patients with symptomatic or asymptomatic HF and a depressed EF <40%.

Analogous to the use of ACE inhibitors, beta blockers should be initiated in low doses (Table 227-4), followed by gradual increments in the dose if lower doses have been well tolerated. The dose of beta blocker should be increased until the doses used are similar to those that have been reported to be effective in clinical trials (Table 227-4). However, unlike ACE inhibitors, which may be titrated upward relatively rapidly, the titration of beta blockers should proceed no more rapidly than at 2-week intervals, be-

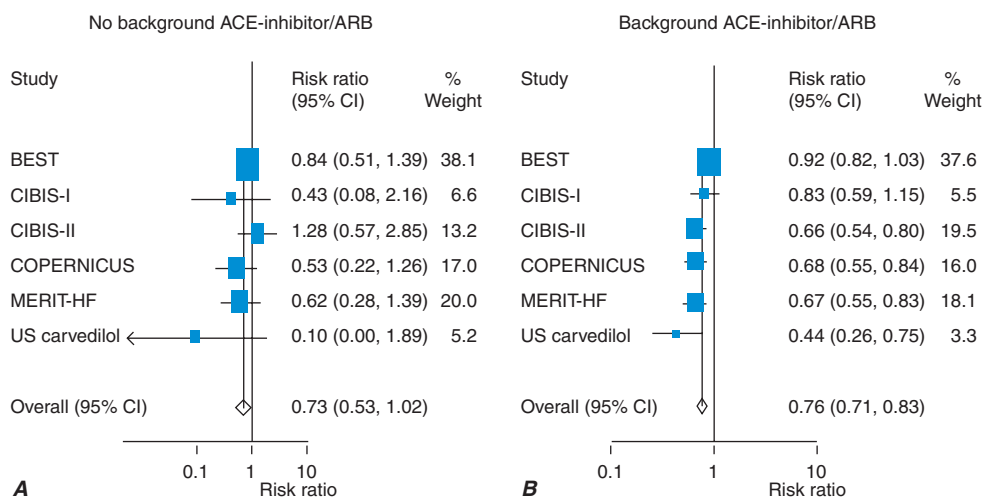

FIGURE 227-5 Meta-analysis of beta blockers on mortality in HF patients with a depressed EF. Effect of beta blockers vs. placebo in patients who were not (***A***) or who were (***B***) receiving an angiotensin-converting enzyme (ACE) inhibitor or an angiotensin receptor blocker (ARB) at baseline in six clinical trials. There was a similar impact of beta-blocker therapy on the endpoints of all-cause mortality as well as death and heart failure hospitalization in both the presence and absence of ACE inhibitor or ARB at baseline. BEST, Beta-blocker Evaluation of Survival Trial (bucindolol); CIBIS, Cardiac Insufficiency Blsoprolol Study (bisoprol); COPERNICUS, Carvedilol prOsPEctive RaNdomlzed Cumulative Survival (carvedilol); MERIT-HF, Metoprolol CR/XL Randomized Intervention Trial in Heart Failure (metoprolol CR/XL). *(Modified from Krum et al: Eur Heart J 26:2154, 2005.)*

cause the initiation and/or increased dosing of these agents may lead to worsening fluid retention consequent to the withdrawal of adrenergic support to the heart and the circulation. Thus, it is important to optimize the dose of diuretic before starting therapy with beta blockers. If worsening fluid retention does occur, it is likely to do so within 3–5 days of initiating therapy, and it will be manifest as an increase in body weight and/or symptoms of worsening HF. The increased fluid retention can usually be managed by increasing the dose of diuretics. In some patients the dose of the beta blocker may have to be reduced.

Contrary to early reports, the aggregate results of clinical trials suggest that beta-blocker therapy is well tolerated by the great majority (≥85%) of HF patients, including patients with comorbid conditions such as diabetes mellitus, chronic obstructive lung disease, and peripheral vascular disease. Nonetheless, there is a subset of patients (10–15%) who remain intolerant to beta blockers because of worsening fluid retention or symptomatic hypotension or bradycardia.

Adverse Effects The adverse effects of beta-blocker use are generally related to the predictable complications that arise from interfering with the adrenergic nervous system. These reactions generally occur within several days of initiating therapy and are generally responsive to adjusting concomitant medications, as described above. Therapy with beta blockers can lead to bradycardia and/or exacerbate heart block. Accordingly, the dose of beta blocker should be reduced if the heart rate decreases to <50 beats/min and/or second or third degree heart block or symptomatic hypotension develops. Beta blockers are not recommended for patients who have asthma with active bronchospasm. Beta blockers that also block the α_1 receptor can lead to vasodilatory side effects.

Aldosterone Antagonists Although classified as potassium-sparing diuretics, drugs that block the effects of aldosterone (spironolactone or eplerenone) have beneficial effects that are independent of the effects of these agents on sodium balance. Although ACE inhibition may transiently decrease aldosterone secretion, with chronic therapy there is a rapid return of aldosterone to levels similar to those before ACE inhibition. Accordingly, the administration of an aldosterone antagonist is recommended for patients with NYHA class IV or class III (previously class IV) HF who have a depressed EF (<35%) and who are receiving standard therapy, including diuretics, ACE inhibitors, and beta blockers. The dose of aldosterone antagonist should be increased until the doses used are similar to those that have been shown to be effective in clinical trials (Table 227-4).

Adverse Effects The major problem with the use of aldosterone antagonists is the development of life-threatening hyperkalemia, which is more prone to occur in patients who are receiving potassium supplements or who have underlying renal insufficiency. Aldosterone antagonists are not recommended when the serum creatinine is >2.5 mg/dL (or creatinine clearance is <30 mL/min) or when the serum potassium is >5.0 mmol/L. Painful gynecomastia may develop in 10–15% of patients who use spironolactone, in which case eplerenone may be substituted.

SPECIAL POPULATIONS The combination of hydralazine and isosorbide dinitrate (Table 227-4) is recommended as part of standard therapy in addition to beta blockers and ACE inhibitors for African Americans with NYHA class II–IV HF. Although the exact mechanism for the effects of this combination is not known, it is believed to be secondary to the beneficial effects of NO on the peripheral circulation. Recent studies suggest that the combination of hydralazine and isosorbide dinitrate may be more effective for patients who have variant genotypic markers (polymorphisms) for the genes that encode for endothelial nitric oxide synthase (NOS3) and aldosterone synthase.

MANAGEMENT OF PATIENTS WHO REMAIN SYMPTOMATIC As noted above, an ACE inhibitor (or an ARB) plus a beta blocker should be standard background therapy for HF patients with a depressed LV EF. Additional pharmacologic therapy should be considered in patients who have persistent symptoms or progressive worsening despite optimized therapy with an ACE inhibitor and beta blocker. Agents that may be considered as part of additional therapy include an ARB, spironolactone, the combination of hydralazine and isosorbide dinitrate, or digitalis. The optimal choice of additional drug therapy to further improve outcome has not been firmly established. Thus, the choice of specific agent will be influenced by clinical considerations, including renal function, serum potassium concentration, blood pressure, and race. The triple combination of an ACE inhibitor, an ARB, and an aldosterone antagonist should not be used because of the high risk of hyperkalemia.

Digoxin is recommended for patients with symptomatic LV systolic dysfunction who have concomitant atrial fibrillation, and it should be considered for patients who have signs or symptoms of HF while receiving standard therapy, including ACE inhibitors and beta blockers. Therapy with digoxin is commonly initiated and maintained at a dose of 0.125–0.25 mg daily. For the great majority of patients, the dose should be 0.125 mg daily, and the serum digoxin level should be <1.0 ng/mL, especially in elderly patients, patients with impaired renal function, and a low lean body mass. Higher doses (and serum concentrations) appear to be less beneficial. There is no indication for using loading doses of digoxin to initiate therapy in patients with HF.

ANTICOAGULATION AND ANTIPLATELET THERAPY Patients with HF have an increased risk for arterial or venous thromboembolic events. In clinical HF trials, the rate of stroke ranges from 1.3 to 2.4% per year. Depressed LV function is believed to promote relative stasis of blood in dilated cardiac chambers with increased risk of thrombus formation. Treatment with warfarin [goal international normalized ratio (INR) 2.0–3.0] is recommended for patients with HF and chronic or paroxysmal atrial fibrillation, or with a history of systemic or pulmonary emboli, including stroke or transient ischemic attack. Patients with symptomatic or asymptomatic ischemic cardiomyopathy and documented recent large anterior MI or recent MI with documented LV thrombus should be treated with warfarin (goal INR 2.0–3.0) for the initial 3 months after MI, unless there are contraindications to its use.

Aspirin is recommended in HF patients with ischemic heart disease for the prevention of MI and death. However, lower doses of aspirin (75 or 81 mg) may be preferable because of the concern of worsening of HF at higher doses.

MANAGEMENT OF CARDIAC ARRHYTHMIAS (See also Chap. 226) Atrial fibrillation occurs in 15–30% of patients with HF and is a frequent cause of cardiac decompensation. Most antiarrhythmic agents, with the exception of amiodarone and dofetilide, have negative inotropic effects and are proarrhythmic. Amiodarone is a class III antiarrhythmic that has little or no negative inotropic and/or proarrhythmic effects and is effective against most supraventricular arrhythmias. Amiodarone is the preferred drug for restoring and maintaining sinus rhythm, and it may improve the success of electrical cardioversion in patients with HF. Amiodarone increases the level of phenytoin and digoxin and prolongs the INR in patients taking warfarin. Therefore it is often necessary to reduce the dose of these drugs by as much as 50% when initiating therapy with amiodarone. The risk of adverse events, such as hyperthyroidism, hypothyroidism, pulmonary fibrosis, and hepatitis, are relatively low, particularly when lower doses of amiodarone are used (100–200 mg/d).

Implantable cardiac defibrillators (ICDs; see below) are highly effective in treating recurrences of sustained ventricular tachycardia and/or ventricular fibrillation in HF patients with recurrent arrhythmias and/or cardiac syncope, and they may be used as stand-alone therapy or in combination with amiodarone and/or a beta blocker (Chap. 226). There is no role for treating ventricular arrhythmias with an antiarrhythmic agent without an ICD.

DEVICE THERAPY **Cardiac Resynchronization** Approximately one-third of patients with a depressed EF and symptomatic HF (NYHA class III–IV) manifest a QRS duration >120 ms. This ECG finding of abnormal inter- or intraventricular conduction has been used to identify patients with dyssynchronous ventricular contraction. The mechanical consequences of ventricular dyssynchrony include suboptimal ventricular filling, a reduction in LV contractility, prolonged duration (and therefore greater severity) of mitral regurgitation, and paradoxical septal wall motion. *Biventricular pacing*, also termed *cardiac resynchronization therapy* (CRT), stimulates both ventricles near-simultaneously, thereby improving the coordination of ventricular contraction and reducing the severity of mitral regurgitation. When CRT is added to optimal medical therapy in patients in sinus rhythm, there is a significant decrease in patient mortality and hospitalization, a reversal of LV remodeling, as well as improved quality of life and exercise capacity. Accordingly, CRT is recommended for patients in sinus rhythm with an EF <35% and a QRS >120 ms and those who remain symptomatic (NYHA III–IV) despite optimal medical therapy. The benefits of CRT in patients with atrial fibrillation have not been established.

Implantable Cardiac Defibrillators (See also Chap. 226) The prophylactic implantation of ICDs in patients with mild to moderate HF (NYHA class II–III) has been shown to reduce the incidence of sudden cardiac death in patients with ischemic or nonischemic cardiomyopathy. Accordingly, implantation of an ICD should be considered for patients in NYHA class II–III HF with a depressed EF of <30–35% who are already on optimal background therapy, including an ACE inhibitor (or ARB), a beta blocker, and an aldosterone antagonist. An ICD may be combined with a biventricular pacemaker in appropriate patients.

MANAGEMENT OF HF WITH A PRESERVED EJECTION FRACTION (>40–50%) Despite the wealth of information with respect to the evaluation and management of HF with a depressed EF, there are no proven and/or approved pharmacologic or device therapies for the management of patients with HF and a preserved EF. Therefore, it is recommended that initial treatment efforts should be focused, wherever possible, on the underlying disease process (e.g., myocardial ischemia, hypertension) associated with HF with preserved EF. Precipitating factors, such as tachycardia or atrial fibrillation, should be treated as quickly as possible through rate control and restoration of sinus rhythm when appropriate. Dyspnea may be treated by reducing total blood volume (dietary sodium restriction and diuretics), decreasing central blood volume (nitrates), or blunting neurohormal activation with ACE inhibitors, ARBs, and/or beta blockers. Treatment with diuretics and nitrates should be initiated at low doses to avoid hypotension and fatigue.

ACUTE HF Defining an Appropriate Therapeutic Strategy The therapeutic goals for the management of acute HF therapy are to (1) stabilize the hemodynamic derangements that provoked the symptoms responsible for the hospitalization, (2) identify and treat the reversible factors that precipitated decompensation, and (3) reestablish an effective outpatient medical regimen that will prevent disease progression and relapse. In most instances this will require hospitalization, often in an intensive care unit (ICU) setting. Every effort should be made to identify the precipitating causes, such as infection, arrhythmias, dietary indiscretion, pulmonary embolism, infective endocarditis, occult myocardial ischemia/infarction, environmental and/or emotional or environmental stress (Table 227-3), since removal of these precipitating events is critical to the success of treatment.

The two primary hemodynamic determinants of acute HF are elevated LV filling pressures and a depressed cardiac output. Frequently the depressed cardiac output is accompanied by an increase in systemic vascular resistance (SVR) as a result of excessive neurohormonal activation. Because these hemodynamic derangements may occur singly or together, patients with acute HF generally present with one of four basic hemodynamic profiles **(Fig. 227-6)**: normal LV filling pressure with normal perfusion (Profile A), elevated LV filling pressure with normal perfusion (Profile B), elevated LV filling pressures with decreased perfusion (Profile C), and normal or low LV filling pressure with decreased tissue perfusion (Profile L).

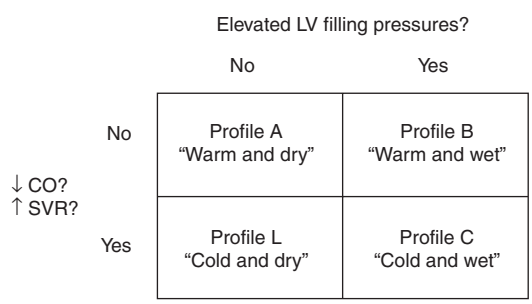

FIGURE 227-6 Hemodynamic profiles in patients with acute heart failure. Most patients can be categorized into one of the four hemodynamic profiles by performing a brief bedside examination that includes examination of the neck veins, lungs, and peripheral extremities. More definitive hemodynamic information may be obtained by performing invasive hemodynamic monitoring, particularly if the patient is gravely ill or if the clinical presentation is unclear. This hemodynamic classification provides a useful guide for selecting the initial optimal therapies for the management of acute HF. LV, left ventricular; CO, cardiac output; SVR, systemic vascular resistance. *(Modified from Grady et al: Circulation102:2443, 2000.)*

Accordingly, the therapeutic approach to treating patients with acute HF should be tailored to reflect the patient's hemodynamic presentation. The goal should be, whenever possible, to restore the patient to a normal hemodynamic profile (Profile A). In many instances the patient's hemodynamic presentation can be approximated from the clinical examination. For example, patients with elevated LV filling pressures may have signs of fluid retention (rales, elevated neck veins, peripheral edema) and are referred to as being "wet," whereas patients with a depressed cardiac output and an elevated SVR generally have poor tissue perfusion manifested by cool distal extremities and are referred to as being "cold." Nonetheless, it should be emphasized that patients with chronic heart failure may not have rales or evidence of peripheral edema at the time of the initial presentation with acute decompensation, which may lead to the underrecognition of elevated filling pressures. In these patients, it may be appropriate to perform invasive hemodynamic monitoring.

Patients who are not congested and have normal tissue perfusion are referred to as being "dry" and "warm," respectively. When acute HF patients present to the hospital with profile A, their symptoms are often due to conditions other than HF (e.g., pulmonary or hepatic disease, or transient myocardial ischemia). More commonly, however, acute HF patients present with congestive symptoms ["warm and wet" (profile B)], in which case treatment of the elevated filling pressures with diuretics and vasodilators is warranted to reduce LV filling pressures. Profile B includes most patients with acute pulmonary edema. **The treatment of this life-threatening condition is described in Chap. 266.**

Patients may also present with congestion and a significant elevated SVR and reduction of cardiac output ["cold and wet" (Profile C)]. In these patients, cardiac output can be increased and LV filling pressures reduced using intravenous vasodilators. Intravenous inotropic agents with vasodilating action [dobutamine, low-dose dopamine, milrinone **(Table 227-5)**] augment cardiac output by stimulating myocardial contractility as well as by functionally unloading the heart.

Patients who present with profile L ("cold and dry") should be carefully evaluated by right-heart catheterization for the presence of an occult elevation of LV filling pressures. If LV filling pressures are low [pulmonary capillary wedge pressure (PCWP) <12 mmHg] a cautious trial of fluid repletion may be considered. The goals of further therapy depend on the clinical situation. Therapy to reach the aforementioned goals may not be possible in some patients, particularly if they have disproportionate RV dysfunction or if they develop cardiorenal syndrome, in which renal function deteriorates during aggressive diuresis. Worsening renal dysfunction occurs in approximately 25% of patients hospitalized with HF and is associated with prolonged hospital stays and higher mortality after discharge.

Pharmacologic Management of Acute HF (Table 227-5)

Vasodilators After diuretics, intravenous vasodilators are the most useful medications for the management of acute HF. By stimulating guanylyl

TABLE 227-5 DRUGS FOR THE TREATMENT FOR ACUTE HEART FAILURE

	Initiating Dose	Maximal Dose
Vasodilators		
Nitroglycerin	20 μg/min	40–400 μg/min
Nitroprusside	10 μg/min	30–350 μg/min
Nesiritide	Bolus 2 μg/kg	0.01–0.03 μg/kg per min[a]
Inotropes		
Dobutamine	1–2 μg/kg per min	2–10 μg/kg per min[b]
Milrinone	Bolus 50 μg/kg	0.1–0.75 μg/kg per min[b]
Dopamine	1–2 μg/kg per min	2–4 μg/kg per min[b]
Levosimendan	Bolus 12 μg/kg	0.1–0.2 μg/kg per min[c]
Vasoconstrictors		
Dopamine for hypotension	5 μg/kg per min	5–15 μg/kg per min
Epinephrine	0.5 μg/kg per min	50 μg/kg per min
Phenylephrine	0.3 μg/kg per min	3 μg/kg per min
Vasopression	0.05 units/min	0.1–0.4 units/min

[a]Usually <4 μg/kg/min.
[b]Inotropes will also have vasodilatory properties.
[c]Approved outside of the United States for the management of acute heart failure.

cyclase within smooth-muscle cells, nitroglycerin, nitroprusside, and nesiritide exert dilating effects on arterial resistance and venous capacitance vessels, which results in a lowering of LV filling pressure, a reduction in mitral regurgitation, and improved forward cardiac output, without increasing heart rate or causing arrhythmias.

Intravenous *nitroglycerin* is generally begun at 20 μg/min and is increased in 20 μg increments until patient symptoms are improved or PCWP is decreased to 16 mmHg without reducing systolic blood pressure below 80 mmHg. The most common side effect of intravenous or oral nitrates is headache, which, if mild, can be treated with analgesics and often resolves during continued therapy.

Nitroprusside is generally initiated at 10 μg/min and increased by 10–20 μg every 10–20 min as tolerated, with the same hemodynamic goals as described above. The rapidity of onset and offset, with a half-life of approximately 2 min, facilitates early establishment of an individual patient's optimal level of vasodilation in the ICU. The major limitation of nitroprusside is side effects from cyanide, which manifests predominantly as gastrointestinal and central nervous system manifestations. Cyanide is most likely to accumulate in patients with severely reduced hepatic perfusion and decreased hepatic function from low cardiac output, and it is more likely to develop in patients receiving >250 μg/min for over 48 h. Suspected cyanide toxicity is treated by decreasing or discontinuing the nitroprusside infusion. Long-term (>48 h) use of both nitroprusside and nitroglycerin is associated with hemodynamic tolerance.

Nesiritide, the newest vasodilator, is a recombinant form of brain-type natriuretic peptide (BNP), which is an endogenous peptide secreted primarily from the LV in response to an increase in wall stress. Nesiritide is given as a bolus (2 μg/kg) followed by a fixed-dose infusion (0.01–0.03 μg/kg per min). Nesiritide effectively lowers LV filling pressures and improves symptoms during the treatment of acute HF. Headache is less common with nesiritide than with nitroglycerin. Although termed a *natriuretic peptide*, nesiritide has not been associated with major diuresis when used alone in clinical trials. It does, however, appear to potentiate the effect of concomitant diuretics such that the total required diuretic dose may be slightly lower.

Hypotension is the most common side effect of all three vasodilating agents, although less so with nesiritide. Hypotension is frequently associated with bradycardia, particularly when nitroglycerin is used. All three drugs can cause pulmonary artery vasodilation, which can lead to worsening hypoxia in patients with underlying ventilation-perfusion abnormalities.

Inotropic Agents Positive inotropic agents produce direct hemodynamic benefits by stimulating cardiac contractility, as well as by producing peripheral vasodilation. Collectively, these hemodynamic effects result in an improvement in cardiac output and a fall in LV filling pressures.

Dobutamine, which is the most commonly used inotropic agent for the treatment of acute HF, exerts its effects by stimulating β_1 and β_2 receptors, with little effect on α_1 receptors. Dobutamine is given as a continuous infusion, at an initial infusion rate of 1–2 μg/kg per min. Higher doses (>5 μg/kg per min) are frequently necessary for severe hypoperfusion; however, there is little added benefit to increasing the dose above 10 μg/kg per min. Patients maintained on chronic infusions for >72 h generally develop tachyphylaxis and require increasing doses.

Milrinone is a phosphodiesterase III inhibitor that leads to increased cAMP by inhibiting its breakdown. Milrinone may act synergistically with β-adrenergic agonists to achieve further increase in cardiac output than either agent alone, and it may also be more effective than dobutamine in increasing cardiac output in the presence of beta blockers. Milrinone may be administered as a bolus dose of 0.5 μg/kg per min, followed by a continuous infusion rate of 0.1–0.75 μg/kg per min. Because milrinone is a more effective vasodilator than dobutamine, it produces a greater reduction in LV filling pressures, albeit with a greater risk of hypotension.

Although short-term use of inotropes provides hemodynamic benefits, these agents are more prone to cause tachyarrhythmias and ischemic events than vasodilators. Therefore inotropes are most appropriately used in clinical settings in which vasodilators and diuretics are not helpful, such as in patients with poor systemic perfusion and/or cardiogenic shock, in patients requiring short-term hemodynamic support after a MI or surgery, and in patients awaiting cardiac transplantation, or as palliative care in patients with advanced HF. If patients require sustained use of intravenous inotropes, strong consideration should be given to the use of an ICD to safeguard against the proarrhythmic effects of these agents.

Vasoconstrictors Vasoconstrictors are used to support systemic blood pressure in patients with HF. Of the three agents that are commonly used (Table 227-5), dopamine is generally the first choice for therapy in situations where modest inotropy and pressor support are required. Dopamine is an endogenous catecholamine that stimulates β_1, α_1 receptors, and dopaminergic receptors (DA_1 and DA_2) in the heart and circulation. The effects of dopamine are dose-dependent. Low doses of dopamine (<2 μg/kg per min) stimulate the DA_1 and DA_2 receptors and cause vasodilation of the splanchnic and renal vasculature. Moderate doses (2–4 μg/kg per min) stimulate the β_1 receptors and cause an increase in cardiac output with little or no change in heart rate or SVR. At higher doses (≥5 μg/kg per min) the effects of dopamine on the α_1 receptors overwhelm the dopaminergic receptors, and vasoconstriction ensues, leading to an increase in SVR, LV filling pressures, and heart rate.

Dopamine also causes release of norepinephrine from nerve terminals, which itself stimulates α_1 and β_1 receptors, thus raising blood pressure. Dopamine is most useful in the treatment of HF patients who have depressed cardiac output with poor tissue perfusion (Profile C). Significant additional inotropic and blood pressure support can be provided by epinephrine, phenylephrine, and vasopressin (Table 227-5); however, prolonged use of these agents can lead to renal and hepatic failure and can cause gangrene of the limbs. Therefore, these agents should not be administered except in true emergency situations.

Mechanical and Surgical Interventions If pharmacologic interventions fail to stabilize the patient with refractory HF, mechanical and surgical interventions may provide effective circulatory support. These include intraaortic balloon counter pulsation, LV assist device, and cardiac transplantation (Chap. 228).

Planning for Hospital Discharge Patient education should take place during the entire hospitalization, with a specific focus on salt and fluid status and obtaining daily weights, in addition to medication schedules. Whereas the majority of patients hospitalized with HF can be stabilized and returned to a good level of function on an oral regimen designed to maintain stability, 30–50% of patients discharged with a diagnosis of HF are rehospitalized within 3–6 months. Although there are multiple reasons for rehospitalization, failure to meet criteria for discharge is perhaps the most frequent. Criteria for discharge should include at least 24 h of stable fluid status, blood pressure, and renal function on the oral regimen planned for home. Patients should be free of dyspnea or symptomatic hypotension while at rest, washing, and walking on the ward.

COR PULMONALE

DEFINITION

Cor pulmonale, often referred to as *pulmonary heart disease*, is defined as dilation and hypertrophy of the right ventricle (RV) in response to diseases of the pulmonary vasculature and/or lung parenchyma. Historically, this definition has excluded congenital heart disease and those diseases in which the right heart fails secondary to dysfunction of the left side of the heart.

ETIOLOGY AND EPIDEMIOLOGY

Cor pulmonale develops in response to acute or chronic changes in the pulmonary vasculature and/or the lung parenchyma that are sufficient to cause pulmonary hypertension. The true prevalence of cor pulmonale is difficult to ascertain for two reasons. First, not all cases of chronic lung disease will develop cor pulmonale, and second, our ability to diagnose pulmonary hypertension and cor pulmonale by routine physical examination and laboratory testing is relatively insensitive. However, recent advances in 2-D echo/Doppler imaging and biomakers (BNP) make it easier to screen for and detect cor pulmonale.

Once patients with chronic pulmonary or pulmonary vascular disease develop cor pulmonale, their prognosis worsens. Although chronic obstructive pulmonary disease (COPD) and chronic bronchitis are responsible for approximately 50% percent of the cases of cor pulmonale in North America (Chap. 254), any disease that affects the pulmonary vasculature (Chap. 244) or parenchyma can lead to cor pulmonale. Table 227-6 provides a list of common diseases that may lead to cor pulmonale. In contrast to COPD, the elevation in pulmonary artery

TABLE 227-6 ETIOLOGY OF CHRONIC COR PULMONALE

Diseases Leading to Hypoxic Vasoconstriction

Idiopathic pulmonary fibrosis

pressure appears to be substantially higher in the interstitial lung diseases (Chap. 255), in which there is an inverse correlation between pulmonary artery pressure and the diffusion capacity for carbon monoxide, as well as patient survival. Sleep-disordered breathing, once thought to be a major mechanism for cor pulmonale, is rarely the sole cause of pulmonary hypertension and RV failure. The combination of COPD and associated daytime hypoxemia is required to cause sustained pulmonary hypertension in obstructive sleep apnea (Chap. 259).

PATHOPHYSIOLOGY AND BASIC MECHANISMS

Although many conditions can lead to cor pulmonale, the common pathophysiologic mechanism in each case is pulmonary hypertension that is sufficient to lead to RV dilation, with or without the development of concomitant RV hypertrophy. The systemic consequences of cor pulmonale relate to alterations in cardiac output as well as salt and water homeostasis. Anatomically, the RV is a thin-walled, compliant chamber that is better suited to handle volume overload than pressure overload. Thus, the sustained pressure overload imposed by pulmonary hypertension and increased pulmonary vascular resistance eventually causes the RV to fail.

The response of the RV to pulmonary hypertension depends on the acuteness and severity of the pressure overload. Acute cor pulmonale occurs after a sudden and severe stimulus (e.g., massive pulmonary embolus), with RV dilatation and failure but no RV hypertrophy (Chap. 256). Chronic cor pulmonale, however, is associated with a more slowly evolving and slowly progressive pulmonary hypertension that leads to RV dilation and hypertrophy. The severity of the pulmonary artery hypertension and the onset of RV failure are influenced by multiple factors that occur intermittently, including hypoxia secondary to alterations in gas exchange, hypercapnia, and acidosis, as well as alterations in RV volume overload that are affected by exercise, heart rate, polycythemia, or increased salt and retention because of a fall in cardiac output (Fig. 227-2). **The most common mechanisms that lead to pulmonary hypertension, including vasoconstriction, activation of the clotting cascade, and obliteration of pulmonary arterial vessels, are discussed in Chap. 244.**

CLINICAL MANIFESTATIONS

Symptoms The symptoms of chronic cor pulmonale are generally related to the underlying pulmonary disorder. Dyspnea, the most common symptom, is usually the result of the increased work of breathing secondary to changes in elastic recoil of the lung (fibrosing lung diseases) or altered respiratory mechanics (e.g., overinflation with COPD), both of which may be aggravated by increased hypoxic respiratory drive. The hypoxia that occurs in lung disease is the result of reduced capillary membrane permeability, ventilation-perfusion mismatch, and occasionally intracardiac or intrapulmonary shunting.

Orthopnea and paroxysmal nocturnal dyspnea are rarely symptoms of isolated right HF. However, when present, these symptoms usually reflect the increased work of breathing in the supine position that results from compromised excursion of the diaphragm. Tussive or effort-related syncope may occur in patients with cor pulmonale with severe pulmonary hypertension because of the inability of the RV to deliver blood adequately to the left side of the heart. The abdominal pain and ascites that occur with cor pulmonale are similar to the right heart failure that ensues in chronic HF. Lower-extremity edema may occur secondary to neurohormonal activation, elevated RV filling pressures, or increased levels of carbon dioxide and hypoxia, which can lead to peripheral vasodilation and edema formation. **The symptoms of acute cor pulmonale with pulmonary embolus are reviewed in Chap. 256.**

Signs Many of the signs that are encountered in cor pulmonale are also present in HF patients with a depressed EF, including tachypnea, elevated jugular venous pressures, hepatomegaly, and lower-extremity edema. Patients may have prominent *v* waves in the jugular venous pulse as a result of tricuspid regurgitation. Other cardiovascular signs include an RV heave palpable along the left sternal border or in the epigastrium. A systolic pulmonary ejection click may be audible to the left of the upper sternum. The increase in intensity of the holosystolic murmur of tricuspid regurgitation with inspiration ("Carvallo's sign") may be eventually lost as RV failure worsens. Cyanosis is a late finding in cor pulmonale and is secondary to a low cardiac output with systemic vasoconstriction and ventilation-perfusion mismatches in the lung.

DIAGNOSIS

The most common cause of right heart failure is not pulmonary parenchymal or vascular disease, but left heart failure. Therefore it is important to evaluate the patient for LV systolic and diastolic dysfunction. The ECG in severe pulmonary hypertension shows P pulmonale, right axis deviation, and RV hypertrophy. Radiographic examination of the chest may show enlargement of the main pulmonary artery, hilar vessels, and the descending right pulmonary artery. Spiral CT scans of the chest are useful in diagnosing acute thromboembolic disease; however, the ventilation-perfusion lung scan remains reliable in most centers for establishing the diagnosis of *chronic thromboembolic disease* (Chap. 256). A high-resolution CT scan of the chest is the most accurate means of diagnosing emphysema and interstitial lung disease.

Two-dimensional echocardiography is useful for measuring RV thickness and chamber dimensions as well as the anatomy of the pulmonary and tricuspid valves. The interventricular septum may move paradoxically during systole in the presence of pulmonary hypertension. As noted, Doppler echocardiography can be used to assess pulmonary artery pressures. MRI is also useful for assessing RV structure and function, particularly in patients who are difficult to image with 2-D echocardiography because of severe lung disease. Right-heart catheterization is useful for confirming the diagnosis of pulmonary hypertension and for excluding elevated left-heart pressures (measured as the PCWP) as a cause for right heart failure. BNP and N-terminal BNP levels are elevated in patients with cor pulmonale secondary to RV stretch and may be dramatically elevated in acute pulmonary embolism.

Rx COR PULMONALE

The primary treatment goal of cor pulmonale is to target the underlying pulmonary disease, since this will lead to a decrease in pulmonary vascular resistance and relieve the pressure overload on the RV. Most pulmonary diseases that lead to chronic cor pulmonale are far advanced and are, therefore, less amenable to treatment. General principles of treatment include decreasing

the work of breathing using noninvasive mechanical ventilation, bronchodilation, and steroids, as well as treating any underlying infection (Chaps. 254, 255). Adequate oxygenation (oxygen saturation ≥90–92%) will also decrease pulmonary vascular resistance and reduce the demands on the RV. Patients should be transfused if they are anemic, and a phlebotomy should be performed to reduce pulmonary artery pressure if the hematocrit exceeds 65%.

Diuretics are effective in the treatment of RV failure, and the indications for their use are similar to those for chronic HF. One caveat of chronic diuretic use is that they may lead to contraction alkalosis and worsening hypercapnea. Digoxin is of uncertain benefit in the treatment of cor pulmonale and may lead to arrhythmias in the setting of tissue hypoxia and acidosis. Therefore, if digoxin is administered, it should be given at low doses and monitored carefully. **The treatment of the acute cor pulmonale that occurs with pulmonary embolus is described in Chap. 256. The treatment of pulmonary hypertension is discussed in Chap. 244.**

228 Cardiac Transplantation and Prolonged Assisted Circulation

Sharon A. Hunt

Advanced or end-stage heart failure is an increasingly frequent sequela as progressively more effective palliation for the earlier stages of heart disease and prevention of sudden death associated with heart disease become more widely recognized and employed (Chap. 227). When patients with end-stage or refractory heart failure are identified, the physician is faced with the decision of advising compassionate end-of-life care or choosing to recommend extraordinary life-extending measures. For the occasional patient who is relatively young and without serious comorbidities, the latter may represent a reasonable option. Current therapeutic options are limited to cardiac transplantation (with the option of mechanical cardiac assistance as a "bridge" to transplantation) or (at least in theory) the option of permanent mechanical assistance of the circulation.

CARDIAC TRANSPLANTATION

Surgical techniques for orthotopic transplantation of the heart were devised in the 1960s and taken into the clinical arena in 1967. The procedure did not gain widespread clinical acceptance until the introduction of "modern" and more effective immunosuppression in the early 1980s. By the 1990s the demand for transplantable hearts met, and then exceeded, the available donor supply and leveled off at about 4000 heart transplants annually worldwide, according to data from the Registry of the International Society for Heart and Lung Transplantation (ISHLT). Subsequently heart transplant activity in the United States has remained stable at ~2200/year, but worldwide activity reported to this Registry has decreased some. This apparent decline in numbers may be a result of the fact that reporting is legally mandated in the United States, but not elsewhere, and several countries have started their own databases.

SURGICAL TECHNIQUE

Donor and recipient hearts are excised in virtually identical operations with incisions made across the atria and atrial septum at the midatrial level (leaving the posterior walls of the atria in place) and across the great vessels just above the semilunar valves. The donor heart is generally "harvested" in an anatomically identical manner by a separate surgical team and transported from the donor hospital in a bag of iced saline solution and then is reanastomosed into the waiting recipient in the orthotopic or normal anatomic position. The only change in surgical technique since this method was first described has been a movement in recent years to move the right atrial anastamosis back to the level of the superior and inferior vena cavae in order to better preserve right atrial geometry and prevent atrial arrhythmias. Both methods of implantation leave the recipient with a surgically denervated heart that does not respond to any direct sympathetic or parasympathetic stimuli but does respond to circulating catecholamines. The physiologic responses of the denervated heart to the demands of exercise are atypical but quite adequate to carry on normal physical activity.

DONOR ALLOCATION SYSTEM

In the United States the allocation of donor organs is accomplished under the supervision of the United Network for Organ Sharing (UNOS), a private organization under contract to the federal government. The United States is divided geographically into eleven regions for donor heart allocation. Allocation of donor hearts within a region is decided according to a system of priority that takes into account (1) the severity of illness, (2) geographic distance from the donor, and (3) patient time on the waiting list. A physiologic limit of ~3 h of "ischemic" (out of body) time for hearts precludes a national sharing of hearts. This allocation system design is reissued annually and is responsive to input from a variety of constituencies, including donor families and transplant professionals.

At the current time, highest priority according to severity of illness is assigned to patients requiring hospitalization at the transplant center for IV inotropic support with a pulmonary artery catheter in place for hemodynamic monitoring or to patients requiring mechanical circulatory support [i.e., intra-aortic balloon pump (IABP), right or left ventricular assist device (RVAD, LVAD), extracorporeal membrane oxygenation (ECMO), or mechanical ventilation]. Second highest priority is given to patients requiring ongoing inotropic support, but without a pulmonary artery catheter in place. All other patients have priority according to their time on the waiting list, and matching is achieved only according to ABO blood group compatibility and gross body size compatibility, although some patients who are "pre-sensitized" and have preexisting anti-HLA antibodies (commonly multiparous women or patients previously multiply transfused) undergo prospective crossmatching with the donor.

INDICATIONS/CONTRAINDICATIONS

Heart failure is an increasingly common cause of death, particularly in the elderly. Most patients who reach what has recently been categorized

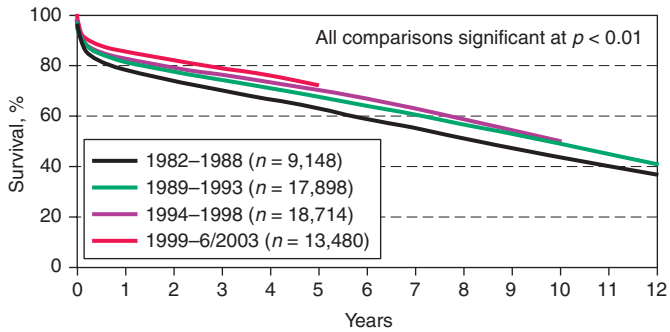

FIGURE 228-1 Adult heart transplantation. Kaplan-Meier. Actuarial survival for heart transplants performed between 1982 and 2003 by era of transplantation. (*J Heart Lung Transplant 24:945, 2005. Data by permission from International Society for Heart and Lung Transplantation.*)

as stage D, or refractory end-stage heart failure, are appropriately treated with compassionate end-of-life care. A subset of such patients who are younger and without significant comorbidities can be considered as candidates for heart transplantation. Exact criteria vary in different centers but generally take into consideration the patient's physiologic age and the existence of comorbidities such as peripheral or cerebrovascular disease, obesity, diabetes, cancer, or chronic infection.

RESULTS

A registry organized by the ISHLT has tracked worldwide and U.S. survival rates after heart transplantation since 1982. The most recent update reveals 83% and 76% survival 1 and 3 years posttransplant, or a posttransplant "half-life" of 9.3 years (Fig. 228-1). The quality of life in these patients is generally excellent, with well over 90% of patients in the registry returning to normal and unrestricted function following transplantation.

IMMUNOSUPPRESSION

Medical regimens employed to provide suppression of the normal immune response to a solid organ allograft vary from center to center and are in a constant state of evolution as more effective agents with improved side-effect profiles and less toxicity are introduced. All currently used regimens are nonspecific, providing general hyporeactivity to foreign antigens rather than donor-specific hyporeactivity as well as the attendant, and unwanted, susceptibility to infections and malignancy. Most cardiac transplant programs currently use a three-drug regimen including a calcineurin inhibitor (cyclosporine or tacrolimus), an inhibitor of T cell proliferation or differentiation (azathioprine, mycophenolate mofetil, or sirolimus), and at least a short initial course of glucocorticoids. Many programs also include an initial "induction" course of polyclonal or monoclonal anti-T cell antibodies in the perioperative period to decrease the frequency or severity of early posttransplant rejection. Most recently introduced have been monoclonal antibodies (daclizumab and basiliximab), which block the interleukin 2 receptor and may provide prevention of allograft rejection without additional global immunosuppression.

Diagnosis of cardiac allograft rejection is usually made with the use of endomyocardial biopsy, either done on a surveillance basis or in response to clinical deterioration. Biopsy surveillance is performed on a regular basis in most programs for the first year postoperatively and for the first 5 years in many programs. Therapy consists of augmentation of immunosuppression, the intensity and duration of which is dictated by the severity of the rejection.

LATE POSTTRANSPLANT MANAGEMENT ISSUES

Increasing numbers of heart transplant patients are surviving for years following transplantation and constitute a population of patients with a number of long-term management issues.

Allograft Coronary Artery Disease Despite usually having young donor hearts, cardiac allograft recipients are prone to develop coronary artery disease (CAD). This CAD is generally a diffuse, concentric, and longitudinal process that is quite different from "ordinary" atherosclerotic CAD, which is more focal and often eccentric. The underlying etiology is most likely primarily immunologic injury of the vascular endothelium, but a variety of risk factors influence its existence and progression and include nonimmunologic factors such as dyslipidemia, diabetes, and cytomegalovirus (CMV) infection. It is hoped that newer and improved immunosuppressive modalities will reduce the incidence and impact of these devastating complications, which currently account for the majority of late posttransplant deaths. Thus far the newer immunosuppressive agents mycophenolate mofetil and the mammalian target of rapamycin (mTOR) inhibitors sirolimus and everolimus have been shown to be associated with short-term lesser incidence and extent of coronary intimal thickening; in anecdotal reports institution of sirolimus was associated with some reversal of the disease. The use of statins has also been shown to be associated with a reduced incidence of this vasculopathy, and these drugs are now almost universally used in transplant recipients unless contraindicated. Palliation of the disease with percutaneous interventions is probably safe and effective in the short term, although the disease often advances relentlessly. Because of the denervated status of the organ, patients rarely experience angina pectoris, even with advanced stages of the disease.

Retransplantation is the only definitive form of therapy for advanced allograft CAD, but the scarcity of donor hearts make the decision to pursue retransplantation a difficult one in an individual patient, as well as a difficult ethical issue.

Malignancy The occurrence of an increased incidence of malignancy is a well-recognized sequela of any program of chronic immunosuppression, and organ transplantation is no exception. Lymphoproliferative disorders are among the most frequent posttransplant complications and, in most cases, seem to be driven by the Epstein-Barr virus. Effective therapy includes reduction of immunosuppression (a clear "double-edged sword" in the setting of a life-sustaining organ), antiviral agents, and traditional chemo- and radiotherapy. Most recently, specific antilymphocyte (CD20) therapy has shown great promise. Cutaneous malignancies (both basal cell and squamous cell carcinomas) also occur with increased frequency in transplant recipients and can pursue very aggressive courses. The role of decreasing immunosuppression for treatment of these cancers is much less clear.

Infections The use of currently available nonspecific immunosuppressive modalities to prevent allograft rejection naturally results in an increased susceptibility to infectious complications in transplant recipients. Although their incidence has decreased since the introduction of cyclosporine, infections with unusual and opportunistic organisms remain the major cause of death during the first postoperative year and remain a threat to the chronically immunosuppressed patient throughout life. Effective therapy depends on careful surveillance for early signs and symptoms of opportunistic infection and an extremely aggressive approach to obtaining a specific diagnosis as well as expertise in recognizing the more common clinical presentations of CMV, *Aspergillus*, and other opportunistic infectious agents.

PROLONGED ASSISTED CIRCULATON

The modern era of mechanical circulatory support can be traced back to 1953 when cardiopulmonary bypass was first used in a clinical setting and ushered in the possibility of brief periods of circulatory support to permit open-heart surgery. There have subsequently been developed a variety of extracorporeal pumps to provide circulatory support for brief periods of time. The use of a mechanical device to support the circulation for more than a few hours got off to a slow start in the 1980s when the first artificial hearts were introduced with much publicity but failed to produce the hoped-for treatment of end-stage heart disease. Subsequently, technology evolved to provide mechanical assistance to (rather than replacement of) the failing ventricle, although newer versions of the total artificial heart are now once again in preliminary clinical trials.

Although conceived of initially as alternatives to biologic replacement of the heart, LVADs were introduced as, and are still employed primarily as, temporary "bridges" to heart transplantation in candidates who begin to fail medical therapy before a donor heart becomes available. Several devices are approved by the U.S. Food and Drug Administration (FDA) and are currently in widespread use. Those that are implantable within the body are compatible with hospital discharge and offer the patient chance for life at home while waiting for a donor heart. However successful such "bridging" is for the individual patient, it does nothing to alleviate the scarcity of donor hearts, and the ultimate goal in the field remains that of providing a reasonable alternative to biologic replacement of the heart—one that is widely and easily available and cost effective.

AVAILABLE DEVICES

In the United States there are currently three FDA-approved devices that are used as bridges to transplantation. There are a number of other devices that are approved only for short-term support for postcardiac surgery shock and these will not be considered here. None of the long-term devices as yet are totally implantable, and, because of this need for transcutaneous connections, all share a common problem with infectious complications. Likewise, all share some tendency to thromboembolic complications as well as the expected possibility of mechanical device failure common to any man-made machine.

The Thoratec LVAD (Thoratec Corp., Pleasanton, CA) is an extracorporeal pump that takes blood from a large cannula placed in the left ventricular apex and propels it forward through an outflow cannula inserted into the ascending aorta. The pump itself sits in the paracorporeal position on the abdomen and is attached to a device console cart with wheels, allowing for limited ambulation. The extracorporeal nature of this pump allows it to be used for small adults for whom the intracorporeal pumps would be too large.

The Novacor LVAD (WorldHeart Inc., Oakland, CA) also takes blood from the left ventricular apex through a cannula and propels it into the ascending aorta through a second cannula. With this device the pump itself is placed in a surgically created pocket in the preperitoneal fascia in the abdomen. A drive line that connects to the power source is tunneled subcutaneously and usually exits in the right upper quadrant of the abdomen.

The HeartMate LVAD (Thoratec Corp., Pleasanton, CA) uses a configuration identical to that of the Novacor device (Fig. 228-2). Differences between the two have to do with the materials used and the tendency for thromboembolic complications. Both commonly lead to hospital discharge and an outpatient wait for a donor heart.

Newer devices, currently in clinical trials, include several axial-flow pumps that have basically the same connections to the circulatory system but are considerably smaller, have fewer moving parts than previous devices, and provide non-pulsatile blood flow. All current axial-flow pumps continue to require transcutaneous connections.

RESULTS

The use of these devices in the United States is limited mainly to patients with postcardiac surgery shock and to those who are "bridged" to transplantation. The results of bridging to transplantation with the available devices are quite good, with nearly 75% of younger patients receiving a transplant by 1 year and those having excellent posttransplant survival rates.

Publication of the REMATCH (Randomized Evaluation of Mechanical Assistance in the Treatment of Heart Failure) trial in 2001 documented a somewhat improved survival in nontransplant candidates with end-stage heart disease randomized to a Heartmate LVAD (albeit with a high rate of complications, especially neurologic ones) as opposed to continued medical therapy; this led to renewed interest in also using the devices as non-biologic permanent replacement of heart function as well as to FDA approval of one device for this indication. This, in turn, led the ISHLT to initiate a Mechanical Circulatory Support database in 2002. This database collects voluntary data from 60 international centers and contained data from 655 patients in its most recent publication. Only 12% of these had the device placed with the intention of permanent, or "destination," use, with survival rates of only 65% at 6 months and 34% at one year.

GOALS

Future developments in this field can be expected in two directions. First, newer generations of the pumps will likely be smaller and simpler mechanically and, most important, totally implantable. Second, increased use of the newer generations of pumps as "permanent" (destination) therapy in patients with end-stage heart failure who are not considered eligible for transplantation will likely happen in the near future. Eventually it is hoped that improved assist devices will be accepted as valid alternatives to biologic replacement of the heart even in transplant-eligible patients and help to modify the supply/demand mismatch for cardiac replacement therapy.

229 Congenital Heart Disease in the Adult

John S. Child

Congenital heart disease (CHD) complicates ~1% of all live births in the general population but occurs in 4% of offspring of women with CHD. Substantial numbers of affected infants and children, estimated at >85% currently, reach adulthood because of successful medical and surgical management or because they have successfully adapted to their particular cardiovascular physiology. More than 800,000 adults with operated or unoperated CHD exist in the United States today; as such, adults now outnumber children with CHD.

ETIOLOGY

CHD is generally the result of aberrant embryonic development of a normal structure or failure of such a structure to progress beyond an early stage of embryonic or fetal development. Malformations are due to complex multifactorial genetic and environmental causes. Recognized chromosomal aberrations and mutations of single genes account for <10% of all cardiac malformations.

The presence of a cardiac malformation as a component of the multiple system involvement in Down syndrome, Turner syndrome, and the trisomy 13-15(D1) and 17-18(E) syndromes may be anticipated in occasional pregnancies by detection of abnormal chromosomes in fetal cells obtained from amniotic fluid or chorionic villus biopsy. Identification in such cells of the enzyme disorders characteristic of Hurler's syndrome, homocystinuria, or type II glycogen storage disease may also allow one to predict cardiac disease.

PATHOPHYSIOLOGY

The anatomic and physiologic changes in the heart and circulation due to any specific CHD lesion are not static but, rather, progress from prenatal life to adulthood. Malformations that are benign or escape detection in childhood may become clinically significant in the adult. For example, a functionally normal congenitally bicuspid aortic valve may thicken and calcify with time, resulting in significant aortic stenosis; or a well-tolerated left-to-right shunt of an atrial septal defect may result in cardiac decompensation or pulmonary hypertension only after the fourth to fifth decade.

Pulmonary Hypertension The status of the pulmonary vascular bed is often a principal determinant of the clinical manifestations and course of a given lesion and of the feasibility of surgical repair. Increased pulmonary arterial pressure results from increased pulmonary blood flow and/or resistance, the latter usually the result of obstructive, obliterative structural changes within the pulmonary vascular bed. It is important to quantitate and compare pulmonary to systemic flows and resistances in patients with severe pulmonary hypertension. The causes of pulmonary vascular obstructive disease are unknown, although increased pulmonary blood flow, increased pulmonary arterial blood pressure, elevated pulmonary venous pressure, erythrocytosis, systemic hypoxemia, acidosis, and the bronchial circulation have been implicated. The term *Eisenmenger syndrome* is applied to patients with a large communication between the two circulations at the aortopulmonary, ventricular, or atrial levels and bidirectional or predominantly right-to-left shunts because of high-resistance and obstructive pulmonary hypertension. Pulmonary arterial vasodilators and both single lung transplantation with intracardiac defect repair and total heart-lung transplantation show promise for improvement in symptoms (Chaps. 228 and 260).

Erythrocytosis Chronic hypoxemia in cyanotic CHD results in secondary *erythrocytosis* due to increased erythropoietin production (Chap. 35). The commonly used term *polycythemia* is a misnomer because white cell counts are normal and platelet counts are normal to decreased. Cyanotic patients with erythrocytosis may have compensated or decompensated hematocrits. Compensated erythrocytosis with iron-replete equilibrium hematocrits rarely result in symptoms of hyperviscosity at hematocrits < 65% and occasionally not even with hematocrits ≥ 70%. Therapeutic phlebotomy is rarely required in compensated erythrocytosis. In contrast, patients with decompensated erythrocytosis fail to establish equilibrium with unstable, rising hematocrits and recurrent hyperviscosity symptoms. Therapeutic phlebotomy, a two-edged sword, allows temporary relief of symptoms but limits oxygen delivery, begets instability of the hematocrit, and compounds the problem by iron depletion. Iron-deficiency symptoms are usually indistinguishable from those of hyperviscosity; progressive symptoms after recurrent phlebotomy are usually due to iron depletion with hypochromic microcytosis. Iron depletion results in a larger number of smaller (microcytic) hypochromic red cells that are less capable of carrying oxygen. Because these microcytes are less deformable in the microcirculation and there are more of them relative to the plasma volume, the viscosity is greater than for an equivalent hematocrit with fewer, larger, iron-replete, deformable cells. As such, iron-depleted erythrocytosis results in increasing symptoms due to decreased oxygen delivery to the tissues.

Hemostasis is abnormal in cyanotic CHD, due in part to the increased blood volume and engorged capillaries, abnormalities in platelet function and sensitivity to aspirin or nonsteroidal anti-inflammatory agents, and abnormalities of the extrinsic and intrinsic coagulation system. Oral contraceptives are often contraindicated for cyanotic women because of the enhanced risk of vascular thrombosis.

The risk of stroke is greatest in children <4 years with cyanotic heart disease and iron deficiency, often with dehydration as an aggravating cause. Adults with cyanotic CHD do not appear to be at increased risk for stroke, unless there are excessive injudicious phlebotomies, inappropriate use of aspirin or anticoagulants, or the presence of atrial arrhythmias or infective endocarditis.

Symptoms of hyperviscosity can be produced in any cyanotic patient with erythrocytosis if dehydration reduces plasma volume. Phlebotomy for symptoms of hyperviscosity not due to dehydration or iron deficiency is a simple outpatient removal of 500 mL of blood over 45 min with isovolumetric replacement with isotonic saline. Acute phlebotomy without volume replacement is contraindicated. Iron repletion in decompensated iron-depleted erythrocytosis reduces iron-deficiency symptoms but must be done gradually to avoid an excessive rise in hematocrit and resultant hyperviscosity.

Pregnancy The physiologic alterations during normal gestation (Chap. 7) can create symptoms and physical findings that may be attributed erroneously to heart disease. The mother's health is most at risk if she has a cardiovascular lesion associated with pulmonary vascular disease and pulmonary hypertension (e.g., Eisenmenger physiology or mitral stenosis) or left ventricular (LV) outflow tract obstruction (e.g., aortic stenosis), but she is also at risk of death with any malformation that may cause heart failure or a hemodynamically important arrhythmia. The fetus is most at risk with maternal cyanosis, heart failure, or pulmonary hypertension. Women with aortic coarctation or Marfan syndrome risk aortic dissection. Patients with cyanotic heart disease, pulmonary hypertension, or Marfan syndrome with a dilated aortic root should not become pregnant; those with correctable lesions should be counseled about the risks of pregnancy with an uncorrected malformation versus repair and later pregnancy. The effect of pregnancy in postoperative patients depends on the outcome of the repair, including the presence and severity of residua, sequelae, or complications. Contraception is an important topic with such patients. Tubal ligation should be considered in those in whom pregnancy is strictly contraindicated.

INFECTIVE ENDOCARDITIS

(See also Chap. 118) Routine antimicrobial prophylaxis is recommended for most patients with CHD, whether operated on or not, for all dental procedures, gastrointestinal and genitourinary surgery, and

TABLE 229-1 COMPLEX ADULT CONGENITAL HEART DISEASE

Cyanotic congenital heart diseases (all forms)

Double-outlet ventricle
Truncus arteriosus
Fontan or Rastelli procedures

some diagnostic procedures, e.g., sigmoidoscopy and cystoscopy. The clinical and bacteriologic profile of infective endocarditis in patients with CHD has changed with the advent of intracardiac surgery and of prosthetic devices. Two major predisposing causes of infective endocarditis are a susceptible cardiovascular substrate and a source of bacteremia. Prophylaxis includes both antimicrobial and hygienic measures. Meticulous dental and skin care is required.

EXERCISE

Advice on athletics and exercise is governed by the nature of the exercise and by the type and severity of the congenital cardiovascular lesion. Patients with LV outflow tract obstruction, if more than moderate, or pulmonary vascular disease risk syncope or sudden death. In unrepaired tetralogy of Fallot, isotonic exercise–induced decrease in systemic vascular resistance relative to the right ventricular (RV) outflow obstruction augments the right-to-left shunt, increases hypoxemia, and causes an increase in subjective breathlessness owing to the response of the respiratory center to the changes in blood gases and pH.

SPECIFIC CARDIAC DEFECTS

Tables 229-1, 229-2, and 229-3 list CHD malformations as complex, intermediate, or simple. The goal of these tables is to suggest when cardiology consultation or advanced CHD specialty care is needed. Patients with complex CHD (which includes most "named" surgeries that usually involve complex CHD) should virtually always be managed in conjunction with an experienced specialty adult CHD center. Intermediate lesions should have initial consultation and subsequent occasional intermittent follow-up with a cardiologist. Simple lesions may be managed by a well-informed internist, though consultation with a cardiologist is occasionally advisable.

ACYANOTIC CONGENITAL HEART DISEASE WITH A LEFT-TO-RIGHT SHUNT

Atrial Septal Defect This is a common cardiac anomaly that may be first encountered in the adult and occurs more frequently in females. The *sinus venosus* type occurs high in the atrial septum near the entry of the superior vena cava into the right atrium and is associated frequently with anomalous pulmonary venous connection from the right lung to the superior vena cava or right atrium. *Ostium primum* anomalies lie adjacent to the atrioventricular valves, either of which may be deformed and regurgitant. Ostium primum defects are common in Down's syndrome; the more complex atrioventricular septal defects with a common atrioventricular valve and a posterior defect of the basal portion of the interventricular septum are more typical of this chromosomal defect. The most common *ostium secundum* type atrial septal defect involves the fossa ovalis and is midseptal in location. This type of defect should not be confused with a *patent foramen ovale*. Anatomic obliteration of the foramen ovale ordinarily follows its functional closure soon after birth, but residual "probe patency" is a normal variant; atrial septal defect denotes a true deficiency of the atrial septum and implies functional and anatomic patency.

TABLE 229-2 INTERMEDIATE COMPLEXITY CONGENITAL HEART DISEASE

Ostium primum or sinus venosus atrial septal defect
Anomalous pulmonary venous drainage, partial or total
Atrioventricular canal defects (partial or complete)
Ventricular septal defect, complicated (e.g., absent or abnormal valves or with associated obstructive lesions, aortic regurgitation)
Coarctation of the aorta
Pulmonic valve stenosis (moderate to severe)
Infundibular right ventricular outflow obstruction of significance
Pulmonary valve regurgitation (moderate to severe)
Patent ductus arteriosus (non closed)—moderate to large
Sinus of Valsalva fistula/aneurysm
Subvalvular or supravalvular aortic stenosis

TABLE 229-3 SIMPLE ADULT CONGENITAL HEART DISEASE

Native disease
Uncomplicated congenital aortic valve disease
Mild congenital mitral valve disease (e.g., except parachute valve, cleft leaflet)
Uncomplicated small atrial septal defect
Uncomplicated small ventricular septal defect
Mild pulmonic stenosis
Repaired conditions
Previously ligated or occluded ductus arteriosus
Repaired secundum or sinus venosus atrial septal defect without residua
Repaired ventricular septal defect without residua

The magnitude of the left-to-right shunt depends on the atrial septal defect size, ventricular diastolic properties, and the relative impedance in the pulmonary and systemic circulations. The left-to-right shunt causes diastolic overloading of the right ventricle and increased pulmonary blood flow.

Patients with atrial septal defect are usually asymptomatic in early life, although there may be some physical underdevelopment and an increased tendency for respiratory infections; cardiorespiratory symptoms occur in many older patients. Beyond the fourth decade, a significant number of patients develop atrial arrhythmias, pulmonary arterial hypertension, bidirectional and then right-to-left shunting of blood, and cardiac failure. Patients exposed to the chronic environmental hypoxia of high altitude tend to develop pulmonary hypertension at younger ages. In some older patients, left-to-right shunting across the defect increases as progressive systemic hypertension and/or coronary artery disease result in reduced compliance of the left ventricle.

PHYSICAL EXAMINATION Examination usually reveals a prominent RV impulse and palpable pulmonary artery pulsation. The first heart sound is normal or split, with accentuation of the tricuspid valve closure sound. Increased flow across the pulmonic valve is responsible for a midsystolic pulmonary outflow murmur. The second heart sound is widely split and is relatively fixed in relation to respiration. A mid-diastolic rumbling murmur, loudest at the fourth intercostal space and along the left sternal border, reflects increased flow across the tricuspid valve. In patients with ostium primum defects, an apical thrill and holosystolic murmur indicate associated mitral or tricuspid regurgitation or a ventricular septal defect.

The physical findings are altered when an increase in the pulmonary vascular resistance results in diminution of the left-to-right shunt. Both the pulmonary outflow and tricuspid inflow murmurs decrease in intensity, the pulmonic component of the second heart sound and a systolic ejection sound are accentuated, the two components of the second heart sound may fuse, and a diastolic murmur of pulmonic regurgitation appears. Cyanosis and clubbing accompany the development of a right-to-left shunt.

In adults with an atrial septal defect and atrial fibrillation, the physical findings may be confused with the findings of mitral stenosis with pulmonary hypertension because the tricuspid diastolic flow murmur and widely split second heart sound may be mistakenly thought to represent the diastolic murmur of mitral stenosis and the mitral "opening snap," respectively.

ELECTROCARDIOGRAM (ECG) In patients with an ostium secundum defect, the ECG usually shows right-axis deviation and an rSr′ pattern in the right precordial leads representing enlargement of the RV outflow tract. An ectopic atrial pacemaker or first-degree heart block may oc-

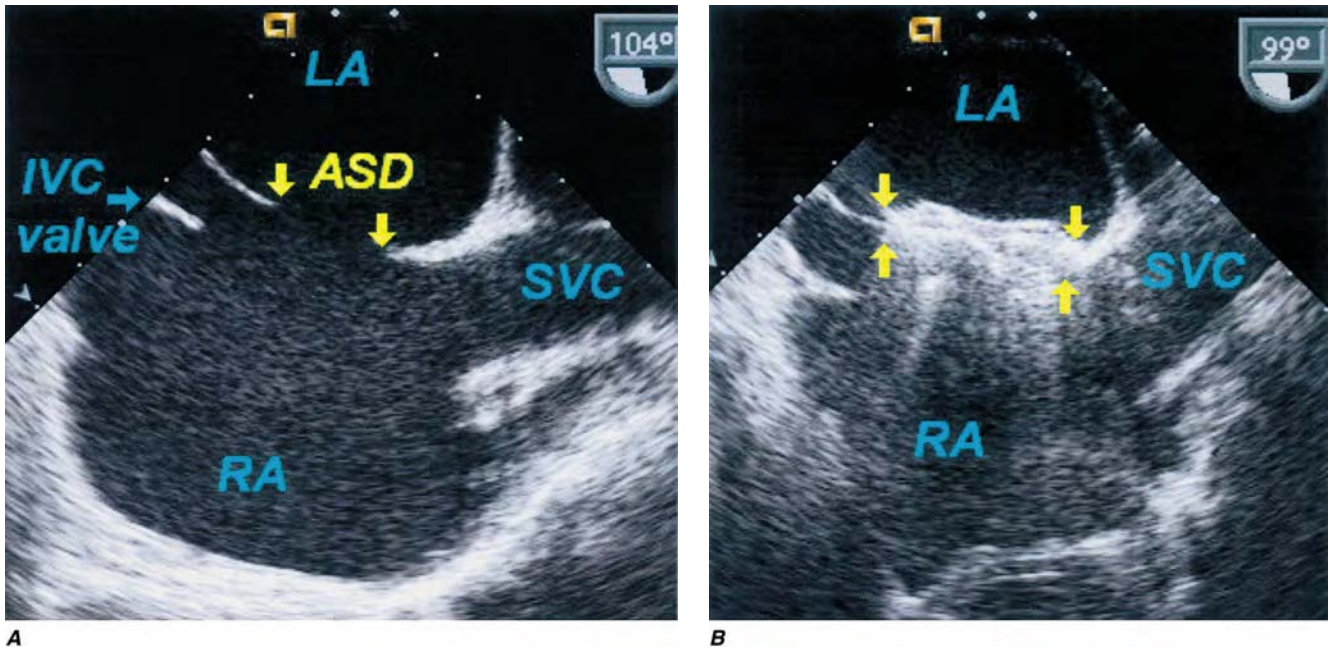

FIGURE 229-1 Secundum atrial septal defect. Transesophageal echocardiogram of secundum ASD and device closure. ***A.*** The atrial septal defect (ASD) between the left atrium (LA) and right atrium (RA) is shown. ***B.*** A percutaneous catheter–delivered device has occluded the defect. IVC, inferior vena cava; SVC, superior vena cava.

cur with defects of the sinus venous type. In ostium primum defect, the RV conduction defect is accompanied by left superior axis deviation and counterclockwise rotation of the frontal plane QRS loop. Varying degrees of RV and right atrial (RA) hypertrophy may occur with each type of defect, depending on the height of the pulmonary artery pressure. *Chest x-ray* reveals enlargement of the right atrium and right ventricle, dilatation of the pulmonary artery and its branches, and increased pulmonary vascular markings.

ECHOCARDIOGRAM Echocardiography reveals pulmonary arterial and RV and RA dilatation with abnormal (paradoxical) ventricular septal motion in the presence of a significant right heart volume overload. The atrial septal defect may be visualized directly by two-dimensional imaging, color flow imaging, or echocontrast. In most institutions, two-dimensional echocardiography plus color Doppler flow examination has supplanted cardiac catheterization. Transesophageal echocardiography is indicated if the transthoracic echocardiogram is ambiguous, which is often the case with sinus venosus defects, or during catheter device closure (Fig. 229-1). Cardiac catheterization is performed if inconsistencies exist in the clinical data, if significant pulmonary hypertension or associated malformations are suspected, or if coronary artery disease is a possibility.

℞ ATRIAL SEPTAL DEFECT

Operative repair, usually with a patch of pericardium or of prosthetic material, or percutaneous transcatheter device closure, if the defect is of an appropriate size and shape, should be advised for all patients with uncomplicated secundum atrial septal defects with significant left-to-right shunting, i.e., pulmonary-to-systemic flow ratios ≥2.0:1.0. Excellent results may be anticipated, at low risk, even in patients >40 years, in the absence of severe pulmonary hypertension. In ostium primum defects, cleft mitral valves may require repair in addition to patch closure of the atrial defect. Closure should not be carried out in patients with small defects and trivial left-to-right shunts or in those with severe pulmonary vascular disease without a significant left-to-right shunt.

Patients with atrial septal defect of the sinus venosus or ostium secundum types rarely die before the fifth decade. During the fifth and sixth decades, the incidence of progressive symptoms, often leading to severe disability, increases substantially. Medical management should include prompt treatment of respiratory tract infections, antiarrhythmic medications for atrial fibrillation or supraventricular tachycardia, and the usual measures for hypertension, coronary disease, or heart failure (Chap. 227), if these complications occur. The risk of infective endocarditis is quite low unless the defect is complicated by valvular regurgitation or has recently been repaired with a patch or device (Chap. 118).

Ventricular Septal Defect Defects of the ventricular septum are common as isolated defects or as a component of a combination of anomalies. The opening is usually single and situated in the membranous portion of the septum. The functional disturbance depends on its size and on the status of the pulmonary vascular bed. Only small or moderate-size defects are usually seen initially in adulthood as most patients with isolated large defects come to medical and, often, surgical attention early in life.

A wide spectrum exists in the natural history of ventricular septal defect, ranging from spontaneous closure to congestive cardiac failure and death in early infancy. Within this spectrum is the possible development of pulmonary vascular obstruction, RV outflow tract obstruction, aortic regurgitation, and infective endocarditis. Spontaneous closure is more common in patients born with a small ventricular septal defect and occurs in early childhood in most patients.

Patients with large ventricular septal defects and pulmonary hypertension are those at greatest risk for developing pulmonary vascular obstruction. Thus, large defects should be corrected surgically early in life when pulmonary vascular disease is still reversible or not yet developed. In patients with severe pulmonary vascular obstruction (Eisenmenger syndrome), symptoms in adult life consist of exertional dyspnea, chest pain, syncope, and hemoptysis. The right-to-left shunt leads to cyanosis, clubbing, and erythrocytosis. In all patients, the degree to which pulmonary vascular resistance is elevated before operation is a critical factor determining prognosis. If the pulmonary vascular resistance is one-third or less of the systemic value, progression of pulmonary vascular disease after operation is unusual. However, if a moderate to severe increase in pulmonary vascular resistance exists preoperatively, either no change or a progression of pulmonary vascular disease is common postoperatively.

RV outflow tract obstruction develops in ~5–10% of patients who present in infancy with a moderate to large left-to-right shunt. With

time, as subvalvular RV outflow tract obstruction progresses, the findings in these patients whose VSD remains sizeable begin to resemble more closely those of the cyanotic tetralogy of Fallot.

In ~5% of patients, aortic valve regurgitation results from insufficient cusp tissue or prolapse of the cusp through the interventricular defect; the aortic regurgitation then complicates and dominates the clinical course.

Two-dimensional *echocardiography* with spectral and color Doppler examination defines the number and location of defects in the ventricular septum and associated anomalies and the hemodynamic physiology of the defect(s). Hemodynamic and angiographic study may be occasionally required to assess the status of the pulmonary vascular bed and clarify details of the altered anatomy.

Rx VENTRICULAR SEPTAL DEFECT

Surgery is not recommended for patients with normal pulmonary arterial pressures with small shunts (pulmonary-to-systemic flow ratios of <1.5 to 2.0:1.0). Operative correction or transcatheter closure is indicated when there is a moderate to large left-to-right shunt with a pulmonary-to-systemic flow ratio >1.5:1.0 or 2.0:1.0, in the absence of prohibitively high levels of pulmonary vascular resistance.

Patent Ductus Arteriosus The ductus arteriosus is a vessel leading from the bifurcation of the pulmonary artery to the aorta just distal to the left subclavian artery. Normally, the vascular channel is open in the fetus but closes immediately after birth. The flow across the ductus is determined by the pressure and resistance relationships between the systemic and pulmonary circulations and by the cross-sectional area and length of the ductus. In most adults with this anomaly, pulmonary pressures are normal and a gradient and shunt from aorta to pulmonary artery persist throughout the cardiac cycle, resulting in a characteristic thrill and a continuous "machinery" murmur with late systolic accentuation at the upper left sternal edge. In adults who were born with a large left-to-right shunt through the ductus arteriosus, pulmonary vascular obstruction (Eisenmenger syndrome) with pulmonary hypertension, right-to-left shunting, and cyanosis have usually developed. Severe pulmonary vascular disease results in reversal of flow through the ductus; unoxygenated blood is shunted to the descending aorta; and the toes, but not the fingers, become cyanotic and clubbed, a finding termed *differential cyanosis*. The leading causes of death in adults with patent ductus are cardiac failure and infective endocarditis; occasionally severe pulmonary vascular obstruction may cause aneurysmal dilatation, calcification, and rupture of the ductus.

Rx PATENT DUCTUS ARTERIOSUS

In the absence of severe pulmonary vascular disease and predominant left-to-right shunting of blood, the patent ductus should be surgically ligated or divided. Transcatheter closure using coils, buttons, plugs, and umbrellas has become commonplace for appropriately shaped defects. Thoracoscopic surgical approaches are considered experimental. Operation should be deferred for several months in patients treated successfully for infective endocarditis because the ductus may remain somewhat edematous and friable.

Aortic Root to Right Heart Shunts The three most common causes of aortic root to right heart shunts are congenital aneurysm of an aortic sinus of Valsalva with fistula, coronary arteriovenous fistula, and anomalous origin of the left coronary artery from the pulmonary trunk. *Aneurysm of an aortic sinus of Valsalva* consists of a separation or lack of fusion between the media of the aorta and the annulus of the aortic valve. Rupture usually occurs in the third or fourth decade of life; most often the aorticocardiac fistula is between the right coronary cusp and the right ventricle, but occasionally, when the noncoronary cusp is involved, the fistula drains into the right atrium. Abrupt rupture causes chest pain, bounding pulses, a continuous murmur accentuated in diastole, and volume overload of the heart. Diagnosis is confirmed by two-dimensional and Doppler echocardiographic studies; cardiac catheterization quantitates the left-to-right shunt, and thoracic aortography visualizes the fistula. Medical management is directed at cardiac failure, arrhythmias, or endocarditis. At operation, the aneurysm is closed and amputated, and the aortic wall is reunited with the heart, either by direct suture or with a patch or prosthesis.

Coronary arteriovenous fistula, an unusual anomaly, consists of a communication between a coronary artery and another cardiac chamber, usually the coronary sinus, right atrium, or right ventricle. The shunt is usually of small magnitude and myocardial blood flow is not usually compromised; if the shunt is large, there may be a coronary "steal" syndrome with myocardial ischemia and possible angina or ventricular arrhythmias. Potential complications include infective endocarditis, thrombus formation with occlusion or distal embolization with myocardial infarction, rupture of an aneurysmal fistula, and, rarely, pulmonary hypertension and congestive failure. A loud, superficial, continuous murmur at the lower or midsternal border usually prompts a further evaluation of asymptomatic patients. Doppler echocardiography demonstrates the site of drainage; if the site of origin is proximal, it may be detectable by two-dimensional echocardiography. Angiography (classic catheterization, CT, or magnetic resonance angiography) permits identification of the size and anatomic features of the fistulous tract, which may be closed by suture or transcatheter obliteration.

The third anomaly causing a shunt from the aortic root to the right heart is *anomalous origin of the left coronary artery from the pulmonary artery*. Myocardial infarction and fibrosis commonly lead to death within the first year, although up to 20% of patients survive to adolescence and beyond without surgical correction. The diagnosis is supported by the ECG findings of an anterolateral myocardial infarction and LVH. Operative management of adults consists of coronary artery bypass with an internal mammary artery graft or saphenous vein–coronary artery graft.

ACYANOTIC CONGENITAL HEART DISEASE WITHOUT A SHUNT

Congenital Aortic Stenosis Malformations that cause obstruction to LV outflow include congenital valvular aortic stenosis, discrete subaortic stenosis, supravalvular aortic stenosis, and hypertrophic obstructive cardiomyopathy (Chap. 231).

VALVULAR AORTIC STENOSIS Bicuspid aortic valves are more common in males than in females. The congenital bicuspid aortic valve, which may initially be functionally normal, is one of the most common congenital malformations of the heart and may go undetected in early life. Because bicuspid valves may develop stenosis or regurgitation with time or be the site of infective endocarditis, the lesion may be difficult to distinguish in older adults from acquired rheumatic or degenerative calcific aortic valve disease. The dynamics of blood flow associated with a congenitally deformed, rigid aortic valve commonly lead to thickening of the cusps and, in later life, to calcification. Hemodynamically significant obstruction causes concentric hypertrophy of the LV wall. The ascending aorta is often dilated, misnamed "poststenotic" dilatation; this is due to histologic abnormalities of the aortic media similar to those in Marfan syndrome, and may result in aortic dissection. Diagnosis is best made by echocardiography, which can reveal the morphology of the aortic valve and aortic root and quantitate the degree of stenosis or regurgitation. **The clinical manifestations and hemodynamic abnormalities are discussed in Chap. 230.**

Rx VALVULAR AORTIC STENOSIS

The medical management of congenital valvular aortic stenosis includes prophylaxis against infective endocarditis and, in patients with diminished cardiac reserve, the administration of digoxin and diuretics and sodium restriction while awaiting operation. A dilated aortic root may require beta blockers. If severe aortic stenosis is present, strenuous physical activity should be avoided even when the patient is asymptomatic, and participation in competitive sports should probably be restricted in patients with milder degrees of ob-

struction. Aortic valve replacement is indicated in adults with critical obstruction, i.e., with an aortic valve area <0.45 cm^2/m^2, with symptoms secondary to LV dysfunction or myocardial ischemia, or with hemodynamic evidence of LV dysfunction. In asymptomatic children or adolescents or young adults with critical aortic stenosis without valvular calcification or these features, aortic balloon valvuloplasty is often useful (Chap. 240). If surgery is contraindicated in older patients because of a complicating medical problem such as malignancy or renal or hepatic failure, balloon valvuloplasty may provide short-term improvement. This procedure may serve as a bridge to aortic valve replacement in patients with severe heart failure.

SUBAORTIC STENOSIS The most common form of subaortic stenosis is the *idiopathic hypertrophic* variety, also termed *hypertrophic cardiomyopathy*, which is present at birth in about one-third of the patients and is discussed in Chap. 231. The *discrete* form of subaortic stenosis consists of a membranous diaphragm or fibromuscular ring encircling the LV outflow tract just beneath the base of the aortic valve. The jet impact from the subaortic stenotic jet on the underside of the aortic valve often begets progressive aortic valve fibrosis and valvular regurgitation. Echocardiography demonstrates the anatomy of the subaortic obstruction; Doppler studies show turbulence proximal to the aortic valve and can quantitate the pressure gradient and severity of aortic regurgitation. Treatment consists of complete excision of the membrane or fibromuscular ring.

SUPRAVALVULAR AORTIC STENOSIS This anomaly consists of a localized or diffuse narrowing of the ascending aorta originating just above the level of the coronary arteries at the superior margin of the sinuses of Valsalva. In contrast to other forms of aortic stenosis, the coronary arteries are subjected to elevated systolic pressures from the left ventricle, are often dilated and tortuous, and are susceptible to premature atherosclerosis. In most patients, a genetic defect for the anomaly is located in the same chromosomal region as elastin on chromosome 7.

Coarctation of the Aorta Narrowing or constriction of the lumen of the aorta may occur anywhere along its length but is most common distal to the origin of the left subclavian artery near the insertion of the ligamentum arteriosum. Coarctation occurs in ~7% of patients with congenital heart disease, is more common in males than females, and is particularly frequent in patients with gonadal dysgenesis (e.g., Turner syndrome). Clinical manifestations depend on the site and extent of obstruction and the presence of associated cardiac anomalies, most commonly a bicuspid aortic valve. Circle of Willis aneurysms may occur in up to 10% and pose a high risk of sudden rupture and death.

Most children and young adults with isolated, discrete coarctation are asymptomatic. Headache, epistaxis, cold extremities, and claudication with exercise may occur, and attention is usually directed to the cardiovascular system when a heart murmur or hypertension in the upper extremities and absence, marked diminution, or delayed pulsations in the femoral arteries are detected on physical examination. Enlarged and pulsatile collateral vessels may be palpated in the intercostal spaces anteriorly, in the axillae, or posteriorly in the interscapular area. The upper extremities and thorax may be more developed than the lower extremities. A midsystolic murmur over the left interscapular space may become continuous if the lumen is narrowed sufficiently to result in a high-velocity jet across the lesion throughout the cardiac cycle. Additional systolic and continuous murmurs over the lateral thoracic wall may reflect increased flow through dilated and tortuous collateral vessels. The ECG usually reveals LV hypertrophy. Chest x-ray may show a dilated left subclavian artery high on the left mediastinal border and a dilated ascending aorta. Indentation of the aorta at the site of coarctation and pre- and poststenotic dilatation (the "3" sign) along the left paramediastinal shadow are almost pathognomonic. Notching of the 3rd to 9th ribs, an important radiographic sign, is due to inferior rib erosion by dilated collateral vessels (Figs. 229-2 and 229-3). Two-dimensional echocardiography from para- or suprasternal windows identifies the site and length of coarctation, while Doppler quantitates the pressure gradient. Transesophageal echocardiography and MRI or

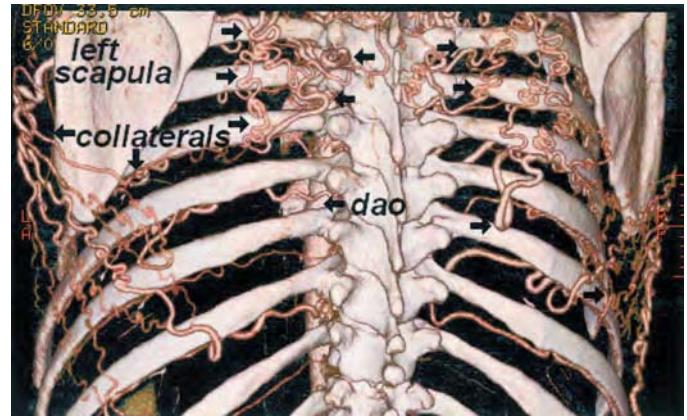

FIGURE 229-2 Aortic coarctation. The extensive collaterals (*left*) underneath the ribs and in the periscapular region are shown on a posterior view of a three-dimensional CT angiogram, which are responsible for rib notching on chest x-ray. dao, descending aorta.

three-dimensional CT allow visualization of the length and severity of the obstruction and the associated collateral arteries (Figs. 229-2 and 229-3). In adults, cardiac catheterization is indicated primarily to evaluate the coronary arteries or to perform catheter based intervention (angioplasty and stent of the coarctation).

The chief hazards of proximal aortic severe hypertension include cerebral aneurysms and hemorrhage, aortic dissection and rupture, premature coronary arteriosclerosis, and LV failure; infective endarteritis may occur on the coarctation site or endocarditis may settle on an associated bicuspid aortic valve.

Rx COARCTATION OF THE AORTA

Treatment is usually surgical, although percutaneous catheter balloon with stent dilatation is now a viable option for many patients. Late postopera-

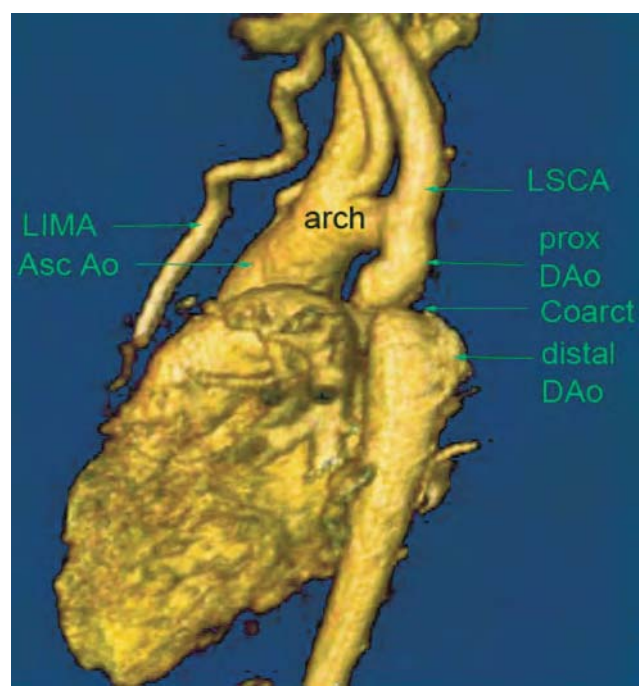

FIGURE 229-3 Aortic coarctation. The coarctation (Coarct) of the aorta is shown in the typical "adult" location in the descending aorta (DAo) just distal to the dilated left subclavian artery (LSCA) in this three-dimensional reconstruction of an MR angiogram. There is a post-coarct aneurysm that is in part due to intrinsic aortic medial tissue weakness. The left internal mammary artery (LIMA) is dilated. Asc Ao, ascending aorta; prox, proximal.

tive systemic hypertension in the absence of residual coarctation appears to be related to the duration of preoperative hypertension. Follow-up of rest and exercise blood pressures is important; in many only excessive systolic hypertension is seen during exercise, in part due to a diffuse vasculopathy. All operated or stented coarctation patients deserve a high-quality MRI or CT imaging procedure in follow-up.

Pulmonary Stenosis with Intact Ventricular Septum Obstruction to RV outflow may be localized to the supravalvular, valvular, or subvalvular levels or occur at a combination of these sites. Multiple sites of narrowing of the peripheral pulmonary arteries are a feature of *rubella embryopathy* and may occur with both the familial and sporadic forms of supravalvular aortic stenosis. Valvular pulmonic stenosis is the most common form of isolated RV obstruction.

The severity of the obstructing lesion, rather than the site of narrowing, is the most important determinant of the clinical course. In the presence of a normal cardiac output, a peak systolic transvalvular pressure gradient between 50 and 80 mmHg is considered to be moderate stenosis; levels below and above that range are classified as mild and severe, respectively. Patients with mild pulmonic stenosis are generally asymptomatic and demonstrate little or no progression in the severity of obstruction with age. In patients with more significant stenosis, the severity may increase with time. Symptoms vary with the degree of obstruction. Fatigue, dyspnea, RV failure, and syncope may limit the activity of older patients, in whom moderate or severe obstruction may prevent an augmentation of cardiac output with exercise. In patients with severe obstruction, the systolic pressure in the right ventricle may exceed that in the left ventricle, since the ventricular septum is intact. RV ejection is prolonged with moderate or severe stenosis, and the sound of pulmonary valve closure is delayed and soft. RV hypertrophy reduces the compliance of that chamber, and a forceful RA contraction is necessary to augment RV filling.

A fourth heart sound, prominent *a* waves in the jugular venous pulse, and, occasionally, presystolic pulsations of the liver reflect vigorous atrial contraction. The clinical diagnosis is supported by a left parasternal lift and harsh systolic crescendo-decrescendo murmur and thrill at the upper left sternal border, typically preceded by a systolic ejection sound if the obstruction is due to a mobile nondysplastic pulmonary valve. The holosystolic murmur of tricuspid regurgitation may accompany severe pulmonic stenosis, especially in the presence of congestive heart failure. Cyanosis usually reflects right-to-left shunting through a patent foramen ovale or atrial septal defect. In patients with supravalvular or peripheral pulmonary arterial stenosis, the murmur is systolic or continuous and is best heard over the area of narrowing, with radiation to the peripheral lung fields.

In mild cases, the ECG is normal, whereas moderate and severe stenoses are associated with RV hypertrophy. The chest x-ray with mild or moderate pulmonic stenosis shows a heart of normal size with normal lung vascularity. In pulmonary valvular stenosis, dilatation of the main and left pulmonary arteries occurs in part due to the direction of the PS jet and in part due to intrinsic tissue weakness. With severe obstruction, RV hypertrophy is generally evident. The pulmonary vascularity may be reduced with severe stenosis, RV failure, and/or a right-to-left shunt at the atrial level. Two-dimensional echocardiography visualizes pulmonary valve morphology; the outflow tract pressure gradient can be quantitated by Doppler echocardiography.

Rx PULMONARY STENOSIS

The cardiac catheter technique of balloon valvuloplasty (Chap. 223) is usually effective. Direct surgical relief of moderate and severe obstruction may be accomplished at a low risk. Multiple stenoses of the peripheral pulmonary arteries are usually inoperable, but narrowing of a proximal branch or at the bifurcation of the main pulmonary trunk may be surgically corrected or undergo balloon dilatation and stenting.

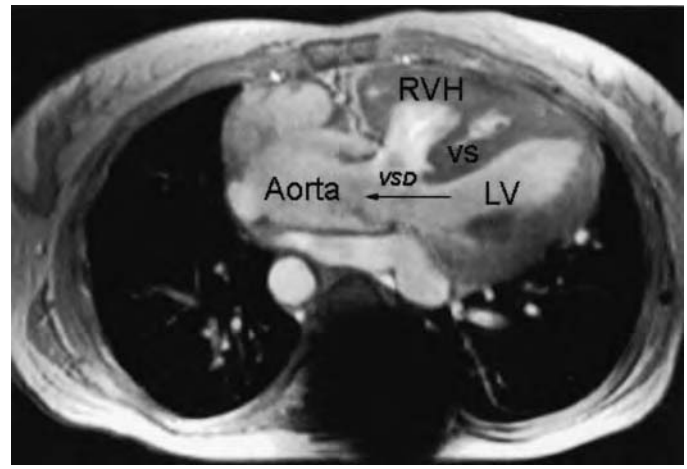

FIGURE 229-4 Tetralogy of Fallot. Magnetic resonance imaging angiogram. A mid-systolic frame showing the malaligned ventricular septal defect (VSD) with the aorta overriding the ventricular septal defect. LV, left ventricle; RVH, RV hypertrophy; VS, ventricular septum.

COMPLEX CONGENITAL HEART LESIONS

Tetralogy of Fallot The four components of the tetralogy of Fallot are malaligned ventricular septal defect, obstruction to RV outflow, aortic override of the ventricular septal defect, and RV hypertrophy due to the RV "seeing" aortic pressure via the large VSD (Fig. 229-4).

The severity of RV outflow obstruction determines the clinical presentation. The severity of hypoplasia of the RV outflow tract varies from mild to complete (pulmonary atresia). Pulmonary valve stenosis and supravalvular and peripheral pulmonary arterial obstruction may coexist; rarely there is unilateral absence of a pulmonary artery (usually the left). A right-sided aortic arch and descending thoracic aorta occur in ~25% of patients with tetralogy.

The relationship between the resistance of blood flow from the ventricles into the aorta and into the pulmonary vessels plays a major role in determining the hemodynamic and clinical picture. When the obstruction is severe, the pulmonary blood flow is reduced markedly, and a large volume of desaturated systemic venous blood is shunted from right to left across the ventricular septal defect. Severe cyanosis and erythrocytosis occur, and symptoms of systemic hypoxemia are prominent. In many infants and children the obstruction is mild but progressive.

The ECG shows RV hypertrophy. Chest x-ray shows a normal-sized, boot-shaped heart (*coeur en sabot*) with a prominent right ventricle and a concavity in the region of the pulmonary conus. Pulmonary vascular markings are typically diminished, and the aortic arch and knob may be on the right side. Two-dimensional echocardiography demonstrates the malaligned ventricular septal defect with the overriding aorta and the site and severity of pulmonary stenosis, which may be subpulmonic (fixed or dynamic), at the pulmonary valve or in the main or branch pulmonary arteries. Classic contrast angiography may provide details regarding the RV outflow tract, pulmonary valve and annulus, and caliber of the main branches of the pulmonary artery as well of possible associated aortopulmonary collaterals. Coronary arteriography identifies the anatomy and course of the coronary arteries. In experienced centers, these issues are often well demonstrated in adults by MR (Fig. 229-4) or CT angiography with 3-dimensional reconstruction.

Rx TETRALOGY OF FALLOT

For a variety of reasons, only a few adults with tetralogy of Fallot have not had some form of previous surgical intervention. Reoperation in adults is most commonly for severe pulmonary regurgitation. Long-term concerns about ventricular function persist. Ventricular and atrial arrhythmias may require medical treatment or electrophysiologic study and ablation. Interventional catheterization may be needed in selected patients (i.e., angio-

plasty and stenting of branch pulmonary stenosis). The aortic root has a medial tissue defect; it is commonly enlarged and associated with aortic regurgitation. Endocarditis remains a risk despite surgical repair.

Complete Transposition of the Great Arteries This condition is commonly called *dextro-* or *D-transposition of the great arteries*. The aorta arises rightward anteriorly from the right ventricle, and the pulmonary artery emerges leftward and posteriorly from the left ventricle, which results in two separate parallel circulations; some communication between them must exist after birth to sustain life. Most patients have an interatrial communication, two-thirds have a patent ductus arteriosus, and about one-third have an associated ventricular septal defect. Transposition is more common in males and accounts for ~10% of cyanotic heart disease.

The course is determined by the degree of tissue hypoxia, the ability of each ventricle to sustain an increased work load in the presence of reduced coronary arterial oxygenation, the nature of the associated cardiovascular anomalies, and the status of the pulmonary vascular bed. By the third decade of life, ~30% of patients will have developed decreased RV function and progressive tricuspid regurgitation, which may lead to congestive heart failure. Pulmonary vascular obstruction develops by 1 to 2 years of age in patients with an associated large ventricular septal defect or large patent ductus arteriosus in the absence of obstruction to LV outflow.

℞ TRANSPOSITION OF THE GREAT ARTERIES

The balloon or blade catheter or surgical creation or enlargement of an interatrial communication in the neonate is the simplest procedure for providing increased intracardiac mixing of systemic and pulmonary venous blood. Systemic–pulmonary artery anastomosis may be indicated in the patient with severe obstruction to LV outflow and diminished pulmonary blood flow. Intracardiac repair may be accomplished by rearranging the venous returns (intraatrial switch, i.e., Mustard or Senning operation) so that the systemic venous blood is directed to the mitral valve and thence to the left ventricle and pulmonary artery, while the pulmonary venous blood is diverted through the tricuspid valve and right ventricle to the aorta. The late survival after these repairs is good, but arrhythmias (e.g., atrial flutter) or conduction defects (e.g., sick sinus syndrome) occur in ~50% of such patients by 30 years after the intraatrial switch surgery. Progressive dysfunction of the systemic subaortic right ventricle, tricuspid regurgitation, ventricular arrhythmias or cardiac arrest and late sudden death are worrisome features. Preferably, this malformation is corrected in infancy by transposing both coronary arteries to the posterior artery and transecting, contraposing, and anastomosing the aorta and pulmonary arteries (arterial switch operation). For those patients with a ventricular septal defect in whom it is necessary to bypass a severely obstructed LV outflow tract, corrective operation employs an intracardiac ventricular baffle and extracardiac prosthetic conduit to replace the pulmonary artery (Rastelli procedure).

Single Ventricle This is a family of complex lesions with both atrioventricular valves or a common atrioventricular valve opening to a single ventricular chamber. Associated anomalies include abnormal great artery positional relationships, pulmonic valvular or subvalvular stenosis, and subaortic stenosis.

Survival to adulthood depends on a relatively normal pulmonary blood flow, yet normal pulmonary resistance, and good ventricular function. Modifications of the Fontan approach are generally applied to carefully selected patients with creation of a pathway(s) from the systemic veins to the pulmonary arteries.

Tricuspid Atresia This malformation is characterized by atresia of the tricuspid valve, an interatrial communication, and, frequently, hypoplasia of the right ventricle and pulmonary artery. The clinical picture is usually dominated by severe cyanosis due to obligatory admixture of systemic and pulmonary venous blood in the left ventricle. The ECG characteristically shows RA enlargement, left-axis deviation, and LV hypertrophy.

Atrial septostomy and palliative operations to increase pulmonary blood flow, often by anastomosis of a systemic artery or vein to a pulmonary artery, may allow survival to the second or third decade. A Fontan atriopulmonary or total cavopulmonary connection may then allow functional correction in those patients with normal or low pulmonary arterial resistance pressure and good LV function.

Ebstein Anomaly Characterized by a downward displacement of the tricuspid valve into the right ventricle, due to anomalous attachment of the tricuspid leaflets, the Ebstein tricuspid valve tissue is dysplastic and results in tricuspid regurgitation. The abnormally situated tricuspid orifice produces an "atrialized" portion of the right ventricle lying between the atrioventricular ring and the origin of the valve, which is continuous with the RA chamber. Often the right ventricle is hypoplastic. Although the clinical manifestations are variable, some patients come to initial attention because of either (1) progressive cyanosis from right-to-left atrial shunting, (2) symptoms due to tricuspid regurgitation and RV dysfunction, or (3) paroxysmal atrial tachyarrhythmias with or without atrioventricular bypass tracts ("WPW" syndrome). Diagnostic findings by two-dimensional echocardiography include the abnormal positional relation between the tricuspid and mitral valves with abnormally increased apical displacement of the septal tricuspid leaflet. Tricuspid regurgitation is quantitated by Doppler examination. Surgical approaches include prosthetic replacement of the tricuspid valve when the leaflets are tethered or repair of the native valve.

Congenitally Corrected Transposition The two fundamental anatomic abnormalities in this malformation are transposition of the ascending aorta and pulmonary trunk and inversion of the ventricles. This arrangement results in desaturated systemic venous blood passing from the right atrium through the mitral valve to the left ventricle and into the pulmonary trunk, whereas oxygenated pulmonary venous blood flows from the left atrium through the tricuspid valve to the right ventricle and into the aorta. Thus, the circulation is corrected functionally. The clinical presentation, course, and prognosis of patients with congenitally corrected transposition vary depending on the nature and severity of any complicating intracardiac anomalies and of development of dysfunction of the systemic subaortic RV. Progressive RV dysfunction and tricuspid regurgitation may also develop in a third of patients by age 30; Ebstein-type anomalies of the left-side tricuspid atrioventricular valve are common. Ventricular septal defect or "pulmonary stenosis" due to obstruction to outflow from the right-sided subpulmonary (anatomic left) ventricle may coexist. Complete heart block occurs at a rate of 2–10% per decade. The diagnosis of the malformation and associated lesions can be established by comprehensive two-dimensional echocardiography and Doppler examination.

Malpositions of the Heart Positional anomalies refer to conditions in which the cardiac apex is in the right side of the chest (*dextrocardia*), or at the midline (*mesocardia*), or in which there is a normal location of the heart in the left side of the chest but abnormal position of the viscera (*isolated levocardia*). Knowledge of the position of the abdominal organs and of the branching pattern of the main stem bronchi is important in categorizing these malpositions. When dextrocardia occurs without situs inversus, when the visceral situs is indeterminate, or if isolated levocardia is present, associated, often complex, multiple cardiac anomalies are usually present. In contrast, mirror-image dextrocardia is usually observed with complete situs inversus, which occurs most frequently in individuals whose hearts are otherwise normal.

SURGICALLY MODIFIED CONGENITAL HEART DISEASE

Because of the enormous strides in cardiovascular surgical techniques that have occurred in the past 50 years, a large number of long-term survivors of corrective operations in infancy and childhood have reached adulthood. These patients are often challenging because of the diversity of anatomic, hemodynamic, and electrophysiologic residua and sequelae of cardiac operations.

The proper care of the survivor of operation for CHD requires that the clinician understand the details of the malformation before operation; pay meticulous attention to the details of the operative procedure; and recognize the postoperative residua (conditions left totally or partially uncorrected), the sequelae (conditions caused by surgery), and the complications that may have resulted from the operation. With the exception of ligation and division of an uncomplicated patent ductus arteriosus, almost every other surgical repair of an anomaly leaves behind or causes some abnormality of the heart and circulation that may range from trivial to serious. Intraoperative transesophageal echocardiography assists in detecting unsuspected lesions, in monitoring the repair, and in verifying a satisfactory result or directing further repair. Thus, even with results that are considered clinically to be good to excellent, continued long-term postoperative follow-up is advisable.

Cardiac operations importantly involving the atria, such as closure of atrial septal defect, repair of total or partial anomalous pulmonary venous return, or venous switch corrections of complete transposition of the great arteries (the Mustard or Senning operations), may be followed years later by sinus node or atrioventricular node dysfunction or by atrial arrhythmias (especially atrial flutter). Intraventricular surgery may also result in electrophysiologic consequences, including complete heart block necessitating pacemaker insertion to avoid sudden death. In addition, valvular problems may arise late after initial cardiac operation. An example is the progressive stenosis of an initially nonobstructive bicuspid aortic valve in the patient who underwent aortic coarctation repair. Such aortic valves may also be the site of infective endocarditis. After repair of the ostium primum atrial septal defect, the cleft mitral valve may become progressively regurgitant. Tricuspid regurgitation may also be progressive in the postoperative patient with tetralogy of Fallot if RV outflow tract obstruction was not relieved adequately at initial surgery. In many patients with surgically modified CHD, inadequate relief of an obstructive lesion, or a residual regurgitant lesion, or a residual shunt will cause or hasten the onset of clinical signs and symptoms of myocardial dysfunction. Despite a good hemodynamic repair, many patients with a subaortic right ventricle develop RV decompensation and signs of "left heart failure." In many patients, particularly those who were cyanotic for many years before operation, a preexisting compromise in ventricular performance is due to the original underlying malformation.

A final category of postoperative problems involves the use of prosthetic valves, patches, or conduits in the operative repair. The special risks include infective endocarditis, thrombus formation, and premature degeneration and calcification of the prosthetic materials. There are many patients in whom extracardiac conduits are required to correct the circulation functionally and often to carry blood to the lungs from the right atrium or right ventricle. These conduits may develop intraluminal obstruction, and, if they include a prosthetic valve, it may show progressive calcification and thickening.

230 Valvular Heart Disease

Patrick O'Gara, Eugene Braunwald

The role of the physical examination in the evaluation of patients with valvular heart disease is also considered in Chaps. e8 and 220; of electrocardiography (ECG) in Chap. 221; of echocardiography and other noninvasive imaging techniques in Chap. 222; and of cardiac catheterization and angiography in Chap. 223.

MITRAL STENOSIS

ETIOLOGY AND PATHOLOGY

Rheumatic fever is the leading cause of mitral stenosis (MS) (Table 230-1). Other less common etiologies of obstruction to left atrial outflow include congenital mitral valve stenosis, cor triatriatum, mitral annular calcification with extension onto the leaflets, systemic lupus erythematosus, rheumatoid arthritis, left atrial myxoma, and infective endocarditis with large vegetations. Pure or predominant MS occurs in approximately 40% of all patients with rheumatic heart disease and a history of rheumatic fever (Chap. 315). In other patients with rheumatic heart disease, lesser degrees of MS may accompany mitral regurgitation (MR) and aortic valve disease. With reductions in the incidence of acute rheumatic fever, particularly in temperate climates and developed countries, the incidence of MS has declined considerably over the past few decades. However, it remains a major problem in developing nations, especially in tropical and semitropical climates (see p. 1480).

In rheumatic MS, the valve leaflets are diffusely thickened by fibrous tissue and/or calcific deposits. The mitral commissures fuse, the chordae tendineae fuse and shorten, the valvular cusps become rigid, and these changes, in turn, lead to narrowing at the apex of the funnel-shaped ("fish-mouth") valve. Although the initial insult to the mitral valve is rheumatic, the later changes may be a nonspecific process resulting from trauma to the valve caused by altered flow patterns due to the initial deformity. Calcification of the stenotic mitral valve immobilizes the leaflets and narrows the orifice further. Thrombus formation and arterial embolization may arise from the calcific valve itself, but in patients with atrial fibrillation (AF), thrombi arise more frequently from the dilated left atrium (LA), particularly the left atrial appendage.

PATHOPHYSIOLOGY

In normal adults, the area of the mitral valve orifice is 4–6 cm^2. In the presence of significant obstruction, i.e., when the orifice area is reduced to < ~2 cm^2, blood can flow from the LA to the left ventricle (LV) only if propelled by an abnormally elevated left atrioventricular pressure gradient (see Fig. 223-2), the hemodynamic hallmark of MS. When the mitral valve opening is reduced to <1 cm^2, often referred to

TABLE 230-1 MAJOR CAUSES OF VALVULAR HEART DISEASES

Valve Lesion	Etiologies
Mitral stenosis	Rheumatic fever
	Congenital

Note: AV, atrioventricular; HOCM, hypertrophic obstructive cardiomyopathy; HTN, hypertension; IE, infective endocarditis; LV, left ventricular; MI, myocardial infarction; MVP, mitral valve prolapse; RA, rheumatoid arthritis; RV, right ventricular; SAM, systolic anterior motion of the anterior mitral valve leaflet; SLE, systemic lupus erythematosus; TVP, tricuspid valve prolapse.

as "severe" MS, a LA pressure of ~25 mmHg is required to maintain a normal cardiac output (CO). The elevated pulmonary venous and pulmonary arterial (PA) wedge pressures reduce pulmonary compliance, contributing to exertional dyspnea. The first bouts of dyspnea are usually precipitated by clinical events that increase the rate of blood flow across the mitral orifice, resulting in further elevation of the LA pressure (see below).

To assess the severity of obstruction hemodynamically, both the transvalvular pressure gradient and the flow rate must be measured (Chap. 223). The latter depends not only on the CO but on the heart rate as well. An increase in heart rate shortens diastole proportionately more than systole and diminishes the time available for flow across the mitral valve. Therefore, at any given level of CO, tachycardia including that associated with AF augments the transvalvular pressure gradient and elevates further the LA pressure. Similar considerations apply to the pathophysiology of tricuspid stenosis.

The LV diastolic pressure and ejection fraction (EF) are normal in isolated MS. In MS and sinus rhythm, the elevated LA and PA wedge pressures exhibit a prominent atrial contraction (*a* wave) and a gradual pressure decline after mitral valve opening (*y* descent) (see Fig. 223-2). In severe MS and whenever pulmonary vascular resistance is significantly increased, the pulmonary arterial pressure (PAP) is elevated at rest and rises further during exercise, often causing secondary elevations of right ventricular (RV) end-diastolic pressure and volume.

Cardiac Output In patients with moderate MS (mitral valve orifice 1.0 cm^2–1.5 cm^2), the CO is normal or almost so at rest but rises subnormally during exertion. In patients with severe MS (valve area <1.0 cm^2), particularly those in whom pulmonary vascular resistance is markedly elevated, the CO is subnormal at rest and may fail to rise or may even decline during activity.

Pulmonary Hypertension The clinical and hemodynamic features of MS are influenced importantly by the level of the PAP. Pulmonary hypertension results from: (1) passive backward transmission of the elevated LA pressure; (2) pulmonary arteriolar constriction, which presumably is triggered by LA and pulmonary venous hypertension (reactive pulmonary hypertension); (3) interstitial edema in the walls of the small pulmonary vessels; and (4) organic obliterative changes in the pulmonary vascular bed. Severe pulmonary hypertension results in RV enlargement, secondary tricuspid regurgitation (TR) and pulmonic regurgitation (PR), as well as right-sided heart failure.

SYMPTOMS

In temperate climates, the latent period between the initial attack of rheumatic carditis (in the increasingly rare circumstances in which a history of one can be elicited) and the development of symptoms due to MS is generally about two decades; most patients begin to experience disability in the fourth decade of life. Studies carried out before the development of mitral valvotomy revealed that once a patient with MS became seriously symptomatic, the disease progressed continuously to death within 2–5 years.

In patients whose mitral orifices are large enough to accommodate a normal blood flow with only mild elevations of LA pressure, marked elevations of this pressure leading to dyspnea and cough may be precipitated by sudden changes in the heart rate, volume status, or CO, as for example with severe exertion, excitement, fever, severe anemia, paroxysmal AF and other tachycardias, sexual intercourse, pregnancy, and thyrotoxicosis. As MS progresses, lesser stresses precipitate dyspnea, and the patient becomes limited in daily activities, and orthopnea and paroxysmal nocturnal dyspnea develop. The development of permanent AF often marks a turning point in the patient's course and is generally associated with acceleration of the rate at which symptoms progress.

Hemoptysis (Chap. 34) results from rupture of pulmonary-bronchial venous connections secondary to pulmonary venous hypertension. It occurs most frequently in patients who have elevated LA pressures without markedly elevated pulmonary vascular resistances and is almost never fatal. *Recurrent pulmonary emboli* (Chap. 256), sometimes with infarction, are an important cause of morbidity and mortality late in the course of MS. *Pulmonary infections*, i.e., bronchitis, bronchopneumonia, and lobar pneumonia, commonly complicate untreated MS, especially during the winter months. *Infective endocarditis* (Chap. 118) is rare in isolated MS.

Pulmonary Changes In addition to the aforementioned changes in the pulmonary vascular bed, fibrous thickening of the walls of the alveoli and pulmonary capillaries occurs commonly in MS. The vital capacity, total lung capacity, maximal breathing capacity, and oxygen uptake per unit of ventilation are reduced (Chap. 246). Pulmonary compliance falls further as pulmonary capillary pressure rises during exercise.

Thrombi and Emboli *Thrombi* may form in the left atria, particularly in the enlarged atrial appendages of patients with MS. Systemic embolization, the incidence of which is 10–20%, occurs more frequently in patients with AF, in older patients, and in those with a reduced CO. However, systemic embolization may be the presenting feature in otherwise asymptomatic patients with only mild MS.

PHYSICAL FINDINGS

(See also Chaps. e8 and 220)

Inspection and Palpation In patients with severe MS, there may be a malar flush with pinched and blue facies. In patients with sinus rhythm and severe pulmonary hypertension or associated tricuspid stenosis (TS), the jugular venous pulse reveals prominent *a* waves due to vigorous right atrial systole. The systemic arterial pressure is usually normal or slightly low. An RV tap along the left sternal border signifies an enlarged RV. A diastolic thrill may be present at the cardiac apex, with the patient in the left lateral recumbent position.

Auscultation The first heart sound (S_1) is usually accentuated and slightly delayed. The pulmonic component of the second heart sound (P_2) also is often accentuated, and the two components of the second heart sound (S_2) are closely split. The opening snap (OS) of the mitral valve is most readily audible in expiration at, or just medial to the cardiac apex. This sound generally follows the sound of aortic valve closure (A_2) by 0.05–0.12 s. The time interval between A_2 and OS varies inversely with the severity of the MS. The OS is followed by a low-pitched, rumbling, diastolic murmur, heard best at the apex with the patient in the left lateral recumbent position (see Fig. 220-4*B*). It is accentuated by mild exercise (e.g., a few rapid sit-ups) carried out just before auscultation. In general, the duration of this murmur correlates with the severity of the stenosis in patients with preserved CO. In patients with sinus rhythm, the murmur often reappears or becomes louder during atrial systole (presystolic accentuation). Soft grade I or II/VI systolic murmurs are commonly heard at the apex or along the left sternal border in patients with pure MS and do not necessarily signify the presence of MR. Hepatomegaly, ankle edema, ascites, and pleural effusion, particularly in the right pleural cavity, may occur in patients with MS and RV failure.

Associated Lesions With severe pulmonary hypertension, a pansystolic murmur produced by functional TR may be audible along the left sternal border. This murmur is usually louder during inspiration and diminishes during forced expiration (Carvallo's sign). When the CO is markedly reduced in MS, the typical auscultatory findings, including the diastolic rumbling murmur, may not be detectable (silent MS), but they may reappear as compensation is restored. The *Graham Steell murmur* of PR, a high-pitched, diastolic, decrescendo blowing murmur along the left sternal border, results from dilatation of the pulmonary valve ring and occurs in patients with mitral valve disease and severe pulmonary hypertension. This murmur may be indistinguishable from the more common murmur produced by aortic regurgitation (AR), though it may increase in intensity with inspiration and is accompanied by a loud P2.

LABORATORY EXAMINATION

ECG In MS and sinus rhythm, the P wave usually suggests LA enlargement (see Fig. 221-8). It may become tall and peaked in lead II and upright in lead V_1 when severe pulmonary hypertension or TS complicates MS and right atrial (RA) enlargement occurs. The QRS complex is usually normal. However, with severe pulmonary hypertension, right axis deviation and RV hypertrophy are often present.

Echocardiogram (See also Chap. 222) Transthoracic two-dimensional echocardiography (TTE) with color flow Doppler imaging provides critical information, including an estimate of the transvalvular peak and mean gradients and of mitral orifice size, the presence and severity of accompanying MR, the extent of restriction of valve leaflets and their thickness, the degree of distortion of the subvalvular apparatus, and the anatomic suitability for percutaneous mitral balloon valvotomy (PMBV; see below). In addition, TTE provides an assessment of the size of the cardiac chambers, an estimation of LV function, an estimation of the pulmonary artery pressure (PAP), and an indication of the presence and severity of associated valvular lesions. Transesophageal echocardiography (TEE) provides superior images and should be employed when TTE is inadequate for guiding therapy. TEE is especially indicated to exclude the presence of left atrial thrombi prior to PMBV.

Chest X-ray The earliest changes are straightening of the upper left border of the cardiac silhouette, prominence of the main pulmonary arteries, dilatation of the upper lobe pulmonary veins, and posterior displacement of the esophagus by an enlarged LA. Kerley B lines are fine, dense, opaque, horizontal lines that are most prominent in the lower and mid-lung fields and that result from distention of interlobular septae and lymphatics with edema when the resting mean LA pressure exceeds approximately 20 mmHg.

DIFFERENTIAL DIAGNOSIS

Like MS, significant MR may also be associated with a prominent diastolic murmur at the apex due to increased flow, but in MR this diastolic murmur commences slightly later than in patients with MS, and there is often clear-cut evidence of LV enlargement. An apical pansystolic murmur of at least grade III/VI intensity as well as an S_3 suggests significant associated MR. Similarly, the apical mid-diastolic murmur associated with severe AR (*Austin Flint murmur*) may be mistaken for MS but can be differentiated from it because it is not intensified in presystole. TS, which occurs rarely in the absence of MS, may mask many of the clinical features of MS or be clinically silent.

Atrial septal defect (Chap. 229) may be mistaken for MS; in both conditions there is often clinical, ECG, and chest x-ray evidence of RV enlargement and accentuation of pulmonary vascularity. However, the absence of LA enlargement and of Kerley B lines and the demonstration of fixed splitting of S_2 all favor atrial septal defect over MS.

Left atrial myxoma (Chap. 233) may obstruct LA emptying, causing dyspnea, a diastolic murmur, and hemodynamic changes resembling those of MS. However, patients with an LA myxoma often have features suggestive of a systemic disease, such as weight loss, fever, anemia, systemic emboli, and elevated serum IgG and interleukin 6 (IL-6) concentrations. The auscultatory findings may change markedly with body position. The diagnosis can be established by the demonstration of a characteristic echo-producing mass in the LA with TTE.

CARDIAC CATHETERIZATION

Left and right heart catheterization is useful when there is a discrepancy between the clinical and TTE findings that cannot be resolved with either TEE or cardiac magnetic resonance (CMR) imaging. The growing experience with CMR for the assessment of patients with valvular heart disease may decrease the need for invasive catheterization. Catheterization is helpful in assessing associated lesions such as aortic stenosis (AS) and AR. Catheterization and coronary arteriography are not usually necessary to aid in the decision about surgery in younger patients, with typical findings of severe obstruction on clinical examination and TTE. In males over 45 years of age, females over 55 years of age, and younger patients with coronary risk factors, especially those with positive noninvasive stress tests for myocardial ischemia, coronary angiography is advisable preoperatively to detect patients with critical coronary obstructions that should be bypassed at the time of

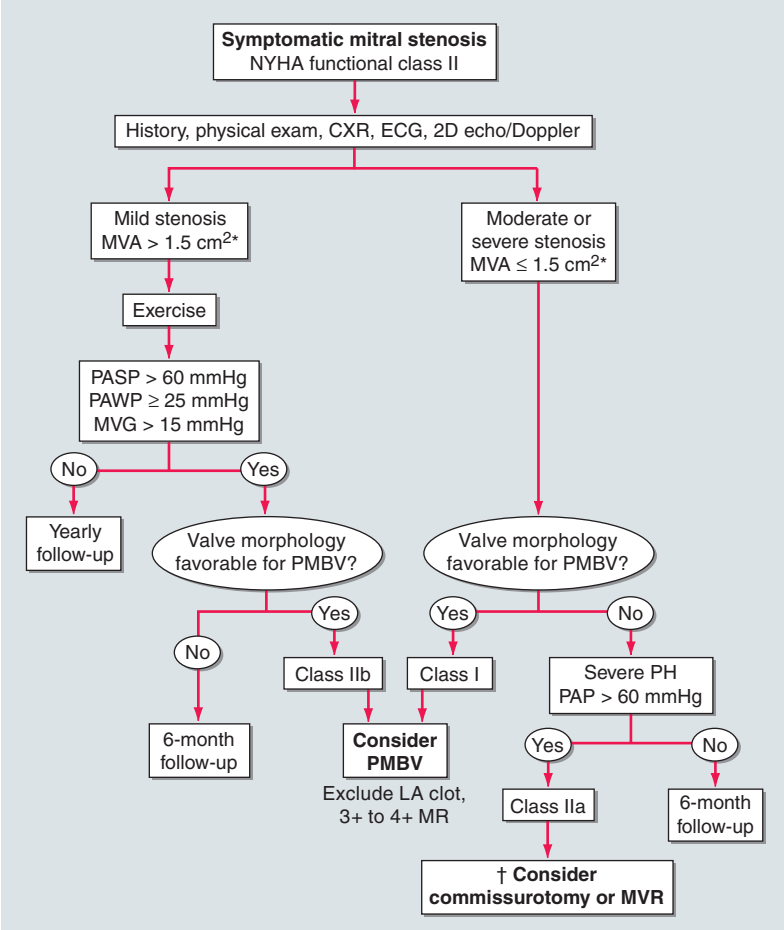

FIGURE 230-1 Management strategy for patients with mitral stenosis (MS) and mild symptoms. †There is controversy as to whether patients with severe MS (MVA <1.0 cm^2) and severe pulmonary hypertension(PH) (PASP >60 mmHg) should undergo percutaneous mitral balloon valvotomy (PMBV) or mitral valve replacement (MVR) to prevent right ventricular failure. CXR, chest x-ray; ECG, electrocardiogram; echo, echocardiography; LA, left atrial; MR, mitral regurgitation; MVA, mitral valve area; MVG, mean mitral valve pressure gradient; NYHA, New York Heart Association; PASP, pulmonary artery systolic pressure; PAWP, pulmonary artery wedge pressure; 2D, 2-dimensional. *(From Bonow et al.)*

operation. Computed tomographic angiography (CTA) (Chap. 222) is now used in some centers to screen preoperatively for the presence of coronary artery disease (CAD) in patients with valvular heart disease. Catheterization and left ventriculography are also indicated in most patients who have undergone PMBV or previous mitral valve surgery and who have redeveloped serious symptoms, if questions remain after both TTE and TEE.

℞ MITRAL STENOSIS

(Fig. 230-1)

Penicillin prophylaxis of Group A β-hemolytic streptococcal infections (Chap. 315) to prevent rheumatic fever is important for at-risk patients with MS **(Table 230-2)**. Recommendations for infective endocarditis prophylaxis have recently changed. In symptomatic patients, some improvement usually occurs with restriction of sodium intake and maintenance doses of oral diuretics. Digitalis glycosides usually do not benefit patients with MS and sinus rhythm, but they are helpful in slowing the ventricular rate of patients with AF. Beta blockers and nondihydropyridine calcium channel blockers (e.g., verapamil or diltiazem) are also useful in this regard. Warfarin to an international normalized ration (INR) of 2–3 should be administered indefinitely to patients with MS who have AF or a history of thromboembolism. The routine use of warfarin in patients in sinus rhythm with LA enlargement (maximal dimension >5.5 cm) with or without spontaneous echo contrast is more controversial.

If AF is of relatively recent onset in a patient whose MS is not severe enough to warrant PMBV or surgical commissurotomy, reversion to sinus rhythm pharmacologically or by means of electrical countershock is indicated. Usually, cardioversion should be undertaken after the patient has had at least 3 consecutive weeks of anticoagulant treatment to a therapeutic INR. If cardioversion is indicated more urgently, then intravenous heparin should be provided and a TEE performed to exclude the presence of left atrial thrombus before the procedure. Conversion to sinus rhythm is rarely successful or sustained in patients with severe MS, particularly those in whom the LA is especially enlarged or in whom AF has been present for more than 1 year.

MITRAL VALVOTOMY Unless there is a contraindication, mitral valvotomy is indicated in symptomatic [New York Heart Association (NYHA) Functional Class II–IV] patients with isolated MS whose effective orifice (valve area) is < ~1.0 cm^2/m^2 body surface area, or <1.5 cm^2 in normal-sized adults. Mitral valvotomy can be carried out by two techniques: PMBV and surgical valvotomy. In PMBV **(Figs. 230-2** and **230-3)**, a catheter is directed into the LA after transseptal puncture, and a single balloon is directed across the valve and inflated in the valvular orifice. Ideal patients have relatively pliable leaflets with little or no commissural calcium. In addition, the subvalvular structures should not be significantly scarred or thickened and there should be no left atrial thombus. The short- and long-term results of this procedure in appropriate patients are similar to those of surgical valvotomy, but with less morbidity and a lower periprocedural mortality rate. Event-free survival in younger (<45 years) patients with pliable valves is excellent, with rates as high as 80–90% over 3–7 years. Therefore, PMBV has become the procedure of choice for such patients when it can be performed by a skilled operator in a high-volume center.

Transthoracic echocardiography is helpful in identifying patients for the percutaneous procedure, and TEE is performed routinely to exclude left atrial thrombus. An "echo score" has been developed to help guide decision-making. The score accounts for the degree of leaflet thickening, calcification, and mobility, and for the extent of subvalvular thickening. A lower score predicts a higher likelihood of successful PMBV.

In patients in whom PMBV is not possible or unsuccessful, or in many patients with restenosis, an "open" valvotomy using cardiopulmonary bypass is necessary. In addition to

TABLE 230-2 MEDICAL THERAPY OF VALVULAR HEART DISEASE

Lesion	Symptom Control	Natural History
Mitral stenosis	Beta blockers, nondihydropyridine calcium channel blockers, or digoxin for rate control of AF; cardioversion for new-onset AF and HF; diuretics for HF	Warfarin for AF or thromboembolism; PCN for RF prophylaxis
Mitral regurgitation	Diuretics for HF Vasodilators for acute MR	Warfarin for AF or thromboembolism Vasodilators for HTN
Aortic stenosis	Diuretics for HF	No proven therapy
Aortic regurgitation	Diuretics and vasodilators for HF	Vasodilators for HTN

Note: Antibiotic prophylaxis is recommended according to current American Heart Association guidelines. For patients with these forms of valvular heart disease, prophylaxis is indicated for a prior history of endocarditis. HF is an indication for surgical or percutaneous treatment, and the recommendations here pertain to short-term therapy prior to definitive correction of the valve lesion. For patients whose comorbidities prohibit surgery, the medical therapies listed can be continued according to available guidelines for the management of HF. See text.

Abbreviations: AF, atrial fibrillation; HF, heart failure; HTN, systemic hypertension; PCN, penicillin; RF, rheumatic fever.

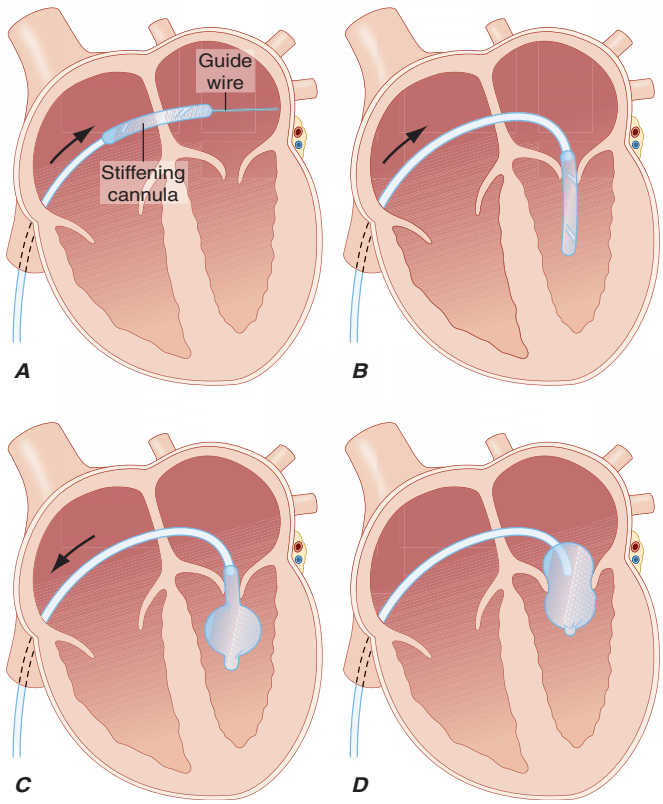

FIGURE 230-2 Inoue balloon technique for mitral balloon valvotomy. ***A.*** After transseptal puncture, the deflated balloon catheter is advanced across the inter-atrial septum, then across the mitral valve and into the left ventricle. ***B.*** The balloon is then inflated stepwise within the mitral orifice.

opening the valve commissures, it is important to loosen any subvalvular fusion of papillary muscles and chordae tendineae and to remove large deposits of calcium, thereby improving valvular function, as well as to remove atrial thrombi. The perioperative mortality rate is ~2%.

Successful valvotomy is defined by a 50% reduction in the mean mitral valve gradient and a doubling of the mitral valve area. Successful valvotomy, whether balloon or surgical, usually results in striking symptomatic and hemodynamic improvement and prolongs survival. However, there is no evidence that the procedure improves the prognosis of patients with

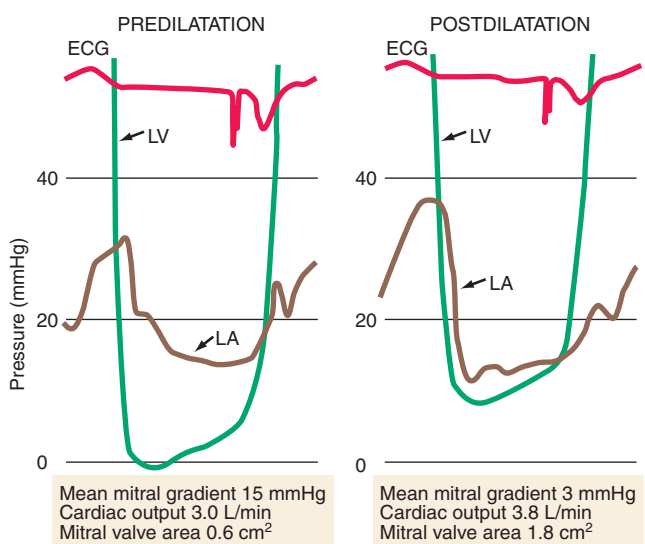

FIGURE 230-3 Simultaneous left atrial (LA) and left ventricular (LV) pressure before and after percutaneous mitral balloon valvuloplasty (PMBV) in a patient with severe mitral stenosis. *(Courtesy of Raymond G. McKay, MD; with permission.)*

TABLE 230-3 MORTALITY RATES AFTER VALVE SURGERY[a]

Operation	Number	Operative Mortality (%)
AVR (isolated)	12,501	2.8
MVR (isolated)	3788	5.3
AVR + CAB	12,748	5.2
MVR + CAB	2683	10.3
AVR + MVR	1018	8.8
MVP	3982	1.0
MVP + CAB	4293	7.0
TV surgery	4358	9.6
PV surgery	432	5.2

[a]Data are for calendar year 2004, in which 594 sites reported a total of 232,050 procedures. Data are available from the Society of Thoracic Surgeons at *http://www.sts.org/sections/stsnationaldatabase/publications/executive/article.html.*

Abbreviations: AVR, aortic valve replacement; CAB, coronary artery bypass; MVR, mitral valve replacement; MVP, mitral valve repair; TV surgery, tricuspid valve repair and replacement; PV surgery, pulmonic valve repair and replacement.

slight or no functional impairment. Therefore, unless recurrent systemic embolization or severe pulmonary hypertension has occurred (PA systolic pressures >50 mmHg at rest or >60 mmHg with exercise), valvotomy is *not* recommended for patients who are entirely asymptomatic and/or who have mild stenosis (mitral valve area >1/5 cm^2). When there is little symptomatic improvement after valvotomy, it is likely that the procedure was ineffective, that it induced MR, or that associated valvular or myocardial disease was present. About half of all patients undergoing surgical mitral valvotomy require reoperation by 10 years. In the pregnant patient with MS, valvotomy should be carried out if pulmonary congestion occurs despite intensive medical treatment. PMBV is the preferred strategy in this setting and is performed with TEE and no or minimal x-ray exposure.

Mitral valve replacement (MVR) is necessary in patients with MS and significant associated MR, those in whom the valve has been severely distorted by previous transcatheter or operative manipulation, or those in whom the surgeon does not find it possible to improve valve function significantly. MVR is now routinely performed with preservation of the chordal attachments to optimize LV functional recovery. Perioperative mortality rates with MVR vary with age, LV function, the presence of CAD, and associated comorbidities. They average 5% overall but are lower in young patients and may be twice as high in older patients with comorbidities **(Table 230-3)**. Since there are also long-term complications of valve replacement (p. 1480), patients in whom preoperative evaluation suggests the possibility that MVR may be required should be operated on only if they have severe MS—i.e., an orifice area ≤1 cm^2—and are in NYHA Class III, i.e., symptomatic with ordinary activity despite optimal medical therapy. The overall 10-year survival of surgical survivors is ~70%. Long-term prognosis is worse in older patients and those with marked disability and marked depression of the CO preoperatively. Pulmonary hypertension and RV dysfunction are additional risk factors for poor outcome.

MITRAL REGURGITATION

ETIOLOGY

MR may result from an abnormality or disease process that affects any one or more of the five functional components of the mitral valve apparatus (leaflets, annulus, chordae tendineae, papillary muscles, and subjacent myocardium) (Table 230-1). Acute MR can occur in the setting of acute myocardial infarction (MI) with papillary muscle rupture (Chap. 239), following blunt chest wall trauma, or during the course of infective endocarditis. With acute MI, the posteromedial papillary muscle is involved much more frequently than the anterolateral papillary muscle because of its singular blood supply. Transient, acute MR can occur during periods of active ischemia and bouts of angina pectoris. Rupture of chordae tendineae can result in "acute on chronic MR" in patients with myxomatous degeneration of the valve apparatus.

Chronic MR can result from rheumatic disease, mitral valve prolapse (MVP) (p. 1472), extensive mitral annular calcification, congenital valve defects, hypertrophic obstructive cardiomyopathy (HOCM), and dilated cardiomyopathy (Chap. 231). Rheumatic heart disease is the cause of chronic MR in only about one-third of cases and occurs

more frequently in males. The rheumatic process produces rigidity, deformity, and retraction of the valve cusps and commissural fusion, as well as shortening, contraction, and fusion of the chordae tendineae. The MR associated with both MVP and HOCM is usually dynamic in nature. MR in HOCM occurs as a consequence of anterior papillary muscle displacement and systolic anterior motion of the anterior mitral valve leaflet into the narrowed LV outflow tract. Annular calcification is especially prevalent among patients with advanced renal disease and is commonly observed in elderly women with hypertension and diabetes. MR may occur as a congenital anomaly (Chap. 229), most commonly as a defect of the endocardial cushions (atrioventricular cushion defects). A cleft anterior mitral valve leaflet accompanies primum atrial septal defect. Chronic MR is frequently secondary to ischemia and may occur as a consequence of ventricular remodeling, papillary muscle displacement, and leaflet tethering, or with fibrosis of a papillary muscle, in patients with healed myocardial infarction(s) and ischemic cardiomyopathy. Similar mechanisms of annular dilatation and ventricular remodeling contribute to the MR that occurs universally among patients with nonischemic forms of dilated cardiomyopathy once the left ventricular end-diastolic dimension reaches 6.0 cm.

Irrespective of cause, chronic severe MR is often progressive, since enlargement of the LA places tension on the posterior mitral leaflet, pulling it away from the mitral orifice and thereby aggravating the valvular dysfunction. Similarly, LV dilatation increases the regurgitation, which in turn enlarges the LA and LV further, causing chordal rupture and resulting in a vicious circle; hence the aphorism "mitral regurgitation begets mitral regurgitation."

PATHOPHYSIOLOGY

The resistance to LV emptying (LV afterload) is reduced in patients with MR. As a consequence, the LV is decompressed into the LA during ejection, and with the reduction in LV size during systole, there is a rapid decline in LV tension. The initial compensation to MR is more complete LV emptying. However, LV volume increases progressively with time as the severity of the regurgitation increases and as LV contractile function deteriorates. This increase in LV volume is often accompanied by a reduced forward CO, though LV compliance is often increased and thus LV diastolic pressure does not elevate until late in the course. The regurgitant volume varies directly with the LV systolic pressure and the size of the regurgitant orifice; as mentioned above, the latter, in turn, is influenced profoundly by the extent of LV and mitral annular dilatation. Since ejection fraction (EF) rises in severe MR in the presence of normal LV function, even a modest reduction in this parameter (<60%) reflects significant dysfunction.

During early diastole, as the distended LA empties, there is a particularly rapid *y* descent in the absence of accompanying MS. A brief, early diastolic LA-LV pressure gradient [often generating a rapid filling sound (S_3) and mid-diastolic murmur masquerading as MS] may occur in patients with pure MR as a result of the very rapid flow of blood across a normal-sized mitral orifice.

Quantitative estimates of left ventricular ejection fraction (LVEF), CO, PA pressure, regurgitant volume, regurgitant fraction (RF), and the effective regurgitant orifice area can be obtained during a careful Doppler echocardiographic examination. These measurements can also be obtained with CMR. Left and right heart catheterization with contrast ventriculography is utilized less frequently. Severe MR is defined by a regurgitant volume ≥60 mL/beat, regurgitant fraction (RF) ≥50%, and effective regurgitant orifice area ≥0.40 cm^2.

LA Compliance In acute severe MR, the regurgitant volume is delivered into a normal-sized LA having normal or reduced compliance. As a result, LA pressures rise markedly for any increase in LA volume. The *v* wave in the LA pressure pulse is usually prominent (see Fig. 223-3), LA and pulmonary venous pressures are markedly elevated, and pulmonary edema is common. Because of the rapid rise in LA pressures during ventricular systole, the murmur of acute MR is early in timing and decrescendo in configuration, as a reflection of the progressive diminution in the LV-LA pressure gradient. LV systolic function in acute MR may be normal, hyperdynamic, or reduced, depending on the clinical context.

Patients with chronic severe MR, on the other hand, develop marked LA enlargement and *increased* LA compliance with little if any increase in LA and pulmonary venous pressures for any increase in LA volume. The LA *v* wave is relatively less prominent. The murmur of chronic MR is classically holosystolic in timing and plateau in configuration, as a reflection of the near-constant LV-LA pressure gradient. These patients usually complain of severe fatigue and exhaustion secondary to a low CO, while symptoms resulting from pulmonary congestion are less prominent initially; AF is almost invariably present once the LA dilates significantly.

Most common are patients whose clinical and hemodynamic features are intermediate between those in the two aforementioned groups.

SYMPTOMS

Patients with chronic mild-to-moderate isolated MR are usually asymptomatic. This form of LV volume overload is well tolerated. Fatigue, exertional dyspnea, and orthopnea are the most prominent complaints in patients with chronic severe MR. Palpitations are common and may signify the onset of AF. Right-sided heart failure, with painful hepatic congestion, ankle edema, distended neck veins, ascites, and secondary TR, occurs in patients with MR who have associated pulmonary vascular disease and marked pulmonary hypertension. On the other hand, acute pulmonary edema is common in patients with acute severe MR.

PHYSICAL FINDINGS

In patients with chronic severe MR, the arterial pressure is usually normal, though the arterial pulse may show a sharp upstroke. A systolic thrill is often palpable at the cardiac apex, the LV is hyperdynamic with a brisk systolic impulse and a palpable rapid-filling wave (S_3), and the apex beat is often displaced laterally.

In patients with acute severe MR, the arterial pressure may be reduced with a narrow pulse pressure, the jugular venous pressure and wave forms may be normal or increased and exaggerated, the apical impulse is not displaced, and signs of pulmonary congestion are prominent.

Auscultation The S_1 is generally absent, soft, or buried in the holosystolic murmur of chronic MR. In patients with severe MR, the aortic valve may close prematurely, resulting in wide but physiologic splitting of S_2. A low-pitched S_3 occurring 0.12–0.17 s after the aortic valve closure sound, i.e., at the completion of the rapid-filling phase of the LV, is believed to be caused by the sudden tensing of the papillary muscles, chordae tendineae, and valve leaflets. It may be followed by a short, rumbling, mid-diastolic murmur, even in the absence of MS. A fourth heart sound is often audible in patients with *acute* severe MR who are in sinus rhythm. A presystolic murmur is not ordinarily heard with isolated MR.

A systolic murmur of at least grade III/VI intensity is the most characteristic auscultatory finding in chronic severe MR. It is usually holosystolic (see Fig. 220-4), but as previously noted it is decrescendo and ceases in mid- to late systole in patients with acute severe MR. The systolic murmur of chronic MR is usually most prominent at the apex and radiates to the axilla. However, in patients with ruptured chordae tendineae or primary involvement of the posterior mitral leaflet with prolapse or flail, the regurgitant jet is eccentric, directed anteriorly, and strikes the LA wall adjacent to the aortic root. In this situation, the systolic murmur is transmitted to the base of the heart and therefore may be confused with the murmur of AS. In patients with ruptured chordae tendineae, the systolic murmur may have a cooing or "sea gull" quality, while a flail leaflet may cause a murmur with a musical quality. The systolic murmur of chronic MR not due to MVP is intensified by isometric exercise (handgrip) but is reduced during the strain phase of the Valsalva maneuver.

LABORATORY EXAMINATION

ECG In patients with sinus rhythm, there is evidence of LA enlargement, but RA enlargement also may be present when pulmonary hypertension is severe. Chronic severe MR is generally associated with AF. In many patients there is no clear-cut ECG evidence of enlargement of either ventricle. In others, the signs of LV hypertrophy are present.

Echocardiogram TTE with Doppler imaging is indicated to assess the mechanism of the MR and its hemodynamic severity. LV function can be assessed from LV end-diastolic and end-systolic volumes and EF. Observations can be made regarding leaflet structure and function, chordal integrity, LA and LV size, annular calcification, and regional and global LV systolic function. Doppler imaging should demonstrate the width or area of the color flow MR jet within the LA, the intensity of the continuous wave Doppler signal, the pulmonary venous flow contour, the early peak mitral inflow velocity, and the quantitative measures of regurgitant volume, RF, and effective regurgitant orifice area. In addition, the PA pressures can be estimated from the TR jet velocity. TTE is also indicated to follow the course of patients with chronic MR and to provide rapid assessment for any clinical change. The echocardiogram in patients with MVP is described in the next section. TEE provides greater detail than TTE (see Fig. 222-3).

Chest X-ray The LA and LV are the dominant chambers in chronic MR; late in the course of the disease, the former may be massively enlarged and forms the right border of the cardiac silhouette. Pulmonary venous congestion, interstitial edema, and Kerley B lines are sometimes noted. Marked calcification of the mitral leaflets occurs commonly in patients with longstanding combined MR and MS. Calcification of the mitral annulus may be visualized, particularly on the lateral view of the chest. Patients with acute severe MR may have asymmetric pulmonary edema if the regurgitant jet is directed predominantly to the orifice of an upper lobe pulmonary vein.

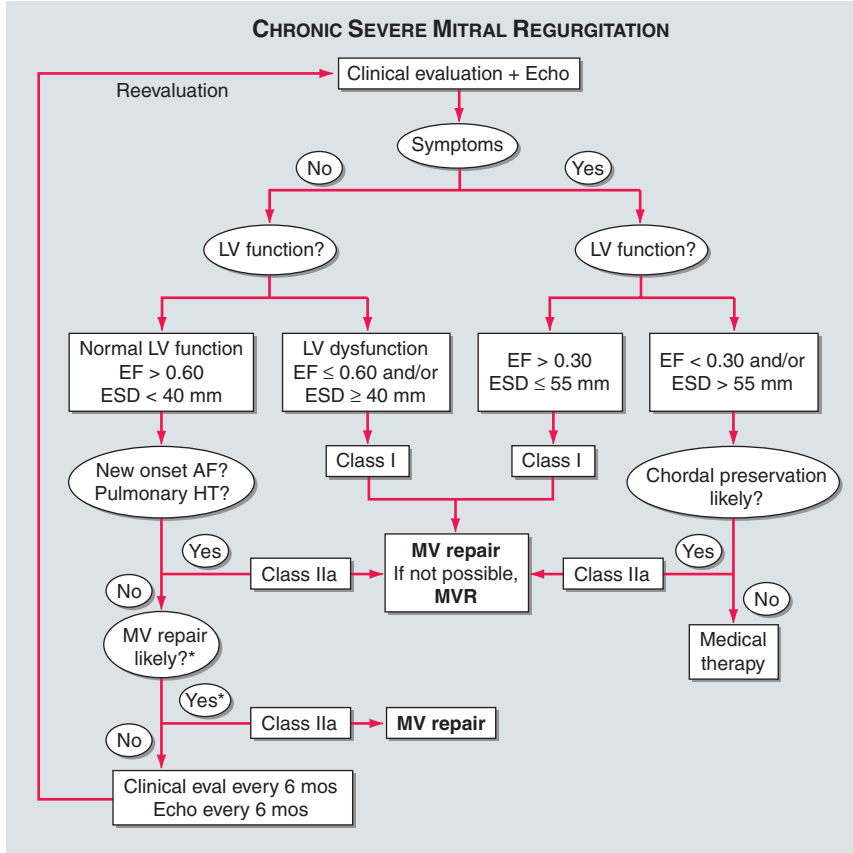

FIGURE 230-4 Management strategy for patients with chronic severe mitral regurgitation. *Mitral valve (MV) repair may be performed in asymptomatic patients with normal left ventricular (LV) function if performed by an experienced surgical team and if the likelihood of successful MV repair is >90%. MITRAL REGURGITATION

(Fig. 230-4)

MEDICAL (Table 230-2) The management of chronic severe MR depends to some degree on its cause. Warfarin should be provided once AF intervenes with a target INR of 2–3. Cardioversion should be considered depending on the clinical context and left atrial size. In contrast to the acute setting, there are no large, long-term prospective studies to substantiate the use of vasodilators for the treatment of chronic, isolated severe MR *in the absence of systemic hypertension*. The severity of MR in the setting of an ischemic or nonischemic dilated cardiomyopathy may diminish with aggressive, evidence-based treatment of heart failure, including the use of diuretics, beta blockers, ACE inhibitors, and digitalis. Asymptomatic patients with severe MR in sinus rhythm with normal LV size and systolic function should avoid isometric forms of exercise.

Patients with acute severe MR require urgent stabilization and preparation for surgery. Diuretics, intravenous vasodilators (particularly sodium nitroprusside), and even intraaortic balloon counterpulsation may be needed for patients with post-MI papillary muscle rupture or other forms of acute severe MR.

SURGICAL In the selection of patients with chronic severe MR for surgical treatment, the often slowly progressive nature of the condition must be balanced against the immediate and long-term risks associated with operation. These risks are significantly lower for primary valve repair than for valve replacement (Table 230-3). Repair usually consists of valve reconstruction utilizing a variety of valvuloplasty techniques and insertion of an annuloplasty ring. Repair spares the patient the long-term adverse consequences of valve replacement, i.e., thromboembolic and hemorrhagic complications in the case of mechanical prostheses and late valve failure necessitating repeat valve replacement in the case of bioprostheses (p. 1480). In addition, by preserving the integrity of the papillary muscles, subvalvular apparatus, and chordae tendineae, mitral repair and valvuloplasty maintain LV function to a relatively greater degree.

Surgery for chronic severe MR is indicated once symptoms occur, especially if valve repair is feasible (Fig. 230-4). Other indications for early consideration of mitral valve repair include recent-onset AF and pulmonary hypertension, defined as a PA pressure ≥50 mmHg at rest or ≥60 mmHg with exercise. Surgical treatment of chronic severe MR is indicated for asymptomatic patients when LV dysfunction is progressive, with LVEF declining below 60% and/or end-systolic cavity dimension on echocardiography rising above 40 mm. These aggressive recommendations for surgery are predicated on the outstanding results achieved with mitral valve repair, particularly when applied to patients with myxomatous disease. Indeed, primary valvuloplasty repair of patients younger than 75 years with normal LV systolic function and no CAD can now be performed by experienced surgeons with <1% perioperative mortality risk. Repair is feasible in up to 95% of patients with myxomatous disease. Long-term durability is excellent; the incidence of reoperative surgery for failed primary repair is ~1% per year for 10 years after surgery. For patients with AF, a left atrial Maze procedure or radiofrequency ablation of the pulmonary vein ostia is often performed to reduce the risk of recurrent AF.

In patients with significantly impaired LV function (EF <30%), the risk of surgery rises, the recovery of LV performance is incomplete, and the long-

term survival is reduced. However, conservative management has little to offer these patients, so operative treatment may be indicated, and the clinical and hemodynamic improvement that follows surgical treatment of patients with advanced disease is occasionally dramatic, especially when severe CAD is also present and bypass grafting can be performed. Though most patients who survive surgery appear to be greatly improved, some degree of myocardial dysfunction often persists, as indicated by a further fall in LVEF.

Patients with acute severe MR can often be stabilized temporarily with appropriate medical therapy, but surgical correction will be necessary, emergently in the case of papillary muscle rupture and within days to weeks in most other settings.

When surgical treatment is contemplated, left and right heart catheterization and left ventriculography *may* be helpful in confirming the presence of severe MR in patients in whom there is a discrepancy between the clinical and TTE findings that cannot be resolved with TEE or CMR. Coronary arteriography identifies patients who require concomitant coronary revascularization.

MITRAL VALVE PROLAPSE

MVP, also variously termed the *systolic click-murmur syndrome*, *Barlow's syndrome*, *floppy-valve syndrome*, and *billowing mitral leaflet syndrome*, is a relatively common but highly variable clinical syndrome resulting from diverse pathogenic mechanisms of the mitral valve apparatus. Among these are excessive or redundant mitral leaflet tissue, which is commonly associated with myxomatous degeneration and greatly increased concentrations of acid mucopolysaccharide.

In most patients with MVP, the cause is unknown, but in some it appears to be a genetically determined collagen disorder. A reduction in the production of type III collagen has been incriminated, and electron microscopy has revealed fragmentation of collagen fibrils.

MVP is a frequent finding in patients with heritable disorders of connective tissue, including Marfan syndrome (Chap. 357), osteogenesis imperfecta, and Ehler-Danlos syndrome.

MVP may be associated with thoracic skeletal deformities similar to but not as severe as those in Marfan syndrome, encompassing a high-arched palate and alterations of the chest and thoracic spine, including the so-called straight back syndrome.

In most patients with MVP, myxomatous degeneration is confined to the mitral (or, less commonly, the tricuspid or aortic) valves without other clinical or pathologic manifestations of disease. The posterior leaflet is usually more affected than the anterior, and the mitral valve annulus is often greatly dilated. In many patients, elongated, redundant, or ruptured chordae tendineae cause or contribute to the regurgitation.

MVP also may occur rarely as a sequel to acute rheumatic fever, in ischemic heart disease, and in various cardiomyopathies, as well as in 20% of patients with ostium secundum atrial septal defect.

MVP may lead to excessive stress on the papillary muscles, which in turn leads to dysfunction and ischemia of the papillary muscles and the subjacent ventricular myocardium. Rupture of chordae tendineae and progressive annular dilatation and calcification also contribute to valvular regurgitation, which then places more stress on the diseased mitral valve apparatus, thereby creating a vicious circle. The ECG changes (see below) and ventricular arrhythmias appear to result from regional ventricular dysfunction related to increased stress placed on the papillary muscles.

CLINICAL FEATURES

MVP is more common in females and occurs most commonly between the ages of 15 and 30 years; the clinical course is often benign. MVP may also be observed in older (>50 years) patients, often males, in whom MR is often more severe and requires surgical treatment. There is an increased familial incidence for some patients, suggesting an autosomal dominant form of inheritance. MVP encompasses a broad spectrum of severities, ranging from only a systolic click and murmur and mild prolapse of the posterior leaflet of the mitral valve to severe MR due to chordal rupture and massive prolapse of both leaflets. In many patients this condition progresses over years or decades. In others it worsens rapidly as a result of chordal rupture or endocarditis.

Most patients are asymptomatic and remain so for their entire lives. However, in North America MVP is now the most common cause of isolated severe MR requiring surgical treatment. Arrhythmias, most commonly ventricular premature contractions and paroxysmal supraventricular and ventricular tachycardia, as well as AF, have been reported and may cause palpitations, light-headedness, and syncope. Sudden death is a very rare complication and occurs most often in patients with severe MR and depressed LV systolic function. There may be an excess risk of sudden death among patients with a flail leaflet. Many patients have chest pain that is difficult to evaluate. It is often substernal, prolonged, and poorly related to exertion, and it rarely resembles angina pectoris. Transient cerebral ischemic attacks secondary to emboli from the mitral valve due to endothelial disruption have been reported, though a causal relationship has not been established. Infective endocarditis may occur in patients with MR and/or leaflet thickening.

Auscultation The most important finding is the mid- or late (nonejection) systolic click, which occurs 0.14 s or more after the S_1 and is thought to be generated by the sudden tensing of slack, elongated chordae tendineae or by the prolapsing mitral leaflet when it reaches its maximum excursion. Systolic clicks may be multiple and may be followed by a high-pitched, late systolic crescendo-decrescendo murmur, which occasionally is "whooping" or "honking" and is heard best at the apex. The click and murmur occur earlier with standing, during the strain of the Valsalva maneuver, and with any intervention that decreases LV volume, exaggerating the propensity of mitral leaflet prolapse. Conversely, squatting and isometric exercises, which increase LV volume, diminish MVP, and the click-murmur complex is delayed, moves away from S1, and may even disappear. Some patients have a mid-systolic click without the murmur; others have the murmur without a click. Still others have both sounds at different times.

LABORATORY EXAMINATION

The ECG most commonly is normal but may show biphasic or inverted T waves in leads II, III, and aVF, and occasionally supraventricular or ventricular premature beats. *TTE* is particularly effective in identifying the abnormal position and prolapse of the mitral valve leaflets. A useful echocardiographic definition of MVP is systolic displacement (in the parasternal long axis view) of the mitral valve leaflets by at least 2 mm into the LA superior to the plane of the mitral annulus. Color flow and continuous wave Doppler imaging is helpful in revealing and evaluating associated MR. TEE is indicated when more accurate information is required and is performed routinely for intraoperative guidance for valve repair. Invasive left ventriculography is rarely necessary but can also show prolapse of the posterior and sometimes of both mitral valve leaflets.

Rx MITRAL VALVE PROLAPSE

Infective endocarditis prophylaxis is indicated only for patients with a prior history of endocarditis. Beta blockers sometimes relieve chest pain and control palpitations. If the patient is symptomatic from severe MR, mitral valve repair (or rarely, replacement) is indicated (Fig. 230-4). Antiplatelet agents such as aspirin should be given to patients with transient ischemic attacks, and if these are not effective, anticoagulants such as warfarin should be considered.

AORTIC STENOSIS

AS occurs in about one-fourth of all patients with chronic valvular heart disease; approximately 80% of adult patients with symptomatic valvular AS are male.

ETIOLOGY

(Table 230-1) AS in adults may be due to degenerative calcification of the aortic cusps. It may be congenital in origin or it may be secondary

to rheumatic inflammation. *Age-related degenerative calcific AS* (also known as senile or sclerocalcific AS) is now the most common cause of AS in adults in North America and Western Europe. About 30% of persons >65 years exhibit aortic valve sclerosis; many of these have a systolic murmur of AS but without obstruction, while 2% exhibit frank stenosis. Aortic sclerosis is defined echocardiographically as focal thickening or calcification of the valve cusps with a peak Doppler transaortic velocity of ≤2.5 m/s. Aortic sclerosis appears to be a marker for an increased risk of coronary heart disease events. On histologic examination these valves frequently exhibit changes similar to those seen with atherosclerosis and vascular inflammation. Interestingly, risk factors for atherosclerosis, such as age, male sex, smoking, diabetes mellitus, hypertension, chronic kidney disease, increased LDL, reduced HDL cholesterol, and elevated C-reactive protein are all risk factors for aortic valve calcification.

The *congenitally affected valve* may be stenotic at birth (Chap. 229) and may become progressively more fibrotic, calcified, and stenotic. In other cases the valve may be congenitally deformed, usually bicuspid [bicuspid aortic valve (BAV)], without serious narrowing of the aortic orifice during childhood; its abnormal architecture makes its leaflets susceptible to otherwise ordinary hemodynamic stresses, which ultimately lead to valvular thickening, calcification, increased rigidity, and narrowing of the aortic orifice.

Rheumatic disease of the aortic leaflets produces commissural fusion, sometimes resulting in a bicuspid-appearing valve. This condition in turn makes the leaflets more susceptible to trauma and ultimately leads to fibrosis, calcification, and further narrowing. By the time the obstruction to LV outflow causes serious clinical disability, the valve is usually a rigid calcified mass, and careful examination may make it difficult or even impossible to determine the etiology of the underlying process. Rheumatic AS is almost always associated with involvement of the mitral valve and with AR.

OTHER FORMS OF OBSTRUCTION TO LEFT VENTRICULAR OUTFLOW

Besides valvular AS, three other lesions may be responsible for obstruction to LV outflow: *hypertrophic obstructive cardiomyopathy* (Chap. 231), *discrete congenital subvalvular AS*, and *supravalvular AS* (Chap. 229). The causes of left ventricular outflow obstruction can be differentiated on the basis of the cardiac examination and Doppler echocardiographic findings.

PATHOPHYSIOLOGY

The obstruction to LV outflow produces a systolic pressure gradient between the LV and aorta. When severe obstruction is suddenly produced experimentally, the LV responds by dilatation and reduction of stroke volume. However, in some patients the obstruction may be present at birth and/or increase gradually over the course of many years, and LV output is maintained by the presence of concentric LV hypertrophy. Initially, this serves as an adaptive mechanism because it reduces toward normal the systolic stress developed by the myocardium, as predicted by the Laplace relation ($S = Pr/h$, where S = systolic wall stress, P = pressure, r = radius, and h = wall thickness). A large transaortic valvular pressure gradient may exist for many years without a reduction in CO or LV dilatation; ultimately, however, excessive hypertrophy becomes maladaptive, and LV function declines.

A mean systolic pressure gradient >40 mmHg with a normal CO or an effective aortic orifice area < ~1.0 cm^2 (or ~<0.6 cm^2/m^2 body surface area in a normal-sized adult)—i.e., less than approximately one-third of the normal orifice—is generally considered to represent severe obstruction to LV outflow (see Fig. 223-4). The elevated LV end-diastolic pressure observed in many patients with severe AS signifies the presence of LV dilatation and/or diminished compliance of the hypertrophied LV wall. Although the CO at rest is within normal limits in most patients with severe AS, it usually fails to rise normally during exercise. Loss of an appropriately timed, vigorous atrial contraction, as occurs in AF or atrioventricular dissociation, may cause rapid progression of symptoms. Late in the course, the CO and LV–aortic pressure gradient decline, and the mean LA, PA, and RV pressures rise.

The hypertrophied LV elevates myocardial oxygen requirements. In addition, even in the absence of obstructive CAD, there may be interference with coronary blood flow. This is because the pressure compressing the coronary arteries exceeds the coronary perfusion pressure, often causing ischemia (especially in the subendocardium), both in the presence and in the absence of coronary arterial narrowing.

SYMPTOMS

AS is rarely of clinical importance until the valve orifice has narrowed to approximately 1.0 cm^2. Even severe AS may exist for many years without producing any symptoms because of the ability of the hypertrophied LV to generate the elevated intraventricular pressures required for a normal stroke volume.

Most patients with pure or predominant AS have gradually increasing obstruction for years but do not become symptomatic until the sixth to eighth decades. Exertional dyspnea, angina pectoris, and syncope are the three cardinal symptoms. Often there is a history of insidious progression of fatigue and dyspnea associated with gradual curtailment of activities. *Dyspnea* results primarily from elevation of the pulmonary capillary pressure caused by elevations of LV diastolic pressures secondary to reduced left ventricular compliance. *Angina pectoris* usually develops somewhat later and reflects an imbalance between the augmented myocardial oxygen requirements and reduced oxygen availability; the former results from the increased myocardial mass and intraventricular pressure, while the latter may result from accompanying CAD, which is not uncommon in patients with AS, as well as from compression of the coronary vessels by the hypertrophied myocardium. Therefore, angina may occur in severe AS even without obstructive epicardial CAD. *Exertional syncope* may result from a decline in arterial pressure caused by vasodilatation in the exercising muscles and inadequate vasoconstriction in nonexercising muscles in the face of a fixed CO, or from a sudden fall in CO produced by an arrhythmia.

Since the CO at rest is usually well maintained until late in the course, marked fatigability, weakness, peripheral cyanosis, cachexia, and other clinical manifestations of a low CO are usually not prominent until this stage is reached. Orthopnea, paroxysmal nocturnal dyspnea, and pulmonary edema, i.e., symptoms of LV failure, also occur only in the advanced stages of the disease. Severe pulmonary hypertension leading to RV failure and systemic venous hypertension, hepatomegaly, AF, and TR are usually late findings in patients with isolated severe AS.

When AS and MS coexist, the reduction in CO induced by MS lowers the pressure gradient across the aortic valve and thereby masks many of the clinical findings produced by AS.

PHYSICAL FINDINGS

The rhythm is generally regular until late in the course; at other times, AF should suggest the possibility of associated mitral valve disease. The systemic arterial pressure is usually within normal limits. In the late stages, however, when stroke volume declines, the systolic pressure may fall and the pulse pressure narrow. The peripheral arterial pulse rises slowly to a delayed sustained peak (pulsus parvus et tardus; see Fig. 220-2). In the elderly, the stiffening of the arterial wall may mask this important physical sign. In many patients the *a* wave in the jugular venous pulse is accentuated. This results from the diminished distensibility of the RV cavity caused by the bulging, hypertrophied interventricular septum.

The LV impulse is usually displaced laterally. A double apical impulse may be recognized, particularly with the patient in the left lateral recumbent position. A systolic thrill is generally present at the base of the heart, in the suprasternal notch, and along the carotid arteries.

Auscultation An early systolic ejection sound is frequently audible in children and adolescents with congenital noncalcific valvular AS. This sound usually disappears when the valve becomes calcified and rigid. As AS increases in severity, LV systole may become prolonged so that the aortic valve closure sound no longer precedes the pulmonic valve closure sound, and the two components may become synchronous, or

aortic valve closure may even follow pulmonic valve closure, causing paradoxic splitting of S_2 (Chap. 220). The sound of aortic valve closure can be heard most frequently in patients with AS who have pliable valves, and calcification diminishes the intensity of this sound. Frequently, an S_4 is audible at the apex and reflects the presence of LV hypertrophy and an elevated LV end-diastolic pressure; an S_3 generally occurs late in the course, when the LV dilates.

The murmur of AS is characteristically an ejection (mid) systolic murmur that commences shortly after the S_1, increases in intensity to reach a peak toward the middle of ejection, and ends just before aortic valve closure (see Fig. 220-4). It is characteristically low-pitched, rough and rasping in character, and loudest at the base of the heart, most commonly in the second right intercostal space. It is transmitted upward along the carotid arteries. Occasionally it is transmitted downward and to the apex, where it may be confused with the systolic murmur of MR (Gallavardin effect). In almost all patients with severe obstruction and preserved CO, the murmur is at least grade III/VI. In patients with mild degrees of obstruction or in those with severe stenosis with heart failure in whom the stroke volume and therefore the transvalvular flow rate are reduced, the murmur may be relatively soft and brief.

LABORATORY EXAMINATION

ECG In most patients with severe AS there is LV hypertrophy (see Fig. 221-9). In advanced cases, ST-segment depression and T-wave inversion (LV "strain") in standard leads I and aVL and in the left precordial leads are evident. However, there is no close correlation between the ECG and the hemodynamic severity of obstruction, and the absence of ECG signs of LV hypertrophy does not exclude severe obstruction.

Echocardiogram The key findings are LV hypertrophy and, in patients with valvular calcification (i.e., most adult patients with symptomatic AS), multiple, bright, thick, echoes from the valve (see Fig. 222-2). Eccentricity of the aortic valve cusps is characteristic of congenitally bicuspid valves. TEE imaging usually displays the obstructed orifice extremely well, but it is not routinely required for adequate characterization. The valve gradient and aortic valve area can be estimated by Doppler measurement of the transaortic velocity. Severe AS is defined by a valve area <1.0 cm^2, whereas moderate AS is defined by a valve area of 1.0–1.5 cm^2 and mild AS by a valve area of 1.5–2.0 cm^2. LV dilatation and reduced systolic shortening reflect impairment of LV function.

Echocardiography is useful for identifying coexisting valvular abnormalities such as MS and AR, which sometimes accompany AS; for differentiating valvular AS from other forms of outflow obstruction; and for measurement of the aortic root. Aneurysmal enlargement (maximal dimension >4.5 cm) of the root or ascending aorta can occur in up to 20% of patients with bicuspid aortic valve disease, independent of the severity of the valve lesion. Dobutamine stress echocardiography is useful for the evaluation of patients with severe AS and severe LV systolic dysfunction (EF <0.35).

Chest X-Ray The chest x-ray may show no or little overall cardiac enlargement for many years. Hypertrophy without dilatation may produce some rounding of the cardiac apex in the frontal projection and slight backward displacement in the lateral view; severe AS is often associated with poststenotic dilatation of the ascending aorta. As noted above, however, aortic enlargement may be an independent process and mediated by the same type of structural changes that occur in patients with Marfan syndrome. Aortic calcification is usually readily apparent on fluoroscopic examination or by echocardiography; the absence of valvular calcification in an adult suggests that severe valvular AS is *not* present. In later stages of the disease, as the LV dilates there is increasing roentgenographic evidence of LV enlargement, pulmonary congestion, and enlargement of the LA, PA, and right side of the heart.

Catheterization Right and left heart catheterization for invasive assessment of AS is performed infrequently but can be useful when there is a discrepancy between the clinical and echocardiographic findings. Concerns have been raised that attempts to cross the aortic valve for measurement of left ventricular pressures are associated with a risk of cerebral embolization. Catheterization is also useful in three distinct categories of patients: (1) *patients with multivalvular disease*, in whom the role played by each valvular deformity should be defined to aid in the planning of definitive operative treatment; (2) *young, asymptomatic patients with noncalcific congenital AS*, to define with precision the severity of obstruction to LV outflow, since operation [which does not usually require aortic valve replacement (AVR)] or PABV may be indicated if severe AS is present, even in the absence of symptoms; balloon valvotomy may follow left heart catheterization immediately; and (3) *patients in whom it is suspected that the obstruction to LV outflow may not be at the aortic valve* but rather in the sub- or supravalvular regions.

Coronary angiography is indicated to detect or exclude CAD in patients >45 years old with severe AS who are being considered for operative treatment. The incidence of significant CAD for which bypass grafting is indicated at the time of AVR exceeds 50% among adult patients.

NATURAL HISTORY

Death in patients with severe AS occurs most commonly in the seventh and eighth decades. Based on data obtained at postmortem examination in patients before surgical treatment became widely available, the average time to death after the onset of various symptoms was as follows: angina pectoris, 3 years; syncope, 3 years; dyspnea, 2 years; congestive heart failure, 1.5–2 years. Moreover, in >80% of patients who died with AS, symptoms had existed for <4 years. Among adults dying with valvular AS, sudden death, which presumably resulted from an arrhythmia, occurred in 10–20%. However, most sudden deaths occurred in patients who had previously been symptomatic; thus, sudden death is very uncommon (<1% per year) in asymptomatic adult patients with severe AS. Obstructive calcific AS is a progressive disease, with an annual reduction in valve area averaging 0.1 cm^2/year and an annual increase in mean gradient averaging 7 mmHg/year.

Rx AORTIC STENOSIS

(Table 230-2, **Fig. 230-5**)

MEDICAL TREATMENT In patients with severe AS (<1.0 cm^2), strenuous physical activity should be avoided, even in the asymptomatic stage. Care must be taken to avoid dehydration and hypovolemia to protect against a significant reduction in CO. Medications used for the treatment of hypertension or CAD, including beta blockers and ACE inhibitors, are generally safe for asymptomatic patients with preserved left ventricular systolic function. Nitroglycerin is helpful in relieving angina pectoris. Retrospective studies have shown that patients with degenerative calcific AS who receive HMG-CoA reductase inhibitors ("statins") exhibit slower progression of leaflet calcification and aortic valve area reduction than those who do not. One prospective randomized clinical trial using high-dose atorvastatin failed to show a measurable benefit, although a more recent trial using rosuvastatin did show a beneficial effect. The role of statin medications may be more clearly defined with further study.

SURGICAL TREATMENT Asymptomatic patients with calcific AS and severe obstruction should be followed carefully for the development of symptoms and by serial echocardiograms for evidence of deteriorating LV function. Operation is indicated in patients with severe AS (valve area <1.0 cm^2 or 0.6 cm^2/m^2 body surface area) who are symptomatic, those who exhibit LV dysfunction (EF <50%), as well as those with an aneurysmal or expanding aortic root (maximal dimension >4.5 cm or annual increase in size >0.5 cm/year), even if they are asymptomatic. In patients without heart failure, the operative risk of AVR is approximately 3% (Table 230-3). It is prudent to postpone operation in patients with severe calcific AS who are truly asymptomatic and who exhibit normal LV function, i.e., EF >50%, since they may continue to do well for years. However, some advocate AVR in patients with severe valve calcification and rapid progression of obstruction. The risk of surgical mortality exceeds that of sudden death in asymptomatic patients. Exercise testing is em-

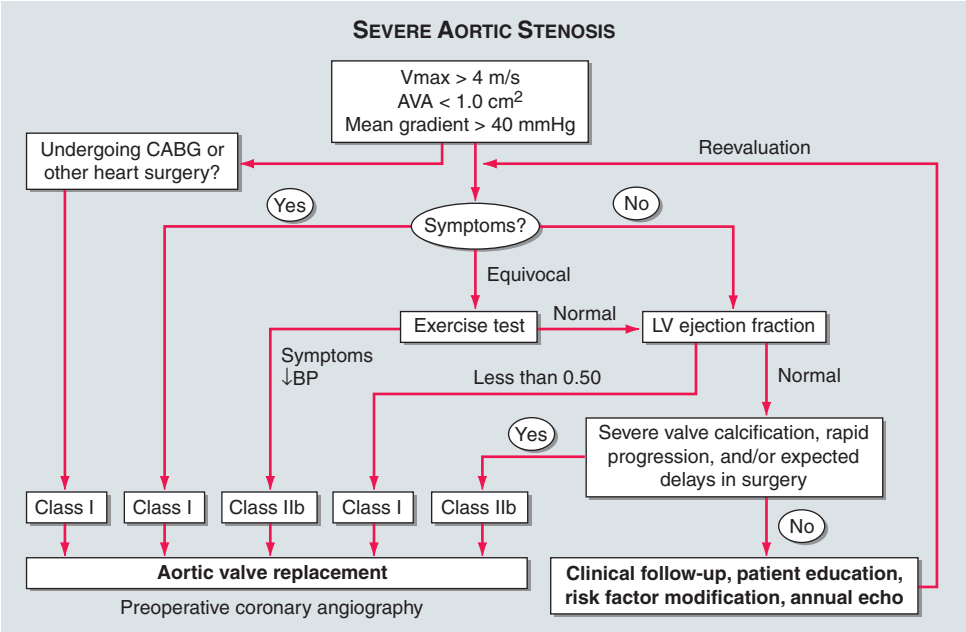

FIGURE 230-5 Management strategy for patients with severe aortic stenosis. Preoperative coronary angiography should be performed routinely as determined by age, symptoms, and coronary risk factors. Cardiac catheterization and angiography may also be helpful when there is discordance between clinical findings and echocardiography. AVA, aortic valve area; BP, blood pressure; CABG, coronary artery bypass graft surgery; echo, echocardiography; LV, left ventricle; Vmax, maximal velocity across aortic valve by Doppler echocardiography. *(From Bonow et al. Modified from CM Otto: J Am Coll Cardiol 47:2141, 2006.)*

ployed in many centers to assess objectively the functional capacity of asymptomatic patients for whom the history is ambiguous. As many as one-third of patients will show signs of functional impairment during exercise for which AVR should be considered. AVR is carried out in asymptomatic patients with severe or moderately severe stenosis who undergo coronary artery bypass grafting. AVR is also routinely performed in patients with moderate AS who are undergoing coronary bypass grafting or aortic root reconstruction.

Operation should, if possible, be carried out before frank LV failure develops; at this late stage, the aortic valve pressure gradient declines as the CO, stroke volume, and EF decline (low gradient, low output AS). In such patients the perioperative risk is high (15–20%), and evidence of myocardial disease may persist even when the operation is technically successful. Furthermore, long-term postoperative survival also correlates inversely with preoperative LV dysfunction. Nonetheless, in view of the even worse prognosis of such patients when they are treated medically, there is usually little choice but to advise surgical treatment, especially in patients in whom contractile reserve can be demonstrated by dobutamine echocardiography (defined by a ≥20% in stroke volume after dobutamine challenge). In patients in whom severe AS and CAD coexist, relief of the AS and revascularization of the myocardium by means of aortocoronary bypass grafting may result in striking clinical and hemodynamic improvement (Table 230-3).

Because many patients with calcific AS are elderly, particular attention must be directed to the adequacy of hepatic, renal, and pulmonary function before AVR is recommended. Age alone is not a contraindication to AVR for AS. The mortality rate depends to a substantial extent on the patient's preoperative clinical and hemodynamic state. The 10-year survival rate of patients with AVR is approximately 60%. Approximately 30% of bioprosthetic valves evidence primary valve failure in 10 years, requiring re-replacement, and an approximately equal percentage of patients with mechanical prostheses develop significant hemorrhagic complications as a consequence of treatment with anticoagulants (p. 1480).

PERCUTANEOUS BALLOON AORTIC VALVULOPLASTY This procedure is preferable to operation in children and young adults with congenital, noncalcific AS (Chap. 229). It is not commonly used in adults with severe calcific AS because of a very high restenosis rate and the risk of procedural complications, but on occasion it has been used successfully as a "bridge to operation" in patients with severe LV dysfunction and shock who are too ill to tolerate surgery.

AORTIC REGURGITATION

ETIOLOGY

(Table 230-1) AR may be caused by primary valve disease or by primary aortic root disease.

Primary Valve Disease In approximately two-thirds of patients with valvular AR, the disease is rheumatic in origin, resulting in thickening, deformity, and shortening of the individual aortic valve cusps, changes that prevent their proper opening during systole and closure during diastole. A rheumatic origin is much less common in patients with isolated AR who do not have associated mitral valve disease. Patients with congenital BAV disease may develop predominant AR. Congenital fenestrations of the aortic valve occasionally produce mild AR. Membranous subaortic stenosis often leads to thickening and scarring of the aortic valve leaflets with secondary AR. Prolapse of an aortic cusp, resulting in progressive chronic AR, occurs in approximately 15% of patients with ventricular septal defect (Chap. 229) but may also occur as an isolated phenomenon or as a consequence of myxomatous degeneration sometimes associated with mitral (p. 1472) and/or tricuspid valve involvement.

AR may result from infective endocarditis, which can develop on a valve previously affected by rheumatic disease, a congenitally deformed valve, or, rarely, on a normal aortic valve, and may lead to perforation or erosion of one or more leaflets. The aortic valve leaflets may become scarred and retracted during the course of syphilis or ankylosing spondylitis and contribute further to the AR that derives primarily from the associated root disease. Although traumatic rupture or avulsion of the aortic valve is an uncommon cause of acute AR, it does represent the most frequent serious lesion in patients surviving nonpenetrating cardiac injuries. The coexistence of hemodynamically significant AS with AR usually excludes all the rarer forms of AR because it occurs almost exclusively in patients with rheumatic or congenital AR. In patients with AR due to primary valvular disease, dilatation of the aortic annulus may occur secondarily and intensify the regurgitation.

Primary Aortic Root Disease AR may also be due entirely to marked aortic dilatation, i.e., aortic root disease, without primary involvement of the valve leaflets; widening of the aortic annulus and separation of the aortic leaflets are responsible for the AR (Chap. 242). Cystic medial degeneration of the ascending aorta, which may or may not be associated with other manifestations of Marfan syndrome; idiopathic dilatation of the aorta; annulo-aortic ectasia; osteogenesis imperfecta; and severe hypertension may all widen the aortic annulus and lead to progressive AR. Occasionally AR is caused by retrograde dissection of the aorta involving the aortic annulus. Syphilis and ankylosing spondylitis, both of which may affect aortic valves, may also be associated with cellular infiltration and scarring of the media of the thoracic aorta, leading to aortic dilatation, aneurysm formation, and severe regurgitation. In syphilis of the aorta (Chap. 162), now a very rare condition, the involvement of the intima may narrow the coronary ostia, which in turn may be responsible for myocardial ischemia.

PATHOPHYSIOLOGY

The total stroke volume ejected by the LV (i.e., the sum of the effective forward stroke volume and the volume of blood that regurgitates back

into the LV) is increased in patients with AR. In patients with wide-open (free) AR, the volume of regurgitant flow may equal the effective forward stroke volume. In contrast to MR, in which a fraction of the LV stroke volume is delivered into the low-pressure LA, in AR the entire LV stroke volume is ejected into a high-pressure zone, the aorta. An increase in the LV end-diastolic volume (increased preload) constitutes the major hemodynamic compensation for AR. The dilatation and eccentric hypertrophy of the LV allow this chamber to eject a larger stroke volume without requiring any increase in the relative shortening of each myofibril. Therefore, severe AR may occur with a normal effective forward stroke volume and a normal left ventricular EF [total (forward plus regurgitant) stroke volume/end-diastolic volume], together with an elevated LV end-diastolic pressure and volume. However, through the operation of Laplace's law, LV dilatation increases the LV systolic tension required to develop any given level of systolic pressure. Chronic AR is thus a state in which LV preload and afterload are both increased. Ultimately, these adaptive measures fail. As LV function deteriorates, the end-diastolic volume rises further and the forward stroke volume and EF decline. Deterioration of LV function often precedes the development of symptoms. Considerable thickening of the LV wall also occurs with chronic AR, and at autopsy the hearts of these patients may be among the largest encountered, sometimes weighing >1000 g.

The reverse pressure gradient from aorta to LV, which drives the AR flow, falls progressively during diastole (see Fig. 223-5), accounting for the decrescendo nature of the diastolic murmur. Equilibration between aortic and LV pressures may occur toward the end of diastole in patients with chronic severe AR, particularly when the heart rate is slow. In patients with acute severe AR, the LV is unprepared for the regurgitant volume load. LV compliance is normal or reduced, and LV diastolic pressures rise rapidly, occasionally to levels >40 mmHg. The LV pressure may exceed the LA pressure toward the end of diastole, and this reversed pressure gradient closes the mitral valve prematurely.

In patients with chronic severe AR, the effective forward CO usually is normal or only slightly reduced at rest, but often it fails to rise normally during exertion. Early signs of LV dysfunction include reduction in the EF. In advanced stages there may be considerable elevation of the LA, PA wedge, PA, and RV pressures and lowering of the forward CO at rest.

Myocardial ischemia may occur in patients with AR because myocardial oxygen requirements are elevated by LV dilatation, hypertrophy, and elevated LV systolic tension. However, a large fraction of coronary blood flow occurs during diastole, when arterial pressure is subnormal, thereby reducing coronary perfusion pressure. This combination of increased oxygen demand and reduced supply may cause myocardial ischemia, particularly of the subendocardium, even in the absence of concomitant CAD.

HISTORY

Approximately three-fourths of patients with pure or predominant valvular AR are males; females predominate among patients with primary valvular AR who have associated mitral valve disease. A history compatible with infective endocarditis may sometimes be elicited from patients with rheumatic or congenital involvement of the aortic valve, and the infection often precipitates or seriously aggravates preexisting symptoms.

In patients with *acute severe AR*, as may occur in infective endocarditis, aortic dissection, or trauma, the LV cannot dilate sufficiently to maintain stroke volume, and LV diastolic pressure rises rapidly with associated marked elevations of LA and PA wedge pressures. Pulmonary edema and/or cardiogenic shock may develop rapidly.

Chronic severe AR may have a long latent period, and patients may remain relatively asymptomatic for as long as 10–15 years. However, uncomfortable awareness of the heartbeat, especially on lying down, may be an early complaint. Sinus tachycardia, during exertion or with emotion, or premature ventricular contractions may produce particularly uncomfortable palpitations as well as head pounding. These complaints may persist for many years before the development of exertional dyspnea, usually the first symptom of diminished cardiac reserve. The dyspnea is followed by orthopnea, paroxysmal nocturnal dyspnea, and excessive diaphoresis. Anginal chest pain occurs frequently in patients with severe AR, even in younger patients, and it is not necessary to invoke the presence of CAD to explain this symptom in patients with severe AR. Anginal pain may develop at rest as well as during exertion. Nocturnal angina may be a particularly troublesome symptom, and it may be accompanied by marked diaphoresis. The anginal episodes can be prolonged and often do not respond satisfactorily to sublingual nitroglycerin. Systemic fluid accumulation, including congestive hepatomegaly and ankle edema, may develop late in the course of the disease.

PHYSICAL FINDINGS

In chronic severe AR, the jarring of the entire body and the bobbing motion of the head with each systole can be appreciated, and the abrupt distention and collapse of the larger arteries are easily visible. The examination should be directed toward the detection of conditions predisposing to AR, such as Marfan syndrome, ankylosing spondylitis, and ventricular septal defect.

Arterial Pulse A rapidly rising "water-hammer" pulse, which collapses suddenly as arterial pressure falls rapidly during late systole and diastole (Corrigan's pulse), and capillary pulsations, an alternate flushing and paling of the skin at the root of the nail while pressure is applied to the tip of the nail (Quincke's pulse), are characteristic of free AR. A booming "pistol-shot" sound can be heard over the femoral arteries (Traube's sign), and a to-and-fro murmur (Duroziez's sign) is audible if the femoral artery is lightly compressed with a stethoscope.

The arterial pulse pressure is widened, and there is an elevation of the systolic pressure, sometimes to as high as 300 mmHg, and a depression of the diastolic pressure. The measurement of arterial diastolic pressure with a sphygmomanometer may be complicated by the fact that systolic sounds are frequently heard with the cuff completely deflated. However, the level of cuff pressure at the time of muffling of the Korotkoff sounds (Phase IV) generally corresponds fairly closely to the true intraarterial diastolic pressure. As the disease progresses and the LV end-diastolic pressure rises, the arterial diastolic pressure may actually rise as well, since the aortic diastolic pressure cannot fall below the LV end-diastolic pressure. For the same reason, acute severe AR may also be accompanied by only a slight widening of the pulse pressure. Such patients are invariably tachycardic as the heart rate increases in an attempt to preserve the CO.

Palpation In patients with chronic severe AR, the LV impulse is heaving and displaced laterally and inferiorly. The systolic expansion and diastolic retraction of the apex are prominent. A diastolic thrill is often palpable along the left sternal border, and a prominent systolic thrill may be palpable in the suprasternal notch and transmitted upward along the carotid arteries. This systolic thrill and the accompanying murmur do not necessarily signify the coexistence of AS. In many patients with pure AR or with combined AS and AR, the carotid arterial pulse is bisferiens, i.e., with two systolic waves separated by a trough (see Fig. 220-2*D*).

Auscultation In patients with severe AR, the aortic valve closure sound (A_2) is usually absent. An S_3 and systolic ejection sound are frequently audible, and occasionally an S_4 also may be heard. The murmur of chronic AR is typically a high-pitched, blowing, decrescendo diastolic murmur, heard best in the third intercostal space along the left sternal border (see Fig. 220-4*B*). In patients with mild AR, this murmur is brief but, as the severity increases, generally becomes louder and longer, indeed holodiastolic. When the murmur is soft, it can be heard best with the diaphragm of the stethoscope and with the patient sitting up, leaning forward, and with the breath held in forced expiration. In patients in whom the AR is caused by primary valvular disease, the diastolic murmur is usually louder along the left than the right sternal border. However, when the murmur is heard best along the right sternal border, it suggests that the AR is caused by aneurysmal dilatation of the aortic root. "Cooing" or musical diastolic murmurs suggest eversion of an aortic cusp vibrating in the regurgitant stream.

A mid-systolic ejection murmur is frequently audible in isolated AR. It is generally heard best at the base of the heart and is transmitted along the carotid vessels. This murmur may be quite loud without signifying aortic obstruction. A third murmur frequently heard in patients with severe AR is the *Austin Flint murmur*, a soft, low-pitched, rumbling mid-diastolic murmur. It is probably produced by the diastolic displacement of the anterior leaflet of the mitral valve by the AR stream but does not appear to be associated with hemodynamically significant mitral obstruction. The auscultatory features of AR are intensified by strenuous handgrip, which augments systemic resistance.

In acute severe AR, the elevation of LV end-diastolic pressure may lead to early closure of the mitral valve, an associated mid-diastolic sound, a soft or absent S_1, a pulse pressure that is not particularly wide, and a soft, short diastolic murmur of AR.

LABORATORY EXAMINATION

ECG In patients with chronic severe AR, the ECG signs of LV hypertrophy become manifest (Chap. 221). In addition, these patients frequently exhibit ST-segment depression and T-wave inversion in leads I, aVL, V_5, and V_6 ("LV strain"). Left axis deviation and/or QRS prolongation denote diffuse myocardial disease, generally associated with patchy fibrosis, and usually signify a poor prognosis.

Echocardiogram The extent and velocity of wall motion are normal or even supernormal, until myocardial contractility declines. A rapid, high-frequency fluttering of the anterior mitral leaflet produced by the impact of the regurgitant jet is a characteristic finding. The echocardiogram is also useful in determining the cause of AR, by detecting dilatation of the aortic annulus and root or aortic dissection (see Fig. 222-3). Thickening and failure of coaptation of the leaflets also may be noted. Color flow Doppler echocardiographic imaging is very sensitive in the detection of AR, and Doppler echocardiography is helpful in assessing its severity. With severe AR, the central jet width exceeds 65% of the left ventricular outflow tract, the regurgitant volume is ≥60 ml/beat, the regurgitant fraction is ≥50%, and there is diastolic flow reversal in the proximal descending thoracic aorta. The continuous wave Doppler profile shows a rapid deceleration time in patients with acute severe AR, due to the rapid increase in LV diastolic pressure. Serial two-dimensional echocardiography is valuable in assessing LV performance and in detecting progressive myocardial dysfunction.

Chest X-ray In chronic severe AR, the apex is displaced downward and to the left in the frontal projection. In the left anterior oblique and lateral projections, the LV is displaced posteriorly and encroaches on the spine. When AR is caused by primary disease of the aortic root, aneurysmal dilatation of the aorta may be noted, and the aorta may fill the retrosternal space in the lateral view. Echocardiography and CT angiography are more sensitive than the chest x-ray for the detection of aortic root enlargement.

Cardiac Catheterization and Angiography When needed, right and left heart catheterization with contrast aortography can provide accurate confirmation of the magnitude of regurgitation and the status of LV function. Coronary angiography is performed routinely in appropriate patients prior to surgery.

Rx AORTIC REGURGITATION

(Fig. 230-6)

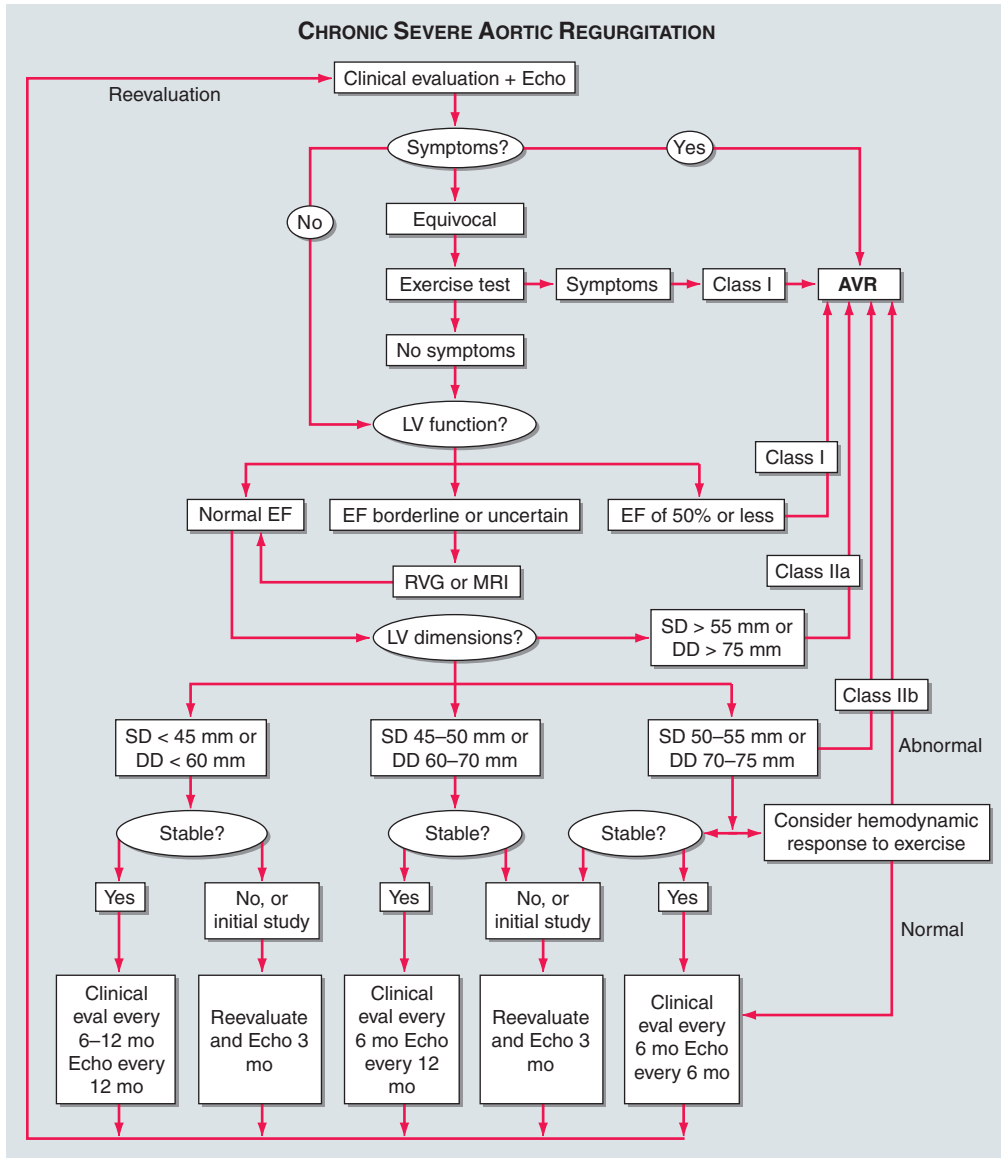

FIGURE 230-6 Management strategy for patients with chronic severe aortic regurgitation. Preoperative coronary angiography should be performed routinely, as determined by age, symptoms, and coronary risk factors. Cardiac catheterization and angiography may also be helpful when there is discordance between clinical findings and echocardiography. "Stable" refers to stable echocardiographic measurements. In some centers, serial follow-up may be performed with radionuclide ventriculography (RVG) or magnetic resonance imaging (MRI) rather than echocardiography (echo) to assess left ventricular (LV) volume and systolic function. AVR, aortic valve replacement; DD, end-diastolic dimension; EF, ejection fraction; eval, evaluation; SD, end-systolic dimension. *(Modified from Bonow et al.)*

ACUTE AORTIC REGURGITATION Patients with acute severe AR may respond to intravenous diuretics and vasodilators (such as sodium nitroprusside), but stabilization is usually short-lived and operation is indicated urgently. Intraaortic balloon counterpulsation is contraindicated. Beta-blockers are also best avoided so as not to reduce the CO further or slow the heart rate, which might allow proportionately more time in diastole for regurgitation to occur. Surgery is the treatment of choice.

CHRONIC AORTIC REGURGITATION Early symptoms of dyspnea and effort intolerance respond to treatment with diuretics and vasodilators (ACE inhibitors, dihydropyridine calcium channel blockers, or hydralazine) may be useful as well. Surgery can then be performed in more controlled circumstances. The use of vasodilators to extend the compensated phase of chronic severe AR before the onset of symptoms or the development of LV dysfunction is more controversial. Expert consensus is strong regarding the need to control systolic blood pressure (goal <140 mmHg) in patients with chronic AR, and vasodilators are an excellent first choice as antihypertensive agents. It is often difficult to achieve adequate control in such patients because of the increased stroke volume. Cardiac arrhythmias and systemic infections are poorly tolerated in patients with severe AR and must be treated promptly and vigorously. Although nitroglycerin and long-acting nitrates are not as helpful in relieving anginal pain as they are in patients with ischemic heart disease, they are worth a trial. Patients with syphilitic aortitis should receive a full course of penicillin therapy (Chap. 162). Beta blockers may be useful to retard the rate of aortic root enlargement in young patients with Marfan syndrome and aortic root dilatation with no or only mild AR. Patients with severe AR should avoid isometric exercises.

SURGICAL TREATMENT In deciding on the advisability and proper timing of surgical treatment, two points should be kept in mind: (1) patients with chronic severe AR usually do not become symptomatic until *after* the development of myocardial dysfunction; and (2) when delayed too long (defined as >1 year from onset of symptoms or LV dysfunction), surgical treatment often does not restore normal LV function. Therefore, in patients with chronic severe AR, careful clinical follow-up and noninvasive testing with echocardiography at approximately 6-month intervals are necessary if operation is to be undertaken at the optimal time, i.e., *after* the onset of LV dysfunction but *prior* to the development of severe symptoms. Operation can be deferred as long as the patient both remains asymptomatic and retains normal LV function.

AVR is indicated for the treatment of severe AR in symptomatic patients irrespective of LV function. In general, operation should be carried out in asymptomatic patients with severe AR and progressive LV dysfunction defined by an LVEF <50%, an LV end-systolic dimension >55mm or end-systolic volume >55 mL/m^2, or an LV diastolic dimension >75 mm. Smaller dimensions may be appropriate thresholds in individuals of smaller stature. Patients with severe AR without indications for operation should be followed by clinical and echocardiographic examination every 3–12 months.

Surgical options for management of aortic valve and root disease have expanded considerably over the past decade. AVR with a suitable mechanical or tissue prosthesis is generally necessary in patients with rheumatic AR and in many patients with other forms of regurgitation. Rarely, when a leaflet has been perforated during infective endocarditis or torn from its attachments to the aortic annulus by thoracic trauma, primary surgical repair may be possible. When AR is due to aneurysmal dilatation of the annulus and ascending aorta rather than to primary valvular involvement, it may be possible to reduce the regurgitation by narrowing the annulus or by excising a portion of the aortic root without replacing the valve. Resuspension of the native aortic valve leaflets is possible in approximately 50% of patients with acute AR in the setting of Type A aortic dissection. In other conditions, however, regurgitation can be eliminated only by replacing the aortic valve, excising the dilated or aneurysmal ascending aorta responsible for the regurgitation, and replacing it with a graft. This formidable procedure entails a higher risk than isolated AVR.

As in patients with other valvular abnormalities, both the operative risk and the late mortality are largely dependent on the stage of the disease and on myocardial function at the time of operation. The overall operative mortality for isolated AVR is about 3% (Table 230-3). However, patients with marked cardiac enlargement and prolonged LV dysfunction experience an operative mortality rate of approximately 10% and a late mortality rate of approximately 5% per year due to LV failure despite a technically satisfactory operation. Nonetheless, because of the very poor prognosis with medical management, even patients with LV failure should be considered for operation.

Patients with acute severe AR require prompt surgical treatment, which may be lifesaving.

TRICUSPID STENOSIS

TS, much less prevalent than MS in North America and Western Europe, is generally rheumatic in origin and is more common in females than in males. It does not occur as an isolated lesion and is usually associated with MS. Hemodynamically significant TS occurs in 5–10% of patients with severe MS; rheumatic TS is commonly associated with some degree of TR. Nonrheumatic causes of TS are rare.

PATHOPHYSIOLOGY

A diastolic pressure gradient between the RA and RV defines TS. It is augmented when the transvalvular blood flow increases during inspiration and declines during expiration. A mean diastolic pressure gradient of 4 mmHg is usually sufficient to elevate the mean RA pressure to levels that result in systemic venous congestion. Unless sodium intake has been restricted and diuretics administered, this venous congestion is associated with hepatomegaly, ascites, and edema, sometimes severe. In patients with sinus rhythm, the RA *a* wave may be extremely tall and may even approach the level of the RV systolic pressure. The *y* descent is prolonged. The CO at rest is usually depressed, and it fails to rise during exercise. The low CO is responsible for the normal or only slightly elevated LA, PA, and RV systolic pressures despite the presence of MS. Thus, the presence of TS can mask the hemodynamic and clinical features of the MS, which usually accompanies it.

SYMPTOMS

Since the development of MS generally precedes that of TS, many patients initially have symptoms of pulmonary congestion. Spontaneous improvement of these symptoms should raise the possibility that TS may be developing. Characteristically, patients complain of relatively little dyspnea for the degree of hepatomegaly, ascites, and edema that they have. However, fatigue secondary to a low CO and discomfort due to refractory edema, ascites, and marked hepatomegaly are common in patients with TS and/or TR. In some patients, TS may be suspected for the first time when symptoms of right-sided failure persist after an adequate mitral valvotomy.

PHYSICAL FINDINGS

Since TS usually occurs in the presence of other obvious valvular disease, the diagnosis may be missed unless it is considered and searched for. Severe TS is associated with marked hepatic congestion, often resulting in cirrhosis, jaundice, serious malnutrition, anasarca, and ascites. Congestive hepatomegaly and, in cases of severe tricuspid valve disease, splenomegaly are present. The jugular veins are distended, and in patients with sinus rhythm there may be giant *a* waves. The *v* waves are less conspicuous, and since tricuspid obstruction impedes RA emptying during diastole, there is a slow *y* descent. In patients with sinus rhythm there may be prominent presystolic pulsations of the enlarged liver as well.

On auscultation, an OS of the tricuspid valve may occasionally be heard approximately 0.06 s after pulmonic valve closure. The diastolic murmur of TS has many of the qualities of the diastolic murmur of MS, and since TS almost always occurs in the presence of MS, the less-common valvular lesion may be missed. However, the tricuspid murmur is generally heard best along the left lower sternal margin and over the xiphoid process, and it is most prominent during presystole in patients with sinus rhythm. The murmur of TS is augmented during inspiration, and it is reduced during expiration and particularly during the strain phase of the Valsalva maneuver, when tricuspid blood flow is reduced.

LABORATORY EXAMINATION

The ECG features of RA enlargement (see Fig. 221-8) include tall, peaked P waves in lead II, as well as prominent, upright P waves in lead V_1. The *absence* of ECG evidence of right ventricular hypertrophy

(RVH) in a patient with right-sided heart failure who is believed to have MS should suggest associated tricuspid valve disease. The chest x-ray in patients with combined TS and MS shows particular prominence of the RA and superior vena cava without much enlargement of the PA and with less evidence of pulmonary vascular congestion than occurs in patients with isolated MS. On echocardiographic examination, the tricuspid valve is usually thickened and domes in diastole; the transvalvular gradient can be estimated by Doppler echocardiography. TTE provides additional information regarding mitral valve structure and function, LV and RV size and function, and PA pressure.

Rx TRICUSPID STENOSIS

Patients with TS generally exhibit marked systemic venous congestion; intensive salt restriction, bed rest, and diuretic therapy are required during the preoperative period. Such a preparatory period may diminish hepatic congestion and thereby improve hepatic function sufficiently so that the risks of operation, particularly bleeding, are diminished. Surgical relief of the TS should be carried out, preferably at the time of surgical mitral valvotomy or MVR, in patients with moderate or severe TS who have mean diastolic pressure gradients exceeding ~4 mmHg and tricuspid orifice areas <1.5–2.0 cm^2. TS is almost always accompanied by significant TR. Operative repair may permit substantial improvement of tricuspid valve function. If repair cannot be accomplished, the tricuspid valve may have to be replaced with a prosthesis, preferably a large bioprosthetic valve. Mechanical valves in the tricuspid position are more prone to thromboembolic complications than in other positions.

TRICUSPID REGURGITATION

Most commonly, TR is functional and secondary to marked dilatation of the tricuspid annulus. Functional TR may complicate RV enlargement of any cause, including inferior wall infarcts that involve the RV. It is commonly seen in the late stages of heart failure due to rheumatic or congenital heart disease with severe pulmonary hypertension (pulmonary artery systolic pressure >55 mmHg), as well as in ischemic heart disease and dilated cardiomyopathy. It is reversible in part if pulmonary hypertension is relieved. Rheumatic fever may produce organic (primary) TR, often associated with TS. Infarction of RV papillary muscles, tricuspid valve prolapse, carcinoid heart disease, endomyocardial fibrosis, infective endocarditis, and trauma all may produce TR. Less commonly, TR results from congenitally deformed tricuspid valves, and it occurs with defects of the atrioventricular canal, as well as with Ebstein's malformation of the tricuspid valve (Chap. 229). TR also develops eventually in patients with chronic RV apical pacing.

As is the case for TS, the clinical features of TR result primarily from systemic venous congestion and reduction of CO. With the onset of TR in patients with pulmonary hypertension, symptoms of pulmonary congestion diminish, but the clinical manifestations of right-sided heart failure become intensified. The neck veins are distended with prominent *v* waves and rapid *y* descents, marked hepatomegaly, ascites, pleural effusions, edema, systolic pulsations of the liver, and a positive hepatojugular reflux. A prominent RV pulsation along the left parasternal region and a blowing holosystolic murmur along the lower left sternal margin, which may be intensified during inspiration and reduced during expiration or the strain of the Valsalva maneuver (Carvallo's sign), are characteristic findings; AF is usually present.

The ECG usually shows changes characteristic of the lesion responsible for the enlargement of the RV that leads to TR, e.g., inferior wall myocardial infarction or severe RVH. Echocardiography may be helpful by demonstrating RV dilatation and prolapsing, flail, scarred, or displaced tricuspid leaflets; the diagnosis of TR can be made by color flow Doppler echocardiography, and its severity can be estimated by Doppler examination (see Fig. 222-4). Severe TR is accompanied by hepatic vein systolic flow reversal. Continuous wave Doppler is also useful in estimating PA pressure. Roentgenographic examination usually reveals enlargement of both the RA and RV.

In patients with severe TR, the CO is usually markedly reduced, and the RA pressure pulse may exhibit no *x* descent during early systole but a prominent *c-v* wave with a rapid *y* descent. The mean RA and the RV end-diastolic pressures are often elevated.

Rx TRICUSPID REGURGITATION

Isolated TR, in the absence of pulmonary hypertension, such as that occurring as a consequence of infective endocarditis or trauma, is usually well tolerated and does not require operation. Indeed, even total excision of an infected tricuspid valve may be well tolerated for several years if the PA pressure is normal. Treatment of the underlying cause of heart failure usually reduces the severity of functional TR, by reducing the size of the tricuspid annulus. In patients with mitral valve disease and TR secondary to pulmonary hypertension and massive RV enlargement, effective surgical correction of the mitral valvular abnormality results in lowering of the PA pressures and gradual reduction or disappearance of the TR without direct treatment of the tricuspid valve. However, recovery may be much more rapid in patients with severe secondary TR if, at the time of mitral valve surgery, and especially when there is measurable enlargement of the tricuspid valve annulus, tricuspid annuloplasty (generally with the insertion of a plastic ring), open tricuspid valve repair, or, in the rare instance of severe organic tricuspid valve disease, tricuspid valve replacement is performed (Table 230-3). Tricuspid annuloplasty or replacement may be required for severe TR with primary involvement of the valve.

PULMONIC VALVE DISEASE

The pulmonic valve is affected by rheumatic fever far less frequently than are the other valves, and it is uncommonly the seat of infective endocarditis. The most common *acquired* abnormality affecting the pulmonic valve is regurgitation secondary to dilatation of the pulmonic valve ring as a consequence of severe pulmonary hypertension. This produces the *Graham Steell murmur*, a high-pitched, decrescendo, diastolic blowing murmur along the left sternal border, which is difficult to differentiate from the far more common murmur produced by AR. Pulmonic regurgitation is usually of little hemodynamic significance; indeed, surgical removal or destruction of the pulmonic valve by infective endocarditis does not produce heart failure unless serious pulmonary hypertension is also present.

The *carcinoid syndrome* may cause pulmonic stenosis and/or regurgitation. Pulmonic regurgitation occurs universally among patients who have undergone childhood repair of Tetralogy of Fallot with reconstruction of the RV outflow tract. **Congenital pulmonic stenosis is discussed in Chap. 229.**

VALVE REPLACEMENT

The results of replacement of any valve are dependent primarily on (1) the patient's myocardial function and general medical condition at the time of operation; (2) the technical abilities of the operative team and the quality of the postoperative care; and (3) the durability, hemodynamic characteristics, and thrombogenicity of the prosthesis. Increased perioperative mortality is associated with advanced age and comorbidity (e.g., pulmonary or renal disease, the need for nonvalvular cardiovascular surgery, diabetes mellitus) as well as with greater levels of preoperative functional disability and pulmonary hypertension. Late complications of valve replacement include paravalvular leakage, thromboemboli, bleeding due to anticoagulants, structural deterioration of the prosthesis, and infective endocarditis.

The considerations involved in the choice between a bioprosthetic (tissue) and artificial mechanical valve are similar in the mitral and aortic positions and in the treatment of stenotic, regurgitant, or mixed lesions. All patients who have undergone replacement of any valve with a mechanical prosthesis are at risk of thromboembolic complications and must be maintained permanently on anticoagulants, a treatment that imposes a hazard of hemorrhage. The primary advantage of bioprostheses over mechanical prostheses is the virtual absence of thromboembolic complications 3 months after implantation, and ex-

cept for patients with chronic AF, few such instances have been associated with their use. The major disadvantage of bioprosthetic valves is their structural deterioration, the incidence of which is inversely proportional to the patient's age. This deterioration results in the need to replace the prosthesis in up to 30% of patients by 10 years and in 50% by 15 years. Rates of structural valve deterioration are higher for mitral than for aortic bioprostheses. This phenomenon may be due in part to the greater closing pressure to which a mitral prosthesis is exposed.

Traditionally, a mechanical prosthesis was considered preferable for a patient under age 65 who could take anticoagulation reliably. Bioprostheses were recommended for older patients (>65 years) who did not otherwise have an indication for anticoagulation (for example, AF). However, more recent surveys of cardiac surgery in the United States, as reflected in the Society of Thoracic Surgeons database, show a clear and progressive trend favoring the implantation of bioprosthetic valves in younger (<65 years) patients. Reasons for this development include improved durability of newer generation bioprostheses, decreased risk at time of reoperation, the aggregate risks of long-term anticoagulation, and patient preference to avoid anticoagulation. Patient preference should be factored into any decision regarding the type of valve replacement. A mechanical prosthesis is reasonable for aortic or mitral valve replacement in patients <65 years without a contraindication to anticoagulation. A bioprosthesis is equally reasonable for aortic or mitral valve replacement in patients <65 years who elect this strategy for lifestyle reasons with full knowledge of the likely need for reoperation over time.

Bioprostheses remain the preferred valve choice for patients >65 years, in both the aortic and mitral position. Bioprosthetic valves are also indicated for women who expect to become pregnant, as well as for others who refuse to take anticoagulation or for whom anticoagulation may be contraindicated. Types of bioprostheses include xenografts (i.e., porcine aortic valves; cryopreserved, mounted bovine pericardium), homograft (allograft) aortic valves obtained from cadavers, as well as pulmonary autografts transplanted into the aortic position. Homograft replacement may be preferred for the management of complicated aortic valve infective endocarditis.

In patients without contraindications to anticoagulants, particularly those under 65 years, a mechanical prosthesis is reasonable. Many surgeons now select the St. Jude prosthesis, a double-disk tilting prosthesis, for replacement of both aortic and mitral valves because of favorable hemodynamic characteristics and possible association with lower thrombogenicity.

GLOBAL BURDEN OF VALVULAR HEART DISEASE

Primary valvular heart disease ranks well below coronary heart disease, stroke, hypertension, obesity, and diabetes as major threats to the public health. Nevertheless, it is the source of significant morbidity and mortality. Rheumatic fever (Chap. 315) is the dominant cause of valvular heart disease in developing countries. Its prevalence has been estimated to range from as low as 1.0 per 100,000 school-age children in Costa Rica to as high as 150 per 100,000 in China. Rheumatic heart disease accounts for 12–65% of hospital admissions related to cardiovascular disease and 2–10% of hospital discharges in some developing countries. Prevalence and mortality rates vary among communities even within the same country as a function of crowding and the availability of medical resources and population-wide programs for detection and treatment of Group A streptococcal pharyngitis. In economically deprived areas, tropical and subtropical climates (particularly on the Indian subcontinent), Central America, and the Middle East, rheumatic valvular disease progresses more rapidly than in more-developed nations and frequently causes serious symptoms in patients <20 years of age. This accelerated natural history may be due to repeated infections with more virulent strains of rheumatogenic streptococci.

TS, a relatively uncommon valvular lesion in North America and Western Europe, is more common in tropical and subtropical climates, especially in southern Asia and in Latin America.

As of the year 2000, worldwide death rates for rheumatic heart disease approximated 5.5 per 100,000 population (n = 332,000), with the highest rates reported from Southeast Asia. Although there have been reports of recent isolated outbreaks of streptococcal infection in North America, valve disease in developed countries is now dominated by degenerative or inflammatory processes that lead to valve thickening, calcification, and dysfunction. The prevalence of valvular heart disease increases with age. Important left-sided valve disease may affect as many as 12–13% of adults over the age of 75.

The incidence of infective endocarditis (Chap. 118) has increased with the aging of the population, the more widespread prevalence of vascular grafts and intracardiac devices, the emergence of more virulent multidrug-resistant microorganisms, and the growing epidemic of diabetes. Infective endocarditis has become a more frequent cause of acute valvular regurgitation.

Bicuspid aortic valve disease affects as many as 1–2% of the population, and an increasing number of childhood survivors of congenital heart disease present later in life with valvular dysfunction. The past several years have witnessed significant improvements in surgical outcomes with progressive refinement of relatively less-invasive techniques. Percutaneous heart valve replacement or repair is under active clinical investigation.

231 Cardiomyopathy and Myocarditis

Joshua Wynne, Eugene Braunwald

The cardiomyopathies are a group of diseases that primarily affect the heart muscle and are *not* the result of congenital, acquired valvular, hypertensive, coronary arterial, or pericardial abnormalities. The diffuse myocardial fibrosis that accompanies multiple myocardial scars produced by myocardial infarctions can impair left ventricular (LV) function and is frequently referred to as *ischemic cardiomyopathy*. This colloquial use of the term *cardiomyopathy* should be avoided; instead, the term should be restricted to a condition *primarily* involving the myocardium.

Two fundamental forms of cardiomyopathy are recognized: (1) a primary type, consisting of heart muscle disease predominantly involving the myocardium and/or of unknown cause; and (2) a secondary type, consisting of myocardial disease of known cause or associated with a systemic disease such as amyloidosis or chronic alcohol use (Table 231-1). In many cases it is not possible to arrive at a specific etiologic diagnosis, and thus it is often more desirable to classify the cardiomyopathies into one of three morphologic types (dilated, restrictive, and hypertrophic) on the basis of differences in their pathophysiology and clinical presentation (Fig. 231-1; Tables 231-2 and 231-3). In some patients, two of these types may be present simultaneously or sequentially. An important additional consideration is whether or not the particular cardiomyopathy in question (whether primary or secondary) has a genetic basis.

DILATED CARDIOMYOPATHY

About one in three cases of congestive heart failure (CHF; Chap. 227) is due to dilated cardiomyopathy (DCM). LV and/or right ventricular (RV) systolic pump function is impaired, leading to progressive cardiac dilatation (remodeling). Symptoms of heart failure (HF) typically appear only after remodeling has been ongoing for some time (months or even years).

TABLE 231-1 CLASSIFICATION OF CARDIOMYOPATHIES

Primary Myocardial Involvement	
Idiopathic (D,R,H)	
Familial (D,R,H)	
Eosinophilic endomyocardial disease (R)	
Endomyocardial fibrosis (R)	
Secondary Myocardial Involvement	
Infective (D)	Connective tissue disorders (D)
Viral myocarditis	Systemic lupus erythematosus
Bacterial myocarditis	Polyarteritis nodosa
Fungal myocarditis	Rheumatoid arthritis
Protozoal myocarditis	Progressive systemic sclerosis
Metazoal myocarditis	Dermatomyositis
Spirochetal	Infiltrations and granulomas (R,D)
Rickettsial	Amyloidosis
Metabolic (D)	Sarcoidosis
Familial storage disease (D,R)	Malignancy
Glycogen storage disease	Neuromuscular (D)
Mucopolysaccharidoses	Muscular dystrophy
Hemochromatosis	Myotonic dystrophy
Fabry's disease	Friedreich's ataxia (H,D)
Deficiency (D)	Sensitivity and toxic reactions (D)
Electrolytes	Alcohol
Nutritional	Radiation
	Drugs
	Peripartum heart disease (D)

Note: The principal clinical manifestation(s) of each etiologic grouping is denoted by D (dilated), R (restrictive), or H (hypertrophic) cardiomyopathy.

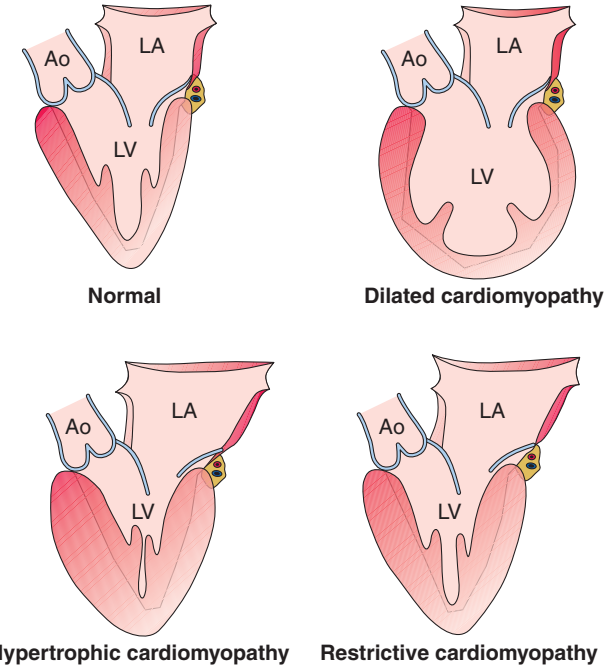

FIGURE 231-1 Drawing comparing the morphologic classes of cardiomyopathies. Ao, aorta; LA, left atrium; LV, left ventricle. *(From BF Waller: J Am Soc Echocardiogr 1:4, 1988.)*

Although no cause is apparent in many cases, DCM is either familial or the end result of myocardial damage produced by a variety of known or unknown infectious, metabolic, or toxic agents. DCM may be the late consequence of acute viral myocarditis (see below), possibly mediated in part through an immunologic mechanism. Although DCM may occur at any age, it most commonly becomes apparent clinically in the third or fourth decades. A reversible form of DCM may be found with alcohol abuse (see below), pregnancy (see below), thyroid disease, cocaine use (see below), and chronic uncontrolled tachycardia.

GENETIC CONSIDERATIONS One-fifth to one-third of patients have familial forms of DCM. Mutations in >20 genes that are transmitted in an autosomal dominant fashion have been described. Most common are mutations in genes encoding sarcomeric proteins, such as α-cardiac actin; β- and α-myosin; heavy chain α-tropomyosin; and troponins T, I, and C. It is believed that the abnormal proteins cause contractile dysfunction by impairing the production and/or transmission of force.

Patients with genetic DCM may also exhibit skeletal myopathies, particularly Duchenne's and Emery-Dreyfuss muscular dystrophy (see below). Mutations in the gene encoding the nuclear envelope protein lamin A/C are also inherited in an autosomal dominant manner; they are responsible for the development of DCM associated with atrioventricular (AV) conduction disorder and other electrophysiologic disturbances that may cause sudden cardiac death (SCD). An X-linked autosomal recessive disorder caused by the dystrophin gene occurs in young males and is associated with a rapid downhill course; mutations in mitochondrial genes have also been reported in DCM.

CLINICAL FEATURES

Symptoms of left- and right-sided CHF usually develop gradually (Chap. 227). Some patients have LV dilatation for months or even years

TABLE 231-2 CLINICAL CLASSIFICATION OF CARDIOMYOPATHIES

1. Dilated: Left and/or right ventricular enlargement, impaired systolic function, congestive heart failure, arrhythmias, emboli
2. Restrictive: Endomyocardial scarring or myocardial infiltration resulting in restriction to left and/or right ventricular filling
3. Hypertrophic: Disproportionate left ventricular hypertrophy, typically involving septum more than free wall, with or without an intraventricular systolic pressure gradient; usually of a nondilated left ventricular cavity

TABLE 231-3 LABORATORY EVALUATION OF THE CARDIOMYOPATHIES

	Dilated	Restrictive	Hypertrophic
Chest roentgenogram	Moderate to marked cardiac silhouette enlargement Pulmonary venous hypertension	Mild cardiac silhouette enlargement	Mild to moderate cardiac silhouette enlargement
Electrocardiogram	ST-segment and T-wave abnormalities	Low voltage, conduction defects	ST-segment and T-wave abnormalities Left ventricular hypertrophy Abnormal Q waves
Echocardiogram	Left ventricular dilatation and dysfunction	Increased left ventricular wall thickness Normal or mildly reduced systolic function	Asymmetric septal hypertrophy (ASH) Systolic anterior motion (SAM) of the mitral valve
Radionuclide studies	Left ventricular dilatation and dysfunction (RVG)	Normal or mildly reduced systolic function (RVG)	Vigorous systolic function (RVG) Perfusion defect (^{201}Tl or technetium sestamibi)
Cardiac catheterization	Left ventricular dilatation and dysfunction Elevated left- and often right-sided filling pressures Diminished cardiac output	Normal or mildly reduced systolic function Elevated left- and right-sided filling pressures	Vigorous systolic function Dynamic left ventricular outflow obstruction Elevated left- and right-sided filling pressures

Note: RVG, radionuclide ventriculogram; ^{201}Tl, thallium 201.

before becoming symptomatic. Although vague chest pain may be present, typical angina pectoris is unusual and suggests the presence of ischemic heart disease. Syncope due to arrhythmias and systemic embolism (often emanating from a ventricular thrombus) may occur.

PHYSICAL EXAMINATION

Variable degrees of cardiac enlargement and findings of CHF (Chap. 227) are noted. In patients with advanced disease, the pulse pressure is narrow and the jugular venous pressure is elevated. Third and fourth heart sounds are common, and mitral or tricuspid regurgitation may occur.

LABORATORY EXAMINATIONS

The chest roentgenogram demonstrates enlargement of the cardiac silhouette due to LV dilatation, although generalized cardiomegaly is often seen. The lung fields may demonstrate pulmonary vascular redistribution and interstitial or, in advanced cases, alveolar edema. The electrocardiogram (ECG) often shows sinus tachycardia or atrial fibrillation, ventricular arrhythmias, left atrial abnormality, low voltage, diffuse nonspecific ST-T-wave abnormalities, and sometimes intraventricular and/or AV conduction defects. Echocardiography, computed tomographic imaging (CTI), and cardiac magnetic resonance imaging (CMRI) show LV dilatation, with normal, minimally thickened, or thinned walls, and systolic dysfunction. Circulating levels of brain natriuretic peptide are usually elevated.

Cardiac catheterization and coronary angiography are often performed to exclude ischemic heart disease, and bedside hemodynamic monitoring may be helpful in the management of selected acutely decompensated patients. Angiography reveals a dilated, diffusely hypokinetic left ventricle, often with some degree of mitral regurgitation. Cardiac CTI may distinguish between DCM and proximal coronary artery disease and, thereby, reduce the need for invasive procedures. Transvenous endomyocardial biopsy is usually not necessary in idiopathic or familial DCM; however, it may be helpful in the recognition of secondary cardiomyopathies, such as amyloidosis and acute myocarditis (see below).

Rx DILATED CARDIOMYOPATHY

Most patients pursue an inexorably downhill course, and the majority, particularly those >55 years, die within 4 years of the onset of symptoms. Patients of African ancestry are more likely to suffer more rapidly progressive CHF and death than Caucasians. Spontaneous improvement or stabilization occurs in about one-quarter of patients. Death is due to either progressive HF or ventricular tachy- or bradyarrhythmia; SCD is a constant threat. Systemic embolization is a concern, and patients should be considered for chronic anticoagulation. Standard therapy of HF, as described in Chap. 227, is indicated. Alcohol should be avoided because of its cardiotoxic effects (see below), as should calcium channel blockers and nonsteroidal anti-inflammatory drugs. Antiarrhythmic agents are best avoided owing to the risk of proarrhythmia. Cardiac resynchronization therapy and insertion of an implantable cardioverter defibrillator (ICD) should be employed in DCM as in HF of other etiologies. In patients with advanced disease who are refractory to other therapies, cardiac transplantation should be considered (Chap. 228).

ALCOHOLIC CARDIOMYOPATHY

Individuals who consume large quantities (>90 g/d) of alcohol over many years may develop a clinical picture resembling idiopathic or familial DCM. The risk of developing cardiomyopathy is partially determined genetically. A polymorphism of the gene encoding the alcohol metabolizing enzyme, alcohol dehydrogenase (*ALDH2*2*), as well as the DD form of the angiotensin-converting enzyme (*ACE*) gene increase the predilection for the development of alcoholic cardiomyopathy. Patients with advanced alcoholic cardiomyopathy and severe CHF have a poor prognosis, particularly if they continue to drink; fewer than one-quarter of such patients survive 3 years. Management consists of abstention, which may halt the progression or even reverse the course of this disease.

A second presentation of alcoholic cardiotoxicity may be found in individuals without overt HF and consists of recurrent supraventricular or ventricular tachyarrhythmias. Termed the *holiday heart syndrome*, it typically appears after a drinking binge; atrial fibrillation is seen most frequently, followed by atrial flutter and frequent ventricular premature depolarizations.

In contrast to the adverse cardiac effects of excessive alcohol consumption, moderate consumption (20–30 g/d) appears to be cardioprotective; it raises high-density lipoprotein (HDL) cholesterol and is associated with a reduced incidence of ischemic heart disease, ischemic stroke, and metabolic syndrome.

PERIPARTUM CARDIOMYOPATHY

(See also Chap. 7) Cardiac dilatation and CHF may develop during the last trimester of pregnancy or within 6 months of delivery. The cause is unknown, although inflammatory myocarditis, immune activation, and gestational hypertension have all been incriminated. The patient who develops peripartum cardiomyopathy typically is multiparous, of African ancestry, and >30 years, although the disease may be found in a wide spectrum of patients. The symptoms, signs, and treatment are similar to those in patients with idiopathic DCM, the latter including implantation of an ICD or cardiac transplantation if the criteria for these therapies are satisfied. The mortality rate of this disorder is around 10%.

The prognosis is related to whether the heart size returns to normal after the first episode of CHF. If it does, subsequent pregnancies may sometimes be tolerated, albeit with an increased risk of recurrent CHF; if the heart remains enlarged, and/or the LV ejection fraction (EF) remains depressed after 6 months, the prognosis is poor, and further pregnancies frequently produce additional myocardial damage, ultimately leading to refractory CHF. Patients who recover from peripartum cardiomyopathy should be encouraged to avoid further pregnancies, particularly if LV dysfunction persists.

NEUROMUSCULAR DISEASE

(See also Chap. 382) Cardiac involvement is common in many of the muscular dystrophies. In *Duchenne's progressive muscular dystrophy*, mutations in a gene that encodes a cardiac structural protein (*dystrophin*) lead to myocyte death. Myocardial involvement is most frequently indicated by a distinctive and unique ECG pattern consisting of tall R waves in the right precordial leads with an R/S ratio > 1.0, often associated with deep Q waves in the limb and lateral precordial leads. A variety of supraventricular and ventricular arrhythmias is frequently found. Rapidly progressive HF may develop despite extended periods of apparent circulatory stability.

Myotonic dystrophy is characterized by a variety of ECG abnormalities, especially disorders of impulse formation and AV conduction, but other overt clinical evidence of heart disease is uncommon. Because of these abnormalities, syncope and sudden death are major hazards. In appropriate patients, insertion of an ICD and/or permanent pacemaker may be effective.

DRUGS

A variety of pharmacologic agents may damage the myocardium acutely, producing a pattern of inflammation (myocarditis, see below), or they may lead to chronic damage of the type seen with DCM. Certain drugs produce only ECG abnormalities, while others may precipitate fulminant CHF and death.

The anthracycline derivatives, particularly doxorubicin (Adriamycin), are powerful antineoplastic agents. Systolic dysfunction and ventricular arrhythmias occur in a dose-dependent manner with a dose >450 mg/m^2 and are frequent with doses >550 mg/m^2. The development of these complications appears to be related to damage to the inner mitochondrial membrane and interference with the synthesis of adenosine triphosphate. This development is related not only to the dose of the drug but also to the presence or absence of several risk factors, which include cardiac irradiation, underlying heart disease, hypertension, and concurrent treatment with cyclophosphamide. At any dose of doxorubicin, patients with these risk factors have a greater frequency of developing HF than do patients lacking them. Doxorubicin cardiotoxicity may occur acutely but more commonly develops a median of 3 months after the last dose. In others, late contractile dysfunction may develop years after doxorubicin administration.

By measuring cardiac-specific troponin and monitoring LV function with radionuclide ventriculography or echocardiography, usually combined with exercise stress, it is possible to document preclinical deterioration of LV function and allow appropriate dose adjustments. Also, monitoring may make it possible to continue doxorubicin even in patients at high risk for developing HF. Efforts to modify the dose schedule by giving the drug more slowly, along with the selective use of potentially cardioprotective agents such as the iron-chelator dexrazoxone, have reduced the risk of cardiotoxicity. Some patients have demonstrated recovery of cardiac function with aggressive management using ACE inhibitors.

Trastuzumab (*Herceptin*), used in the treatment of breast cancer, causes cardiomyopathy in 7% of patients when used as monotherapy and four times as frequently when combined with doxorubicin. High-dose *cyclophosphamide* may produce CHF acutely or within 2 weeks of administration; a characteristic histopathologic feature is myocardial edema and hemorrhagic necrosis. LV dysfunction has also been reported with the administration of the nonreceptor tyrosine kinase inhibitor *imatinib mesylate* (Gleevec), used in the treatment of chronic myeloid leukemia.

ECG changes and arrhythmias may result from treatment with tricyclic antidepressants, the phenothiazines, emetine, lithium, and various aerosol propellants. *Cocaine abuse* (Chap. 389) is associated with a variety of life-threatening cardiac complications, including SCD, myocarditis, DCM, and acute myocardial infarction (resulting from coronary spasm and/or thrombosis with or without underlying coronary artery disease). Nitrates, calcium channel blockers, antiplatelet agents, and benzodiazepines have been used to treat cocaine-induced cardiotoxicities.

ARRHYTHMOGENIC RIGHT VENTRICULAR CARDIOMYOPATHY/DYSPLASIA (ARVC/D)

ARVC/D is a familial cardiomyopathy characterized by progressive fibrofatty replacement of the right ventricle and, to a much lesser degree, of the LV myocardium. It is most commonly inherited in an autosomal dominant manner and is caused by multiple mutations of several genes encoding proteins that constitute desmosomes, structures that maintain normal contacts between cells. It has been suggested that abnormalities in the desmosomes cause detachment of myocytes with consequent myocyte apoptosis and fibrofatty replacement. Among the desmosomal protein genes, the most common gene mutation occurs in plakophilin-2 (*PKP-2*). Mutations in the cardiac ryanodine receptor gene (*RyR2*) and other genes have also been described.

On clinical examination, patients may manifest RV failure with jugular venous distention, hepatomegaly, and edema. Clinical manifestations usually develop during the second decade and include ventricular tachyarrhythmias as well as varying degrees of RV failure; both of these complications may be fatal.

The ECG typically shows QRS prolongation localized to the right precordial leads and left bundle branch block–type ventricular tachycardia. CTI and CMRI typically show RV dilatation, RV aneurysm, and fatty replacement (Fig. 231-2).

Restriction from competitive sports and antiarrhythmic therapy with beta blockers or amiodarone may be useful. Implantation of an ICD may be required (Chap. 226). If RV failure becomes intractable, cardiac transplantation (Chap. 228) may be necessary.

TAKO-TSUBO (STRESS) CARDIOMYOPATHY

Also known as *apical ballooning syndrome*, this uncommon cardiac syndrome is characterized by the abrupt onset of severe chest discomfort preceded by a very stressful emotional or physical event. It occurs most commonly in women >50 years and is accompanied by ST-segment elevations and/or deep T-wave inversions in the precordial leads. No obstruction in the epicardial coronary arteries is noted on angiography.

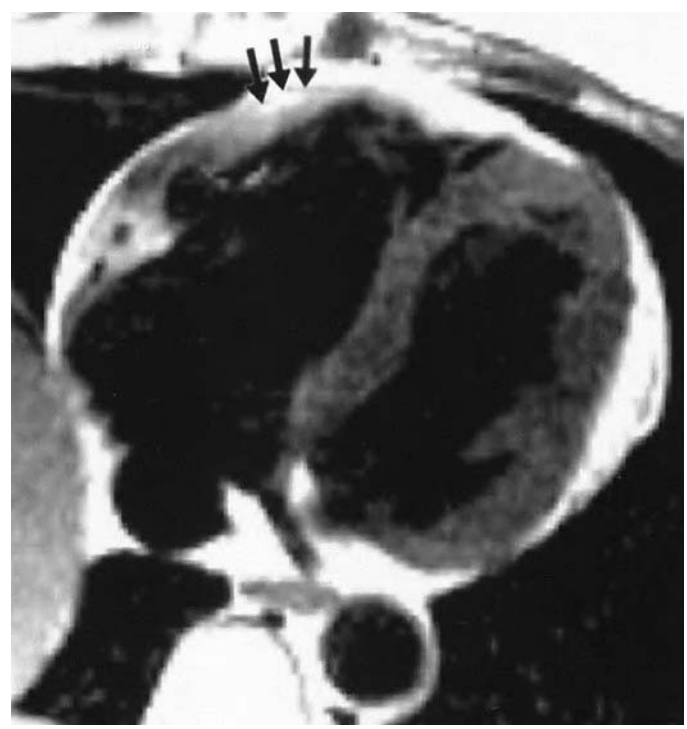

FIGURE 231-2 CMRI showing right ventricular (RV) enlargement (*left*) and fatty replacement of the RV myocardium (*black arrows*) of a patient with arrhythmogenic RV dysplasia. *(From S Sen-Chowdhry et al: Am J Med 117:685, 2004; with permission.)*

There is severe akinesia of the distal portion of the left ventricle with reduction of the EF. Troponins are usually mildly elevated. Cardiac imaging typically shows "ballooning" of the left ventricle in end-systole, especially of the LV apex. All of these changes, which are often quite dramatic, are reversible within 3–7 days and do not cause long-term cardiac dysfunction or disability.

The mechanism responsible for Tako-tsubo cardiomyopathy is not clear, although it is likely that an adrenergic surge that includes circulating catecholamines, acting on the epicardial coronary vessels and/or coronary microcirculation, is involved. Although beta blockers are used in therapy, there is no definitive evidence that they are beneficial.

LEFT VENTRICULAR NONCOMPACTION

Left ventricular noncompaction (LVNC) is a recently characterized uncommon congenital cardiomyopathy that may present at any age with symptoms of CHF, thromboembolism, or ventricular arrhythmias. It results from the arrest of normal embryogenesis, with the persistence of the deep recesses and sinusoids in the myocardium that characterize the embryonic heart. These sinusoids and associated spongy network of myocardial fibers ordinarily undergo organization and "compaction" early in embryonic life; when this fails to occur, LVNC results. This condition is diagnosed on echocardiography by the demonstration of multiple deep trabeculations into the myocardium, all of which communicate with the ventricular cavity, associated with LV contractile dysfunction. Standard therapy for CHF is routinely employed, typically along with chronic anticoagulation.

HYPERTROPHIC CARDIOMYOPATHY

Hypertrophic cardiomyopathy (HCM) is characterized by LV hypertrophy, typically of a nondilated chamber, without obvious cause, such as hypertension or aortic stenosis. It is found in about 1 in 500 of the general population. Two features of HCM have attracted the greatest attention: (1) asymmetric LV hypertrophy, often with preferential hypertrophy of the interventricular septum; and (2) a dynamic LV outflow tract pressure gradient, related to narrowing of the subaortic area. About one-third of patients with HCM demonstrate an outflow tract pressure gradient at rest and a similar fraction develop one with provocation. The ubiquitous pathophysiologic abnormality is *diastolic* dysfunction, which can be detected by Doppler tissue imaging and results in elevated LV end-diastolic pressures; the latter may be present despite a hyperdynamic, nondilated LV.

The pattern of hypertrophy is distinctive in HCM and usually differs from that seen in secondary hypertrophy (as in hypertension or aortic stenosis). Most patients have striking regional variations in the extent of hypertrophy in different portions of the left ventricle, and the majority demonstrate a ventricular septum whose thickness is disproportionately increased when compared with the free wall. Other patients may demonstrate symmetric hypertrophy, while others have mid-ventricular cavity obstruction or disproportionate involvement of the apex or LV free wall. In the disproportionately hypertrophied portions of the left ventricle, there is a bizarre and disorganized arrangement of myocytes, with disorganization of the myofibrillar architecture, along with a variable degree of myocardial fibrosis and thickening of the small intramural coronary arteries.

GENETIC CONSIDERATIONS About half of all patients with HCM have a positive family history compatible with autosomal dominant transmission. More than 400 mutations of 11 different genes that encode sarcomeric proteins have been identified; these account for ~60% of cases. The most common are mutations of the cardiac β-myosin heavy chain gene on chromosome 14. Others involve α-myosin heavy chains; cardiac troponins C, I, and T; cardiac myosin-binding protein C; actin; myosin light chains; and titin. Certain mutations are associated with more malignant prognoses. Many sporadic cases of HCM probably represent spontaneous mutations. Echocardiographic studies have confirmed that by the age of 20, when full expression has usually occurred, about one-half of the first-degree relatives of patients with familial HCM have evidence of the disease. However, in many of these relatives the extent of hypertrophy is mild, no outflow tract pressure gradient is present, and symptoms are not prominent. Since the hypertrophic characteristics may not be apparent in childhood, a single normal echocardiogram in a child does not exclude the presence of the disease. Screening by echocardiography of first-degree relatives between the ages of 12 and 20 should be carried out every 12–24 months, unless the diagnosis is established or excluded by genetic testing.

Genetic Testing Although not yet routinely available, genetic testing may allow a definitive diagnosis of HCM with a genetic cause to be established by identifying a mutation in a gene encoding a sarcomeric protein. Genetic testing can identify family members who are at risk for developing HCM and who, therefore, require echocardiographic screening and follow-up. It can also exclude the disease in family members.

CLINICAL FEATURES

The clinical course of HCM is highly variable. Many patients are asymptomatic or mildly symptomatic and may be relatives of patients with known disease. Unfortunately, the first clinical manifestation may be SCD, frequently occurring in children and young adults during or after physical exertion. Indeed, HCM is the most common cause of SCD in young competitive athletes. In symptomatic patients, the most common complaint is dyspnea, largely due to diastolic ventricular dysfunction, which impairs ventricular filling and leads to elevated LV diastolic, left atrial, and pulmonary capillary pressures. Other symptoms include syncope, angina pectoris, and fatigue. Symptoms are not closely related to the presence or severity of an outflow pressure gradient.

PHYSICAL EXAMINATION

Most patients demonstrate a double or triple apical precordial impulse and a fourth heart sound. Those with intraventricular pressure gradients may have a rapidly rising arterial pulse. The hallmark of obstructive HCM is a systolic murmur, which is typically harsh, diamond-shaped, and usually begins well after the first heart sound. The murmur is best heard at the lower left sternal border as well as at the apex, where it is often more holosystolic and blowing in quality, no doubt due to the mitral regurgitation that usually accompanies obstructive HCM.

HEMODYNAMICS

In contrast to the obstruction produced by a fixed narrowed orifice, such as valvular aortic stenosis, the pressure gradient in HCM, when present, is dynamic and may change between examinations and even from beat to beat. Obstruction appears to result from narrowing of the LV outflow tract by systolic anterior movement (SAM) of the mitral valve against the hypertrophied septum.

Three basic mechanisms are involved in the production and intensification of the dynamic intraventricular obstruction: (1) increased LV contractility, (2) decreased ventricular preload, and (3) decreased aortic impedance and pressure (afterload). Interventions that increase myocardial contractility, such as exercise and sympathomimetic amines, and those that reduce ventricular preload, such as the strain phase of the Valsalva maneuver, sudden standing, or nitroglycerin, reduce LV end-diastolic volume and, thereby, may cause an increase in the gradient and the murmur. Conversely, elevation of arterial pressure by squatting, sustained handgrip, augmentation of venous return by passive leg raising, and expansion of the blood volume (as during pregnancy) all increase ventricular volume and ameliorate the gradient and murmur.

LABORATORY EVALUATION

The ECG commonly shows LV hypertrophy and widespread deep, broad Q waves. The latter suggest an old myocardial infarction but actually reflect severe septal hypertrophy. Many patients demonstrate arrhythmias, both atrial (supraventricular tachycardia or atrial fibrillation) and ventricular (ventricular tachycardia), during ambulatory (Holter) monitoring. *Chest roentgenography* may be normal, although a mild to moderate increase in the cardiac silhouette is common.

The mainstay of the diagnosis of HCM is the *echocardiogram*, which demonstrates LV hypertrophy, often with the septum ≥1.3 times the thickness of the posterior LV free wall. The septum may demonstrate an unusual "ground-glass" appearance, probably related to its myocardial fibrosis. SAM of the mitral valve, often accompanied by mitral regurgitation, is found in patients with pressure gradients. The LV cavity typically is small in HCM, with vigorous motion of the posterior wall but with reduced septal excursion. An uncommon form of cardiomyopathy, characterized by apical hypertrophy, is associated with giant negative T waves on the ECG and a "spade-shaped" LV cavity; it usually has a benign clinical course. CMRI is superior to echocardiography in providing accurate measurements of regional hypertrophy and in identifying sites of regional fibrosis.

Although cardiac catheterization is not required to diagnose HCM, the two typical *hemodynamic* features are an elevated LV diastolic pressure due to diminished compliance and, in some patients, a systolic pressure gradient, usually between the body of the left ventricle and the subaortic region. When a gradient is not present, it can be induced in some patients by provocative maneuvers, such as infusion of isoproterenol, inhalation of amyl nitrite, the Valsalva maneuver, or a premature ventricular contraction.

℞ HYPERTROPHIC CARDIOMYOPATHY

Since SCD often occurs during or just after physical exertion, competitive sports and very strenuous activities should be proscribed. Dehydration should be avoided, and diuretics used with caution. β-Adrenergic blockers ameliorate angina pectoris and syncope in one-third to one-half of patients. Although resting intraventricular pressure gradients are usually unchanged, these drugs may limit the increase in the gradient that occurs during exercise. It does not appear that β-adrenergic blockers offer any protection against SCD. Amiodarone appears to be effective in reducing the frequency of supraventricular as well as of life-threatening ventricular arrhythmias, and anecdotal data suggest that it may reduce the risk of SCD. Nondihydropyridine calcium channel blockers (verapamil and diltiazem) may reduce the stiffness of the left ventricle, reduce the elevated diastolic pressures, increase exercise tolerance, and, in some instances, reduce the severity of outflow tract pressure gradients. Disopyramide has been used in some patients to reduce LV contractility and the outflow pressure gradient; it may reduce symptoms as well.

Digitalis, diuretics, nitrates, dihydropyridine calcium blockers, vasodilators, and β-adrenergic agonists are best avoided, particularly in patients with known LV outflow tract pressure gradients. Alcohol ingestion may produce sufficient vasodilatation to exacerbate an outflow pressure gradient.

Atrial fibrillation is poorly tolerated, and a strong effort should be made to restore and then maintain sinus rhythm. Slowing of the heart rate with a β-adrenergic blocker or ablation of the AV node and insertion of a pacemaker may be indicated when sinus rhythm cannot be sustained.

Surgical myotomy/myectomy of the hypertrophied septum usually abolishes intraventricular obstruction and provides lasting symptomatic improvement in about three-quarters of severely symptomatic patients with large pressure gradients who are unresponsive to medical management. Infarction of the interventricular septum induced by ethanol injections into the septal artery (alcohol septal ablation) can also reduce obstruction and improve symptoms. However, it should be carried out only by experts.

The insertion of an ICD should be considered in patients with a high-risk profile for SCD (see below).

PROGNOSIS

The natural history of HCM is variable, although many patients never exhibit any clinical manifestations. Atrial fibrillation is common late in the course of the disease; its onset often leads to the development of or an increase in symptoms. Infective endocarditis occurs in <10% of patients. However, endocarditis prophylaxis is currently recommended only in HCM patients with a prior episode of infective endocarditis. Progression of HCM to left ventricular dilatation and dysfunction (DCM) with wall thinning and disappearance of a preexisting outflow pressure gradient (so-called burnt out HCM) occurs in 5–10% of patients and may be associated with nonresponsive CHF requiring cardiac transplantation.

The major cause of mortality in HCM is SCD, which may occur in asymptomatic patients or interrupt an otherwise stable course in symptomatic ones. Patients at increased risk of SCD include those with a history of resuscitation, recurrent syncope, ventricular tachycardia on ambulatory monitoring or at electrophysiologic testing, marked ventricular hypertrophy (ventricular septal thickness >30 mm), failure of blood pressure to rise during exercise, a family history of SCD, and certain genetic mutations.

INHERITED METABOLIC CARDIOMYOPATHIES WITH LEFT VENTRICULAR HYPERTROPHY

Cardiac Danon Disease This condition is caused by mutations in an X-linked lysosome-associated membrane protein (LAMP2). It is characterized by enlarged ventricular myocytes with periodic acid Schiff (PAS)–positive inclusions. Patients present in childhood with CHF and serious arrhythmias. The ECG shows severe LV hypertrophy and ventricular preexcitation.

Glycogen Storage Cardiomyopathy (See also Chap. 356) This recently characterized condition is caused by a mutation in the γ_2 regulatory subunit (*PRKAG2*) of adenosine monophosphate–activated protein kinase (AMPK). It is characterized by ventricular hypertrophy resembling that observed in hypertrophic cardiomyopathies and enlarged myocytes with vacuoles in the myocytes that stain for glycogen.

Fabry Disease (See also Chap. 355) This X-linked autosomal recessive lysosomal storage disorder is caused by deficiency of lysosomal α-galactoside A and can lead to the accumulation of glycosphingolipids in the heart, with ventricular hypertrophy resembling HCM. Because of severe impairment in ventricular filling, it is sometimes classified as a restrictive cardiomyopathy (see below). It may be associated with AV conduction abnormalities and ventricular tachyarrhythmias. CMRI is helpful in establishing the diagnosis. Treatment consists of enzyme replacement therapy with agalsidase β.

Friedreich's Ataxia (See also Chap. 382) This is an autosomal recessive spinocerebellar degenerative disease caused by inadequate levels of frataxin, a protein involved in mitochondrial iron metabolism. Approximately one-half of the patients develop cardiac symptoms. The ECG most commonly demonstrates ST-segment and T-wave abnormalities. Echocardiography and other imaging studies (CTI, CMRI) usually show symmetric LV hypertrophy or asymmetric hypertrophy of the interventricular septum compared with the free wall. Although the gross morphologic appearance of the heart in Friedreich's ataxia may be similar to that in HCM (see above), cellular disarray is lacking.

RESTRICTIVE CARDIOMYOPATHY

The hallmark of the restrictive cardiomyopathies (RCMs) is abnormal diastolic function (Chap. 217); the ventricular walls are excessively rigid and impede ventricular filling. In late stages systolic function is also impaired. Myocardial fibrosis, hypertrophy, or infiltration due to a variety of causes is responsible. Myocardial involvement with *amyloid* is a common cause of secondary restrictive cardiomyopathy, although restriction is also seen in the transplanted heart, in hemochromatosis, glycogen deposition, endomyocardial fibrosis, sarcoidosis, hypereosinophilic disease, and scleroderma; following mediastinal irradiation; and in neoplastic infiltration and myocardial fibrosis of diverse causes. In many of these conditions, particularly those with substantial concomitant endocardial involvement, partial obliteration of the ventricular cavity by fibrous tissue and thrombus contributes to the abnormally increased resistance to ventricular filling. Thromboembolic complications are frequent in such patients.

CLINICAL FEATURES

The inability of the ventricles to fill limits cardiac output and raises filling pressures; thus, exercise intolerance and dyspnea are usually promi-

nent. As a result of persistently elevated systemic venous pressure, these patients commonly have dependent edema, ascites, and an enlarged, tender, and often pulsatile liver. The jugular venous pressure is elevated and does not fall normally (or may rise) with inspiration (Kussmaul's sign). The heart sounds may be distant, and third and fourth heart sounds are common. In contrast to constrictive pericarditis (Chap. 232), which RCM resembles in many respects, the apex impulse is usually easily palpable, and mitral regurgitation is more common.

LABORATORY EXAMINATIONS

In patients with infiltrative cardiomyopathies, the ECG often shows low-voltage, nonspecific ST-T-wave abnormalities and various arrhythmias. Pericardial calcification on x-ray, which occurs in constrictive pericarditis, is absent. Echocardiography, CTI, and CMRI typically reveal symmetrically thickened LV walls and normal or slightly reduced ventricular volumes and systolic function; the atria are usually dilated. Doppler echocardiography typically shows diastolic dysfunction. Cardiac catheterization shows a reduced cardiac output, elevation of the RV and LV end-diastolic pressures, and a dip-and-plateau configuration of the diastolic portion of the ventricular pressure pulses resembling constrictive pericarditis.

Differentiation of RCM from constrictive pericarditis (Chap. 232) is of importance because the latter is often curable by surgery. Helpful in the differentiation of these two conditions are RV transvenous endomyocardial biopsy (by revealing myocardial infiltration or fibrosis in RCM) and CTI or CMRI (by demonstrating a thickened pericardium in constrictive pericarditis but not in RCM).

℞ RESTRICTIVE CARDIOMYOPATHY

Management is usually disappointing, except for hemochromatosis (see below) and Fabry's disease (see above). Chronic anticoagulation is often recommended to reduce the risk of embolization from the heart.

EOSINOPHILIC ENDOMYOCARDIAL DISEASE

Also called *Loeffler's endocarditis* and *fibroplastic endocarditis*, this condition occurs in temperate climates. It appears to be a subcategory of the hypereosinophilic syndrome (Chap. 249) in which the heart is predominantly involved, with cardiac damage the apparent result of the toxic effects of eosinophilic proteins. Typically, the endocardium of either or both ventricles is thickened markedly, with involvement of the underlying myocardium. Cardiac imaging typically reveals ventricular thickening, especially of the posterobasal LV wall. Mitral regurgitation is frequently present on Doppler echocardiography. Large mural thrombi may develop in either ventricle, thereby compromising the size of the ventricular cavity and serving as a source of pulmonary and systemic emboli. Hepatosplenomegaly and localized eosinophilic infiltration of other organs are usually present. Management usually includes diuretics, afterload-reducing agents, and anticoagulation. The use of glucocorticoids and hydroxyurea appears to improve survival. Surgical treatment with resection of fibrotic tissue and mitral valve repair or replacement may be helpful in selected patients.

CARDIAC AMYLOIDOSIS

(See also Chap. 324) Involvement of the heart is the most frequent cause of death in *primary amyloidosis* (AL) and *hereditary amyloidosis* (ATTR), with deposition of amyloid in the cardiac interstitium. On gross pathologic examination, the heart is firm, rubbery, and noncompliant and has a waxy appearance. Clinically significant cardiac involvement is uncommon in the secondary form. Focal deposits of amyloid in the hearts of elderly persons (*senile cardiac amyloidosis*), although common, are usually clinically insignificant.

Four clinical presentations (alone or in combination) are seen: (1) diastolic dysfunction, (2) systolic dysfunction, (3) arrhythmias and conduction disturbances, and (4) orthostatic hypotension. The two-dimensional echocardiogram may be helpful in establishing the diagnosis of amyloidosis and may show a thickened myocardial wall with a diffuse, hyperrefractile "speckled" appearance. CMRI typically shows late gadolinium enhancement of the subendocardium. Aspiration of abdominal fat or biopsy of the myocardium or other organs permits the ante mortem diagnosis to be established in over three-quarters of cases.

Chemotherapy, often with alkylating agents such as melphalan, together with glucocorticoids, appears to have improved survival in individual cases. Heart transplantation (often combined with bone marrow transplantation or liver or kidney transplantation for hereditary amyloidosis) may help selected patients. However, the overall prognosis is poor, especially in the primary form with advanced cardiac involvement.

OTHER RESTRICTIVE CARDIOMYOPATHIES

Iron-overload cardiomyopathy (hemochromatosis) (Chap. 351) is often the result of multiple transfusions or a hemoglobinopathy, most frequently β-thalassemia; the familial (autosomal recessive) form should be suspected if cardiomyopathy occurs in the presence of diabetes mellitus, hepatic cirrhosis, and increased skin pigmentation. The diagnosis may be confirmed by endomyocardial biopsy. CMRI shows a reduced T2* signal as iron levels rise. Phlebotomy may be of some benefit if employed early in the course of the disease. Continuous subcutaneous administration of deferoxamine or other iron chelators may reduce body iron stores and result in clinical improvement.

Myocardial *sarcoidosis* (Chap. 322) is generally associated with other manifestations of systemic disease. It may cause restrictive as well as congestive features, since cardiac infiltration by sarcoid granulomas results not only in increased stiffness of the myocardium but also in diminished systolic contractile function. A variety of arrhythmias, including high-grade AV block, have been noted. A common cardiac manifestation of systemic sarcoidosis is RV overload due to pulmonary hypertension as a result of parenchymal pulmonary involvement. Many patients are treated empirically with glucocorticoids.

The *carcinoid syndrome* (Chap. 230) results in endocardial fibrosis and stenosis and/or regurgitation of the tricuspid and/or pulmonary valve; morphologically similar lesions have been seen with the use of the anorexic agents fenfluramine and phentermine.

MYOCARDITIS

Myocarditis, i.e., cardiac inflammation, is most commonly the result of an infectious process, frequently complicated by autoimmunity. Myocarditis may also result from hypersensitivity to drugs (most commonly tricyclic antidepressants, antibiotics, and antipsychotics) or it may be caused by irradiation, chemicals, or physical agents. While almost every infective agent is capable of producing myocarditis (Table 231-1), clinically significant acute myocarditis in the United States is caused most commonly by viruses, especially Coxsackievirus B, adenovirus, hepatitis C virus, and HIV. Symptomatic viral myocarditis may be secondary to continued viral replication and/or autoimmune activation following viral infection.

CLINICAL FEATURES

Patients with viral myocarditis may give a history of a preceding upper respiratory febrile illness or a flulike syndrome, and viral nasopharyngitis or tonsillitis may be evident. The clinical spectrum ranges from an asymptomatic state, with the presence of myocarditis inferred only by the finding of transient electrocardiographic ST-T-wave abnormalities, to a fulminant condition with arrhythmias, acute CHF, and early death. In some patients, myocarditis simulates an acute coronary syndrome (Chap. 238), with chest pain, ECG changes, and elevated serum levels of troponin, but it typically occurs in patients younger than those with coronary atherosclerosis.

The *physical examination* is often normal, although more severe cases may show a muffled first heart sound, along with a third heart sound and a murmur of mitral regurgitation. A pericardial friction rub may be audible in patients with associated pericarditis. The isolation of virus from the stool, pharyngeal washings, or other body fluids

and changes in specific antibody titers may be helpful clinically. Endomyocardial biopsy, carried out early in the illness, may show round-cell infiltration and necrosis of adjacent myocytes. CMRI frequently exhibits contrast enhancement (Chap. 222) and is valuable in identifying sites likely to exhibit typical histologic changes on biopsy, as well as in monitoring the activity of the disease.

Although viral myocarditis is most often self-limited and without sequelae, severe involvement may recur. Acute viral myocarditis, especially when accompanied by severe LV dysfunction (LVEF < 35%), may progress to a chronic form and to DCM.

℞ MYOCARDITIS

Exercise may be deleterious in patients with acute myocarditis, and strenuous activity should be proscribed until the ECG and LV function have returned to normal. Patients who develop CHF should be treated with the usual measures (Chap. 227). Arrhythmias are common and are occasionally difficult to manage. Deaths attributed to CHF, tachyarrhythmias, and AV block have been reported; the ECG should be monitored during the acute illness and in patients with arrhythmias.

Patients with fulminant myocarditis may require mechanical cardiopulmonary support or cardiac transplantation; however, the majority of these patients survive, and many demonstrate substantial recovery of LV function.

MYOCARDITIS IN PATIENTS WITH HIV

(See also Chap. 182) Many HIV-infected patients have subclinical cardiac involvement, including pericardial effusion, right-sided chamber enlargement, arrhythmias, and neoplastic involvement. Overt clinical manifestations are seen in 10% of HIV patients. The most common finding is LV dysfunction that in some cases appears to be due to infection of the myocardium by the virus itself. In other patients, the heart is affected by one of the various opportunistic infections common in HIV-AIDS, such as toxoplasmosis; by cardiac involvement by neoplastic disorders; or by toxicity from anti-HIV drugs. CHF in HIV myocarditis may respond, at least transiently, to standard anti-HIV therapy.

BACTERIAL MYOCARDITIS

Bacterial involvement of the heart is uncommon, but when it does occur, it is usually as a complication of infective endocarditis (Chap. 118) in which abscess formation involves the valve rings and interventricular septum.

Diphtheritic myocarditis develops in over one-quarter of patients with diphtheria (Chap. 131); it is one of the more serious complications and the most common cause of death in this infection. Cardiac damage is due to the liberation of a toxin that inhibits protein synthesis and leads to a dilated, flabby, hypocontractile heart. The conduction system is frequently involved, as well. Cardiomegaly and severe CHF typically appear after the first week of illness. Prompt therapy with antitoxin is critical; antibiotic therapy is also indicated but is of less urgency.

GIANT CELL MYOCARDITIS

This rare myocarditis of unknown cause is characterized by rapidly progressive CHF and ventricular tachyarrhythmia and occurs most commonly in the third or fourth decades; approximately two-thirds of patients die within 1 year. At necropsy, the distinctive features include cardiac enlargement, ventricular thrombi, grossly visible serpiginous areas of necrosis in both ventricles, and microscopic evidence of giant cells within an extensive inflammatory infiltrate. The etiology of giant cell myocarditis has not been identified, although an autoimmune cause appears to be likely. While treatment with immunosuppressive therapy may help some patients, cardiac transplantation is often necessary.

LYME CARDITIS

(See also Chap. 166) Lyme disease is caused by a tick-borne spirochete and is most common in the Northeast, upper Midwest, and Pacific Coastal regions of the United States during the summer months. About 10% of patients develop symptomatic cardiac involvement during the acute phase of the disease. AV conduction abnormalities are the most common manifestations of involvement and may lead to syncope. Concomitant myopericarditis is not uncommon, and mild, asymptomatic LV dysfunction may occur.

Intravenous ceftriaxone or penicillin is indicated in all but the mildest forms of Lyme carditis, in which case oral amoxicillin or doxycycline is employed. Hospitalization with ECG monitoring is indicated in patients with second- or third-degree AV block. A temporary pacemaker may be needed for symptomatic AV block, but permanent pacing is rarely required. Although glucocorticoids are often given, their effectiveness in reversing AV block is uncertain. Long-term cardiac manifestations of Lyme disease are uncommon.

GLOBAL CONSIDERATIONS

CHAGAS HEART DISEASE

(See also Chaps. 206 and e37) Chagas disease, caused by the protozoan *Trypanosoma cruzi* and transmitted by an insect vector, the reduvid bug, produces an extensive myocarditis that typically becomes evident years after the initial infection. It is one of the more common causes of heart disease encountered in Central and South America; in rural endemic areas, 20–75% of the population may be affected. It has been estimated that ~18 million persons are affected, with 200,000 new cases each year. An increasing number of cases are found in the United States as patients migrate from endemic areas; in rare cases, it has been transmitted by transfusion and organ donation.

About 1% of infected individuals have an acute illness, which may include acute myocarditis that usually resolves in 2–3 months. After a quiescent, asymptomatic period, the so-called *indeterminate phase*, approximately one-third of infected persons develop chronic myocardial damage. A combination of infection by the parasite as well as autoimmune reactions are responsible for the cardiac manifestations. Cardiac involvement in chronic Chagasic heart disease varies widely, from asymptomatic to severe cardiac failure involving the left ventricle, and sometimes the right ventricle, and/or AV block. This condition, which is more frequent in males, is characterized by dilatation of several cardiac chambers, fibrosis and thinning of the ventricular wall, aneurysm formation in the left ventricle (Fig. 231-3), and mural thrombi. Survival is poor in patients who develop overt CHF. The cause of death is either intractable CHF or SCD secondary to an arrhythmia, with a minority of patients dying from embolic phenomena.

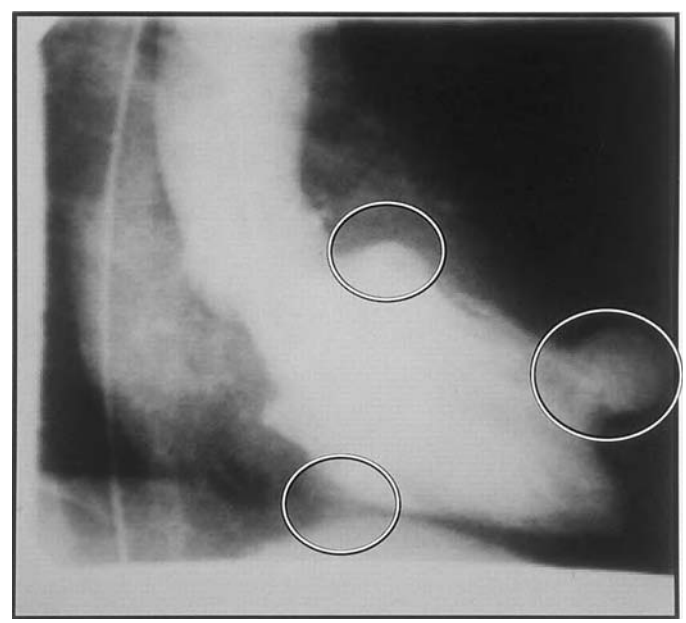

FIGURE 231-3 Left ventriculogram of a 55-year-old woman with chronic Chagas disease. Multiple left ventricular aneurysms are noted in inferobasal, anterior, and inferior aspects of left ventricle (circled). *(From P Venegoni, HS Bhatia: Circulation 96:1363, 1997.)*

The ECG is abnormal in most patients and typically shows low voltage, along with right bundle branch block and left anterior hemiblock, and may progress to complete AV block. The chest roentgenogram may show LV enlargement. Echocardiography may reveal hypokinesis of the posterior LV wall and relatively preserved septal motion. Ventricular arrhythmias are common and are seen on Holter monitoring, especially during and after exertion.

℞ CHAGAS HEART DISEASE

Therapy is directed toward amelioration of the CHF and ventricular tachyarrhythmias; oral amiodarone appears to be particularly effective in treating the latter. Progressive conduction system disease and AV block may require implantation of a pacemaker. Anticoagulation reduces the risk of thromboembolism. Medical therapy is often unsatisfactory or unavailable (especially in poor rural areas); however, a more promising tactic in endemic areas is the use of insecticides to eliminate the vector.

CARDIOMYOPATHY IN AFRICA

Endomyocardial Fibrosis This is a progressive disease that presents as a RCM. It occurs most commonly in children and young adults residing in tropical and subtropical Africa, particularly Uganda and Nigeria, as well as in tropical Asia and South America. It is related and similar to hypereosinophilic endomyocardial disease (see above), although the eosinophilia is less severe and the course more chronic in endomyocardial fibrosis. Endomyocardial fibrosis is a frequent cause of CHF in Africa, accounting for up to one-quarter of deaths due to heart disease. The condition is characterized by severe fibrosis of the endocardium, with involvement of the inflow portion of the right or left ventricle (or both). Endomyocardial fibrosis often involves the AV valves, producing valvular regurgitation. The apex of the ventricles may be obliterated by a mass of thrombus and fibrous tissue.

The clinical picture depends on which ventricle and AV valve shows predominant involvement; left-sided involvement results in symptoms of pulmonary congestion, while predominant right-sided disease presents features of systemic venous congestion. Medical treatment is often disappointing, and surgical excision of the fibrotic endocardium and replacement of the involved AV valve have led to substantial symptomatic improvement in some patients.

Dilated Cardiomyopathy DCM is a common cause of heart failure in Africa and has been reported in up to one-half of patients hospitalized with CHF. The etiology of DCM in Africa is multifactorial. Infection with *Toxoplasma gondii* and *Coxsackievirus B* has been reported to be common in DCM patients in Nigeria, while *African trypanosomiasis* appears to be a common cause in Cameroon. Excess alcohol ingestion is considered to be causal or an important contributory factor in almost one-half of cases of DCM; severe thiamine deficiency may be present in some of these patients as well.

Peripartum cardiomyopathy is far more common in Africa than in North America or Europe; the incidence has been reported to be especially high in Nigeria. Pathogenetic factors that may be operative include low socioeconomic status, high parity, prolonged lactation, excessive dietary salt intake, and selenium deficiency.

CARDIOMYOPATHY IN ASIA

Thiamine (vitamin B_1) deficiency (Chap. 71) occurs in Asian countries, especially China, where polished rice, deficient in thiamine, is a major component of the diet and flour is not enriched with thiamine, as it is in the West. However, thiamine deficiency in the West may occur in patients with severe alcoholism.

So-called *wet beri-beri heart disease* is an important clinical manifestation of serious thiamine deficiency. It is characterized by cardiac failure secondary to a high cardiac output state caused by arteriolar vasodilation; it is associated with tachycardia, wide pulse pressure, a third heart sound, and warm extremities. ECG findings include reduced voltage, diffuse T-wave abnormalities and prolongation of the QT interval. On chest x-ray, the heart appears diffusely enlarged with pulmonary congestion. The response to thiamine is usually dramatic, but it should be accompanied by diuretics.

Selenium deficiency (Chap. 71) is also most common in China. It may cause *Keshan's disease*, a dilated cardiomyopathy with cardiomegaly, ventricular arrhythmias, and heart failure.

232 Pericardial Disease

Eugene Braunwald

NORMAL FUNCTIONS OF THE PERICARDIUM

The normal pericardium is a double-layered sac; the visceral pericardium is a serous membrane that is separated by a small quantity (15–50 mL) of fluid, an ultrafiltrate of plasma, from the fibrous parietal pericardium. The normal pericardium, by exerting a restraining force, prevents sudden dilation of the cardiac chambers, especially of the right atrium and ventricle, during exercise and with hypervolemia. It also restricts the anatomic position of the heart, minimizes friction between the heart and surrounding structures, prevents displacement of the heart and kinking of the great vessels, and probably retards the spread of infections from the lungs and pleural cavities to the heart. Notwithstanding the foregoing, total absence of the pericardium, either congenital or following surgery, does not produce obvious clinical disease. In partial left pericardial defects, the main pulmonary artery and left atrium may bulge through the defect; very rarely, herniation and subsequent strangulation of the left atrium may cause sudden death.

ACUTE PERICARDITIS

Acute pericarditis, by far the most common pathologic process involving the pericardium, may be classified both clinically and etiologically (Table 232-1). Pain, a pericardial friction rub, electrocardiographic changes, and pericardial effusion with cardiac tamponade and paradoxical pulse are cardinal manifestations of many forms of acute pericarditis.

Chest pain is an important but not invariable symptom in various forms of acute pericarditis (Chap. 13); it is usually present in the acute infectious types and in many of the forms presumed to be related to hypersensitivity or autoimmunity. Pain is often absent in slowly developing tuberculous, postirradiation, neoplastic, or uremic pericarditis. The pain of acute pericarditis is often severe, retrosternal and left precordial, and referred to the neck, arms, or the left shoulder. Often the pain is pleuritic, consequent to accompanying pleural inflammation, i.e., sharp and aggravated by inspiration, coughing, and changes in body position, but sometimes it is a steady, constricting pain that radiates into either arm or both arms and resembles that of myocardial ischemia; therefore, confusion with acute myocardial infarction (AMI) is common. Characteristically, however, pericardial pain may be relieved by sitting up and leaning forward and is intensified by lying supine. The differentiation of AMI from acute pericarditis becomes perplexing when, with acute pericarditis, serum biomarkers of myocardial damage such as creatine kinase and troponin rise, presumably because of concomitant involvement of the epicardium in the inflammatory process (an epi-myocarditis) with resulting myocyte necrosis. However, these elevations, if they occur, are quite modest, given the extensive electrocardiographic ST-segment elevation in pericarditis. This dissociation is useful in the differentiation between these conditions.

The *pericardial friction rub,* audible in about 85% of patients, may have up to three components per cardiac cycle, is high-pitched, and is described as rasping, scratching, or grating (Chap. 220); it can be elicited sometimes only when the diaphragm of the stethoscope is applied firmly to the chest wall at the left lower sternal border. It is heard most frequently at end-expiration with the patient upright and leaning forward. The rub is often inconstant, and the loud to-and-fro leathery sound may disappear within a few hours, possibly to reappear on the following day. A pericardial rub is heard throughout the respiratory cycle, while a pleural rub disappears when respiration is suspended.

The *electrocardiogram* (ECG) in acute pericarditis without massive effusion usually displays changes secondary to acute subepicardial inflammation (see Fig. 232-1). It typically evolves through four stages. In stage 1, there is widespread elevation of the ST segments, often with upward concavity, involving two or three standard limb leads and V_2 to V_6, with reciprocal depressions only in aVR and sometimes V_1, as well as PR-segment depression. Usually there are no significant changes in QRS complexes. In stage 2, after several days, the ST segments return to normal, and only then, or even later, do the T waves become inverted (stage 3). Ultimately, weeks or months after the onset of acute pericarditis, the ECG returns to normal in stage 4. In contrast, in AMI, ST elevations are convex, and reciprocal depression is usually more prominent; QRS changes occur, particularly the development of Q waves, as well as notching and loss of R-wave amplitude; and T-wave inversions are usually seen within hours *before* the ST segments have become isoelectric. Sequential ECGs are useful in distinguishing acute pericarditis from AMI. In the latter, elevated ST segments return to normal within hours.

Early repolarization is a normal variant and may also be associated with widespread ST-segment elevation, most prominent in left precordial leads. However, in this condition the T waves are usually tall and the ST/T ratio is <0.25; importantly, this ratio is higher in acute pericarditis. Depression of the PR segment (below the TP segment) is also common and reflects atrial involvement.

TABLE 232-1 CLASSIFICATION OF PERICARDITIS

Clinical Classification

I. Acute pericarditis (<6 weeks)
  A. Fibrinous
  B. Effusive (serous or sanguineous)
II. Subacute pericarditis (6 weeks to 6 months)
  A. Effusive-constrictive
  B. Constrictive
III. Chronic pericarditis (>6 months)
  A. Constrictive
  B. Effusive
  C. Adhesive (nonconstrictive)

Etiologic Classification

I. Infectious pericarditis
  A. Viral (coxsackievirus A and B, echovirus, mumps, adenovirus, hepatitis, HIV)
  B. Pyogenic (pneumococcus, streptococcus, staphylococcus, *Neisseria, Legionella*)
  C. Tuberculous
  D. Fungal (histoplasmosis, coccidioidomycosis, *Candida,* blastomycosis)
  E. Other infections (syphilitic, protozoal, parasitic)
II. Noninfectious pericarditis
  A. Acute myocardial infarction
  B. Uremia
  C. Neoplasia
    1. Primary tumors (benign or malignant, mesothelioma)
    2. Tumors metastatic to pericardium (lung and breast cancer, lymphoma, leukemia)
  D. Myxedema
  E. Cholesterol
  F. Chylopericardium
  G. Trauma
    1. Penetrating chest wall
    2. Nonpenetrating
  H. Aortic dissection (with leakage into pericardial sac)
  I. Postirradiation
  J. Familial Mediterranean fever
  K. Familial pericarditis
    1. Mulibrey nanism[a]
  L. Acute idiopathic
  M. Whipple's disease
  N. Sarcoidosis
III. Pericarditis presumably related to hypersensitivity or autoimmunity
  A. Rheumatic fever
  B. Collagen vascular disease (SLE, rheumatoid arthritis, ankylosing spondylitis, scleroderma, acute rheumatic fever, Wegener's granulomatosis)
  C. Drug-induced (e.g., procainamide, hydralazine, phenytoin, isoniazide, minoxidil, anticoagulants, methysergide)
  D. Postcardiac injury
    1. Postmyocardial infarction (Dressler's syndrome)
    2. Postpericardiotomy
    3. Posttraumatic

[a]An autosomal recessive syndrome, characterized by growth failure, muscle hypotonia, hepatomegaly, ocular changes, enlarged cerebral ventricles, mental retardation, ventricular hypertrophy, and chronic constrictive pericarditis.

PERICARDIAL EFFUSION

In acute pericarditis, effusion is usually associated with pain and/or the above-mentioned ECG changes, as well as with an enlargement of the cardiac silhouette. Pericardial effusion is especially important clinically when it develops within a relatively short time as it may lead to cardiac tamponade (see below). Differentiation from cardiac enlargement may be difficult on physical examination, but heart sounds may be fainter with pericardial effusion. The friction rub may disappear, and the apex impulse may vanish, but sometimes it remains palpable, albeit medial to the left border of cardiac dullness. The base of the left lung may be compressed by pericardial fluid, producing *Ewart's sign*, a patch of dullness and increased fremitus (and egophony) beneath the angle of the left scapula. The chest roentgenogram may show a "water bottle" configuration of the cardiac silhouette (Fig. 232-2) but may also be normal.

Diagnosis *Echocardiography* (Chap. 222) is the most effective imaging technique available since it is sensitive, specific, simple, noninvasive, may be performed at the bedside, and can identify accompanying cardiac tamponade (see below) (Fig. 232-3). The presence of pericardial fluid is recorded by two-dimensional transthoracic echocardiography

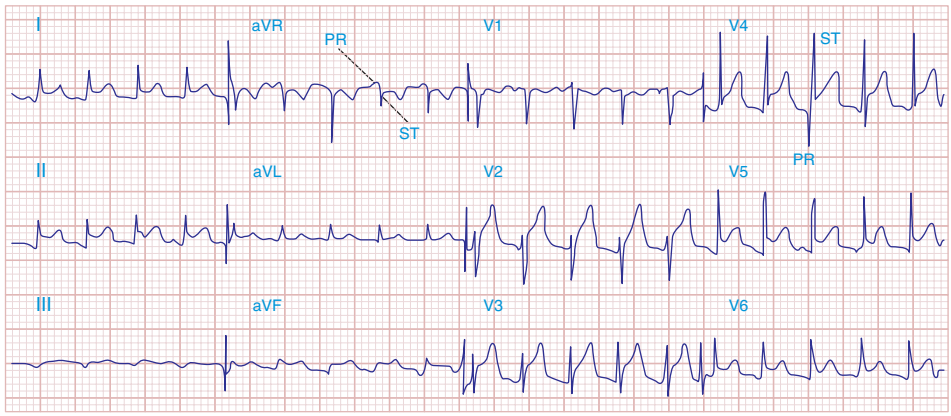

FIGURE 232-1 Acute pericarditis often produces diffuse ST-segment elevations (in this case in leads I, II, aVF, and V_2 to V_6) due to a ventricular current of injury. Note also the characteristic PR-segment deviation (opposite in polarity to the ST segment) due to a concomitant atrial injury current.

as a relatively echo-free space between the posterior pericardium and left ventricular epicardium in patients with small effusions, and as a space between the anterior right ventricle and the parietal pericardium just beneath the anterior chest wall in those with larger effusions. In the latter the heart may swing freely within the pericardial sac. When severe, the extent of this motion alternates and may be associated with electrical alternans. Echocardiography allows localization and estimation of the quantity of pericardial fluid.

The diagnosis of pericardial fluid or thickening may be confirmed by computed tomography (CT) or magnetic resonance imaging (MRI) (Fig. 232-4). These techniques may be superior to echocardiography in detecting loculated pericardial effusions, pericardial thickening, and the presence of pericardial masses.

CARDIAC TAMPONADE

The accumulation of fluid in the pericardial space in a quantity sufficient to cause serious obstruction to the inflow of blood to the ventricles results in cardiac tamponade. This complication may be fatal if it is not recognized and treated promptly. The three most common causes of tamponade are neoplastic disease, idiopathic pericarditis, and pericardial effusion secondary to renal failure. Tamponade may also result from bleeding into the pericardial space either following cardiac operations and trauma (including cardiac perforation during cardiac catheterization, percutaneous coronary intervention, or insertion of pacemaker wires) or from tuberculosis and hemopericardium. The latter may occur when a patient with any form of acute pericarditis is treated with anticoagulants.

The three principal features of tamponade (*Beck's triad*) are hypotension, soft or absent heart sounds, and jugular venous distention with a prominent *x* descent but an absent *y* descent. There are both limitation of ventricular filling and reduction of cardiac output. The quantity of fluid necessary to produce this critical state may be as small as 200 mL when the fluid develops rapidly or >2000 mL in slowly developing effusions when the pericardium has had the opportunity to stretch and adapt to an increasing volume. The volume of fluid required to produce tamponade also varies directly with the thickness of the ventricular myocardium and inversely with the thickness of the parietal pericardium.

Tamponade may also develop more slowly, and under these circumstances the clinical manifestations may resemble those of heart failure, including dyspnea, orthopnea, and hepatic engorgement. A high index of suspicion for cardiac tamponade is required since, in many instances, no obvious cause for pericardial disease is apparent, and it should be considered in any patient with hypotension and elevation of jugular venous pressure. Otherwise unexplained enlargement of the cardiac silhouette (especially in subacute or chronic tamponade), reduction in

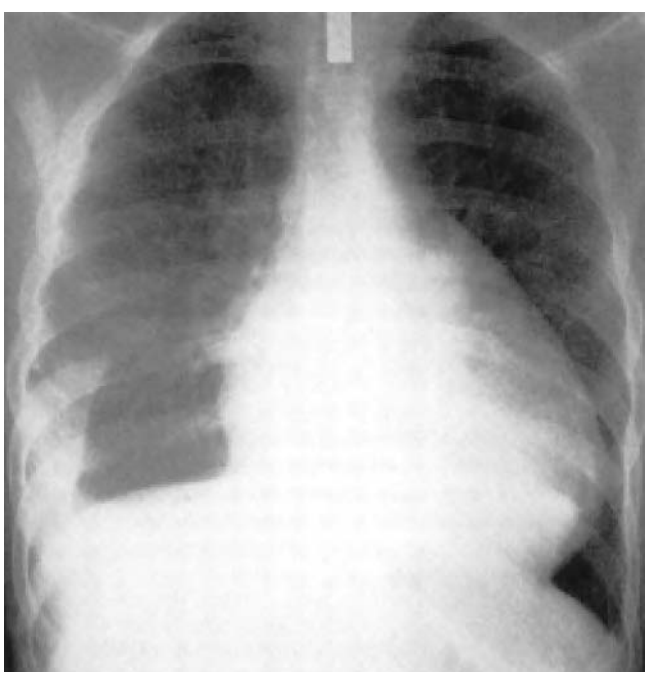

FIGURE 232-2 Chest radiogram from a patient with a pericardial effusion showing typical "water bottle" heart. There is also a right pleural effusion. *[From SS Kabbani, M LeWinter, in MH Crawford et al (eds): Cardiology. London, Mosby, 2001.]*

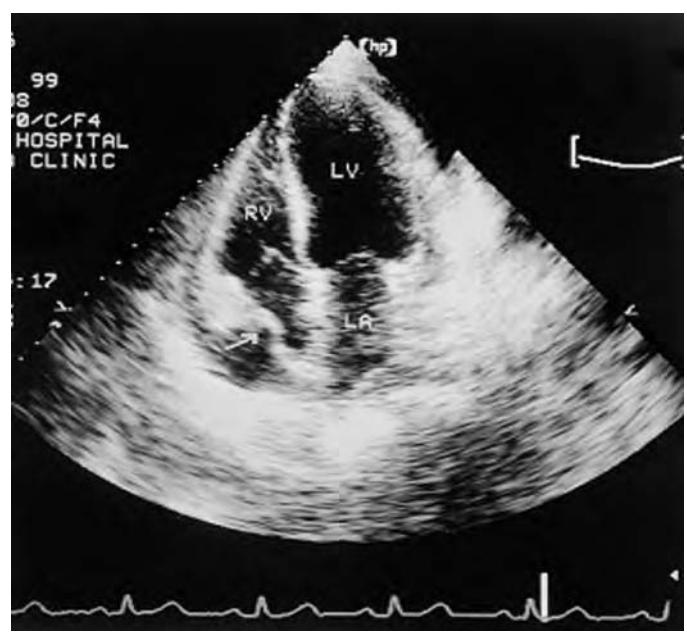

FIGURE 232-3 Apical four-chamber echocardiogram recorded in a patient with a moderate pericardial effusion and evidence of hemodynamic compromise. The frame is recorded in early ventricular systole, immediately after atrial contraction. Note that the right atrial wall is indented inward and its curvature is frankly reversed (*arrow*), implying elevated intrapericardial pressure above right atrial pressure. LA, left atrium; LV, left ventricle; RV, right ventricle. *[From WF Armstrong: Echocardiography, in DP Zipes et al (eds): Braunwald's Heart Disease, 7th ed. Philadelphia, Elsevier, 2005.]*

FIGURE 232-4 Chronic pericardial effusion in a 54-year-old female patient with Hodgkin's disease seen in contrast-enhanced 64-slice CT. The arrows point at the pericardial effusion (LV, left ventricle; RV, right ventricle; RA, right atrium). Due to the timing of the scan relative to contrast injection, only the blood in the left ventricle is contrast-enhanced, hence the low attenuation in the right-sided chambers. *(Courtesy of Stephan Achenbach, MD; with permission.)*

amplitude of the QRS complexes, and *electrical alternans* of the P, QRS, or T waves each should raise the suspicion of cardiac tamponade.

Table 232-2 lists the features that distinguish acute cardiac tamponade from constrictive pericarditis.

Paradoxical Pulse This important clue to the presence of cardiac tamponade consists of a greater than normal (10 mmHg) inspiratory decline in systolic arterial pressure. When severe, it may be detected by palpating weakness or disappearance of the arterial pulse during inspiration, but usually sphygmomanometric measurement of systolic pressure during slow respiration is required.

Since both ventricles share a tight incompressible covering, i.e., the pericardial sac, the inspiratory enlargement of the right ventricle in cardiac tamponade compresses and reduces left ventricular volume; leftward bulging of the interventricular septum further reduces the left ventricular cavity as the right ventricle enlarges during inspiration. Thus, in cardiac tamponade the normal inspiratory augmentation of right ventricular volume causes an exaggerated reciprocal reduction in left ventricular volume. Also, respiratory distress increases the fluctuations in intrathoracic pressure, which exaggerates the mechanism just described. Right ventricular infarction (Chap. 239) may resemble cardiac tamponade with hypotension, elevated jugular venous pressure, an absent *y* descent in the jugular venous pulse, and, occasionally, pulsus paradoxus. The differences between these two conditions are shown in Table 232-2.

Paradoxical pulse occurs not only in cardiac tamponade but also in approximately one-third of patients with constrictive pericarditis (see below). This physical finding is not pathognomonic of pericardial disease because it may be observed in some cases of hypovolemic shock, acute and chronic obstructive airways disease, and pulmonary embolus.

Low-pressure tamponade refers to mild tamponade in which the intrapericardial pressure is increased from its slightly subatmospheric levels to +5 to +10 mmHg; in some instances, hypovolemia coexists. As a consequence, the central venous pressure is normal or only slightly elevated, while arterial pressure is unaffected and there is no paradoxical pulse. The patients are asymptomatic or complain of mild weakness and dyspnea. The diagnosis is aided by echocardiography, and both hemodynamic and clinical manifestations improve following pericardiocentesis.

Diagnosis Since immediate treatment of cardiac tamponade may be lifesaving, prompt measures to establish the diagnosis by echocardiography should be undertaken (Fig. 232-2). When pericardial effusion causes tamponade, Doppler ultrasound shows that tricuspid and pulmonic valve flow velocities increase markedly during inspiration, while pulmonic vein, mitral, and aortic flow velocities diminish. Often the right ventricular cavity is reduced in diameter, and there is late diastolic inward motion (collapse) of the right ventricular free wall and of the right atrium. Transesophageal echocardiography may be necessary to diagnose a loculated or hemorrhagic effusion responsible for cardiac tamponade.

TABLE 232-2 FEATURES THAT DISTINGUISH CARDIAC TAMPONADE FROM CONSTRICTIVE PERICARDITIS AND SIMILAR CLINICAL DISORDERS

Characteristic	Tamponade	Constrictive Pericarditis	Restrictive Cardiomyopathy	RVMI
Clinical				
Pulsus paradoxus	Common	Usually absent	Rare	Rare
Jugular veins				
Prominent *y* descent	Absent	Usually present	Rare	Rare
Prominent *x* descent	Present	Usually present	Present	Rare
Kussmaul's sign	Absent	Present	Absent	Present
Third heart sound	Absent	Absent	Rare	May be present
Pericardial knock	Absent	Often present	Absent	Absent
Electrocardiogram				
Low ECG voltage	May be present	May be present	May be present	Absent
Electrical alternans	May be present	Absent	Absent	Absent
Echocardiography				
Thickened pericardium	Absent	Present	Absent	Absent
Pericardial calcification	Absent	Often present	Absent	Absent
Pericardial effusion	Present	Absent	Absent	Absent
RV size	Usually small	Usually normal	Usually normal	Enlarged
Myocardial thickness	Normal	Normal	Usually increased	Normal
Right atrial collapse and RVDC	Present	Absent	Absent	Absent
Increased early filling, ↑ mitral flow velocity	Absent	Present	Present	May be present
Exaggerated respiratory variation in flow velocity	Present	Present	Absent	Absent
CT/MRI				
Thickened/calcific pericardium	Absent	Present	Absent	Absent
Cardiac catheterization				
Equalization of diastolic pressures	Usually present	Usually present	Usually absent	Absent or present
Cardiac biopsy helpful?	No	No	Sometimes	No

Abbreviations: RV, right ventricle; RVMI, right ventricular myocardial infarction; RVDC, right ventricular diastolic collapse; ECG, electrocardiograph.

Rx CARDIAC TAMPONADE

Patients with acute pericarditis should be observed frequently for the development of an effusion; if a large effusion is present, the patient should be hospitalized and watched closely for signs of tamponade. Arterial and venous pressures and heart rate should be monitored or followed carefully and serial echocardiograms obtained.

PERICARDIOCENTESIS If manifestations of tamponade appear, echocardiographically guided pericardiocentesis using an apical, parasternal, or, most commonly, a subxiphoid approach must be carried out at once as reduction of the elevated intrapericardial pressure may be lifesaving. Intravenous saline may be administered as the patient is being readied for the procedure. Intrapericardial pressure should be measured before fluid is withdrawn, and the pericardial cavity should be drained as completely as possible. A small, multiholed catheter advanced over the needle inserted into the pericardial cavity may be left in place to allow draining of the pericardial space if fluid reaccumulates. Surgical drainage through a limited (subxiphoid) thoracotomy may be required in recurrent tamponade, when it is necessary to remove loculated effusions, and/or when it is necessary to obtain tissue for diagnosis.

Pericardial fluid obtained from an effusion often has the physical characteristics of an exudate. Bloody fluid is most commonly due to neoplasm in the United States and tuberculosis in developing nations but may also be found in the effusion of rheumatic fever, post-cardiac injury, and post-myocardial infarction, as well as in the pericarditis associated with renal failure or dialysis. Transudative pericardial effusions may occur in heart failure.

The pericardial fluid should be analyzed for red and white blood cells, and cytologic studies for cancer, microscopic studies, and cultures should be obtained. The presence of DNA of *Mycobacterium tuberculosis* determined by polymerase chain reaction or an elevated adenosine deaminase activity (>30 U/L) strongly supports the diagnosis of tuberculous pericarditis (Chap. 158).

VIRAL OR IDIOPATHIC FORM OF ACUTE PERICARDITIS

In some cases of this common disorder, coxsackievirus A or B or the virus of influenza, echovirus, mumps, herpes simplex, chickenpox, adenovirus, cytomegalovirus, Epstein-Barr, or HIV has been isolated from pericardial fluid and/or appropriate elevations in viral antibody titers have been noted. In many instances, acute pericarditis occurs in association with illnesses of known viral origin and, presumably, are caused by the same agent. Commonly, there is an antecedent infection of the respiratory tract, but in many patients such an association is not evident, and viral isolation and serologic studies are negative. Pericardial effusion is a common cardiac manifestation of HIV; it is usually secondary to infection (often mycobacterial) or neoplasm, most frequently lymphoma. In full-blown AIDS, pericardial effusion is associated with a shortened survival (Chap. 182).

Most frequently, a viral causation cannot be established; the term *idiopathic acute pericarditis* is then appropriate. Viral or idiopathic acute pericarditis occurs at all ages but is more frequent in young adults, and is often associated with pleural effusions and pneumonitis. The almost simultaneous development of fever and precordial pain, often 10 to 12 days after a presumed viral illness, constitutes an important feature in the differentiation of acute pericarditis from AMI, in which pain precedes fever. The constitutional symptoms are usually mild to moderate, and a pericardial friction rub is often audible. The disease ordinarily runs its course in a few days to 4 weeks. The ST-segment alterations in the ECG usually disappear after 1 or more weeks, but the abnormal T waves may persist for several years and be a source of confusion in persons without a clear history of pericarditis.

Pleuritis and pneumonitis frequently accompany pericarditis. Accumulation of some pericardial fluid is common, and both tamponade and constrictive pericarditis are possible complications. Recurrent (relapsing) pericarditis occurs in about one-fourth of patients with acute idiopathic pericarditis. In a smaller number, there are multiple recurrences.

Rx IDIOPATHIC ACUTE PERICARDITIS

Hyperimmune globulin has been reported to be beneficial in cytomegalovirus, adenovirus, and parvovirus pericarditis, while interferon α has been reported to be so in coxsackie B pericarditis. In acute idiopathic pericarditis there is no specific therapy, but bed rest and anti-inflammatory treatment with aspirin (2–4 mg/d) may be given. If this is ineffective, one of the nonsteroidal anti-inflammatory drugs (NSAIDs), such as ibuprofen (400–800 mg qid) or colchicine (0.6 mg bid), is often effective. Glucocorticoids (e.g., prednisone, 40–80 mg daily) usually suppress the clinical manifestations of the acute illness and may be useful in patients in whom purulent bacterial pericarditis has been excluded and in patients with pericarditis secondary to connective tissue disorders and renal failure (see below). Anticoagulants should be avoided since their use could cause bleeding into the pericardial cavity and tamponade.

After the patient has been asymptomatic and afebrile for about a week, the dose of the NSAID may be tapered gradually. Colchicine may prevent recurrences, but when recurrences are multiple, frequent, disabling, continue beyond 2 years, and are not controlled by pulses of high doses of glucocorticoids, pericardiectomy may be carried out in an attempt to terminate the illness.

Postcardiac Injury Syndrome Acute pericarditis may appear under a variety of circumstances that have one common feature: previous injury to the myocardium with blood in the pericardial cavity. The syndrome may develop after a cardiac surgery (postpericardiotomy syndrome); after cardiac trauma, blunt or penetrating (Chap. 233); or after perforation of the heart with a catheter. Rarely, it follows AMI.

The clinical picture mimics acute viral or idiopathic pericarditis. The principal symptom is the pain of acute pericarditis, which usually develops 1 to 4 weeks following the cardiac injury (1 to 3 days following AMI) but sometimes appears only after an interval of months. Recurrences are common and may occur up to 2 years or more after the injury. Fever with temperature up to 40°C, pericarditis, pleuritis, and pneumonitis are the outstanding features, and the bout of illness usually subsides in 1 or 2 weeks. The pericarditis may be of the fibrinous variety or it may be a pericardial effusion, which is often serosanguineous, but rarely causes tamponade. Leukocytosis, an increased sedimentation rate, and electrocardiographic changes typical of acute pericarditis may also occur.

The mechanisms responsible for this syndrome have not been identified, but they are probably the result of a hypersensitivity reaction to antigen which originates from injured myocardial tissue and/or pericardium. Circulating myocardial antisarcolemmal and antifibrillar autoantibodies occur frequently, but their precise role has not been defined. Viral infection may also play an etiologic role, since antiviral antibodies are often elevated in patients who develop this syndrome following cardiac surgery.

Often no treatment is necessary aside from aspirin and analgesics. The management of pericardial effusion and tamponade is discussed above. When the illness is followed by a series of disabling recurrences, therapy with an NSAID, colchicine, or a glucocorticoid is usually effective.

DIFFERENTIAL DIAGNOSIS

Since there is no specific test for *acute idiopathic pericarditis*, the diagnosis is one of exclusion. Consequently, all other disorders that may be associated with acute fibrinous pericarditis must be considered. A common diagnostic error is mistaking acute viral or idiopathic pericarditis for AMI and vice versa. When acute fibrinous pericarditis is associated with AMI (Chap. 239), it is characterized by fever, pain, and a friction rub in the first 4 days following the development of the infarct. ECG abnormalities (such as the appearance of Q waves, brief ST-segment elevations with reciprocal changes, and earlier T-wave changes in AMI) and the extent of the elevations of myocardial enzymes are helpful in differentiating pericarditis from AMI.

Pericarditis secondary to post-cardiac injury is differentiated from acute idiopathic pericarditis chiefly by timing. If it occurs within a few days or weeks of an AMI, a chest blow, a cardiac perforation, or cardiac operation, it may be justified to conclude that the two are probably related. If the infarct has been silent or the chest blow forgotten, the relationship to the pericarditis may not be recognized.

It is important to distinguish *pericarditis due to collagen vascular disease* from acute idiopathic pericarditis. Most important in the differen-

tial diagnosis is the pericarditis due to systemic lupus erythematosus (SLE; Chap. 313) or drug-induced (procainamide or hydralazine) lupus. Pain is often present in pericarditis due to collagen vascular disease. Sometimes in SLE the pericarditis appears as an asymptomatic effusion and, rarely, tamponade develops. When pericarditis occurs in the absence of any obvious underlying disorder, the diagnosis of SLE may be suggested by a rise in the titer of antinuclear antibodies. Acute pericarditis is an occasional complication of *rheumatoid arthritis*, *scleroderma*, and *polyarteritis nodosa*, and other evidence of these diseases is usually obvious. Asymptomatic pericardial effusion is also frequent in these disorders. It is important to question every patient with acute pericarditis about the ingestion of procainamide, hydralazine, isoniazid, cromolyn, and minoxidil, since these drugs can cause this syndrome. The pericarditis of *acute rheumatic fever* is generally associated with evidence of severe pancarditis and with cardiac murmurs (Chap. 315).

Pyogenic (purulent) pericarditis is usually secondary to cardiothoracic operations, by extension of infection from the lungs or pleural cavities, from rupture of the esophagus into the pericardial sac, or rupture of a ring abscess in a patient with infective endocarditis, or can occur if septicemia complicates aseptic pericarditis. It is accompanied by fever, chills, septicemia, and evidence of infection elsewhere and generally has a poor prognosis. The diagnosis is made by examination of the pericardial fluid. Acute pericarditis may also complicate the viral, pyogenic, mycobacterial, and fungal infections that occur with HIV infection.

Pericarditis of renal failure (Chap. 274) occurs in up to one-third of patients with chronic uremia *(uremic pericarditis)*, is also seen in patients undergoing chronic dialysis with normal levels of blood urea and creatinine, and is termed *dialysis-associated pericarditis*. These two forms of pericarditis may be fibrinous and are generally associated with an effusion that may be sanguineous. A friction rub is common, but pain is usually absent or mild. Treatment with a nonsteroidal anti-inflammatory drug and intensification of dialysis are usually adequate. Occasionally, tamponade occurs and pericardiocentesis is required. When the pericarditis of renal failure is recurrent or persistent, a pericardial window should be created or pericardiectomy may be necessary.

Pericarditis due to *neoplastic diseases* results from extension or invasion of metastatic tumors (most commonly carcinoma of the lung and breast, malignant melanoma, lymphoma, and leukemia) to the pericardium; pain, atrial arrhythmias, and tamponade are complications that occur occasionally. Diagnosis is made by pericardial fluid cytology or pericardial biopsy. *Mediastinal irradiation* for neoplasm may cause acute pericarditis and/or chronic constrictive pericarditis after eradication of the tumor. Unusual causes of acute pericarditis include syphilis, fungal infection (histoplasmosis, blastomycosis, aspergillosis, and candidiasis), and parasitic infestation (amebiasis, toxoplasmosis, echinococcosis, trichinosis).

CHRONIC PERICARDIAL EFFUSIONS

Chronic pericardial effusions are sometimes encountered in patients without an antecedent history of acute pericarditis. They may cause few symptoms per se, and their presence may be detected by finding an enlarged cardiac silhouette on chest roentgenogram. Tuberculosis is a common cause (Chap. 158).

Other Causes *Myxedema* may be responsible for chronic pericardial effusion that is sometimes massive but rarely, if ever, causes cardiac tamponade. The cardiac silhouette is markedly enlarged, and an echocardiogram distinguishes cardiomegaly from pericardial effusion. The diagnosis of myxedema can be confirmed by tests for thyroid function (Chap. 335). Myxedematous pericardial effusion responds to thyroid hormone replacement.

Neoplasms, SLE, rheumatoid arthritis, mycotic infections, radiation therapy to the chest, pyogenic infections, and chylopericardium may also cause chronic pericardial effusion and should be considered and specifically sought in such patients.

Aspiration and analysis of the pericardial fluid are often helpful in diagnosis. Pericardial fluid should be analyzed as described on p. 1492. Grossly sanguineous pericardial fluid results most commonly from a neoplasm, tuberculosis, renal failure, or slow leakage from an aortic aneurysm. Pericardiocentesis may resolve large effusions, but pericardiectomy may be required with recurrence. Intrapericardial instillation of sclerosing agents or antineoplastic agents (e.g., bleomycin) may be used to prevent reaccumulation of fluid.

CHRONIC CONSTRICTIVE PERICARDITIS

This disorder results when the healing of an acute fibrinous or serofibrinous pericarditis or the resorption of a chronic pericardial effusion is followed by obliteration of the pericardial cavity with the formation of granulation tissue. The latter gradually contracts and forms a firm scar, encasing the heart and interfering with filling of the ventricles. In developing nations where the condition is prevalent, a high percentage of cases is of tuberculous origin, but in North America this is now an infrequent cause. Chronic constrictive pericarditis may follow acute or relapsing viral or idiopathic pericarditis, trauma with organized blood clot, cardiac surgery of any type, mediastinal irradiation, purulent infection, histoplasmosis, neoplastic disease (especially breast cancer, lung cancer, and lymphoma), rheumatoid arthritis, SLE, and chronic renal failure with uremia treated by chronic dialysis. In many patients the cause of the pericardial disease is undetermined, and in them an asymptomatic or forgotten bout of viral pericarditis, acute or idiopathic, may have been the inciting event.

The basic physiologic abnormality in patients with chronic constrictive pericarditis is the inability of the ventricles to fill because of the limitations imposed by the rigid, thickened pericardium or the tense pericardial fluid. In constrictive pericarditis, ventricular filling is unimpeded during early diastole but it is reduced abruptly when the elastic limit of the pericardium is reached, while in cardiac tamponade, ventricular filling is impeded throughout diastole. In both conditions, ventricular end-diastolic and stroke volumes are reduced and the end-diastolic pressures in both ventricles and the mean pressures in the atria, pulmonary veins, and systemic veins are all elevated to similar levels, i.e., within 5 mmHg of one another. Despite these hemodynamic changes, myocardial function may be normal or only slightly impaired in chronic constrictive pericarditis. However, the fibrotic process may extend into the myocardium and cause myocardial scarring, and atrophy, and venous congestion may then be due to the combined effects of the pericardial and myocardial lesions.

In constrictive pericarditis, the right and left atrial pressure pulses display an M-shaped contour, with prominent *x* and *y* descents; the *y* descent, which is absent or diminished in cardiac tamponade, is the most prominent deflection in constrictive pericarditis; it reflects rapid early filling of the ventricles. The *y* descent is interrupted by a rapid rise in atrial pressure during early diastole, when ventricular filling is impeded by the constricting pericardium. These characteristic changes are transmitted to the jugular veins, where they may be recognized by inspection. In constrictive pericarditis, the ventricular pressure pulses in both ventricles exhibit characteristic "square root" signs during diastole. These hemodynamic changes, although characteristic, are not pathognomonic of constrictive pericarditis and may also be observed in cardiomyopathies characterized by restriction of ventricular filling (Chap. 231) (Table 232-2).

CLINICAL AND LABORATORY FINDINGS

Weakness, fatigue, weight gain, increased abdominal girth, abdominal discomfort, a protuberant abdomen, and edema are common. The patient often appears chronically ill, and in advanced cases there are anasarca, skeletal muscle wasting, and cachexia. Exertional dyspnea is common, and orthopnea may occur, although it is usually not severe. Acute left ventricular failure (acute pulmonary edema) is very uncommon. The cervical veins are distended and may remain so even after intensive diuretic treatment, and venous pressure may fail to decline during inspiration (*Kussmaul's sign*). The latter is frequent in chronic pericarditis but may also occur in tricuspid stenosis, right ventricular infarction, and restrictive cardiomyopathy.

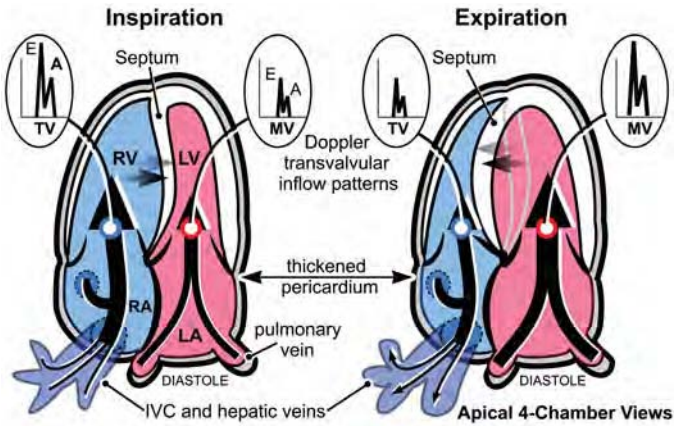

FIGURE 232-5 Constrictive pericarditis Doppler schema of respirophasic changes in mitral and tricuspid inflow. Reciprocal patterns of ventricular filling are assessed on pulsed Doppler examination of mitral (MV) and tricuspid (TV) inflow. *(Courtesy of Bernard E. Bulwer, MD; with permission.)*

The pulse pressure is normal or reduced. In about one-third of the cases, a paradoxical pulse (p. 1491) can be detected. Congestive hepatomegaly is pronounced and may impair hepatic function and cause jaundice; ascites is common and is usually more prominent than dependent edema. The apical pulse is reduced and may retract in systole (*Broadbent's sign*). The heart sounds may be distant; an early third heart sound, i.e., a pericardial knock, occurring 0.09 to 0.12 s after aortic valve closure at the cardiac apex, is often conspicuous; it occurs with the abrupt cessation of ventricular filling. A systolic murmur of tricuspid regurgitation may be present.

The *ECG* frequently displays low voltage of the QRS complexes and diffuse flattening or inversion of the T waves. Atrial fibrillation is present in about one-third of patients. The *chest roentgenogram* shows a normal or slightly enlarged heart; pericardial calcification is most common in tuberculous pericarditis.

Inasmuch as the usual physical signs of cardiac disease (murmurs, cardiac enlargement) may be inconspicuous or absent in chronic constrictive pericarditis, hepatic enlargement and dysfunction associated with jaundice and intractable ascites may lead to a mistaken diagnosis of hepatic cirrhosis. This error can be avoided if the neck veins are inspected carefully in patients with ascites and hepatomegaly. Given a clinical picture resembling hepatic cirrhosis, but with the added feature of distended neck veins, careful search for thickening of the pericardium by CT (Fig. 222-8) or MRI should be carried out and may disclose this curable or remediable form of heart disease.

The two-dimensional transthoracic *echocardiogram* typically shows pericardial thickening, dilatation of the inferior vena cava and hepatic veins, and a sharp halt in ventricular filling in early diastole, with normal ventricular systolic function and flattening of the left ventricular posterior wall. Atrial enlargement may be seen, especially in patients with long-standing constrictive physiology. There is a distinctive pattern of transvalvular flow velocity on Doppler flow-velocity echocardiography. During inspiration there is an exaggerated reduction in blood flow velocity in the pulmonary veins and across the mitral valve and a leftward shift of the ventricular septum; the opposite occurs during expiration. Diastolic flow velocity in the vena cavae into the right atrium and across the tricuspid valve increases in an exaggerated manner during inspiration and declines during expiration (Fig. 232-5). However, echocardiography cannot definitively exclude the diagnosis of constrictive pericarditis. MRI and CT scanning (Fig. 232-6) are more accurate than echocardiography in establishing or excluding the presence of a thickened pericardium. Pericardial thickening and even pericardial calcification, however, are not synonymous with constrictive pericarditis since they may occur without seriously impairing ventricular filling.

DIFFERENTIAL DIAGNOSIS

Like chronic constrictive pericarditis, cor pulmonale (Chap. 227) may be associated with severe systemic venous hypertension but little pulmonary congestion; the heart is usually not enlarged, and a paradoxical pulse may be present. However, in cor pulmonale, advanced parenchymal pulmonary disease is usually obvious and venous pressure *falls* during inspiration, i.e., Kussmaul's sign is negative. *Tricuspid stenosis* (Chap. 230) may also simulate chronic constrictive pericarditis; congestive hepatomegaly, splenomegaly, ascites, and venous distention may be equally prominent. However, in tricuspid stenosis, a characteristic murmur as well as the murmur of accompanying mitral stenosis are usually present. In tricuspid stenosis, a paradoxical pulse and a steep, deep *y* descent in the jugular venous pulse do *not* occur, serving to differentiate it from chronic constrictive pericarditis.

Because constrictive pericarditis can be corrected surgically, it is important to distinguish chronic constrictive pericarditis from restrictive cardiomyopathy (Chap. 231), which has a similar physiologic abnormality, i.e., restriction of ventricular filling. In many of these patients the ventricular wall is thickened on echocardiographic examination (Table 232-2). The features favoring the diagnosis of restrictive cardiomyopathy over chronic constrictive pericarditis include a well-defined apex beat, cardiac enlargement, and pronounced orthopnea with attacks of acute left ventricular failure, left ventricular hypertrophy, gallop sounds (in place of a pericardial knock), bundle branch block, and in some cases abnormal Q waves on the ECG. The typical echocardiographic features of constrictive pericarditis (see above) are useful in the differential diagnosis in chronic constrictive pericarditis (Fig. 232-5). CT scanning (usually with contrast) and MRI are key in distinguishing between restrictive cardiomyopathy and chronic constrictive pericarditis. In the former, the ventricular walls are hypertrophied, while in the latter the pericardium is thickened and sometimes calcified. When a patient has progressive, disabling, and unresponsive congestive heart failure and displays any of the features of constrictive heart disease, Doppler echocardiography to record respiratory effects on transvalvular flow, and an MRI or CT scan should be obtained to detect or exclude constrictive pericarditis, since the latter is usually curable.

Rx CONSTRICTIVE PERICARDITIS

Pericardial resection is the only definitive treatment of constrictive pericarditis, but dietary sodium restriction and diuretics are useful during pre-

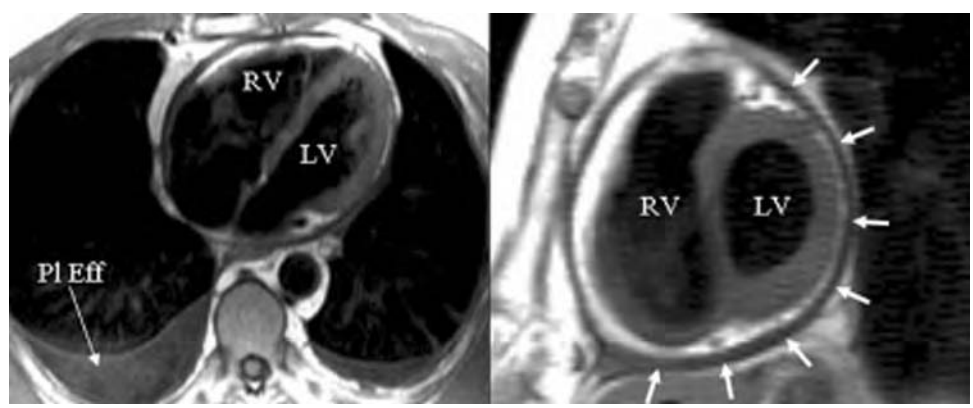

FIGURE 232-6 Cardiovascular magnetic resonance in a patient with constrictive pericarditis. On the right is a basal short-axis view of the ventricles showing a thickened pericardium encasing the heart (*arrows*). On the left is a transaxial view, again showing the thickened pericardium, particularly over the right heart, but also a pleural effusion (Pl Eff). LV, left ventricle; RV, right ventricle. *[From D Pennell: Cardiovascular magnetic resonance, in DP Zipes et al (eds): Braunwald's Heart Disease, 7th ed. Philadelphia, Elsevier, 2005.]*

operative preparation. Coronary arteriography should be carried out preoperatively in patients older than 50 years to exclude unsuspected coronary disease. The benefits derived from cardiac decortication are usually progressive over a period of months. The risk of this operation depends on the extent of penetration of the myocardium by the calcific process, by the severity of myocardial atrophy, by the extent of secondary impairment of hepatic and/or renal function, and by the patient's general condition. Operative mortality is in the range of 5 to 10%; the patients with the most severe disease are at highest risk. Therefore, surgical treatment should be carried out relatively early in the course.

Subacute Effusive-Constrictive Pericarditis This form of pericardial disease is characterized by the combination of a tense effusion in the pericardial space and constriction of the heart by thickened pericardium. It shares a number of features both with chronic pericardial effusion producing cardiac compression and with pericardial constriction. It may be caused by tuberculosis (see below), multiple attacks of acute idiopathic pericarditis, radiation, traumatic pericarditis, renal failure, scleroderma, and neoplasms. The heart is generally enlarged, and a paradoxical pulse and a prominent *x* descent (without a prominent *y* descent) are present in the atrial and jugular venous pressure pulses. Following pericardiocentesis, the physiologic findings may change from those of cardiac tamponade to those of pericardial constriction, with a "square root" sign in the ventricular pressure pulse and a prominent *y* descent in the atrial and jugular venous pressure pulses. Furthermore, the intrapericardial pressure and the central venous pressure may decline, but not to normal. The diagnosis can be established by pericardiocentesis followed by pericardial biopsy. In many patients the condition progresses to the chronic constrictive form of the disease. Wide excision of both the visceral and parietal pericardium is usually effective therapy.

Tuberculous Pericardial Disease This chronic infection is a common cause of chronic pericardial effusion, although less so in the United States than in Africa, Asia, the Middle East, and other parts of the developing world where active tuberculosis is endemic (Chap. 158). The clinical picture is that of a chronic, systemic illness in a patient with pericardial effusion. It is important to consider this diagnosis in a patient with known tuberculosis, with HIV, and with fever, chest pain, weight loss, and enlargement of the cardiac silhouette of undetermined origin. Inasmuch as treatment is quite effective, overlooking a tuberculous pericardial effusion may have serious consequences. If the etiology of chronic pericardial effusion remains obscure, despite detailed analysis of the pericardial fluid (see above), a pericardial biopsy, preferably by a limited thoracotomy, should be performed. If definitive evidence is then still lacking but the specimen shows granulomata with caseation, antituberculous chemotherapy (Chap. 158) is indicated.

If the biopsy specimen shows a thickened pericardium, pericardiectomy should be carried out in order to prevent the development of constriction, a serious complication of tuberculosis that occurs in about one-half of patients with tuberculous pericardial effusion despite treatment with chemotherapy and glucocorticoids. Tubercular cardiac constriction should be treated surgically while the patient is receiving antituberculous chemotherapy. In many patients, subacute effusive-constrictive pericarditis develops.

OTHER DISORDERS OF THE PERICARDIUM

Pericardial cysts appear as rounded or lobulated deformities of the cardiac silhouette, most commonly at the right cardiophrenic angle. They do not cause symptoms, and their major clinical significance lies in the possibility of confusion with a tumor, ventricular aneurysm, or massive cardiomegaly. *Tumors* involving the pericardium are most commonly secondary to malignant neoplasms originating in or invading the mediastinum, including carcinoma of the bronchus and breast, lymphoma, and melanoma. The most common *primary* malignant tumor is the mesothelioma. The usual clinical picture of malignant pericardial tumor is an insidiously developing, often bloody, pericardial effusion. Surgical exploration is required to establish a definitive diagnosis and to carry out definitive or, more commonly, palliative treatment.

233 Tumors and Trauma of the Heart

Eric H. Awtry, Wilson S. Colucci

TUMORS OF THE HEART

PRIMARY TUMORS

Primary tumors of the heart are rare. Approximately three-quarters are histologically benign, over half of which are myxomas. Malignant tumors, almost all of which are sarcomas, account for 25% of primary cardiac tumors (Table 233-1). All cardiac tumors, regardless of pathologic type, have the potential to cause life-threatening complications. Many tumors are now curable by surgery; thus, early diagnosis is imperative.

Clinical Presentation Cardiac tumors may present with a wide array of cardiac and noncardiac manifestations, which depend in large part on the location and size of the tumor. Many of the manifestations are nonspecific features of more common forms of heart disease, such as chest pain, syncope, heart failure, murmurs, arrhythmias, conduction disturbances, and pericardial effusion with or without tamponade. Additionally, embolic phenomena and constitutional symptoms may occur.

Myxoma Myxomas are the most common type of primary cardiac tumor in all age groups, accounting for one-third to one-half of all cases at postmortem and for about three-quarters of the tumors treated surgically. They occur at all ages, most commonly in the third through sixth decades, with a female predilection. Approximately 90% of myxomas are sporadic; the remainder are familial with autosomal dominant transmission. The familial variety often occurs as part of a syndrome complex (Carney complex) that comprises (1) myxomas (cardiac, skin, and/or breast), (2) lentigines and/or pigmented nevi, and (3) endocrine overactivity (primary nodular adrenal cortical disease with or without Cushing's syndrome, testicular tumors, and/or pituitary adenomas with gigantism or acromegaly). Certain constellations of findings have been referred to as the *NAME* syndrome (nevi, atrial myxoma, myxoid neurofibroma, and ephelides) or the *LAMB* syndrome (lentigines, atrial myxoma, and blue nevi), although these likely represent subsets of the Carney complex. The genetic basis of

this complex has not been completely elucidated; however, patients frequently have mutations in the tumor-suppressor gene *PRKAR1A*, which encodes the protein kinase A type I-α regulatory subunit.

Pathologically, myxomas are gelatinous structures consisting of myxoma cells embedded in a stroma rich in glycosaminoglycans. Most are pedunculated on a fibrovascular stalk and average 4–8 cm in diameter. Most are solitary and located in the atria, particularly the left atrium, where they usually arise from the interatrial septum in the vicinity of the fossa ovalis. In contrast to sporadic tumors, familial or myxoma syndrome tumors tend to occur in younger individuals, are often multiple, may be ventricular in location, and are more likely to recur after initial resection.

Myxomas commonly present with obstructive signs and symptoms. The most common clinical presentation mimics that of mitral valve disease—either stenosis owing to tumor prolapse into the mitral orifice or regurgitation resulting from tumor-induced valvular trauma. Ventricular myxomas may cause outflow obstruction similar to that caused by subaortic or subpulmonic stenosis. The symptoms and signs of myxoma may be sudden in onset or positional in nature, owing to the effects of gravity on tumor position. A characteristic low-pitched sound, referred to as a "tumor plop," may be appreciated on auscultation during early or mid-diastole and is thought to result from the impact of the tumor against the mitral valve or ventricular wall. Myxomas may also present with peripheral or pulmonary emboli or with constitutional signs and symptoms, including fever, weight loss, cachexia, malaise, arthralgias, rash, digital clubbing, Raynaud's phenomenon, hypergammaglobulinemia, anemia, polycythemia, leukocytosis, elevated erythrocyte sedimentation rate, thrombocytopenia, or thrombocytosis. Not surprisingly, patients with myxomas are frequently misdiagnosed as having endocarditis, collagen vascular disease, or a paraneoplastic syndrome.

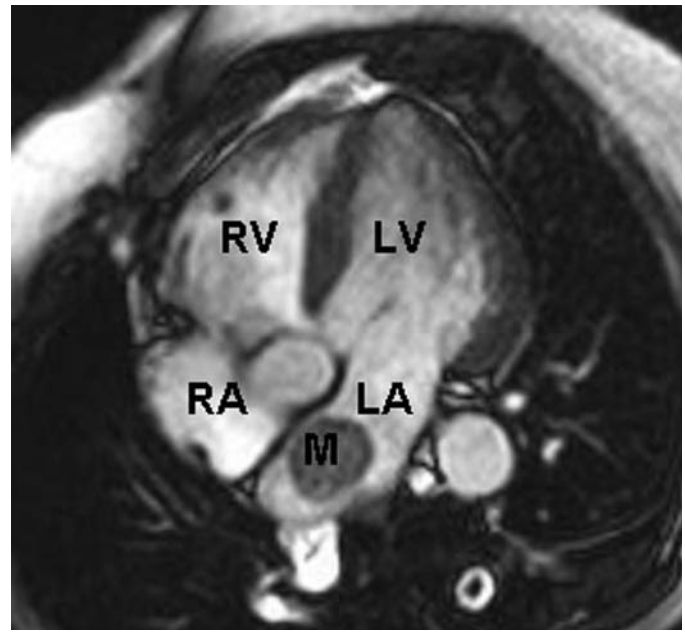

FIGURE 233-2 Cardiac MRI demonstrating a rounded mass (M) within the left atrium (LA). Pathologic evaluation at the time of surgery revealed it to be an atrial myxoma. LV, left ventricle; RA, right atrium; RV, right ventricle.

Two-dimensional transthoracic or omniplane transesophageal echocardiography is useful in the diagnosis of cardiac myxoma and allows assessment of tumor size and determination of the site of tumor attachment, both important considerations in the planning of surgical excision (Fig. 233-1). CT and MRI may provide important information regarding size, shape, composition, and surface characteristics of the tumor (Fig. 233-2).

Although cardiac catheterization and angiography were previously performed routinely prior to tumor resection, they are no longer considered mandatory when adequate noninvasive information is available and other cardiac disorders (e.g., coronary artery disease) are not considered likely. Additionally, catheterization of the chamber from which the tumor arises carries the risk of tumor embolization. Because myxomas may be familial, echocardiographic screening of first-degree relatives is appropriate, particularly if the patient is young and has multiple tumors or evidence of myxoma syndrome.

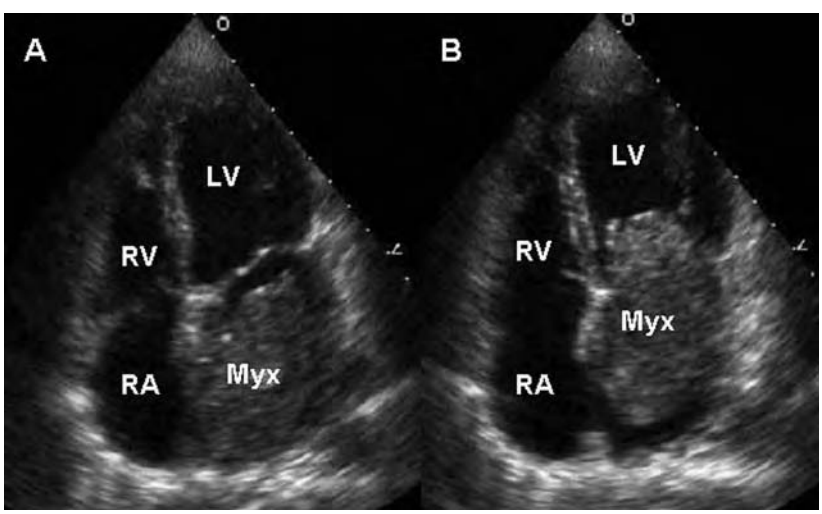

FIGURE 233-1 Transthoracic echocardiogram demonstrating a large atrial myxoma. The myxoma (Myx) fills the entire left atrium in systole (*panel A*) and prolapses across the mitral valve and into the left ventricle (LV) during diastole (*panel B*). Rx PRIMARY TUMOR

Surgical excision utilizing cardiopulmonary bypass is indicated, regardless of tumor size, and is generally curative. Myxomas recur in ~12–22% of familial cases but in only 1–2% of sporadic cases. Tumor recurrence is most likely due to multifocal lesions in the former and inadequate resection in the latter.

Other Benign Tumors Cardiac *lipomas*, although relatively common, are usually incidental findings at post-

mortem examination; however, they may grow as large as 15 cm and may present with symptoms owing to mechanical interference with cardiac function, arrhythmias, or conduction disturbances, or as an abnormality of the cardiac silhouette on chest x-ray. *Papillary fibroelastomas* are the most common tumors of the cardiac valves. Although usually clinically silent, they can cause valve dysfunction and may embolize distally, resulting in transient ischemic attacks, stroke, or myocardial infarction. Therefore, these tumors should be resected even when asymptomatic. *Rhabdomyomas* and *fibromas* are the most common cardiac tumors in infants and children and usually occur in the ventricles where they may produce mechanical obstruction to blood flow, thereby mimicking valvular stenosis, congestive heart failure (CHF), restrictive or hypertrophic cardiomyopathy, or pericardial constriction. Rhabdomyomas are probably hamartomatous growths, are multiple in 90% of cases, and are strongly associated with tuberous sclerosis. These tumors have a tendency to regress completely or partially; only those tumors that cause obstruction require surgical resection. Fibromas are usually single, are often calcified, tend to grow and cause obstructive symptoms, and should be resected. *Hemangiomas* and *mesotheliomas* are generally small tumors, most often intramyocardial in location, and may cause atrioventricular (AV) conduction disturbances and even sudden death as a result of their propensity to develop in the region of the AV node. Other benign tumors arising from the heart include *teratoma*, *chemodectoma*, *neurilemoma*, *granular cell myoblastoma*, and *bronchogenic cysts*.

Sarcoma Almost all primary cardiac malignancies are sarcomas, which may be of several histologic types. In general, these tumors are characterized by rapid progression culminating in the patient's death within weeks to months from the time of presentation, as a result of hemodynamic compromise, local invasion, or distant metastases. Sarcomas commonly involve the right side of the heart, are characterized by rapid growth, frequently invade the pericardial space, and may obstruct the cardiac chambers or vena cavae. Sarcomas may also occur on the left side of the heart and may be mistaken for myxomas.

Rx SARCOMA

At the time of presentation these tumors have often spread too extensively to allow for surgical excision. Although scattered reports exist of palliation with surgery, radiotherapy, and/or chemotherapy, the response of cardiac sarcomas to these therapies is generally poor. The one exception appears to be cardiac lymphosarcomas, which may respond to a combination of chemo- and radiotherapy.

TUMORS METASTATIC TO THE HEART

Tumors metastatic to the heart are much more common than primary tumors, and their incidence is likely to increase as the life expectancy of patients with various forms of malignant neoplasms is extended by more effective therapy. Although cardiac metastases occur in 1–20% of all tumor types, the relative incidence is especially high in malignant melanoma and, to a somewhat lesser extent, in leukemia and lymphoma. In absolute terms, the most common primary originating sites of cardiac metastases are carcinoma of the breast and lung, reflecting the high incidence of these cancers. Cardiac metastases almost always occur in the setting of widespread primary disease, and most often either primary or metastatic disease exists elsewhere in the thoracic cavity. Nevertheless, cardiac metastasis may occasionally be the initial presentation of an extrathoracic tumor.

Cardiac metastases may occur via hematogenous or lymphangitic spread or by direct tumor invasion. They generally manifest as small, firm nodules; diffuse infiltration may also occur, especially with sarcomas or hematologic neoplasms. The pericardium is most often involved, followed by myocardial involvement of any chamber, and, rarely, by involvement of the endocardium or cardiac valves.

Cardiac metastases are clinically apparent only ~10% of the time, are usually not the cause of the patient's presentation, and rarely are the cause of death. The vast majority occur in the setting of a previously recognized malignant neoplasm. When symptomatic, cardiac metastases may result in a variety of clinical features, including dyspnea, acute pericarditis, cardiac tamponade, ectopic tachyarrhythmias, heart block, CHF, and rapid enlargement of the cardiac silhouette on chest x-ray. As with primary cardiac tumors, the clinical presentation reflects more the location and size of the tumor rather than its histologic type. Many of these signs and symptoms may also result from myocarditis, pericarditis, or cardiomyopathy induced by radiotherapy or chemotherapy.

Electrocardiographic (ECG) findings are nonspecific. On chest x-ray, the cardiac silhouette is most often normal but may be enlarged or exhibit a bizarre contour. Echocardiography is useful for identifying pericardial effusions and for visualizing larger metastases, although CT and radionuclide imaging with gallium or thallium may more clearly define the tumor burden. Cardiac MRI offers superb image quality and plays a central role in the diagnostic evaluation of cardiac metastases and cardiac tumors in general. Pericardiocentesis may allow for a specific cytologic diagnosis in patients with malignant pericardial effusions. Angiography is rarely necessary but may delineate discrete lesions.

Rx TUMORS METASTATIC TO THE HEART

Most patients with cardiac metastases have advanced malignant disease; thus, therapy is generally palliative and consists of treatment of the primary tumor. Symptomatic malignant pericardial effusions should be drained by pericardiocentesis. Concomitant instillation of a sclerosing agent (e.g., tetracycline) may delay or prevent reaccumulation of the effusion, while creation of a pericardial window allows drainage of the effusion to the pleural space.

TRAUMATIC CARDIAC INJURY

Traumatic cardiac injury may be caused by either penetrating or nonpenetrating trauma. *Penetrating injuries* most often result from gunshot or knife wounds, and the site of entry is usually obvious. *Nonpenetrating injuries* most often occur during motor vehicle accidents, either from a rapid deceleration injury or from impact of the chest against the steering wheel, and may be associated with significant cardiac injury even in the absence of external signs of thoracic trauma.

Myocardial contusions are the most common form of nonpenetrating cardiac injury and may initially be overlooked in trauma patients as the clinical focus is directed toward other more obvious injuries. Myocardial necrosis may occur as a direct result of the blunt injury or as a result of traumatic coronary laceration or thrombosis. The contused myocardium is pathologically similar to infarcted myocardium and may be associated with atrial or ventricular arrhythmias, conduction disturbances including bundle branch block, or ECG abnormalities resembling those of infarction or pericarditis. Thus, it is important to consider contusion as a cause of otherwise unexplained ECG changes in a trauma patient. Serum creatine kinase (CK-MB) isoenzyme levels are increased in ~20% of patients suffering blunt chest trauma but may be falsely elevated in the presence of massive skeletal muscle injury. Cardiac troponin levels are more specific for identifying cardiac injury in this setting. Echocardiography is useful in detecting structural and functional sequelae of contusion, including wall motion abnormalities, pericardial effusion, valvular dysfunction, and ventricular rupture. Although radionuclide scanning can detect myocardial contusion, its role is limited, given the ease and availability of echocardiography.

Rupture of the cardiac valves or their supporting structures, most commonly of the tricuspid or mitral valve, leads to acute valvular incompetence. This complication is usually heralded by the development of a loud murmur, may be associated with rapidly progressive heart failure, and can be diagnosed by either transthoracic or transesophageal echocardiography.

The most serious consequence of nonpenetrating injury is myocardial rupture, which may result in hemopericardium and tamponade (free wall rupture) or intracardiac shunting (ventricular septal rupture). Although generally fatal, up to 40% of patients with cardiac rup-

ture have been reported to survive long enough to reach a specialized trauma center. Hemopericardium may also result from traumatic rupture of a pericardial vessel or a coronary artery. Additionally, a pericardial effusion may develop weeks or even months after blunt chest trauma as a manifestation of the post-cardiac injury syndrome, which resembles the post-pericardiotomy syndrome (Chap. 232).

Blunt, nonpenetrating, often innocent-appearing injuries to the chest may trigger ventricular fibrillation even in absence of overt signs of injury. This syndrome, referred to as *commotio cordis*, occurs most often in adolescents during sporting events (e.g., baseball, hockey, football, and lacrosse) and likely results from an impact to the chest wall overlying the heart during the susceptible phase of repolarization just prior to the peak of the T wave. Survival depends on prompt defibrillation.

Sudden emotional or physiologic trauma may precipitate a transient cardiomyopathy that is characterized by dysfunction of the mid-portion and apex of the left ventricle with hyperdynamic function at the ventricular base. This syndrome, referred to as *Tako-Tsubo syndrome* or the *apical ballooning syndrome*, is more common in women and usually presents with chest pain, anterior ST-segment elevation, and mildly elevated cardiac enzymes despite the absence of significant epicardial coronary artery disease. The pathophysiology of this syndrome likely relates to catecholamine excess, and possibly to coronary vasospasm. The prognosis is favorable, and complete and spontaneous resolution of the ventricular dysfunction usually occurs within several weeks.

Rupture of the aorta, usually just above the aortic valve or at the site of the ligamentum arteriosum, is a common consequence of nonpenetrating chest trauma and is the most common vascular deceleration injury. The clinical presentation is similar to that of aortic dissection (Chap. 242). The arterial pressure and pulse amplitude may be increased in the upper extremities and decreased in the lower extremities, and chest x-ray may reveal mediastinal widening. Occasionally, aortic rupture is contained by the aortic adventitia, resulting in a false, or *pseudo-*, aneurysm that may be discovered months or years after the initial injury.

Penetrating injuries of the heart produced by knife or bullet wounds usually result in rapid clinical deterioration and frequently in death as a result of hemopericardium/pericardial tamponade or massive hemorrhage. Nonetheless, up to half of such patients may survive long enough to reach a specialized trauma center if immediate resuscitation is performed. Prognosis in these patients relates to the mechanism of injury, their clinical condition at presentation, and the specific cardiac chamber(s) involved. Iatrogenic cardiac or coronary arterial perforation may occur as a complication during placement of central venous or intracardiac catheters, pacemaker leads, or intracoronary stents and is associated with a better prognosis than other forms of penetrating cardiac trauma.

Traumatic rupture of a great vessel from penetrating injury is usually associated with hemothorax and, less often, hemopericardium. Local hematoma formation may compress major vessels and produce ischemic symptoms, and AV fistulae may develop, occasionally resulting in high-output CHF.

Occasionally, patients who survive penetrating cardiac injuries may subsequently present with a new cardiac murmur or CHF as a result of mitral regurgitation or an intracardiac shunt (i.e., ventricular or atrial septal defect, aortopulmonary fistula, or coronary AV fistula) that was undetected at the time of their initial injury or developed subsequently. Therefore, trauma patients should be carefully examined several weeks after their injury. If a mechanical complication is suspected, it can be confirmed by echocardiography or cardiac catheterization.

℞ TRAUMATIC CARDIAC INJURY

The treatment of an uncomplicated myocardial contusion is similar to that for a myocardial infarction, except that anticoagulation is contraindicated, and should include monitoring for the development of arrhythmias and mechanical complications such as cardiac rupture (Chap. 239). Acute myocardial failure resulting from traumatic valve rupture usually requires urgent operative correction. Immediate thoracotomy should be carried out for most cases of penetrating injury or if there is evidence of cardiac tamponade and/or shock regardless of the type of trauma. Pericardiocentesis may be lifesaving in patients with tamponade but is usually only a temporizing maneuver while they await definitive surgical therapy. Pericardial hemorrhage often leads to constriction (Chap. 232), which must be treated by decortication.

234 Cardiac Manifestations of Systemic Disease

Eric H. Awtry, Wilson S. Colucci

The common systemic disorders that have associated cardiac manifestations are summarized in Table 234-1.

DIABETES MELLITUS

(See also Chap. 338) Diabetes mellitus, both insulin- and non-insulin-dependent, is an independent risk factor for coronary artery disease (CAD; Chap. 235), accounting for 14–50% of new cases of cardiovascular disease. Furthermore, CAD is the most common cause of death in adults with diabetes mellitus. In the diabetic population the incidence of CAD relates to the duration of diabetes and the level of glycemic control, and its pathogenesis involves endothelial dysfunction, increased lipoprotein peroxidation, increased inflammation, a prothrombotic state, and associated metabolic abnormalities.

Diabetic patients are more likely to suffer a myocardial infarction, have a greater burden of CAD, have larger infarct size, and suffer more postinfarct complications, including heart failure, shock, and death, than nondiabetics. Importantly, diabetic patients are more likely to have atypical ischemic symptoms; nausea, dyspnea, pulmonary edema, arrhythmias, heart block, or syncope may be their anginal equivalent. Additionally, "silent ischemia," resulting from autonomic nervous system dysfunction, is more common in diabetics, accounting for up to 90% of their ischemic episodes. Thus, one must have a low threshold for suspecting CAD in diabetic patients. The treatment of diabetics with CAD must include aggressive risk factor management (Chap. 338). Pharmacologic therapy and revascularization are similar in diabetics and nondiabetics, excepting that diabetics have greater morbidity and mortality associated with revascularization, have an increased risk of restenosis after percutaneous coronary intervention (PCI), and likely have improved survival when treated with surgical bypass compared with PCI for multivessel CAD.

TABLE 234-1 COMMON SYSTEMIC DISORDERS AND THEIR ASSOCIATED CARDIAC MANIFESTATIONS

Systemic Disorder	Common Cardiac Manifestations	Chapter
Diabetes mellitus	CAD, atypical angina, CMP, systolic or diastolic CHF	338
Protein-calorie malnutrition	Dilated CMP, CHF	72
Thiamine deficiency	High-output failure, dilated CMP	71
Hyperhomocysteinemia	Premature atherosclerosis	71
Obesity	CMP, systolic or diastolic CHF	74
Hyperthyroidism	Palpitations, SVT, atrial fibrillation, hypertension	335
Hypothyroidism	Hypotension, bradycardia, dilated CMP, CHF, pericardial effusion	335
Malignant carcinoid	Tricuspid and pulmonary valve disease, right heart failure	344
Pheochromocytoma	Hypertension, palpitations, CHF	337
Acromegaly	Systolic or diastolic heart failure	333
Rheumatoid arthritis	Pericarditis, pericardial effusions, coronary arteritis, myocarditis, valvulitis	314
Seronegative arthropathies	Aortitis, aortic and mitral insufficiency, conduction abnormalities	318
Systemic lupus erythematosus	Pericarditis, Libman-Sacks endocarditis, myocarditis, arterial and venous thrombosis	313
HIV	Myocarditis, dilated CMP, pericardial effusion	182
Amyloidosis	CHF, restrictive CMP, valvular regurgitation, pericardial effusion	324
Sarcoidosis	CHF, dilated or restrictive CMP, ventricular arrhythmias, heart block	322
Hemochromatosis	CHF, arrhythmias, heart block	351
Marfan syndrome	Aortic aneurysm and dissection, aortic insufficiency, mitral valve prolapse	357
Ehlers-Danlos syndrome	Aortic and coronary aneurysms, mitral and tricuspid valve prolapse	357

Note: CAD, coronary artery disease; CHF, congestive heart failure; CMP, cardiomyopathy; SVT, supraventricular tachycardia.

Patients with diabetes mellitus may also have abnormal left ventricular systolic and diastolic function, reflecting concomitant epicardial CAD and hypertension, coronary microvascular disease, endothelial dysfunction, ventricular hypertrophy, and autonomic dysfunction. A restrictive cardiomyopathy may be present with abnormal myocardial relaxation and elevated ventricular filling pressures. Histologically, interstitial fibrosis is seen, and intramural arteries may demonstrate intimal thickening, hyaline deposition, and inflammatory changes. Diabetic patients have an increased risk of developing clinical heart failure, which likely contributes to their excessive cardiovascular morbidity and mortality. There is some evidence that insulin therapy may ameliorate diabetes-related myocardial dysfunction.

MALNUTRITION AND VITAMIN DEFICIENCY

Malnutrition (See also Chap. 72) In patients whose intake of protein, calories, or both is severely deficient, the heart may become thin, pale, and hypokinetic with myofibrillar atrophy and interstitial edema. The systolic pressure and cardiac output fall, and the pulse pressure narrows. Generalized edema is common and relates to a variety of factors, including reduced serum oncotic pressure and myocardial dysfunction. Such profound states of protein and calorie malnutrition, termed *kwashiorkor* and *marasmus,* respectively, are most common in underdeveloped countries. However, significant nutritional heart disease may also occur in developed nations, particularly in patients with chronic diseases such as AIDS, in patients with anorexia nervosa, and in patients with severe cardiac failure in whom gastrointestinal hypoperfusion and venous congestion may lead to anorexia and malabsorption. Open-heart surgery poses increased risk in malnourished patients, and they may benefit from preoperative hyperalimentation.

Thiamine Deficiency (Beriberi) (See also Chap. 71) Generalized malnutrition is often accompanied by thiamine deficiency, although this hypovitaminosis may also occur in the presence of an adequate protein and caloric intake, particularly in the Far East where polished rice deficient in thiamine may be a major dietary component. In Western nations where the use of thiamine-enriched flour is widespread, clinical thiamine deficiency is limited primarily to alcoholics, food faddists, and patients receiving chemotherapy. Nonetheless, when thiamine stores are measured using the thiamine-pyrophosphate effect (TPPE), thiamine deficiency has been found in 20–90% of patients with chronic heart failure. This deficiency appears to result from both reduced dietary intake and a diuretic-induced increase in the urinary excretion of thiamine. The acute administration of thiamine to these patients increases the left ventricular ejection fraction and the excretion of salt and water.

Clinically, patients with thiamine deficiency usually have evidence of generalized malnutrition, peripheral neuropathy, glossitis, and anemia. The classic cardiovascular syndrome is characterized by high-output heart failure, tachycardia, and often elevated left and right ventricular filling pressures. The major cause of the high-output state is vasomotor depression leading to reduced systemic vascular resistance, the precise mechanism of which is not understood. The cardiac examination reveals a wide pulse pressure, tachycardia, a third heart sound, and, frequently, an apical systolic murmur. The ECG may reveal decreased voltage, a prolonged QT interval, and T-wave abnormalities. The chest x-ray generally reveals cardiomegaly and signs of congestive heart failure (CHF). The response to thiamine is often dramatic, with an increase in systemic vascular resistance, a decrease in cardiac output, clearing of pulmonary congestion, and a reduction in heart size often occurring in 12–48 h. Although the response to inotropes and diuretics may be poor before thiamine therapy, these agents may be important *after* thiamine is given, since the left ventricle may not be able to handle the increased work load presented by the return of vascular tone.

Vitamin B_6, B_{12}, and Folate Deficiency (See also Chap. 71) Vitamin B_6, B_{12}, and folate are cofactors in the metabolism of homocysteine. Their deficiency probably contributes to the majority of cases of hyperhomocysteinemia, a disorder associated with increased atherosclerotic risk. Supplementation of these vitamins has reduced the incidence of hyperhomocysteinemia in the United States; however, the clinical cardiovascular benefit of normalizing elevated homocysteine levels remains unproven.

OBESITY

(See also Chap. 74) Severe obesity, especially abdominal obesity, is associated with an increase in cardiovascular morbidity and mortality. Although obesity itself is not considered a disease, it is associated with an increased prevalence of hypertension, glucose intolerance, and atherosclerotic CAD. In addition, obese patients have a distinct cardiovascular abnormality characterized by increased total and central blood volumes, cardiac output, and left ventricular filling pressure. The elevated cardiac output appears to be required to support the metabolic needs of the excess adipose tissue. Left ventricular filling pressure is often at the upper limits of normal at rest and rises excessively with exercise. As a result of chronic volume overload, eccentric cardiac hypertrophy with cardiac dilatation and ventricular dysfunction may develop. Pathologically, there are left and, in some cases, right ventricular hypertrophy and generalized cardiac dilatation. Pulmonary congestion, peripheral edema, and exercise intolerance may all ensue; however, the recognition of these findings may be difficult in massively obese patients.

Weight reduction is the most effective therapy and results in reduction in blood volume and in the return of cardiac output toward normal. However, rapid weight reduction may be dangerous, as cardiac arrhythmias and sudden death owing to electrolyte imbalance have been described. Treatment with angiotensin-converting enzyme inhibitors, sodium restriction, and diuretics may be useful to control heart failure symptoms. This form of heart disease should be distinguished from the Pickwickian syndrome (Chap. 258), which may share several

of the cardiovascular features of heart disease secondary to severe obesity but, in addition, frequently has components of central apnea, hypoxemia, pulmonary hypertension, and cor pulmonale.

THYROID DISEASE

(See also Chap. 335) Thyroid hormone exerts a major influence on the cardiovascular system by a number of direct and indirect mechanisms and, not surprisingly, cardiovascular effects are prominent in both hypo- and hyperthyroidism. Thyroid hormone causes increases in total-body metabolism and oxygen consumption that indirectly increase the cardiac workload. In addition, thyroid hormone exerts direct inotropic, chronotropic, and dromotropic effects that are similar to those seen with adrenergic stimulation (e.g., tachycardia, increased cardiac output); they are mediated at least partly by both transcriptional and nontranscriptional effects of thyroid hormone on myosin, calcium-activated ATPase, Na^+,K^+-ATPase, and myocardial β-adrenergic receptors.

Hyperthyroidism Common cardiovascular manifestations of hyperthyroidism include palpitations, systolic hypertension, and fatigue. Sinus tachycardia is present in ~40% of patients and atrial fibrillation in ~15%. Physical examination may reveal a hyperdynamic precordium, a widened pulse pressure, increases in the intensity of the first heart sound and the pulmonic component of the second heart sound, and a third heart sound. An increased incidence of mitral valve prolapse has been described in hyperthyroid patients, in which case a midsystolic murmur may be heard at the left sternal border with or without a systolic ejection click. A systolic pleuropericardial friction rub (*Means-Lerman scratch*) may be heard at the left second intercostal space during expiration and is thought to result from the hyperdynamic cardiac motion.

Elderly patients with hyperthyroidism may present with only cardiovascular manifestations of thyrotoxicosis, such as sinus tachycardia, atrial fibrillation, and hypertension, all of which may be resistant to therapy until the hyperthyroidism is controlled. Angina pectoris and CHF are unusual with hyperthyroidism unless there is coexistent heart disease; in such cases, symptoms often resolve with treatment of the hyperthyroidism.

Hypothyroidism Cardiac manifestations of hypothyroidism include a reduction in cardiac output, stroke volume, heart rate, blood pressure, and pulse pressure. Pericardial effusions are present in about one-third of patients, rarely progress to tamponade, and likely result from increased capillary permeability. Other clinical signs include cardiomegaly, bradycardia, weak arterial pulses, distant heart sounds, and pleural effusions. Although the signs and symptoms of myxedema may mimic those of CHF, in the absence of other cardiac disease, myocardial failure is uncommon. The electrocardiogram (ECG) generally reveals sinus bradycardia and low voltage, and may show prolongation of the QT interval, decreased P-wave voltage, prolonged AV conduction time, intraventricular conduction disturbances, and nonspecific ST-T wave abnormalities. Chest x-ray may show cardiomegaly, often with a "water bottle" configuration, pleural effusions, and, in some cases, evidence of CHF. Pathologically, the heart is pale and dilated, and often demonstrates myofibrillar swelling, loss of striations, and interstitial fibrosis.

Patients with hypothyroidism frequently have elevations of cholesterol and triglycerides, resulting in premature atherosclerotic CAD. Before treatment with thyroid hormone, patients with hypothyroidism frequently do not have angina pectoris, presumably because of the low metabolic demands caused by their condition. However, angina and myocardial infarction may be precipitated during initiation of thyroid hormone replacement, especially in elderly patients with underlying heart disease. Therefore, replacement should be done with care, starting with low doses that are increased gradually.

MALIGNANT CARCINOID

(See also Chap. 344) Carcinoid tumors most often originate in the small bowel and elaborate a variety of vasoactive amines (e.g., serotonin), kinins, indoles, and prostaglandins that are believed to be responsible for the diarrhea, flushing, and labile blood pressure that characterize the carcinoid syndrome. Some 50% of patients with carcinoid syndrome have cardiac involvement, usually manifesting as abnormalities of the right-sided cardiac structures. These patients invariably have hepatic metastases allowing vasoactive substances to circumvent hepatic metabolism. Left-sided cardiac involvement is rare and indicates either pulmonary carcinoid or an intracardiac shunt. Pathologically, carcinoid lesions are fibrous plaques that consist of smooth-muscle cells embedded in a stroma of glycosaminoglycans and collagen. They occur on the cardiac valves where they cause valvular dysfunction, as well as on the endothelium of the cardiac chambers and great vessels.

Carcinoid heart disease most often presents as tricuspid regurgitation, pulmonic stenosis, or both. In some cases a high cardiac output state may occur, presumably as a result of a decrease in systemic vascular resistance resulting from vasoactive substances released by the tumor. Treatment with somatostatin analogues (e.g., octreotide) or interferon-α improves symptoms and survival in patients with carcinoid heart disease but does not appear to improve valvular abnormalities. In some severely symptomatic patients, valve replacement is indicated. Coronary artery spasm, presumably due to a circulating vasoactive substance, may occur in patients with carcinoid syndrome.

PHEOCHROMOCYTOMA

(See also Chap. 337) In addition to causing labile or sustained hypertension, the high circulating levels of catecholamines resulting from a pheochromocytoma may also cause direct myocardial injury. Focal myocardial necrosis and inflammatory cell infiltration are present in ~50% of patients who die with pheochromocytoma and may contribute to clinically significant left ventricular failure and pulmonary edema. In addition, associated hypertension results in left ventricular hypertrophy. Left ventricular dysfunction and CHF may resolve after removal of the tumor.

ACROMEGALY

(See also Chap. 333) Exposure of the heart to excessive growth hormone may cause CHF as a result of high cardiac output, diastolic dysfunction owing to ventricular hypertrophy (with increased left ventricular chamber size or wall thickness), or global systolic dysfunction. Hypertension occurs in up to one-third of patients with acromegaly and is characterized by suppression of the renin-angiotensin-aldosterone axis and increases in total-body sodium and plasma volume. Some form of cardiac disease occurs in about one-third of patients with acromegaly and is associated with a doubling of the risk of cardiac death.

RHEUMATOID ARTHRITIS AND THE COLLAGEN VASCULAR DISEASES

Rheumatoid Arthritis (See also Chap. 314) Rheumatoid arthritis may be associated with inflammatory changes in any or all cardiac structures, although pericarditis is the most common clinical entity. Pericardial effusions may be found echocardiographically in 10–50% of patients with rheumatoid arthritis, particularly those with subcutaneous nodules. Nonetheless, only a small fraction of these patients have symptomatic pericarditis and, when present, it usually follows a benign course, only occasionally progressing to cardiac tamponade or constrictive pericarditis. The pericardial fluid is generally exudative, with decreased concentrations of complement and glucose and elevated cholesterol. Coronary arteritis with intimal inflammation and edema is present in ~20% of cases but only rarely results in angina pectoris or myocardial infarction. Inflammation and granuloma formation may affect the cardiac valves, most often the mitral and aortic, and may cause clinically significant regurgitation owing to valve deformity. Myocarditis is uncommon and rarely results in cardiac dysfunction.

Treatment is directed at the underlying rheumatoid arthritis and may include glucocorticoids. Urgent pericardiocentesis should be performed in patients with tamponade, while pericardiectomy is usually required in cases of pericardial constriction.

Seronegative Arthropathies (See also Chap. 318) The seronegative arthropathies, including ankylosing spondylitis, reactive arthritis, pso-

riatic arthritis, and the arthritides associated with ulcerative colitis and regional enteritis, are all strongly associated with the HLA-B27 histocompatibility antigen and may be accompanied by a pancarditis and proximal aortitis. The aortic inflammation is usually limited to the aortic root but may extend to involve the aortic valve, mitral valve, and ventricular myocardium, resulting in aortic and mitral regurgitation, conduction abnormalities, and ventricular dysfunction. One-tenth of patients have significant aortic insufficiency and one-third have conduction disturbances; both are more common in patients with peripheral joint involvement and long-standing disease. Treatment with aortic valve replacement and permanent pacemaker placement may be required. Occasionally, aortic regurgitation precedes the onset of arthritis, and, therefore, the diagnosis of a seronegative arthritis should be considered in young males with isolated aortic regurgitation.

Systemic Lupus Erythematosus (SLE) (See also Chap. 313) A significant percentage of patients with SLE have cardiac involvement. Pericarditis is common, occurring in about two-thirds of patients, and generally follows a benign course, although rarely tamponade or constriction may result. The characteristic endocardial lesions of SLE are verrucous valvular abnormalities, known as *Libman Sacks endocarditis*. They are most often located on the left-sided cardiac valves, particularly on the ventricular surface of the posterior mitral leaflet, and are made up almost entirely of fibrin. These lesions may embolize or become infected but rarely cause hemodynamically important valvular regurgitation. Myocarditis generally parallels the activity of the disease and, although common histologically, seldom results in clinical heart failure unless associated with hypertension. While arteritis of epicardial coronary arteries may occur, it rarely results in myocardial ischemia. There is, however, an increased incidence of coronary atherosclerosis that likely is related more to associated risk factors and glucocorticoid use than to SLE itself. Patients with the antiphospholipid antibody syndrome may have a higher incidence of cardiovascular abnormalities, including valvular regurgitation, venous and arterial thrombosis, premature stroke, myocardial infarction, pulmonary hypertension, and cardiomyopathy.

SECTION 5 VASCULAR DISEASE

235 The Pathogenesis, Prevention, and Treatment of Atherosclerosis

Peter Libby

PATHOGENESIS

Atherosclerosis remains the major cause of death and premature disability in developed societies. Moreover, current predictions estimate that by the year 2020 cardiovascular diseases, notably atherosclerosis, will become the leading global cause of total disease burden. Although many generalized or systemic risk factors predispose to its development, atherosclerosis affects various regions of the circulation preferentially and yields distinct clinical manifestations depending on the particular circulatory bed affected. Atherosclerosis of the coronary arteries commonly causes myocardial infarction (Chap. 239) and angina pectoris (Chap. 237). Atherosclerosis of the arteries supplying the central nervous system frequently provokes strokes and transient cerebral ischemia (Chap. 364). In the peripheral circulation, atherosclerosis causes intermittent claudication and gangrene and can jeopardize limb viability. Involvement of the splanchnic circulation can cause mesenteric ischemia. Atherosclerosis can affect the kidneys either directly (e.g., renal artery stenosis) or as a frequent site of atheroembolic disease (Chap. 242).

Even within a given arterial bed, stenoses due to atherosclerosis tend to occur focally, typically in certain predisposed regions. In the coronary circulation, for example, the proximal left anterior descending coronary artery exhibits a particular predilection for developing atherosclerotic disease. Likewise, atherosclerosis preferentially affects the proximal portions of the renal arteries and, in the extracranial circulation to the brain, the carotid bifurcation. Indeed, atherosclerotic lesions often form at branching points of arteries, regions of disturbed blood flow. Not all manifestations of atherosclerosis result from stenotic, occlusive disease. Ectasia and development of aneurysmal disease, for example, frequently occur in the aorta (Chap. 242). In addition to focal, flow-limiting stenoses, nonocclusive intimal atherosclerosis also occurs diffusely in affected arteries, as shown by intravascular ultrasound and postmortem studies.

Atherogenesis in humans typically occurs over a period of many years, usually many decades. Growth of atherosclerotic plaques probably does not occur in a smooth, linear fashion, but rather discontinuously, with periods of relative quiescence punctuated by periods of rapid evolution. After a generally prolonged "silent" period, atherosclerosis may become clinically manifest. The clinical expressions of atherosclerosis may be *chronic*, as in the development of stable, effort-induced angina pectoris or of predictable and reproducible intermittent claudication. Alternatively, a dramatic *acute* clinical event, such as myocardial infarction, a stroke, or sudden cardiac death, may first herald the presence of atherosclerosis. Other individuals may never experience clinical manifestations of arterial disease despite the presence of widespread atherosclerosis demonstrated post-mortem.

INITIATION OF ATHEROSCLEROSIS

An integrated view of experimental results in animals and studies of human atherosclerosis suggests that the "fatty streak" represents the initial lesion of atherosclerosis. These early lesions most often seem to arise from focal increases in the content of lipoproteins within regions of the intima. This accumulation of lipoprotein particles may not result simply from an increased permeability, or "leakiness," of the overlying endothelium (Fig. 235-1). Rather, these lipoproteins may collect in the intima of arteries because they bind to constituents of the extracellular matrix, increasing the residence time of the lipid-rich particles within the arterial wall. Lipoproteins that accumulate in the extracellular space of the intima of arteries often associate with glycosaminoglycans of the arterial extracellular matrix, an interaction that may slow the egress of these lipid-rich particles from the intima. Lipoprotein particles in the

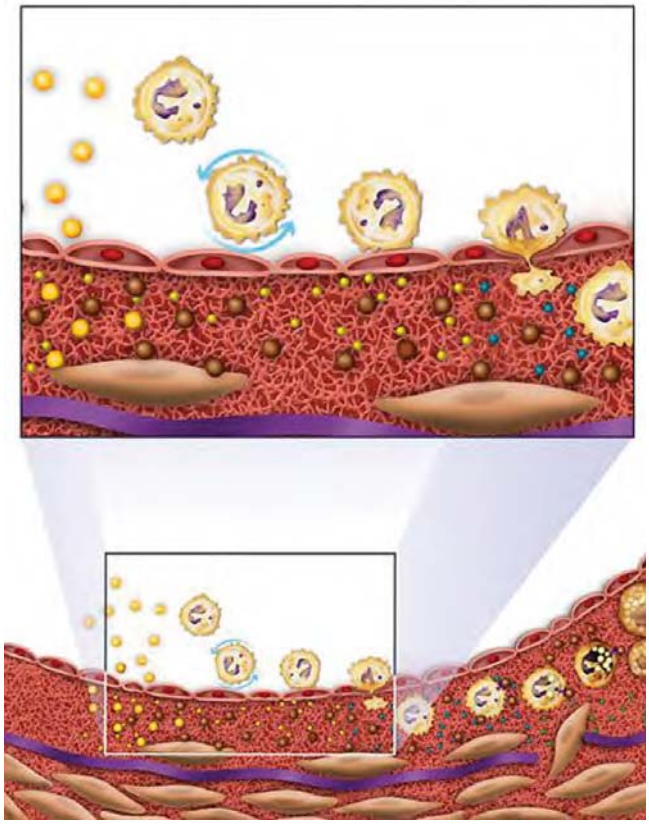

FIGURE 235-1 Cross-sectional view of an artery depicting steps in development of an atheroma, from left to right. The *upper panel* shows a detail of the boxed area below. The endothelial monolayer overlying the intima contacts blood. Hypercholesterolemia promotes accumulation of LDL particles (light spheres) in the intima. The lipoprotein particles often associate with constituents of the extracellular matrix, notably proteoglycans. Sequestration within the intima separates lipoproteins from some plasma antioxidants and favors oxidative modification. Such modified lipoprotein particles (darker spheres) may trigger a local inflammatory response responsible for signaling subsequent steps in lesion formation. The augmented expression of various adhesion molecules for leukocytes recruits monocytes to the site of a nascent arterial lesion.

Once adherent, some white blood cells will migrate into the intima. The directed migration of leukocytes probably depends on chemoattractant factors including modified lipoprotein particles themselves and chemoattractant cytokines depicted by the smaller spheres, such as the chemokine macrophage chemoattractant protein-1 produced by vascular wall cells in response to modified lipoproteins. Leukocytes in the evolving fatty streak can divide and exhibit augmented expression of receptors for modified lipoproteins (scavenger receptors). These mononuclear phagocytes ingest lipids and become foam cells, represented by a cytoplasm filled with lipid droplets. As the fatty streak evolves into a more complicated atherosclerotic lesion, smooth-muscle cells migrate from the media (*bottom of lower panel*), through the internal elastic membrane (*solid wavy line*), and accumulate within the expanding intima where they lay down extracellular matrix that forms the bulk of the advanced lesion (*bottom panel, right-hand side*).

extracellular space of the intima, particularly those retained by binding to matrix macromolecules, may undergo oxidative modifications. Considerable evidence supports a pathogenic role for products of oxidized lipoproteins in atherogenesis. Lipoproteins sequestered from plasma antioxidants in the extracellular space of the intima become particularly susceptible to oxidative modification, giving rise to hydroperoxides, lysophospholipids, oxysterols, and aldehydic breakdown products of fatty acids and phospholipids. Modifications of the apoprotein moieties may include breaks in the peptide backbone as well as derivatization of certain amino acid residues. Local production of hypochlorous acid by myeloperoxidase associated with inflammatory cells within the plaque yields chlorinated species such as chlorotyrosyl moieties. Considerable evidence supports the presence of such oxidation products in atherosclerotic lesions.

Leukocyte Recruitment Accumulation of leukocytes characterizes the formation of early atherosclerotic lesions (Fig. 235-1). Thus, from its very inception, atherogenesis involves elements of inflammation, a process that now provides a unifying theme in the pathogenesis of this disease. The inflammatory cell types typically found in the evolving atheroma include monocyte-derived macrophages and lymphocytes. A number of adhesion molecules or receptors for leukocytes expressed on the surface of the arterial endothelial cell likely participate in the recruitment of leukocytes to the nascent atheroma. Constituents of oxidatively modified low-density lipoprotein (LDL) can augment expression of leukocyte adhesion molecules. This example illustrates how the accumulation of lipoproteins in the arterial intima may link mechanistically with leukocyte recruitment, a key event in lesion formation.

Laminar shear forces such as those encountered in most regions of normal arteries can also suppress the expression of leukocyte adhesion molecules. Sites of predilection for atherosclerotic lesions (e.g., branch points) often have disturbed laminar flow. Ordered, pulsatile laminar shear of normal blood flow augments the production of nitric oxide by endothelial cells. This molecule, in addition to its vasodilator properties, can act at the low levels constitutively produced by arterial endothelium as a local anti-inflammatory autacoid, e.g., limiting local adhesion molecule expression. Exposure of endothelial cells to laminar shear stress increases the transcription of Kruppel-like factor 2 (KLF2) and reduces the expression of a thioredoxin-interacting protein (Txnip) that inhibits the activity of thioredoxin. KLF2 augments the activity of endothelial nitric oxide synthase, and reduced Txnip levels boost the function of the endogenous antioxidant thioredoxin. Laminar shear stress also stimulates endothelial cells to produce superoxide dismutase, an antioxidant enzyme. These examples indicate how hemodynamic forces may influence the cellular events that underlie atherosclerotic lesion initiation and provide a potential explanation for the favored localization of atherosclerotic lesions at sites that experience disturbance to laminar shear stress.

Once captured on the surface of the arterial endothelial cell by adhesion receptors, the monocytes and lymphocytes penetrate the endothelial layer and take up residence in the intima. In addition to products of modified lipoproteins, cytokines (protein mediators of inflammation) can regulate the expression of adhesion molecules involved in leukocyte recruitment. For example, interleukin 1 (IL-1) or tumor necrosis factor α (TNF-α) induces or augments the expression of leukocyte adhesion molecules on endothelial cells. Because products of lipoprotein oxidation can induce cytokine release from vascular wall cells, this pathway may provide an additional link between arterial accumulation of lipoproteins and leukocyte recruitment. Chemoattractant cytokines such as monocyte chemoattractant protein 1 appear to direct the migration of leukocytes into the arterial wall.

Foam Cell Formation Once resident within the intima, the mononuclear phagocytes mature into macrophages and become lipid-laden foam cells, a conversion that requires the uptake of lipoprotein particles by receptor-mediated endocytosis. One might suppose that the well-recognized "classical" receptor for LDL mediates this lipid uptake; however, patients or animals lacking effective LDL receptors due to genetic alterations (e.g., familial hypercholesterolemia) have abundant arterial lesions and extraarterial xanthomata rich in macrophage-derived foam cells. In addition, the exogenous cholesterol suppresses expression of the LDL receptor; thus, the level of this cell-surface receptor for LDL decreases under conditions of cholesterol excess. Candidates for alternative receptors that can mediate lipid-loading of foam cells include a growing number of macrophage "scavenger" receptors, which preferentially endocytose modified lipoproteins, and other receptors for oxidized LDL or beta very low density lipoprotein

(β-VLDL). Monocyte attachment to the endothelium, migration into the intima, and maturation to form lipid-laden macrophages thus represent key steps in the formation of the fatty streak, the precursor of fully formed atherosclerotic plaques.

ATHEROMA EVOLUTION AND COMPLICATIONS

Although the fatty streak commonly precedes the development of a more advanced atherosclerotic plaque, not all fatty streaks progress to form complex atheromata. By ingesting lipids from the extracellular space, the mononuclear phagocytes bearing such scavenger receptors may remove lipoproteins from the developing lesion. Some lipid-laden macrophages may leave the artery wall, exporting lipid in the process. Lipid accumulation, and hence propensity to form atheroma, ensues if the amount of lipid entering the artery wall exceeds that removed by mononuclear phagocytes or other pathways.

Export by phagocytes may constitute one response to local lipid overload in the evolving lesion. Another mechanism, reverse cholesterol transport mediated by high-density lipoproteins (HDL), probably provides an independent pathway for lipid removal from atheroma. This transfer of cholesterol from the cell to the HDL particle involves specialized cell surface molecules such as the ATP binding cassette (ABC) transporters. *ABCA1*, the gene mutated in Tangier disease, a condition characterized by very low HDL levels, transfers cholesterol from cells to nascent HDL particles and ABCG1 to mature HDL particles. "Reverse cholesterol transport" mediated by these ABC transporters allows HDL loaded with cholesterol to deliver it to hepatocytes by binding to scavenger receptor B 1 or other receptors. The liver cell can metabolize the sterol to bile acids that can be excreted. This export pathway from macrophage foam cells to peripheral cells such as hepatocytes explains part of HDL's antiatherogenic action. (Anti-inflammatory and antioxidant properties may also contribute to HDL's atheroprotective effects.) Thus, macrophages may play a vital role in the dynamic economy of lipid accumulation in the arterial wall during atherogenesis.

Some lipid-laden foam cells within the expanding intimal lesion perish. Some foam cells may die as a result of programmed cell death, or *apoptosis*. This death of mononuclear phagocytes results in formation of the lipid-rich center, often called the *necrotic core*, in established atherosclerotic plaques. Macrophages loaded with modified lipoproteins may elaborate cytokines and growth factors that can further signal some of the cellular events in lesion complication. While accumulation of lipid-laden macrophages characterizes the fatty streak, build-up of fibrous tissue formed by extracellular matrix typifies the more advanced atherosclerotic lesion. The smooth-muscle cell synthesizes the bulk of the extracellular matrix of the complex atherosclerotic lesion. A number of growth factors or cytokines elaborated by mononuclear phagocytes can stimulate smooth-muscle cell proliferation and production of extracellular matrix. Cytokines found in the plaque, including IL-1 or TNF-α, can induce local production of growth factors, including forms of platelet-derived growth factor (PDGF), fibroblast growth factors, and others, that may contribute to plaque evolution and complication. Other cytokines, notably interferon γ (IFN-γ) derived from activated T cells within lesions, can limit the synthesis of interstitial forms of collagen by smooth-muscle cells. These examples illustrate how atherogenesis involves a complex mix of mediators that in the balance determines the characteristics of particular lesions.

The arrival of smooth-muscle cells and their elaboration of extracellular matrix probably provides a critical transition, yielding a fibrofatty lesion in place of a simple accumulation of macrophage-derived foam cells. For example, PDGF elaborated by activated platelets, macrophages, and endothelial cells can stimulate the migration of smooth-muscle cells normally resident in the tunica media into the intima. Such growth factors and cytokines produced locally can stimulate the proliferation of resident smooth-muscle cells in the intima as well as those that have migrated from the media. Transforming growth factor β (TGF-β), among other mediators, potently stimulates interstitial collagen production by smooth-muscle cells. These mediators may arise not only from neighboring vascular cells or leukocytes (a "paracrine" pathway) but also, in some instances, from the same cell that responds to the factor (an "autocrine" pathway). Together, these alterations in smooth-muscle cells, signaled by these mediators acting at short distances, can hasten transformation of the fatty streak into a more fibrous smooth-muscle cell and extracellular matrix-rich lesion.

In addition to locally produced mediators, products of blood coagulation and thrombosis likely contribute to atheroma evolution and complication. This involvement justifies the use of the term *atherothrombosis* to convey the inextricable links between atherosclerosis and thrombosis. Fatty streak formation begins beneath a morphologically intact endothelium. In advanced fatty streaks, however, microscopic breaches in endothelial integrity may occur. Microthrombi rich in platelets can form at such sites of limited endothelial denudation owing to exposure of the thrombogenic extracellular matrix of the underlying basement membrane. Activated platelets release numerous factors that can promote the fibrotic response, including PDGF and TGF-β. Thrombin itself generates fibrin, not only during coagulation but also through protease-activated receptors that can signal smooth-muscle migration, proliferation, and extracellular matrix production. Many arterial mural microthrombi resolve without clinical manifestation by a process of local fibrinolysis, resorption, and endothelial repair, yet can lead to lesion progression by stimulating these pro-fibrotic functions of smooth-muscle cells (**Fig. 235-2*D***).

Microvessels As atherosclerotic lesions advance, abundant plexuses of microvessels develop in connection with the artery's vasa vasorum. Newly developing microvascular networks may contribute to lesion complications in several ways. These blood vessels provide an abundant surface area for leukocyte trafficking and may serve as the portal of entry and exit of white blood cells from the established atheroma. Microvessels in the plaques may also furnish foci for intraplaque hemorrhage. Like the neovessels in the diabetic retina, microvessels in the atheroma may be friable and prone to rupture and can produce focal hemorrhage. Such a vascular leak leads to thrombosis in situ and thrombin generation from prothrombin. In addition to its role in blood coagulation, thrombin can modulate many aspects of vascular cell function, as described above. Atherosclerotic plaques often contain fibrin and hemosiderin, an indication that episodes of intraplaque hemorrhage contribute to plaque complications.

CALCIFICATION As they advance, atherosclerotic plaques also accumulate *calcium*. Proteins usually found in bone also localize in atherosclerotic lesions, e.g., osteocalcin, osteopontin, and bone morphogenetic proteins. Mineralization of the atherosclerotic plaque recapitulates many aspects of bone formation.

Plaque Evolution Although atherosclerosis research has focused much attention on proliferation of smooth-muscle cells, as in the case of macrophages, smooth-muscle cells can also undergo apoptosis in the atherosclerotic plaque. Indeed, complex atheromata often have a mostly fibrous character and lack the hypercellularity of less advanced lesions. This relative paucity of smooth-muscle cells in advanced atheromata may result from the predominance of cytostatic mediators such as TGF-β or IFN-γ (which can inhibit smooth-muscle cell proliferation) and also from smooth-muscle cell apoptosis. Some of the same pro-inflammatory cytokines that activate atherogenic functions of vascular wall cells can also sensitize these cells to undergo apoptosis.

Thus, during the evolution of the atherosclerotic plaque, a complex balance between entry and egress of lipoproteins and leukocytes, cell proliferation and cell death, extracellular matrix production and remodeling as well as calcification and neovascularization contribute to lesion formation. Multiple and often competing signals regulate these various cellular events. Increasingly, we appreciate links between atherogenic risk factors, inflammation, and the altered behavior of intrinsic vascular wall cells and infiltrating leukocytes that underlie the complex pathogenesis of these lesions.

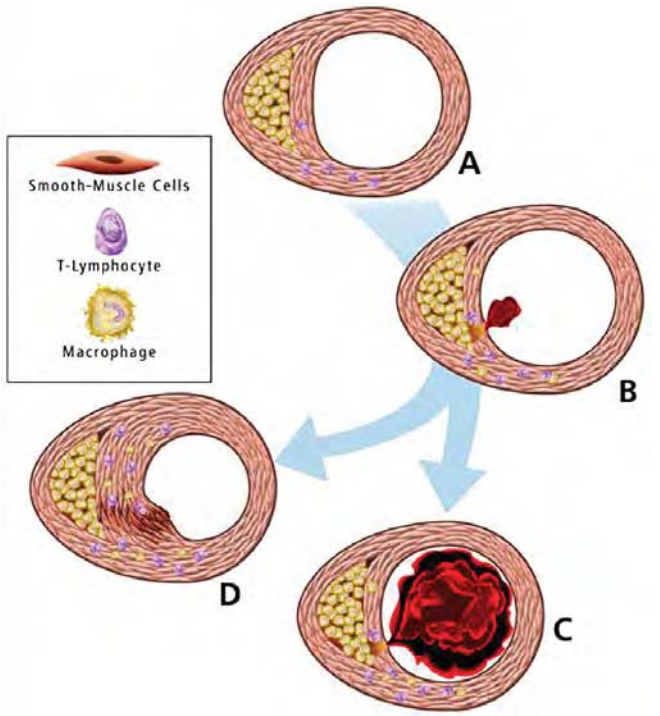

FIGURE 235-2 Plaque rupture, thrombosis, and healing. *A.* Arterial remodeling during atherogenesis. During the initial part of the life history of an atheroma, growth is often outward, preserving the caliber of lumen. This phenomenon of "compensatory enlargement" accounts in part for the tendency of coronary arteriography to underestimate the degree of atherosclerosis. ***B.*** Rupture of the plaque's fibrous cap causes thrombosis. Physical disruption of the atherosclerotic plaque commonly causes arterial thrombosis by allowing blood coagulant factors to contact thrombogenic collagen found in the arterial extracellular matrix and tissue factor produced by macrophage-derived foam cells in the lipid core of lesions. In this manner, sites of plaque rupture form the nidus for thrombi. The normal artery wall possesses several fibrinolytic or antithrombotic mechanisms that tend to resist thrombosis and lyse clots that begin to form in situ. Such antithrombotic or thrombolytic molecules include thrombomodulin, tissue and urokinase-type plasminogen activators, heparan sulfate proteoglycans, prostacyclin, and nitric oxide. ***C.*** When the clot overwhelms the endogenous fibrinolytic mechanisms, it may propagate and lead to arterial occlusion. The consequences of this occlusion depend on the degree of existing collateral vessels. In a patient with chronic multivessel, occlusive coronary artery disease, collateral channels have often formed. In such circumstances, even a total arterial occlusion may not lead to myocardial infarction, or it may produce an unexpectedly modest or a non-ST-segment elevation infarct because of collateral flow. In the patient with less advanced disease and without substantial stenotic lesions to provide a stimulus to collateral vessel formation, sudden plaque rupture and arterial occlusion commonly produces ST-segment elevation infarction. These are the types of patients who may present with myocardial infarction or sudden death as a first manifestation of coronary atherosclerosis. In some cases, the thrombus may lyse or organize into a mural thrombus without occluding the vessel. Such instances may be clinically silent. ***D.*** The subsequent thrombin-induced fibrosis and healing causes a fibroproliferative response that can lead to a more fibrous lesion, one that can produce an eccentric plaque that causes a hemodynamically significant stenosis. In this way, a nonocclusive mural thrombus, even if clinically silent or causing unstable angina rather than infarction, can provoke a healing response that can promote lesion fibrosis and luminal encroachment. Such a sequence of events may convert a "vulnerable" atheroma with a thin fibrous cap prone to rupture into a more "stable" fibrous plaque with a reinforced cap. Angioplasty of unstable coronary lesions may "stabilize" the lesions by a similar mechanism, producing a wound followed by healing.

CLINICAL SYNDROMES OF ATHEROSCLEROSIS

Atherosclerotic lesions occur ubiquitously in Western societies. Most atheromata produce no symptoms, and many never cause clinical manifestations. Numerous patients with diffuse atherosclerosis may succumb to unrelated illnesses without ever having experienced a clinically significant manifestation of atherosclerosis. What accounts for this variability in the clinical expression of atherosclerotic disease?

Arterial remodeling during atheroma formation (Fig. 235-2*A*) represents a frequently overlooked but clinically important feature of lesion evolution. During the initial phases of atheroma development, the plaque usually grows outward, in an abluminal direction. Vessels affected by atherogenesis tend to increase in diameter, a phenomenon known as *compensatory enlargement*, in a type of vascular remodeling. The growing atheroma does not encroach upon the arterial lumen until the burden of atherosclerotic plaque exceeds ~40% of the area encompassed by the internal elastic lamina. Thus, during much of its life history, an atheroma will not cause stenosis that can limit tissue perfusion.

Flow-limiting stenoses commonly form later in the history of the plaque. Many such plaques cause stable syndromes such as demand-induced angina pectoris or intermittent claudication in the extremities. In the coronary and other circulations, even total vascular occlusion by atheroma does not invariably lead to infarction. The hypoxic stimulus of repeated bouts of ischemia characteristically induces formation of collateral vessels in the myocardium, mitigating the consequences of an acute occlusion of an epicardial coronary artery. By contrast, we now appreciate that many lesions that cause acute or unstable atherosclerotic syndromes, particularly in the coronary circulation, may arise from atherosclerotic plaques that do not produce a flow-limiting stenosis. Such lesions may produce only minimal luminal irregularities on traditional angiograms and often do not meet the traditional criteria for "significance" by arteriography. Instability of such nonocclusive stenoses may explain the frequency of myocardial infarction as an initial manifestation of coronary artery disease (in at least one-third of cases) in patients who report no prior history of angina pectoris, a syndrome usually caused by flow-limiting stenoses.

Plaque Instability and Rupture

Postmortem studies afford considerable insight into the microanatomic substrate underlying the "instability" of plaques that do not cause critical stenoses. A superficial erosion of the endothelium or a frank plaque rupture or fissure usually produces the thrombus that causes episodes of unstable angina pectoris or the occlusive and relatively persistent thrombus that causes acute myocardial infarction (Fig. 235-2*B*). In the case of carotid atheromata, a deeper ulceration that provides a nidus for formation of platelet thrombi may cause transient cerebral ischemic attacks.

Rupture of the plaque's fibrous cap (Fig. 235-2*C*) permits contact between coagulation factors in the blood with highly thrombogenic tissue factor expressed by macrophage foam cells in the plaque's lipid-rich core. If the ensuing thrombus is nonocclusive or transient, the episode of plaque disruption may not cause symptoms or may result in episodic ischemic symptoms such as rest angina. Occlusive thrombi that endure will often cause acute myocardial infarction, particularly in the absence of a well-developed collateral circulation supplying the affected territory. Repetitive episodes of plaque disruption and healing provide one likely mechanism of transition of the fatty streak to a more complex fibrous lesion (Fig. 235-2*D*). The healing process in arteries, as in skin wounds, involves the laying down of new extracellular matrix and fibrosis.

Not all atheromata exhibit the same propensity to rupture. Pathologic studies of culprit lesions that have caused acute myocardial infarction reveal several characteristic features. Plaques that have caused fatal thromboses tend to have thin fibrous caps, relatively large lipid cores, and a high content of macrophages. Morphometric studies of such culprit lesions show that at sites of plaque rupture macrophages and T lymphocytes predominate and contain relatively few smooth-muscle cells. The cells that concentrate at sites of plaque rupture bear markers of inflammatory activation. The presence of the transplantation, or histocompatibility, antigen HLA-DR provides one convenient gauge of the

degree of inflammation in cells in atheroma. Resting cells in normal arteries seldom express this transplantation antigen. However, macrophages and smooth-muscle cells at sites of human coronary artery plaque disruption do bear this inducible cell-surface marker. Therefore, the presence of HLA-DR-positive macrophages and T cells indicates an ongoing inflammatory response at sites of plaque rupture. In addition, patients with active atherosclerosis and acute coronary syndromes display signs of disseminated inflammation. For example, atherosclerotic plaques and even microvascular endothelial cells at sites remote from the "culprit" lesion of an acute coronary syndrome can exhibit markers of activation such as HLA-DR.

Inflammatory mediators regulate processes that govern the integrity of the plaque's fibrous cap and hence its propensity to rupture. For example, the T cell–derived cytokine IFN-γ, found in atherosclerotic plaques and required to induce the HLA-DR present at sites of rupture, can inhibit growth and collagen synthesis of smooth-muscle cells, as noted above. Cytokines derived from activated macrophages and lesional T cells can elicit the expression of genes encoding proteolytic enzymes that can degrade the extracellular matrix of the plaque's fibrous cap. Thus, inflammatory mediators can impair collagen synthesis required for maintenance and repair of the fibrous cap and trigger degradation of extracellular matrix macromolecules, processes that weaken the plaque's fibrous cap and enhance its vulnerability to rupture. In contrast to plaques with these features of vulnerability, those with a dense extracellular matrix and relatively thick fibrous cap without substantial tissue factor-rich lipid cores seem generally resistant to rupture and unlikely to provoke thrombosis.

Features of the biology of the atheromatous plaque in addition to its degree of luminal encroachment influence the clinical manifestations of this disease. This enhanced understanding of plaque biology provides insight into the diverse ways in which atherosclerosis can present clinically and why the disease may remain silent or stable for prolonged periods, punctuated by acute complications at certain times. Increased understanding of atherogenesis provides new insight into the mechanisms linking it to the risk factors discussed below, indicates the ways in which current therapies may improve outcomes, and also suggests new targets for future intervention.

PREVENTION AND TREATMENT

THE CONCEPT OF ATHEROSCLEROTIC RISK FACTORS

The systematic study of risk factors for atherosclerosis emerged from a coalescence of experimental results as well as cross-sectional and ultimately longitudinal studies in humans. The prospective, community-based Framingham Heart Study provided rigorous support for the concept that hypercholesterolemia, hypertension, and other factors correlated with cardiovascular risk. Similar observational studies performed worldwide bolstered the concept of "risk factors" for cardiovascular disease.

From a practical viewpoint, the cardiovascular risk factors that have emerged from such studies fall into two categories: those modifiable by lifestyle and/or pharmacotherapy and those such as age and gender that are immutable. The weight of evidence supporting various risk factors differs. For example, hypercholesterolemia and hypertension certainly predict coronary risk, but other so-called nontraditional risk factors, such as levels of homocysteine, lipoprotein (a) [Lp(a)], or infection, remain controversial. Moreover, the causality of some biomarkers that predict cardiovascular risk, such as C-reactive protein (CRP), remains uncertain. Table 235-1 lists the risk factors recognized by the current National Cholesterol Education Project Adult Treatment Panel III (ATP III). The sections below will consider some of these risk factors and approaches to their modification.

TABLE 235-1 MAJOR RISK FACTORS (EXCLUSIVE OF LDL CHOLESTEROL) THAT MODIFY LDL GOALS

- Cigarette smoking
- Hypertension (BP ≥140/90 mmHg or on antihypertensive medication)
- Low HDL cholesterol[a] [<1.0 mmol/L (<40 mg/dL)]
- Diabetes mellitus
- Family history of premature CHD
  - CHD in male first-degree relative <55 years
  - CHD in female first-degree relative <65 years
- Age (men ≥45 years; women ≥55 years)
- Lifestyle risk factors
  - Obesity (BMI ≥30 kg/m^2)
  - Physical inactivity
  - Atherogenic diet
- Emerging risk factors
  - Lipoprotein(a)
  - Homocysteine
  - Prothrombotic factors
  - Proinflammatory factors
  - Impaired fasting glucose
  - Subclinical atherogenesis

[a]HDL cholesterol ≥1.6 mmol/L (≥60 mg/dL) counts as a "negative" risk factor; its presence removes one risk factor from the total count.

Note: LDL, low-density lipoprotein; BP, blood pressure; HDL, high-density lipoprotein; CHD, coronary heart disease; BMI, body-mass index.

Source: Modified from Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III). JAMA 285:2486, 2001.

Lipid Disorders Abnormalities in plasma lipoproteins and derangements in lipid metabolism rank among the most firmly established and best understood risk factors for atherosclerosis. Chap. 350 describes the lipoprotein classes and provides a detailed discussion of lipoprotein metabolism. Current ATP III guidelines recommend lipid screening in all adults >20 years. The screen should include a fasting lipid profile (total cholesterol, triglycerides, LDL cholesterol, and HDL cholesterol) repeated every 5 years.

ATP III guidelines strive to match the intensity of treatment to an individual's risk. A quantitative estimate of risk places individuals in one of three treatment strata (Table 235-2). The first step in applying these guidelines involves counting an individual's risk factors (Table 235-1). Individuals with fewer than two risk factors fall into the lowest treatment intensity stratum [LDL goal <4.1 mmol/L (<160 mg/dL)]. In those with two or more risk factors, the next step involves a simple

TABLE 235-2 LDL CHOLESTEROL GOALS AND CUTPOINTS FOR THERAPEUTIC LIFESTYLE CHANGES (TLC) AND DRUG THERAPY IN DIFFERENT RISK CATEGORIES

	LDL Level, mmol/L (mg/dL)		
Risk Category	**Goal**	**Initiate TLC**	**Consider Drug Therapy**
Very high ACS, or CHD w/DM, or mult CRF	<1.8 (<70)	≥1.8 (≥70)	≥1.8 (≥70)
High CHD or CHD risk equivalents (10-year risk > 20%) If LDL < 2.6 (<100)	<2.6 (<100) [optional goal: <1.8 (<70)] <1.8 (<70)	≥2.6 (≥100)	≥2.6 (≥100) [<2.6 (<100): consider drug Rx]
Moderately high 2+ risk factors (10-year risk, 10–20%)	<2.6 (<100)	≥3.4 (≥130)	≥3.4 (≥130) [2.6–3.3 (100–129): consider drug Rx]
Moderate 2+ risk factors (risk < 10%)	<3.4 (<130)	≥3.4 (≥130)	≥4.1 (≥160)
Lower 0–1 risk factor	<4.1 (<160)	≥4.1 (≥160)	≥4.9 (≥190)

Note: LDL, low-density lipoprotein; ACS, acute coronary syndrome; CHD, coronary heart disease; DM, diabetes mellitus; CRF, coronary risk factors.

calculation that estimates the 10-year risk of developing coronary heart disease (CHD) (Table 235-2); see also *http://www.nhlbi.nih.gov/guidelines/cholesterol/* for the algorithm and a downloadable risk calculator. Those with a 10-year risk ≤20% fall into the intermediate stratum [LDL goal <3.4 mmol/L (<130 mg/dL)]. Those with a calculated 10-year CHD risk of >20%, any evidence of established atherosclerosis, or diabetes (now considered a CHD risk-equivalent) fall into the most intensive treatment group [LDL goal <2.6 mmol/L (<100 mg/dL)]. Members of the ATP III panel have recently suggested 1.8 mmol/L (70 mg/dL) as a goal for very high risk and as an optional goal for high-risk patients based on recent clinical trial data (Table 235-2).

The first maneuver to achieve the LDL goal involves therapeutic lifestyle changes (TLC), including specific diet and exercise recommendations established by the guidelines. According to ATP III criteria, those with LDL levels exceeding goal for their risk group by >0.8 mmol/L (>30 mg/dL) merit consideration for drug therapy. In patients with triglycerides > 2.6 mmol/L (>200 mg/dL), ATP III guidelines specify a secondary goal for therapy, "non-HDL cholesterol" (simply, the HDL cholesterol level subtracted from the total cholesterol). Cutpoints for therapeutic decision for non-HDL cholesterol are 0.8 mmol/L (30 mg/dL) more than those for LDL.

An extensive and growing body of rigorous evidence now supports the effectiveness of aggressive management of dyslipidemia. Addition of drug therapy to dietary and other nonpharmacologic measures reduces cardiovascular risk in patients with established coronary atherosclerosis and also in individuals who have not previously suffered CHD events (Fig. 235-3). As guidelines often lag the emerging clinical trial evidence base, the practitioner may elect to exercise clinical judgment in making therapeutic decisions in individual patients.

LDL-lowering therapies do not appear to exert their beneficial effect on cardiovascular events by causing a marked "regression" of obstructive coronary lesions. Angiographically monitored studies of lipid lowering have shown at best a modest reduction in coronary artery stenoses over the duration of study. Yet these same studies consistently show substantial decreases in coronary events. These results suggest that the beneficial mechanism of lipid lowering does not require a substantial reduction in the fixed stenoses. Rather, the benefit may derive from "stabilization" of atherosclerotic lesions without decreased stenosis. Such stabilization of atherosclerotic lesions and the attendant decrease in coronary events may result from the egress of lipids or by favorably influencing aspects of the biology of atherogenesis discussed above. In addition, as sizeable lesions may protrude abluminally rather than into the lumen due to complementary enlargement, shrinkage of such plaques might not be apparent on angiograms. The consistent benefit of LDL lowering by 3-hydroxy-3-methylgluatryl coenzyme A (HMG-CoA) reductase inhibitors (statins) observed in many risk groups may depend not only on their salutary effects on the lipid profile but also on direct modulation of plaque biology independent of lipid lowering.

A new class of LDL-lowering medications reduces cholesterol absorption from the proximal small bowel by targeting an enterocyte cholesterol transporter with the unwieldy name Niemann-Pick C1-like 1 protein (NPC1L1). The NPC1L1 inhibitor ezetimibe provides a useful adjunct to current therapies to achieve LDL goals; however, no clinical trial evidence yet demonstrates that ezetimibe benefits CHD outcomes.

As the mechanism by which elevated LDL levels promote atherogenesis likely involves oxidative modification, several trials have tested the possibility that antioxidant vitamin therapy might reduce CHD events. Rigorous and well-controlled clinical trials have failed to demonstrate that antioxidant vitamin therapy improves CHD outcomes. Therefore, the current evidence base does *not* support the use of antioxidant vitamins for this indication.

The clinical use of effective pharmacologic strategies for lowering LDL has markedly reduced cardiovascular events, but even their optimal utilization in clinical trials prevents only a minority of these endpoints. Hence other aspects of the lipid profile have become tempting targets for addressing the residual burden of cardiovascular disease that persists despite aggressive LDL lowering. Indeed, in the "post-statin" era, patients with LDL levels at or below target not infrequently present with acute coronary syndromes. Low levels of HDL remain a prevalent problem in patients with coronary artery disease. Blood HDL levels vary inversely with those of triglycerides, and the independent role of triglycerides as a cardiovascular risk factor remains unsettled. For these reasons, approaches to raising HDL have emerged as a prominent next hurdle in the management of dyslipidemia. Weight loss and physical activity can raise HDL. Nicotinic acid, particularly in combination with statins, can robustly raise HDL. Some clinical trial data support the effectiveness of nicotinic acid in cardiovascular risk reduction. However, flushing and pruritus remain a challenge to patient acceptance, even with improved dosage forms of nicotinic acid. The identification of a cell-surface receptor for nicotinic acid may speed understanding of its mechanism of action and spur the development of new approaches to raising HDL.

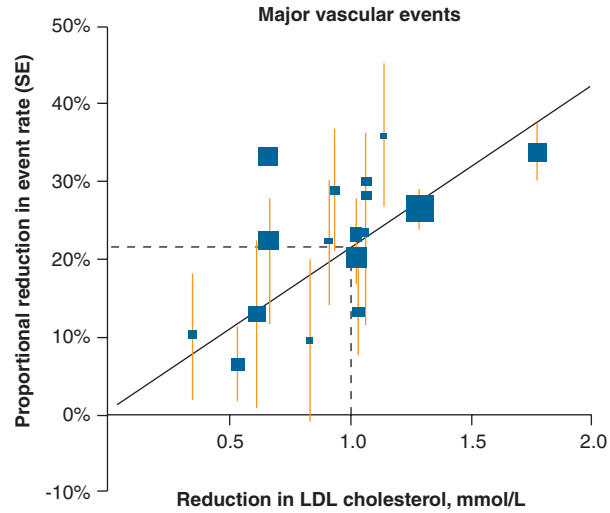

FIGURE 235-3 Lipid lowering reduces coronary events, as reflected on this graph showing the reduction in major cardiovascular events as a function of LDL level in a compendium of clinical trials with statins. *(Adapted from CTT Collaborators, Lancet 366:1267, 2005.)* The Management of Elevated Cholesterol in the Primary Prevention Group of Adult Japanese (MEGA), Treating to New Targets (TNT), and Incremental Decrease in Endpoints through Aggressive Lipid Lowering (IDEAL) studies have been added.

Agonists of nuclear receptors that raise HDL levels provide another potential avenue to cardiovascular risk reduction. Peroxisome proliferator–activated receptor alpha (PPAR-α) agonists effectively raise HDL (by increasing transcription of its major apolipoprotein, AI) and lower triglyceride levels (by decreasing transcription of apolipoprotein CIII, an inhibitor of lipoprotein lipase, hence augmenting catabolism of triglyceride-rich lipoproteins). Cardiovascular outcome trials with PPAR-α and -γ agonists have yielded mixed results to date. Other agents in clinical development raise HDL levels by inhibiting cholesteryl ester transfer protein. Clinical studies currently underway will assess the effectiveness of this strategy to increase HDL in improvement of patient outcomes.

Hypertension (See also Chap. 241) A wealth of epidemiologic data support a relationship between hypertension and atherosclerotic risk, and extensive clinical trial evidence has established that pharmacologic treatment of hypertension can reduce the risk of stroke, heart failure, and CHD events.

Diabetes Mellitus, Insulin Resistance, and the Metabolic Syndrome (See also Chap. 338) Most patients with diabetes mellitus die of atherosclerosis and its complications. Aging and rampant obesity in the U.S. population underlie a current epidemic of type 2 diabetes mellitus. The abnormal lipoprotein profile associated with insulin resistance, known as *diabetic dyslipidemia*, accounts for part of the elevated car-

diovascular risk in patients with type 2 diabetes. While diabetic patients often have LDL cholesterol levels near average, the LDL particles tend to be smaller and denser, and, therefore, more atherogenic. Other features of diabetic dyslipidemia include low HDL and elevated triglyceride levels. Hypertension also frequently accompanies obesity, insulin resistance, and dyslipidemia. Indeed, the ATP III guidelines now recognize this cluster of risk factors and provide criteria for diagnosis of the "metabolic syndrome" (Table 235-3). Despite legitimate concerns regarding whether clustered components confer more risk than an individual component, the metabolic syndrome concept has considerable clinical utility.

Therapeutic objectives for intervention in these patients include addressing the underlying causes, including obesity and low physical activity, by initiating TLC. The ATP III guidelines provide an explicit step-by-step plan for implementing TLC, and treatment of the component risk factors should accompany TLC. Establishing that strict glycemic control reduces the risk of macrovascular complications of diabetes has proven much more elusive than the established beneficial effects on microvascular complications such as retinopathy or renal disease. In the absence of clear-cut evidence that tight glycemic control reduces coronary risk in patients with type 2, attention to other aspects of risk in this patient population assumes even greater importance. In this regard, multiple clinical trials, including the recent Collaborative Atorvastatin Diabetes Study (CARDS) that addressed specifically the diabetic population, have demonstrated unequivocal benefit of HMG-CoA reductase inhibitor therapy in diabetic patients over all ranges of LDL cholesterol levels. The Veterans Affairs HDL Intervention Trial (VA-HIT) showed that gemfibrozil, a PPAR-α agonist, reduced CHD and stroke in a population of men, many of whom had features of the metabolic syndrome. The recent Fenofibrate Intervention and Event Lowering in Diabetes (FIELD) trial did not meet its primary endpoint of reduced CHD death or nonfatal myocardial infarction but did show a significant reduction in a composite endpoint of total cardiovascular events. A cardiovascular endpoint study in diabetic patients with the PPAR-γ agonist pioglitazone likewise did not meet its multipartite primary endpoint but did show a significant reduction in a secondary composite endpoint of all-cause mortality, nonfatal myocardial infarction, and stroke. In view of the consistent benefit for diabetic populations of statin treatment, and the thus far equivocal results with PPAR agonists, the current stance of the American Diabetic Association that statins be considered for persons with diabetes older than 40 who have a total cholesterol level ≥ 135 appears amply justified. Among the oral hypoglycemic agents, metformin possesses the best evidence base for cardiovascular event reduction.

Diabetic populations appear to derive particular benefit from antihypertensive strategies that block the action of angiotensin II. Thus, the antihypertensive regimen for patients with the metabolic syndrome should include angiotensin-converting enzyme inhibitors or angiotensin receptor blockers when possible. Most of these individuals will require more than one antihypertensive agent to achieve the recently updated American Diabetes Association blood pressure goal of 130/80 mmHg.

TABLE 235-3 CLINICAL IDENTIFICATION OF THE METABOLIC SYNDROME—ANY THREE RISK FACTORS

Risk Factor	Defining Level
Abdominal obesity[a]	
Men (waist circumference)[b]	>102 cm (>40 in.)
Women	>88 cm (>35 in.)
Triglycerides	>1.7 mmol/L (>150 mg/dL)
HDL cholesterol	
Men	<1.0 mmol/L (<40 mg/dL)
Women	<1.3 mmol/L (<50 mg/dL)
Blood pressure	≥130/≥85 mmHg
Fasting glucose	>6.1 mmol/L (>110 mg/dL)

[a]Overweight and obesity are associated with insulin resistance and the metabolic syndrome. However, the presence of abdominal obesity is more highly correlated with the metabolic risk factors than is an elevated body-mass index (BMI). Therefore, the simple measure of waist circumference is recommended to identify the BMI component of the metabolic syndrome.

[b]Some male patients can develop multiple metabolic risk factors when the waist circumference is only marginally increased, e.g., 94–102 cm (37–39 in.). Such patients may have a strong genetic contribution to insulin resistance. They should benefit from life-style changes, similarly to men with categorical increases in waist circumference.

Male Gender/Postmenopausal State Decades of observational studies have verified excess coronary risk in men compared with premenopausal women. After menopause, however, coronary risk accelerates in women. At least part of the apparent protection against CHD in premenopausal women derives from their relatively higher HDL levels compared with those of men. After menopause, HDL values fall in concert with increased coronary risk. Estrogen therapy lowers LDL cholesterol and raises HDL cholesterol, changes that should decrease coronary risk.

Multiple observational and experimental studies suggested that estrogen therapy reduces coronary risk. However, a spate of recent clinical trials has failed to demonstrate a net benefit of estrogen with or without progestins on CHD outcomes. In the Heart and Estrogen/Progestin Replacement Study (HERS), postmenopausal female survivors of acute myocardial infarction were randomized to an estrogen/progestin combination or to placebo. This study showed no overall reduction in recurrent coronary events in the active treatment arm. Indeed, early in the 5-year course of this trial, there was a trend toward an actual increase in vascular events in the treated women. Extended follow-up of this cohort did not disclose an accrual of benefit in the treatment group. The Women's Health Initiative (WHI) study arm using a similar estrogen plus progesterone regimen was halted due to a small but significant hazard of cardiovascular events, stroke, and breast cancer. The estrogen without progestin arm of WHI (conducted in women without a uterus) ceased early due to an increase in strokes, and failed to afford protection from myocardial infarction or CHD death during observation over 7 years. The excess cardiovascular events in these trials may result from an increase in thromboembolism (Chap. 342). Physicians should work with women to provide information and help weigh the small but evident CHD risk of estrogen ± progestin vs. the benefits on postmenopausal symptoms and osteoporosis, taking personal preferences into account. Post hoc analyses of observational studies suggest that estrogen therapy in women younger than or closer to menopause than the women enrolled in WHI might confer cardiovascular benefit. Thus, the timing in relation to menopause or age at which estrogen therapy begins may influence its risk/benefit balance.

The lack of efficacy of estrogen therapy in cardiovascular risk reduction highlights the need for redoubled attention to known modifiable risk factors in women. In the recent clinical trials with HMG-CoA reductase inhibitors, women, when included, have derived benefits at least commensurate with those seen in men.

Dysregulated Coagulation or Fibrinolysis Thrombosis ultimately causes the gravest complications of atherosclerosis. The propensity to form thrombi and/or to lyse clots once they form clearly influences the manifestations of atherosclerosis. Thrombosis provoked by atheroma rupture and subsequent healing may promote plaque growth. Certain individual characteristics can influence thrombosis or fibrinolysis and have received attention as potential coronary risk factors. For example, fibrinogen levels correlate with coronary risk and provide information regarding coronary risk independent of the lipoprotein profile. Elevated fibrinogen levels might promote thrombosis. As an acute-phase reactant, fibrinogen may also serve as a marker of inflammation.

The stability of an arterial thrombus depends on the balance between fibrinolytic factors, such as plasmin, and inhibitors of the fibrinolytic system, such as plasminogen activator inhibitor 1 (PAI-1). However, the levels of tissue plasminogen activator and PAI-1 in plasma have not proved to add considerable information beyond the lipid profile to the assessment of cardiovascular risk. Lp(a) (Chap. 350) may modulate fibrinolysis, and although individuals with elevated Lp(a) levels have increased CHD risk, Lp(a) levels do not potently predict risk in the population at large.

Aspirin reduces CHD events in several contexts. Chap. 237 discusses aspirin therapy in stable ischemic heart disease, Chap. 238 reviews recommendations for aspirin treatment in acute coronary syndromes, and Chap. 364 describes aspirin's role in preventing recurrent ischemic stroke. In primary prevention, pooled trial data show that low-dose aspirin treatment (81 mg qd to 325 mg alternate days) can reduce risk of first myocardial infarction in men. Although the recent Women's Health Study (WHS) showed that aspirin (100 mg alternate days) reduced strokes by 17%, it did not prevent myocardial infarction in women. Current American Heart Association (AHA) guidelines recommend the use of low-dose aspirin (75–160 mg/d) in women with high cardiovascular risk (≥20% 10-year risk), for men with a ≥10% 10-year risk of CHD, and for all aspirin-tolerant patients with established cardiovascular disease who lack contraindications.

Homocysteine A large body of literature suggests a relationship between hyperhomocysteinemia and coronary events. Several mutations in the enzymes involved in homocysteine accumulation correlate with thrombosis and, in some studies, coronary risk. Prospective studies have not shown a robust utility of hyperhomocysteinemia in CHD risk stratification. Clinical trials have not shown that intervention to lower homocysteine levels reduces CHD events. Fortification of the U.S. diet with folic acid to reduce neural tube defects has lowered homocysteine levels in the population at large. Measurement of homocysteine levels should be reserved for individuals with atherosclerosis at a young age or out of proportion to established risk factors. Physicians who advise consumption of supplements containing folic acid should consider that this treatment might mask pernicious anemia.

Inflammation An accumulation of clinical evidence shows that markers of inflammation correlate with coronary risk. For example, plasma levels of CRP, as measured by a high-sensitivity assay, prospectively predict risk of myocardial infarction. CRP levels also correlate with outcome of patients with acute coronary syndromes. In contrast to several other novel risk factors, CRP adds predictive information to that derived from established risk factors, such as those included in the Framingham score (Fig. 235-4). Elevated levels of the acute-phase reactant CRP may reflect merely ongoing inflammation rather than a direct etiologic role for CRP in coronary artery disease.

Elevations in acute-phase reactants such as fibrinogen or CRP could reflect overall atherosclerotic burden and/or extravascular inflammation that potentiate atherosclerosis or its complications. In all likelihood, both lesional and extravascular factors contribute to elevation of inflammatory markers in patients at risk for coronary events. Visceral adipose tissue releases pro-inflammatory cytokines that drive CRP production and may represent a major extravascular stimulus to elevation of inflammatory markers in obese and overweight individuals. Indeed, CRP levels rise with body mass index (BMI), and weight reduction lowers CRP levels. Infectious agents might also furnish inflammatory stimuli related to cardiovascular risk. However, the results of recent sufficiently powered randomized clinical trials do not support the use of antibiotics to reduce CHD risk.

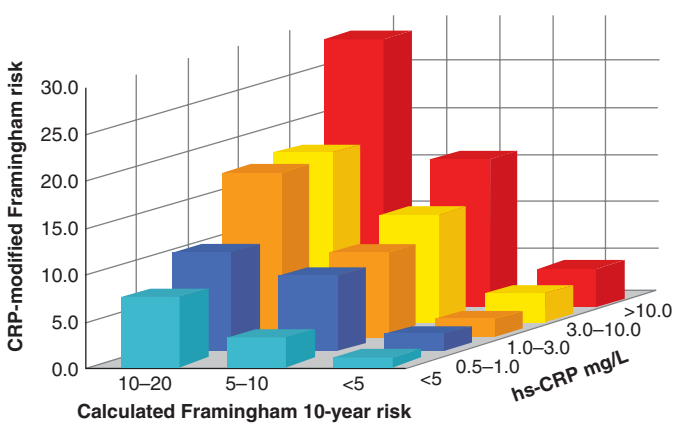

FIGURE 235-4 C-reactive protein (CRP) level adds to the predictive value of the Framingham score. hs-CRP, high-sensitivity measurement of CRP. *(Adapted from PM Ridker et al: Circulation 109:2818, 2004.)*

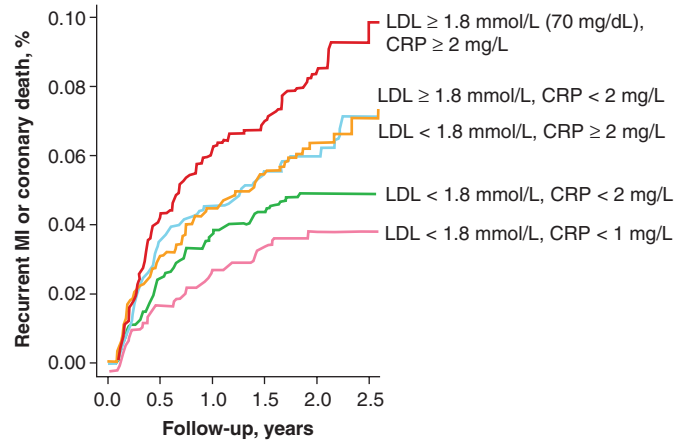

FIGURE 235-5 Evidence that both LDL-lowering and anti-inflammatory actions contribute to the benefit of statin therapy in survivors of acute coronary syndrome. See text for explanation. hs-CRP, high-sensitivity measurement of C-reactive protein (CRP); MI, myocardial infarction. *(Adapted from PM Ridker et al: N Engl J Med 352:20, 2005.)*

Intriguing evidence suggests that lipid-lowering therapy reduces coronary events in part by muting the inflammatory aspects of the pathogenesis of atherosclerosis. A prespecified analysis of the Pravastatin or Atorvastatin Evaluation and Infection Therapy (PROVE-IT) trial, conducted in patients stabilized after acute coronary syndromes, showed that participants who achieved both below median LDL and CRP had fewer recurrent cardiovascular events than those who fell below only one of these cut points (Fig. 235-5). Those with both LDL and CRP above the median fared worst of all. The anti-inflammatory effect of statins appears independent of LDL lowering, as these two variables correlated very poorly in individual subjects in multiple clinical trials.

Lifestyle Modification The prevention of atherosclerosis presents a long-term challenge to all health care professionals and for public health policy as well. Both individual practitioners and organizations providing health care should strive to help patients optimize their risk factor profile long before atherosclerotic disease becomes manifest. The current accumulation of cardiovascular risk in youth and in certain minority populations presents a particularly vexing concern from a public health perspective.

The care plan for all patients seen by internists should include measures to assess and minimize cardiovascular risk. Physicians must counsel patients regarding the health risks of tobacco use and provide guidance and resources regarding smoking cessation. Likewise, physicians should advise all patients about prudent dietary and physical activity habits for maintaining ideal body weight. Both National Institutes of Health and AHA statements recommend at least 30 min of moderate-intensity physical activity per day. Obesity, particularly the male pattern of centripetal or visceral fat accumulation, can contribute to the elements of the metabolic syndrome (Table 235-3). Physicians should encourage their patients to take personal responsibility for behavior related to modifiable risk factors for development of premature atherosclerotic disease. Conscientious counseling and patient education may forestall the need for pharmacologic measures intended to reduce coronary risk.

Issues in Risk Assessment A growing panel of markers of coronary risk presents a perplexing array to the practitioner. Markers measured in peripheral blood include size fractions of LDL particles and concentrations of homocysteine, Lp(a), fibrinogen, CRP, PAI-1, myeloperoxidase, and lipoprotein-associated phospholipase A_2, among many others. In general, such specialized tests add little to the information

available from a careful history and physical examination combined with measurement of a plasma lipoprotein profile and fasting blood glucose. The high-sensitivity CRP measurement may well prove an exception in view of its robustness in risk prediction, its ease of reproducible and standardized measurement, its relative stability in individuals over time, and, most importantly, its ability to add to the risk information disclosed by standard measurements such as the components of the Framingham risk score (Fig. 235-4). Given the utility of high-sensitivity CRP measurement in predicting a gamut of important cardiovascular outcomes, this simple blood test may prove useful in the future in guiding therapy, particularly in primary prevention. Current advisories, however, recommend the use of this test only in individuals with intermediate risk of a CHD event (10–20%, 10-year risk). Clinical trials now under way will test the hypothesis that CRP levels can guide therapy. Results such as those from PROVE-IT (Fig. 235-5) suggest that CRP may prove a valid target of therapy, a proposition that requires more investigation before general adoption in practice.

Similar concerns pertain to the use of specialized radiographic estimations of coronary artery calcification and of the rapidly emerging computed tomographic coronary angiograms (CTA). Accumulating information indicates that the amount of calcium determined by such techniques as electron beam CT correlates with coronary risk; however, the utility of using such estimates of coronary artery calcium content as a guide to therapy remains unproven, particularly in asymptomatic individuals. Multidetector CTA provides visually appealing images of the epicardial coronary arteries yet still requires rigorous validation as a cardiovascular risk marker or guide to therapy. Inappropriate use of such imaging modalities might promote excessive invasive diagnostic and therapeutic procedures. Widespread application of such modalities for screening should await proof that clinical benefit derives from their application.

Progress in human genetics holds considerable promise for risk prediction and for individualization of cardiovascular therapy. Many reports have identified single nucleotide polymorphisms in candidate genes as predictors of cardiovascular risk. To date, the validation of such genetic markers of risk and drug-responsiveness in multiple populations has often proved disappointing. The advent of technology that permits relatively rapid and inexpensive genome-wide screens, and of powerful bioinformatics tools, should spur haplotype analyses and unbiased identification of risk and therapy-response genotypes in the future.

THE CHALLENGE OF IMPLEMENTATION: CHANGING PHYSICIAN AND PATIENT BEHAVIOR

Despite declining age-adjusted rates of coronary death, cardiovascular mortality is on the rise due to the overall aging of the population. There is a powerful global trend toward increased atherosclerotic disease. Enormous challenges remain regarding translation of the current evidence base into practice. We must learn how to help individuals adopt a healthy lifestyle and how to deploy our increasingly powerful pharmacologic tools most economically and effectively. The obstacles to implementation of current evidence-based prevention and treatment of atherosclerosis include economics, education, physician awareness, and patient adherence to recommended regimens. Future goals in the field of treatment of atherosclerosis should include more widespread implementation of the current evidence-based guidelines regarding risk-factor management and, when appropriate, drug therapy.

236 The Metabolic Syndrome

Robert H. Eckel

The metabolic syndrome (syndrome X, insulin resistance syndrome) consists of a constellation of metabolic abnormalities that confer increased risk of cardiovascular disease (CVD) and diabetes mellitus (DM). The criteria for the metabolic syndrome have evolved since the original definition by the World Health Organization in 1998, reflecting growing clinical evidence and analysis by a variety of consensus conferences and professional organizations. The major features of the metabolic syndrome include central obesity, hypertriglyceridemia, low HDL cholesterol, hyperglycemia, and hypertension (Table 236-1).

EPIDEMIOLOGY

Prevalence of the metabolic syndrome varies across the globe, in part reflecting the age and ethnicity of the populations studied and the diagnostic criteria applied. In general, the prevalence of metabolic syndrome increases with age. The highest recorded prevalence worldwide is in Native Americans, with nearly 60% of women ages 45–49 and 45% of men ages 45–49 meeting National Cholesterol Education Program, Adult Treatment Panel III (NCEP:ATPIII) criteria. In the United States, metabolic syndrome is less common in African-American men but more common in Mexican-American women. Based on data from the National Health and Nutrition Examination Survey (NHANES) III, the age-adjusted prevalence of the metabolic syndrome in the United States is 34% for men and 35% for women. In France, a 30–64-year-old cohort shows a <10% prevalence for each gender, although 17.5% are affected in the 60–64 age range. Greater industrialization worldwide is associated with rising rates of obesity, which is anticipated to dramatically increase prevalence of the metabolic syndrome, especially as the population ages. Moreover, the rising prevalence and severity of obesity in children is initiating features of the metabolic syndrome in a younger population.

The frequency distribution of the five components of the syndrome for the U.S. population (NHANES III) is summarized in Fig. 236-1. Increases in waist circumference predominate in women whereas fasting triglycerides >150 mg/dL and hypertension are more likely in men.

RISK FACTORS

Overweight/Obesity Although the first description of the metabolic syndrome occurred in the early twentieth century, the worldwide overweight/obesity epidemic has been the driving force for more recent rec-

e22 Atlas of Atherosclerosis

Peter Libby

We have learned a great deal about the biology of human atherosclerosis in recent years, with new information about the risk factors for atherosclerosis expanding considerably. The application of vascular biology to human atherosclerosis has revealed many new insights into the mechanisms that promote clinical events. The series of animated video presentations presented here illustrates some of the evolving information regarding risk factors for atherosclerosis and the pathophysiology of clinical events.

We have long appreciated the importance of blood pressure as a risk factor for atherosclerosis and cardiovascular events. More recent clinical information has highlighted the importance of pulse pressure, that is, the difference between the systolic pressure and minimum diastolic arterial pressure, as a prognostic indicator of cardiovascular risk. The video clip on pulse pressure explains the pathophysiology of this readily measured clinical variable.

We possess a great deal of knowledge regarding the role of cholesterol in the prediction of atherosclerosis and its complications; however, our knowledge of the mechanism that links hypercholesterolemia to cardiovascular events has lagged the epidemiologic and observational findings. Low-density lipoprotein (LDL) provides an example of a well-understood cardiovascular risk factor. Several of the animations included in this series highlight the role of modified LDL as a trigger for inflammation and other aspects of the pathobiology of arterial plaques that lead to their aggravation and clinical events. We now possess useful tools for modulating LDL. Yet, other aspects of dyslipidemia are on the rise and provide a growing challenge to the practitioner. In particular, low levels of high-density lipoprotein (HDL) and elevated levels of triglycerides characterize the constellation of findings denoted by some as "metabolic syndrome." In the wake of increasing obesity worldwide, these features of the lipoprotein profile require renewed focus. Several of the animations in this collection discuss the concept of the metabolic syndrome and the role of components of the lipid profile other than LDL in atherogenesis.

Our traditional approach to atherosclerosis focused on arterial stenoses as a cause of ischemia and cardiovascular events. We now possess effective revascularization modalities for addressing flow-limiting stenoses, but we recognize that atherosclerotic plaques that do not cause stenoses may nonetheless precipitate clinical events, such as unstable angina or acute myocardial infarction. Thus we must add to our traditional focus on stenosis an enlarged appreciation of the pathobiology of atherosclerosis that underlies many acute coronary syndromes. The animation on the development and complication of the atherosclerotic plaque explains some of these emerging concepts in plaque activation as they apply to the precipitation of thrombotic complications of atherosclerosis.

VIDEO e22-1 (Play video) **Pulse pressure.** Considerable evidence suggests that pulse pressure serves as an important risk factor for future cardiovascular events. This video clip explains the derivation of pulse pressure and some of the pathophysiology that determines this parameter. *(With permission from the Academy for Health Care Education.)*

VIDEO e22-2 (Play video) **Plaque instability.** We currently understand that most coronary thromboses result from a physical disruption of the atherosclerotic plaque. This video animation explains some of the current concepts of the pathophysiology of atherosclerotic plaque disruption and how it triggers arterial thrombosis.

VIDEO e22-3 (Play video) **Lipoprotein menagerie.** The lipid profile confers important information regarding cardiovascular risk and the effects of therapies; understanding lipoprotein metabolism provides insight into the pathophysiology of arterial disease. This video animation presents the rudiments of the metabolism of lipoproteins important in clinical medicine.

VIDEO e22-4 (Play video) **Formation and complication of atherosclerotic plaques.** We now understand the generation of atherosclerotic plaques as a dynamic process involving an interchange between cells of the artery wall, inflammatory cells recruited from blood, and risk factors such as lipoproteins. This video animation reviews current thinking about how risk factors alter the biology of the artery wall and can incite initiation and progression of atherosclerosis. This presentation also discusses the importance of inflammation in these processes, and portrays the role of inflammation in plaque disruption and thrombosis. Finally, this animation depicts the concept of stabilization of atherosclerotic plaques by intervention such as lipid lowering.

VIDEO e22-5 (Play video) **Atherogenesis.** This video clip highlights some of the current thinking about mechanisms of atherogenesis.

VIDEO e22-6 (Play video) **Metabolic syndrome.** A number of important cardiovascular risk factors tend to cluster in a pattern described by some as the "metabolic syndrome." While controversy persists regarding whether cardiovascular risk due to these factors is additive or synergistic, their clinical importance is growing. This animation discusses some of the metabolic derangements that underlie the "metabolic syndrome."

TABLE 236-1 NCEP:ATPIII 2001 AND IDF CRITERIA FOR THE METABOLIC SYNDROME

NCEP:ATPIII 2001	IDF Criteria for Central Adiposity[a]		
Three or more of the following:	**Waist Circumference**		
	Men	**Women**	**Ethnicity**
Central obesity: Waist circumference >102 cm (M), >88 cm (F)	≥94 cm	≥80 cm	Europid, Sub-Saharan African, Eastern & Middle Eastern
Hypertriglyceridemia: Triglycerides ≥150 mg/dL or specific medication	≥90 cm	≥80 cm	South Asian, Chinese, and ethnic South & Central American
Low HDL cholesterol: <40 mg/dL and <50 mg/dL, respectively, or specific medication	≥85 cm	≥90 cm	Japanese
Hypertension: Blood pressure ≥130 mm systolic or ≥85 mm diastolic or specific medication	**Two or more of the following:**		
Fasting plasma glucose ≥100 mg/dL or specific medication or previously diagnosed type 2 diabetes	Fasting triglycerides >150 mg/dL or specific medication		
	HDL cholesterol <40 mg/dL and <50 mg/dL for men and women, respectively, or specific medication		
	Blood pressure >130 systolic or >85 mm diastolic or previous diagnosis or specific medication		
	Fasting plasma glucose ≥100 mg/dL or previously diagnosed type 2 diabetes		

[a]In this analysis, the following thresholds for waist circumference were used: White men, ≥94 cm; African-American men, ≥94 cm; Mexican-American men, ≥90 cm; white women, ≥80 cm; African-American women, ≥80 cm; Mexican-American women, ≥80 cm. For participants whose designation was "other race—including multiracial," thresholds that were once based on Europid cut points (≥94 cm for men and ≥80 cm for women) and once based on South Asian cut points (≥90 cm for men and ≥80 cm for women) were used. For participants who were considered "other Hispanic," the IDF thresholds for ethnic South and Central Americans were used.

Abbreviations: NCEP:ATPIII, National Cholesterol Education Program, Adult Treatment Panel III; IDF, International Diabetes Foundation HDL, high-density lipoprotein.

ognition of the syndrome. Central adiposity is a key feature of the syndrome, reflecting the fact that the syndrome's prevalence is driven by the strong relationship between waist circumference and increasing adiposity. However, despite the importance of obesity, patients who are normal weight may also be insulin-resistant and have the syndrome.

Sedentary Lifestyle Physical inactivity is a predictor of CVD events and related mortality. Many components of the metabolic syndrome are associated with a sedentary lifestyle, including increased adipose tissue (predominantly central); reduced HDL cholesterol; and a trend toward increased triglycerides, blood pressure, and glucose in the genetically susceptible. Compared with individuals who watched television or videos or used their computer <1 h daily, those who carried out these behaviors for >4 h daily have a twofold increased risk of the metabolic syndrome.

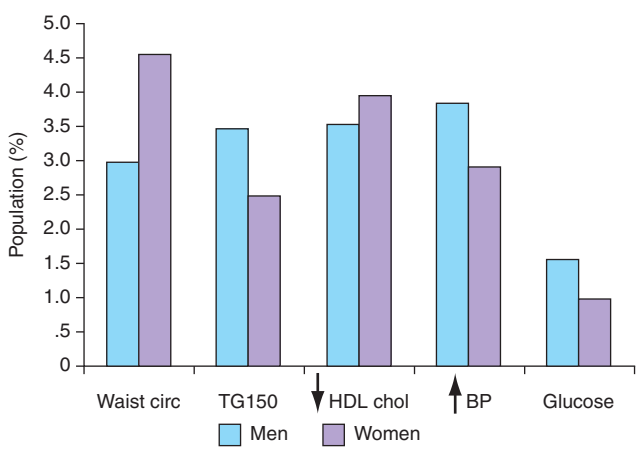

FIGURE 236-1 Prevalence of the metabolic syndrome components, from NHANES III. NHANES, National Health and Nutrition Examination Survey; TG, triglyceride; HDL, high-density lipoprotein; BP, blood pressure. *(From ES Ford et al: JAMA 287:356, 2002; with permission.)*

Aging The metabolic syndrome affects 44% of the U.S. population older than age 50. A greater percentage of women older than age 50 have the syndrome than men. The age dependency of the syndrome's prevalence is seen in most populations around the world.

Diabetes Mellitus DM is included in both the NCEP and International Diabetes Foundation (IDF) definitions of the metabolic syndrome. It is estimated that the large majority (~75%) of patients with type 2 diabetes or impaired glucose tolerance (IGT) have the metabolic syndrome. The presence of the metabolic syndrome in these populations relates to a higher prevalence of CVD compared to patients with type 2 diabetes or IGT without the syndrome.

Coronary Heart Disease The approximate prevalence of the metabolic syndrome in patients with coronary heart disease (CHD) is 50%, with a prevalence of 37% in patients with premature coronary artery disease (≤ age 45), particularly in women. With appropriate cardiac rehabilitation and changes in lifestyle (e.g., nutrition, physical activity, weight reduction, and, in some cases, pharmacologic agents), the prevalence of the syndrome can be reduced.

Lipodystrophy Lipodystrophic disorders in general are associated with the metabolic syndrome. Both genetic (e.g., Berardinelli-Seip congenital lipodystrophy, Dunnigan familial partial lipodystrophy) and acquired (e.g., HIV-related lipodystrophy in patients treated with highly active antiretroviral therapy) forms of lipodystrophy may give rise to severe insulin resistance and many of the metabolic syndrome's components.

ETIOLOGY

Insulin Resistance The most accepted and unifying hypothesis to describe the pathophysiology of the metabolic syndrome is insulin resistance, caused by an incompletely understood defect in insulin action (Chap. 338). The onset of insulin resistance is heralded by postprandial hyperinsulinemia, followed by fasting hyperinsulinemia and, ultimately, hyperglycemia.

An early major contributor to the development of insulin resistance is an overabundance of circulating fatty acids (Fig. 236-2). Plasma albumin-bound free fatty acids (FFAs) are derived predominantly from adipose tissue triglyceride stores released by hormone-sensitive lipase. Fatty acids are also derived through the lipolysis of triglyceride-rich lipoproteins in tissues by lipoprotein lipase (LPL). Insulin mediates both antilipolysis and the stimulation of LPL in adipose tissue. Of note, the inhibition of lipolysis in adipose tissue is the most sensitive pathway of insulin action. Thus, when insulin resistance develops, increased lipolysis produces more fatty acids, which further decrease the antilipolytic effect of insulin. Excessive fatty acids enhance substrate availability and create insulin resistance by modifying downstream signaling. Fatty acids impair insulin-mediated glucose uptake and accumulate as triglycerides in both skeletal and cardiac muscle, whereas increased glucose production and triglyceride accumulation are seen in liver.

The oxidative stress hypothesis provides unifying theory for aging and the predisposition to the metabolic syndrome. In studies carried out in insulin-resistant subjects with obesity or type 2 diabetes, in the offspring of patients with type 2 diabetes, and in the elderly, a defect has been identified in mitochondrial oxidative phosphorylation, leading to the accumulation of triglycerides and related lipid molecules in muscle. The accumulation of lipids in muscle is associated with insulin resistance.

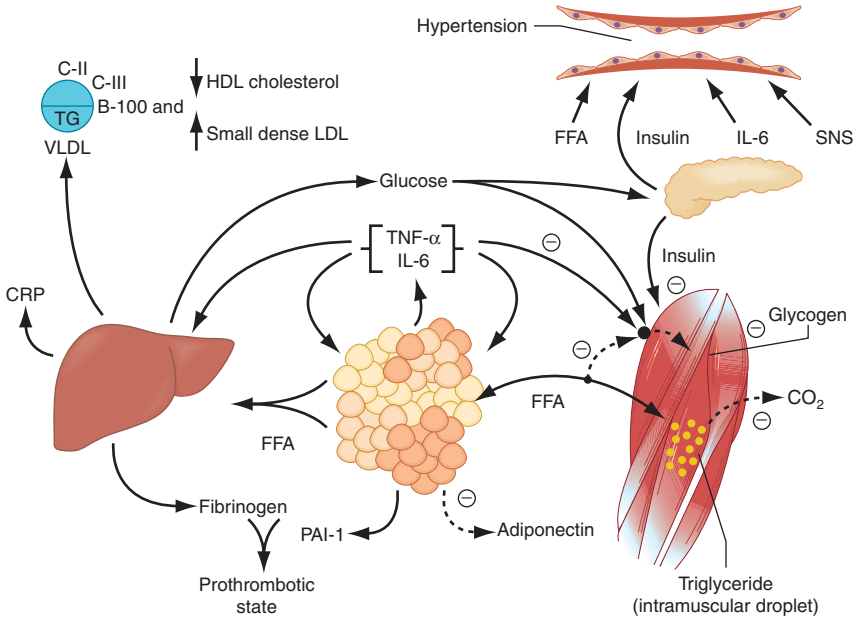

FIGURE 236-2 Pathophysiology of the metabolic syndrome. Free fatty acids (FFAs) are released in abundance from an expanded adipose tissue mass. In the liver, FFAs result in an increased production of glucose, triglycerides and secretion of very low density lipoproteins (VLDLs). Associated lipid/lipoprotein abnormalities include reductions in high-density lipoprotein (HDL) cholesterol and an increased density of low-density lipoproteins (LDLs). FFAs also reduce insulin sensitivity in muscle by inhibiting insulin-mediated glucose uptake. Associated defects include a reduction in glucose partitioning to glycogen and increased lipid accumulation in triglyceride (TG). Increases in circulating glucose, and to some extent FFA, increase pancreatic insulin secretion, resulting in hyperinsulinemia. Hyperinsulinemia may result in enhanced sodium reabsorption and increased sympathetic nervous system (SNS) activity and contribute to the hypertension, as might increased levels of circulating FFAs. The proinflammatory state is superimposed and contributory to the insulin resistance produced by excessive FFAs. The enhanced secretion of interleukin 6 (IL-6) and tumor necrosis factor α (TNF-α) produced by adipocytes and monocyte-derived macrophages results in more insulin resistance and lipolysis of adipose tissue triglyceride stores to circulating FFAs. IL-6 and other cytokines also enhance hepatic glucose production, VLDL production by the liver, and insulin resistance in muscle. Cytokines and FFAs also increase the hepatic production of fibrinogen and adipocyte production of plasminogen activator inhibitor 1 (PAI-1), resulting in a prothrombotic state. Higher levels of circulating cytokines also stimulate the hepatic production of C-reactive protein (CRP). Reduced production of the anti-inflammatory and insulin sensitizing cytokine adiponectin are also associated with the metabolic syndrome. *(Reprinted from Eckel et al., with permission from Elsevier.)*

Increased Waist Circumference Waist circumference is an important component of the most recent and frequently applied diagnostic criteria for the metabolic syndrome. However, measuring waist circumference does not reliably distinguish between a large waist due to increases in subcutaneous adipose tissue vs. visceral fat; this distinction requires CT or MRI. With increases in visceral adipose tissue, adipose tissue-derived FFAs are directed to the liver. On the other hand, increases in abdominal subcutaneous fat release lipolysis products into the systemic circulation and avoid more direct effects on hepatic metabolism. Relative increases in visceral versus subcutaneous adipose tissue with increasing waist circumference in Asians and Asian Indians may explain the greater prevalence of the syndrome in these populations compared to African-American men in whom subcutaneous fat predominates. It is also possible that visceral fat is a marker for, but not the source of, excess postprandial FFAs in obesity.

Dyslipidemia (See also Chap. 350) In general, FFA flux to the liver is associated with increased production of apoB–containing, triglyceride-rich very low density lipoproteins (VLDLs). The effect of insulin on this process is complex, but *hypertriglyceridemia* is an excellent marker of the insulin-resistant condition.

The other major lipoprotein disturbance in the metabolic syndrome is a *reduction in HDL cholesterol*. This reduction is a consequence of changes in HDL composition and metabolism. In the presence of hypertriglyceridemia, a decrease in the cholesterol content of HDL is a consequence of reduced cholesteryl ester content of the lipoprotein core in combination with cholesteryl ester transfer protein–mediated alterations in triglyceride making the particle small and dense. This change in lipoprotein composition also results in an increased clearance of HDL from the circulation. The relationships of these changes in HDL to insulin resistance are likely indirect, occurring in concert with the changes in triglyceride-rich lipoprotein metabolism.

In addition to HDL, LDLs are also modified in composition. With fasting serum triglycerides >2.0 mM (~180 mg/dL), there is almost always a predominance of small dense LDLs. Small dense LDLs are thought to be more atherogenic. They may be toxic to the endothelium, and they are able to transit through the endothelial basement membrane and adhere to glycosaminoglycans. They also have increased susceptibility to oxidation and are selectively bound to scavenger receptors on monocyte-derived macrophages. Subjects with increased small dense LDL particles and hypertriglyceridemia also have increased cholesterol content of both VLDL1 and VLDL2 subfractions. This relatively cholesterol-rich VLDL particle may also contribute to the atherogenic risk in patients with metabolic syndrome.

Glucose Intolerance (See also Chap. 338) The defects in insulin action lead to impaired suppression of glucose production by the liver and kidney and reduced glucose uptake and metabolism in insulin-sensitive tissues, i.e., muscle and adipose tissue. The relationship between impaired fasting glucose (IFG) or impaired glucose tolerance (IGT) and insulin resistance is well supported by human, nonhuman primate, and rodent studies. To compensate for defects in insulin action, insulin secretion and/or clearance must be modified to sustain euglycemia. Ultimately, this compensatory mechanism fails, usually because of defects in insulin secretion, resulting in progress from IFG and/or IGT to DM.

Hypertension The relationship between insulin resistance and hypertension is well established. Paradoxically, under normal physiologic conditions, insulin is a vasodilator with secondary effects on sodium reabsorption in the kidney. However, in the setting of insulin resistance, the vasodilatory effect of insulin is lost, but the renal effect on sodium reabsorption is preserved. Sodium reabsorption is increased in Caucasians with the metabolic syndrome but not in Africans or Asians. Insulin also increases the activity of the sympathetic nervous system, an effect that may also be preserved in the setting of the insulin resistance. Finally, insulin resistance is characterized by pathway-specific impairment in phosphatidylinositol 3-kinase signaling. In the endothelium, this may cause an imbalance between the production of nitric oxide and secretion of endothelin-1, leading to decreased blood flow. Although these mechanisms are provocative, when insulin action is assessed by levels of fasting insulin or by the Homeostasis Model Assessment (HOMA), insulin resistance contributes only modestly to the increased prevalence of hypertension in the metabolic syndrome.

Proinflammatory Cytokines The increases in proinflammatory cytokines, including interleukin (IL) 1, IL-6, IL-18, resistin, tumor necrosis

factor (TNF) α, and C-reactive protein (CRP), reflect overproduction by the expanded adipose tissue mass (Fig. 236-2). Adipose tissue-derived macrophages may be the primary source of pro-inflammatory cytokines locally and in the systemic circulation. It remains unclear, however, how much of the insulin resistance is caused by the paracrine vs. endocrine effects of these cytokines.

Adiponectin Adiponectin is an anti-inflammatory cytokine produced exclusively by adipocytes. Adiponectin enhances insulin sensitivity and inhibits many steps in the inflammatory process. In the liver, adiponectin inhibits the expression of gluconeogenic enzymes and the rate of glucose production. In muscle, adiponectin increases glucose transport and enhances fatty acid oxidation, partially due to activation of AMP kinase. Adiponectin is reduced in the metabolic syndrome. The relative contribution of adiponectin deficiency versus overabundance of the proinflammatory cytokines remains unclear.

CLINICAL FEATURES

Symptoms and Signs The metabolic syndrome is typically unassociated with symptoms. On physical examination, waist circumference may be expanded and blood pressure elevated. The presence of one or either of these signs should alert the clinician to search for other biochemical abnormalities that may be associated with the metabolic syndrome. Less frequently, lipoatrophy or acanthosis nigricans is found on exam. Because these physical findings are typically associated with severe insulin resistance, other components of the metabolic syndrome should be expected.

Associated Diseases • ***CARDIOVASCULAR DISEASE*** The relative risk for new-onset CVD in patients with the metabolic syndrome, in the absence of diabetes, averages between 1.5- and threefold. In an 8-year follow-up of middle-aged men and women in the Framingham Offspring Study (FOS), the population attributable risk for patients with the metabolic syndrome to develop CVD was 34% in men and 16% in women. In the same study, both the metabolic syndrome and diabetes predicted ischemic stroke with greater risk for patients with the metabolic syndrome than for diabetes alone (19% vs 7%), particularly in women (27% vs 5%). Patients with metabolic syndrome are also at increased risk for peripheral vascular disease.

TYPE 2 DIABETES Overall, the risk for type 2 diabetes in patients with the metabolic syndrome is increased three- to fivefold. In the FOS's 8-year follow-up of middle-aged men and women, the population-attributable risk for developing type 2 diabetes was 62% in men and 47% in women.

Other Associated Conditions In addition to the features specifically associated with metabolic syndrome, insulin resistance is accompanied by other metabolic alterations. These included increases in apoB and C III, uric acid, prothrombotic factors (fibrinogen, plasminogen activator inhibitor 1), serum viscosity, asymmetric dimethylarginine, homocysteine, white blood cell count, pro-inflammatory cytokines, CRP, microalbuminuria, nonalcoholic fatty liver disease (NAFLD) and/or nonalcoholic steatohepatitis (NASH), polycystic ovarian disease (PCOS), and obstructive sleep apnea (OSA).

NONALCOHOLIC FATTY LIVER DISEASE (See also Chap. 303) Fatty liver is relatively common. However, in NASH, both triglyceride accumulation and inflammation coexist. NASH is now present in 2–3% of the population in the United States and other Western countries. As the prevalence of overweight/obesity and the metabolic syndrome increases, NASH may become one of the more frequent causes of end-stage liver disease and hepatocellular carcinoma.

HYPERURICEMIA (See also Chap. 353) Hyperuricemia reflects defects in insulin action on the renal tubular reabsorption of uric acid, whereas the increase in asymmetric dimethylarginine, an endogenous inhibitor of nitric oxide synthase, relates to endothelial dysfunction. Microalbuminuria may also be caused by altered endothelial pathophysiology in the insulin-resistant state.

POLYCYSTIC OVARY SYNDROME (See also Chap. 341) PCOS is highly associated with the metabolic syndrome, with a prevalence between 40 and 50%. Women with PCOS are 2–4 times more likely to have the metabolic syndrome compared to women without PCOS.

OBSTRUCTIVE SLEEP APNEA (See also Chap. 28) OSA is commonly associated with obesity, hypertension, increased circulating cytokines, IGT, and insulin resistance. With these associations, it is not surprising that the metabolic syndrome is frequently present. Moreover, when biomarkers of insulin resistance are compared between patients with OSA and weight-matched controls, insulin resistance is more severe in patients with OSA. Continuous positive airway pressure (CPAP) treatment in OSA patients improves insulin sensitivity.

DIAGNOSIS

The diagnosis of the metabolic syndrome relies on satisfying the criteria listed in Table 236-1 using tools at the bedside and in the laboratory. Because the NCEP:ATPIII and IDF criteria are similar, either can be used. The medical history should include evaluation of symptoms for OSA in all patients and PCOS in premenopausal women. Family history will help determine risk for CVD and DM. Blood pressure and waist circumference measurements provide information necessary for the diagnosis.

Laboratory Tests Fasting lipids and glucose are needed to determine if the metabolic syndrome is present. The measurement of additional biomarkers associated with insulin resistance must be individualized. Such tests might include apo B, high-sensitivity CRP, fibrinogen, uric acid, urinary microalbumin, and liver function tests. A sleep study should be performed if symptoms of OSA are present. If PCOS is suspected based on clinical features and anovulation, testosterone, luteinizing hormone, and follicle-stimulating hormone should be measured.

Rx THE METABOLIC SYNDROME

LIFESTYLE (See also Chap. 75) Obesity is the driving force behind the metabolic syndrome. Thus, weight reduction is the primary approach to the disorder. With weight reduction, the improvement in insulin sensitivity is often accompanied by favorable modifications in many components of the metabolic syndrome. In general, recommendations for weight loss include a combination of caloric restriction, increased physical activity, and behavior modification. For weight reduction, caloric restriction is the most important component, whereas increases in physical activity are important for maintenance of weight loss. Some, but not all, evidence suggests that the addition of exercise to caloric restriction may promote relatively greater weight loss from the visceral depot. The tendency for weight regain after successful weight reduction underscores the need for long-lasting behavioral changes.

Diet Before prescribing a weight-loss diet, it is important to emphasize that it takes a long time for a patient to achieve an expanded fat mass; thus, the correction need not occur quickly. On the basis of ~3500 kcal = one lb of fat, ~500 kcal restriction daily equates to a weight reduction of 1 lb per week. Diets restricted in carbohydrate typically provide a rapid initial weight loss. However, after one year, the amount of weight reduction is usually unchanged. Thus, adherence to the diet is more important than which diet is chosen. Moreover, there is concern about diets enriched in saturated fat, particularly for patients at risk for CVD. Therefore, a high quality of the diet—i.e., enriched in fruits, vegetables, whole grains, lean poultry, and fish—should be encouraged to provide the maximum overall health benefit.

Physical Activity Before a physical activity recommendation is provided to patients with the metabolic syndrome, it is important to ensure that this increased activity does not incur risk. Some high-risk patients should undergo formal cardiovascular evaluation before initiating an exercise pro-

gram. For the inactive participant, gradual increases in physical activity should be encouraged to enhance adherence and to avoid injury. Although increases in physical activity can lead to modest weight reduction, 60–90 min of daily activity is required to achieve this goal. Even if an overweight or obese adult is unable to achieve this level of activity, they still derive a significant health benefit from at least 30 min of moderate intensity daily activity. The caloric value of 30 min of a variety of activities can be found at *http://www.americanheart.org/presenter.jhtml?identifier=3040364*. Of note, a variety of routine activities—such as gardening, walking, and housecleaning—require moderate caloric expenditure. Thus, physical activity need not be defined solely in terms of formal exercise such as jogging, swimming, or tennis.

Obesity (See also Chap. 75) In some patients with the metabolic syndrome, treatment options need to extend beyond lifestyle intervention. Weight-loss drugs come in two major classes: appetite suppressants and absorption inhibitors. Appetite suppressants approved by the Food and Drug Administration include phentermine (for short-term use only, 3 months) and sibutramine. Orlistat inhibits fat absorption by ~30% and is moderately effective compared to placebo (~5% weight loss). Orlistat has been shown to reduce the incidence of type 2 diabetes, an effect that was especially evident in patients with baseline IGT.

Bariatric surgery is an option for patients with the metabolic syndrome who have a body mass index (BMI) of >40 kg/m^2 or >35 kg/m^2 with comorbidities. Gastric bypass results in a dramatic weight reduction and improvement in the features of metabolic syndrome. At present, however, a survival benefit has yet to be realized.

LDL CHOLESTEROL (See also Chap. 350) The rationale for the NCEP:ATP III panel to develop criteria for the metabolic syndrome was to go beyond LDL cholesterol in identifying and reducing risk for CVD. The working assumption by the panel was that LDL cholesterol goals had already been achieved, and increasing evidence supports a linear reduction in CVD events with progressive lowering of LDL cholesterol. For patients with the metabolic syndrome and diabetes, LDL cholesterol should be reduced to <100 mg/dL and perhaps further in patients with a history of CVD events. For patients with the metabolic syndrome without diabetes, the Framingham risk score may predict a 10-year CVD risk that exceeds 20%. In these subjects, LDL cholesterol should also be reduced to <100 mg/dL. With a 10-year risk of < 20%, however, the targeted LDL cholesterol goal is < 130 mg/dL.

Diets restricted in saturated fats (<7% of calories), trans fat (as few as possible), and cholesterol (<200 mg daily) should be applied aggressively. If LDL cholesterol remains above goal, then pharmacologic intervention is needed. Statins (HMG-CoA reductase inhibitors), which produce a 20–60% lowering of LDL cholesterol, are generally the first choice for medication intervention. Of note, for each doubling of the statin dose, there is only ~6% additional lowering of LDL cholesterol. Side effects are rare and include an increase in hepatic transaminases and/or myopathy. The cholesterol absorption inhibitor ezetimibe is well tolerated and should be the second choice. Ezetimibe typically reduces LDL cholesterol by 15–20%. The bile acid sequestrants cholestyramine and colestipol are more effective than ezetimibe but must be used with caution in patients with the metabolic syndrome because they often increase triglycerides. In general, bile sequestrants should not be administered when fasting triglycerides are >200 mg/dL. Side effects include gastrointestinal symptoms (palatability, bloating, belching, constipation, anal irritation). Nicotinic acid has modest LDL cholesterol–lowering capabilities (<20%). Fibrates are best employed to lower LDL cholesterol when both LDL cholesterol and nontriglycerides are elevated. Fenofibrate may be more effective than gemfibrozil in this group.

TRIGLYCERIDES The NCEP:ATPIII has focused on non-HDL cholesterol rather than triglycerides. However, a fasting triglyceride value of <150 mg/dL is recommended. In general, the response of fasting triglycerides relates to the amount of weight reduction achieved. A weight reduction of >10% is necessary to lower fasting triglycerides.

A fibrate (gemfibrozil or fenofibrate) is the drug of choice to lower fasting triglycerides and typically achieve a 35–50% reduction. Concomitant administration with drugs metabolized by the 3A4 cytochrome P450 system (including some statins) greatly increases the risk of myopathy. In these cases, fenofibrate may be preferable to gemfibrozil. In the Veterans Affairs HDL Intervention Trial (VA-HIT), gemfibrozil was administered to men with known CHD and levels of HDL cholesterol <40 mg/dL. A coronary disease event and mortality benefit was experienced predominantly in men with hyperinsulinemia and/or diabetes, many of whom retrospectively had the metabolic syndrome. Of note, the amount of triglyceride lowering in the VA-HIT did not predict benefit. Although levels of LDL cholesterol did not change, a decrease in LDL particle number related to benefit. Although several additional clinical trials have been performed, these have not shown clear evidence that fibrates reduce CVD risk as a consequence of triglyceride lowering.

Other drugs that lower triglycerides include statins, nicotinic acid, and high doses of omega-3 fatty acids. When choosing a statin for this purpose, the dose must be high for the "less potent" statins (lovastatin, pravastatin, fluvastatin) or intermediate for the "more potent" statins (simvastatin, atorvastatin, rosuvastatin). The effect of nicotinic acid on fasting triglycerides is dose-related and less than fibrates (~20–40%). In patients with the metabolic syndrome and diabetes, nicotinic acid may increase fasting glucose. Omega-3 fatty acid preparations that include high doses of docosahexaenoic acid and eicosapentaenoic acid (~3.0–4.5 g daily) lower fasting triglycerides by ~40%. No interactions with fibrates or statins occur, and the main side effect is eructation with a fishy taste. This can be partially blocked by ingesting the nutraceutical after freezing. Clinical trials of nicotinic acid or high-dose omega-3 fatty acids in patients with the metabolic syndrome have not been reported.

HDL CHOLESTEROL Beyond weight reduction, there are very few lipid-modifying compounds that increase HDL cholesterol. Statins, fibrates, and bile acid sequestrants have modest effects (5–10%), and there is no effect on HDL cholesterol with ezetimibe or omega-3 fatty acids. Nicotinic acid is the only currently available drug with predictable HDL cholesterol-raising properties. The response is dose-related and can increase HDL cholesterol ~30% above baseline. There is little evidence at present that raising HDL has a benefit on CVD events independent of lowering LDL cholesterol, particularly in patients with the metabolic syndrome.

BLOOD PRESSURE (See also Chap. 241) The direct relationship between blood pressure and all-cause mortality has been well established, including patients with hypertension (>140/90) versus prehypertension (>120/80 but <140/90) versus individuals with normal blood pressure (<120/80). In patients with the metabolic syndrome without diabetes, the best choice for the first antihypertensive should usually be an ACE inhibitor or an angiotensin II receptor blocker, as these two classes of drugs appear to reduce the incidence of new-onset type 2 diabetes. In all patients with hypertension, a sodium-restricted diet enriched in fruits and vegetables and low-fat dairy products should be advocated. Home monitoring of blood pressure may assist in maintaining good blood pressure control.

IMPAIRED FASTING GLUCOSE (See also Chap. 338) In patients with the metabolic syndrome and type 2 diabetes, aggressive glycemic control may favorably modify fasting triglycerides and/or HDL cholesterol. In those patients with IFG without a diagnosis of diabetes, a lifestyle intervention that includes weight reduction, dietary fat restriction, and increased physical activity has been shown to reduce the incidence of type 2 diabetes. Metformin has also been shown to reduce the incidence of diabetes, although the effect was less than that seen with lifestyle intervention.

INSULIN RESISTANCE (See also Chap. 338) Several drug classes [biguanides, thiazolidinediones (TZDs)] increase insulin sensitivity. If insulin resistance is the primary pathophysiologic mechanism for the metabolic syndrome, then representative drugs in these classes should reduce its prevalence. Both metformin and TZDs enhance insulin action in the liver and suppress endogenous glucose production. TZDs, but not metformin, also improve insulin-mediated glucose uptake in muscle and adipose tissue. Benefits of both drugs have also been seen in patients with NAFLD and PCOS, and they have been shown to reduce markers of inflammation and small dense LDL. In general, the beneficial effects of TZDs appear superior to those of metformin.

237 Ischemic Heart Disease

Elliott M. Antman, Andrew P. Selwyn, Eugene Braunwald, Joseph Loscalzo

Ischemic heart disease (IHD) is a condition in which there is an inadequate supply of blood and oxygen to a portion of the myocardium; it typically occurs when there is an imbalance between myocardial oxygen supply and demand. The most common cause of myocardial ischemia is atherosclerotic disease of an epicardial coronary artery (or arteries) sufficient to cause a regional reduction in myocardial blood flow and inadequate perfusion of the myocardium supplied by the involved coronary artery.

EPIDEMIOLOGY

IHD causes more deaths and disability and incurs greater economic costs than any other illness in the developed world. IHD is the most common, serious, chronic, life-threatening illness in the United States, where 13 million persons have IHD, >6 million have angina pectoris, and >7 million have sustained a myocardial infarction (MI). A high-fat and energy-rich diet, smoking, and a sedentary lifestyle are associated with the emergence of IHD (Chap. 235). In the United States and western Europe, it is growing among low-income groups rather than high-income groups (who are adopting more healthful lifestyles), while primary prevention has delayed the disease to later in life in all socioeconomic groups.

Obesity, insulin resistance, and type 2 diabetes mellitus are increasing and are powerful risk factors for IHD. With urbanization in the developing world, the prevalence of risk factors for IHD is increasing rapidly in these regions such that a majority of the global burden of IHD is now occurring in low-income and middle-income countries. Population subgroups that appear to be particularly affected are men in South Asian countries, especially India. Given the projection of large increases in IHD throughout the world, IHD is likely to become the most common cause of death worldwide by 2020.

PATHOPHYSIOLOGY

Central to an understanding of the pathophysiology of myocardial ischemia is the concept of myocardial supply and demand. Under normal conditions, for any given level of a demand for oxygen, the myocardium will be supplied with oxygen-rich blood to prevent underperfusion of myocytes and the subsequent development of ischemia and infarction. The major determinants of myocardial oxygen demand (MVO_2) are heart rate, myocardial contractility, and myocardial wall tension (stress). An adequate supply of oxygen to the myocardium requires a satisfactory level of oxygen-carrying capacity of the blood (determined by the inspired level of oxygen, pulmonary function, and hemoglobin concentration and function) and an adequate level of coronary blood flow. Blood flows through the coronary arteries in a phasic fashion, with the majority occurring during diastole. About 75% of the total coronary resistance to flow occurs across three sets of arteries: (1) large epicardial arteries (Resistance 1 = R_1), (2) prearteriolar vessels (R_2), and (3) arteriolar and intramyocardial capillary vessels (R_3). In the absence of significant flow-limiting atherosclerotic obstructions, R_1 is trivial; the major determinant of coronary resistance is found in R_2 and R_3.

The normal coronary circulation is dominated and controlled by the heart's requirements for oxygen. This need is met by the ability of the coronary vascular bed to vary its resistance (and, therefore, blood flow) considerably while the myocardium extracts a high and relatively fixed percentage of oxygen. Normally, intramyocardial resistance vessels demonstrate an immense capacity for dilation (R_2 and R_3 decrease). For example, the changing oxygen needs of the heart with exercise and emotional stress affect coronary vascular resistance and in this manner regulate the supply of oxygen and substrate to the myocardium (*metabolic regulation*). The coronary resistance vessels also adapt to physiologic alterations in blood pressure in order to maintain coronary blood flow at levels appropriate to myocardial needs (*autoregulation*).

By reducing the lumen of the coronary arteries, atherosclerosis limits appropriate increases in perfusion when the demand for flow is augmented, as occurs during exertion or excitement. When the luminal reduction is severe, myocardial perfusion in the basal state is reduced. Coronary blood flow can also be limited by spasm (see "Prinzmetal's Variant Angina" in Chap. 238), arterial thrombi, and, rarely, coronary emboli as well as by ostial narrowing due to aortitis. Congenital abnormalities, such as origin of the left anterior descending coronary artery from the pulmonary artery, may cause myocardial ischemia and infarction in infancy, but this cause is very rare in adults.

Myocardial ischemia can also occur if myocardial oxygen demands are markedly increased and when coronary blood flow may be limited, as occurs in severe left ventricular (LV) hypertrophy due to aortic stenosis. The latter can present with angina that is indistinguishable from that caused by coronary atherosclerosis largely owing to subendocardial ischemia (Chap. 230). A reduction in the oxygen-carrying capacity of the blood, as in extremely severe anemia or in the presence of carboxyhemoglobin, rarely causes myocardial ischemia by itself but may lower the threshold for ischemia in patients with moderate coronary obstruction.

Not infrequently, two or more causes of ischemia coexist, such as an increase in oxygen demand due to LV hypertrophy secondary to hypertension and a reduction in oxygen supply secondary to coronary atherosclerosis and anemia. Abnormal constriction or failure of normal dilation of the coronary resistance vessels can also cause ischemia. When it causes angina, this condition is referred to as *microvascular angina*.

CORONARY ATHEROSCLEROSIS

Epicardial coronary arteries are the major site of atherosclerotic disease. The major risk factors for atherosclerosis [high plasma low-density lipoprotein (LDL), low plasma high-density lipoprotein (HDL), cigarette smoking, hypertension, and diabetes mellitus] (Chap. 235) disturb the normal functions of the vascular endothelium. These functions include local control of vascular tone, maintenance of an antithrombotic surface, and impairment of inflammatory cell adhesion and diapedesis. The loss of these defenses leads to inappropriate constriction, luminal thrombus formation, and abnormal interactions with blood leukocytes, especially monocytes, and platelets. Monocyte interaction ultimately results in the subintimal collections of fat, smooth-muscle cells, fibroblasts, and intercellular matrix (i.e., atherosclerotic plaques), which develop at irregular rates in different segments of the epicardial coronary tree and lead eventually to segmental reductions in cross-sectional area.

There is also a predilection for atherosclerotic plaques to develop at sites of increased turbulence in coronary flow, such as at branch points in the epicardial arteries. When a stenosis reduces the diameter of an epicardial artery by 50%, there is a limitation on the ability to increase flow to meet increased myocardial demand. When the diameter is reduced by ~80%, blood flow at rest may be reduced, and further minor decreases in the stenotic orifice area can reduce coronary flow dramatically and cause myocardial ischemia.

Segmental atherosclerotic narrowing of epicardial coronary arteries is caused most commonly by the formation of a plaque, which is subject to rupture or erosion of the cap separating the plaque from the bloodstream. Upon exposure of the plaque contents to blood, two important and interrelated processes are set in motion: (1) platelets are activated and aggregate; and (2) the coagulation cascade is activated, leading to deposition of fibrin strands. A thrombus composed of platelet aggregates and fibrin strands traps red blood cells and can reduce coronary blood flow, leading to the clinical manifestations of myocardial ischemia.

The location of the obstruction influences the quantity of myocardium rendered ischemic and determines the severity of the clinical manifestations. Thus, critical obstructions in vessels, such as the left main coronary artery or the proximal left anterior descending coronary artery, are particularly hazardous. Severe coronary narrowing and myocardial ischemia are frequently accompanied by the development of collateral vessels, especially when the narrowing develops gradually. When well developed, such vessels can, by themselves, provide sufficient blood flow to sustain the viability of the myocardium at rest but not during conditions of increased demand.

With progressive worsening of a proximal epicardial artery stenosis, the distal resistance vessels (when they function normally) dilate to reduce vascular resistance and maintain coronary blood flow. A pressure gradient develops across the proximal stenosis, and poststenotic pressure falls. When the resistance vessels are maximally dilated, myocardial blood flow becomes dependent on the pressure in the coronary artery distal to the obstruction. In these circumstances, ischemia, manifest clinically by angina or electrocardiographically by ST-segment deviation, can be precipitated by increases in myocardial oxygen demand caused by physical activity, emotional stress, and/or tachycardia. Changes in the caliber of the stenosed coronary artery due to physiologic vasomotion, loss of endothelial control of dilation (as occurs in diabetes mellitus), pathologic spasm (Prinzmetal's angina), or small platelet-rich plugs can also upset the critical balance between oxygen supply and demand and thereby precipitate myocardial ischemia.

EFFECTS OF ISCHEMIA

During episodes of inadequate perfusion caused by coronary atherosclerosis, myocardial tissue oxygen tension falls and may cause transient disturbances of the mechanical, biochemical, and electrical functions of the myocardium. Coronary atherosclerosis is a focal process that usually causes nonuniform ischemia. Regional disturbances of ventricular contractility cause segmental akinesia or, in severe cases, bulging (dyskinesia), which can greatly reduce myocardial pump function.

The abrupt development of severe ischemia, as occurs with total or subtotal coronary occlusion, is associated with almost instantaneous failure of normal muscle contraction and relaxation. The relatively poor perfusion of the subendocardium causes more intense ischemia of this portion of the wall (compared with the subepicardial region). Ischemia of large portions of the ventricle causes transient LV failure, and if the papillary muscle apparatus is involved, mitral regurgitation can occur. When ischemia is transient, it may be associated with angina pectoris; when it is prolonged, it can lead to myocardial necrosis and scarring with or without the clinical picture of acute MI (Chap. 239).

A wide range of abnormalities in cell metabolism, function, and structure underlie these mechanical disturbances during ischemia. The normal myocardium metabolizes fatty acids and glucose to carbon dioxide and water. With severe oxygen deprivation, fatty acids cannot be oxidized, and glucose is degraded to lactate; intracellular pH is reduced, as are the myocardial stores of high-energy phosphates, i.e., ATP and creatine phosphate. Impaired cell membrane function leads to the leakage of potassium and the uptake of sodium by myocytes, as well as an increase in cytosolic calcium. The severity and duration of the imbalance between myocardial oxygen supply and demand determine whether the damage is reversible (≤20 min for total occlusion in the absence of collaterals) or whether it is permanent, with subsequent myocardial necrosis (>20 min).

Ischemia also causes characteristic changes in the electrocardiogram (ECG) such as repolarization abnormalities, as evidenced by inversion of T waves and, when more severe, by displacement of ST segments (Chap. 221). Transient T-wave inversion likely reflects nontransmural, intramyocardial ischemia; transient ST-segment depression often reflects subendocardial ischemia; and ST-segment elevation is thought to be caused by more severe transmural ischemia. Another important consequence of myocardial ischemia is electrical instability, which may lead to isolated ventricular premature beats or even ventricular tachycardia or ventricular fibrillation (Chap. 226). Most patients who die suddenly from IHD do so as a result of ischemia-induced ventricular tachyarrhythmias (Chap. 267).

ASYMPTOMATIC VERSUS SYMPTOMATIC IHD

Postmortem studies on accident victims and military casualties in western countries have shown that coronary atherosclerosis often begins to develop prior to age 20 and is widespread even among adults who were asymptomatic during life. Exercise stress tests in asymptomatic persons may show evidence of silent myocardial ischemia, i.e., exercise-induced ECG changes not accompanied by angina pectoris; coronary angiographic studies of such persons may reveal coronary artery plaques and previously unrecognized obstructions (Chap. 223). Postmortem examination of patients with such obstructions without a history of clinical manifestations of myocardial ischemia often shows macroscopic scars secondary to MI in regions supplied by diseased coronary arteries, with or without collateral circulation. According to population studies, ~25% of patients who survive acute MI may not come to medical attention, and these patients carry the same adverse prognosis as those who present with the classic clinical picture of acute MI (Chap. 239). Sudden death may be unheralded and is a common presenting manifestation of IHD (Chap. 267).

Patients with IHD can also present with cardiomegaly and heart failure secondary to ischemic damage of the LV myocardium that may have caused no symptoms prior to the development of heart failure; this condition is referred to as *ischemic cardiomyopathy*. In contrast to the asymptomatic phase of IHD, the symptomatic phase is characterized by chest discomfort due to either angina pectoris or acute MI (Chap. 239). Having entered the symptomatic phase, the patient may exhibit a stable or progressive course, revert to the asymptomatic stage, or die suddenly.

STABLE ANGINA PECTORIS

This episodic clinical syndrome is due to transient myocardial ischemia. Males constitute ~70% of all patients with angina pectoris and an even greater fraction of those less than 50 years of age. **Various diseases that cause myocardial ischemia as well as the numerous forms of discomfort with which it may be confused are discussed in Chap. 13.**

HISTORY

The typical patient with angina is a man older than 50 years or a woman older than 60 years of age who complains of chest discomfort, usually described as heaviness, pressure, squeezing, smothering, or choking, and only rarely as frank pain. When the patient is asked to localize the sensation, he or she will typically place their hand over the sternum, sometimes with a clenched fist, to indicate a squeezing, central, substernal discomfort (Levine's sign). Angina is usually crescendo-decrescendo in nature, typically lasts 2–5 min, and can radiate to either shoulder and to both arms (especially the ulnar surfaces of the forearm and hand). It can also arise in or radiate to the back, interscapular region, root of the neck, jaw, teeth, and epigastrium. Angina is rarely

localized below the umbilicus or above the mandible. A useful finding in assessing the patient with chest discomfort is the fact that myocardial ischemic discomfort does not radiate to the trapezius muscles; such a radiation pattern is more typical of pericarditis.

Although episodes of angina are typically caused by exertion (e.g., exercise, hurrying, or sexual activity) or emotion (e.g., stress, anger, fright, or frustration) and are relieved by rest, they may also occur at rest (Chap. 238) and while the patient is recumbent (angina decubitus). The patient may be awakened at night by typical chest discomfort and dyspnea. Nocturnal angina may be due to episodic tachycardia, diminished oxygenation as the respiratory pattern changes during sleep, or expansion of the intrathoracic blood volume that occurs with recumbency; the latter causes an increase in cardiac size (end-diastolic volume), in wall tension, and in myocardial oxygen demand that lead to ischemia and transient LV failure.

The threshold for the development of angina pectoris may vary by time of day and emotional state. Many patients report a fixed threshold for angina, which occurs predictably at a certain level of activity, such as climbing two flights of stairs at a normal pace. In these patients, coronary stenosis and myocardial oxygen supply are fixed, and ischemia is precipitated by an increase in myocardial oxygen demand; they are said to have *stable exertional angina*. In other patients, the threshold for angina may vary considerably within any given day and from day to day. In such patients, variations in myocardial oxygen supply, most likely due to changes in coronary vascular tone, may play an important role in defining the pattern of angina. A patient may report symptoms upon minor exertion in the morning (a short walk or shaving), yet, by midday, may be capable of much greater effort without symptoms. Angina may also be precipitated by unfamiliar tasks, a heavy meal, exposure to cold, or a combination.

Exertional angina is typically relieved by slowing or ceasing activities in 1–5 min and even more rapidly by rest and sublingual nitroglycerin (see below). Indeed, the diagnosis of angina should be suspect if it does not respond to the combination of these measures. The severity of angina can be conveniently summarized by the Canadian Cardiac Society functional classification (Table 237-1). Its impact on the patient's functional capacity can be described using the New York Heart Association functional classification (Table 237-1).

Sharp, fleeting chest pain or a prolonged, dull ache localized to the left submammary area is rarely due to myocardial ischemia. However, especially in women and diabetics, angina pectoris may be atypical in location and not strictly related to provoking factors. In addition, this symptom may exacerbate and remit over days, weeks, or months. Its occurrence can be seasonal, being more frequent in the winter in temperate climates. Anginal "equivalents" are symptoms of myocardial ischemia other than angina. These include dyspnea, nausea, fatigue, and faintness, and are more common in the elderly and in diabetic patients.

Systematic questioning of the patient with suspected IHD is important to uncover the features of an unstable syndrome associated with increased risk, such as angina occurring with less exertion than in the past or occurring at rest or awakening the patient from sleep. Since coronary atherosclerosis is often accompanied by similar lesions in other arteries, the patient with angina should be questioned and examined for peripheral arterial disease (intermittent claudication, Chap. 243), stroke, or transient ischemic attacks (Chap. 364). It is also important to uncover a family history of premature IHD (<45 years in first-degree male relatives and <55 in female relatives) and the presence of diabetes mellitus, hyperlipidemia, hypertension, cigarette smoking, and other risk factors for coronary atherosclerosis (Chap. 235). The history of typical angina pectoris establishes the diagnosis of IHD until proven otherwise. In patients with atypical angina (Chap. 13), the coexistence of advanced age, male gender, the postmenopausal state, and risk factors for atherosclerosis increase the likelihood of hemodynamically significant coronary disease.

TABLE 237-1 CARDIOVASCULAR DISEASE CLASSIFICATION CHART

Class	New York Heart Association Functional Classification	Canadian Cardiovascular Society Functional Classification
I	Patients have cardiac disease but *without* the resulting *limitations* of physical activity. Ordinary physical activity does not cause undue fatigue, palpitation, dyspnea, or anginal pain.	Ordinary physical activity, such as walking and climbing stairs, *does not cause angina*. Angina present with strenuous or rapid or prolonged exertion at work or recreation.
II	Patients have cardiac disease resulting in *slight limitation* of physical activity. They are comfortable at rest. Ordinary physical activity results in fatigue, palpitation, dyspnea, or anginal pain.	*Slight limitation* of ordinary activity. Walking or climbing stairs rapidly, walking uphill, walking or stair climbing after meals, in cold, or when under emotional stress or only during the few hours after awakening. Walking more than two blocks on the level and climbing more than one flight of stairs at a normal pace and in normal conditions.
III	Patients have cardiac disease resulting in *marked limitation* of physical activity. They are comfortable at rest. Less than ordinary physical activity causes fatigue, palpitation, dyspnea, or anginal pain.	*Marked limitation* of ordinary physical activity. Walking one to two blocks on the level and climbing more than one flight of stairs in normal conditions.
IV	Patients have cardiac disease resulting in *inability* to carry on any physical activity without discomfort. Symptoms of cardiac insufficiency or of the anginal syndrome may be present even at rest. If any physical activity is undertaken, discomfort is increased.	*Inability* to carry on any physical activity without discomfort—anginal syndrome may be present at rest.

PHYSICAL EXAMINATION

This is often normal in patients with stable angina when they are asymptomatic, but it may reveal evidence of atherosclerotic disease at other sites, such as an abdominal aortic aneurysm, carotid arterial bruits, and diminished arterial pulse in the lower extremities, or of risk factors for atherosclerosis, such as xanthelasmas and xanthomas (Chap. 235). Examination of the fundi may reveal an increased light reflex and arteriovenous nicking as evidence of hypertension. There may also be signs of anemia, thyroid disease, and nicotine stains on the fingertips from cigarette smoking. Palpation may reveal cardiac enlargement and abnormal contraction of the cardiac impulse (left ventricular akinesia or dyskinesia).

Auscultation can uncover arterial bruits, a third and/or fourth heart sound, and, if acute ischemia or previous infarction has impaired papillary muscle function, an apical systolic murmur due to mitral regurgitation. These auscultatory signs are best appreciated with the patient in the left lateral decubitus position. Aortic stenosis, aortic regurgitation (Chap. 230), pulmonary hypertension (Chap. 244), and hypertrophic cardiomyopathy (Chap. 231) must be excluded, since these disorders may cause angina in the absence of coronary atherosclerosis. Examination during an anginal attack is useful, since ischemia can cause transient LV failure with the appearance of a third and/or fourth heart sound, a dyskinetic cardiac apex, mitral regurgitation, and even pulmonary edema. Tenderness of the chest wall, localization of the discomfort with a single fingertip on the chest, or reproduction of the pain with palpation of the chest makes it unlikely that it is caused by myocardial ischemia.

LABORATORY EXAMINATION

Although the diagnosis of IHD can be made with a high degree of confidence from the clinical examination, a number of simple laboratory

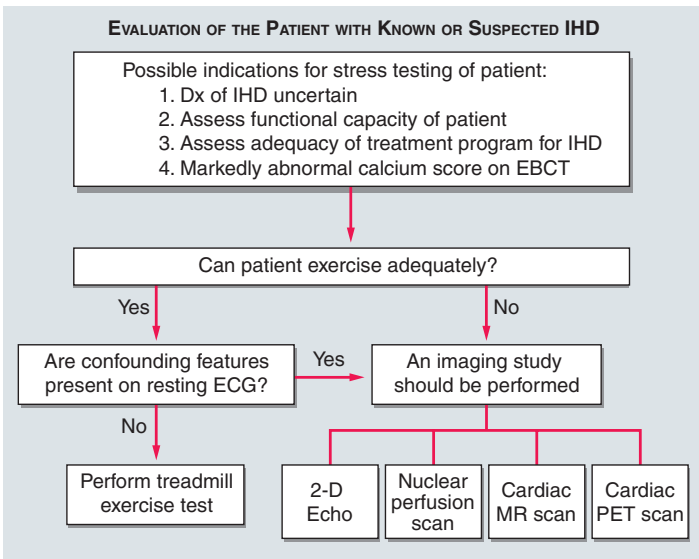
tests can be helpful. The urine should be examined for evidence of diabetes mellitus and renal disease (including microalbuminuria) since these conditions accelerate atherosclerosis. Similarly, examination of the blood should include measurements of lipids (cholesterol—total, LDL, HDL—and triglycerides), glucose, creatinine, hematocrit, and, if indicated based on the physical examination, thyroid function. A chest x-ray is important as it may show the consequences of IHD, i.e., cardiac enlargement, ventricular aneurysm, or signs of heart failure. These signs can support the diagnosis of IHD and are important in assessing the degree of cardiac damage.

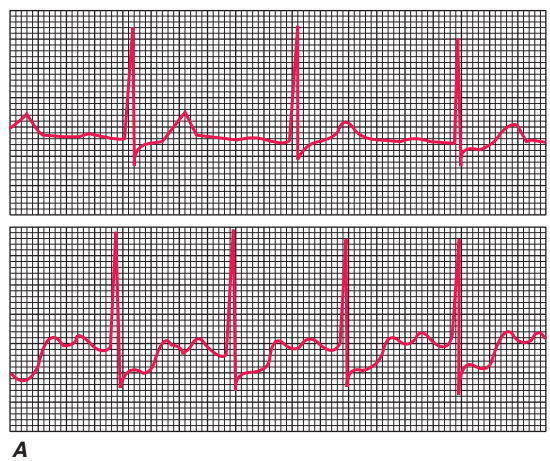
ELECTROCARDIOGRAM

A 12-lead ECG recorded at rest may be normal in patients with typical angina pectoris, but there may also be signs of an old myocardial infarction (Chap. 221). Although repolarization abnormalities—i.e., ST-segment and T-wave changes—as well as LV hypertrophy and intraventricular conduction disturbances are suggestive of IHD, they are nonspecific since they can also occur in pericardial, myocardial, and valvular heart disease or, in the case of the former, transiently with anxiety, changes in posture, drugs, or esophageal disease. Dynamic ST-segment and T-wave changes that accompany episodes of angina pectoris and disappear thereafter are more specific.

STRESS TESTING

Electrocardiographic The most widely used test for both the diagnosis of IHD and estimating the prognosis involves recording the 12-lead ECG before, during, and after exercise, usually on a treadmill (Fig. 237-1). The test consists of a standardized incremental increase in external workload (Table 237-2) while the symptoms, ECG, and arm blood pressure are monitored. Performance is usually symptom-limited, and the test is discontinued upon evidence of chest discomfort, severe shortness of breath, dizziness, severe fatigue, ST-segment depression >0.2 mV (2 mm), a fall in systolic blood pressure >10 mmHg, or the development of a ventricular tachyarrhythmia. This test seeks to discover any limitation in exercise performance, to detect typical ECG signs of myocardial ischemia, and to establish their relationship to chest discomfort. The ischemic ST-segment response is generally defined as flat or downsloping depression of the ST segment >0.1 mV below baseline (i.e., the PR segment) and lasting longer than 0.08 s (Fig. 237-1). Upsloping or junctional ST-segment changes are not





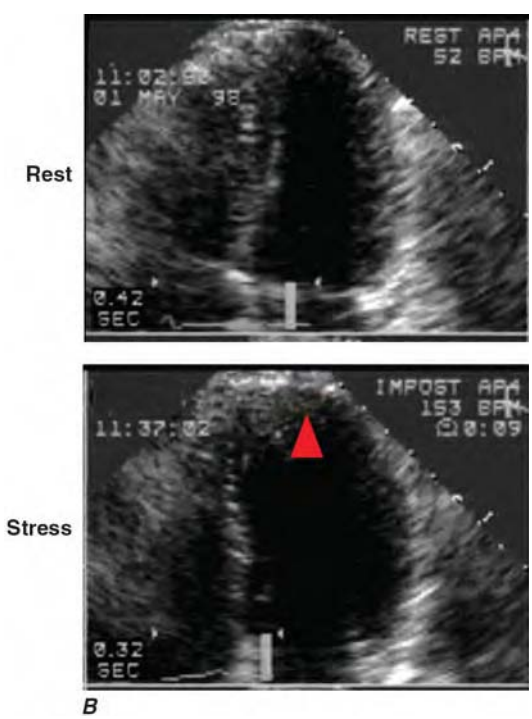


FIGURE 237-1 Evaluation of the patient with known or suspected ischemic heart disease. At the top of the figure is an algorithm for identifying patients who should be referred for stress testing and the decision pathway for determining if a standard treadmill exercise with ECG monitoring alone is adequate. A specialized imaging study is necessary if the patient cannot exercise adequately (pharmacologic challenge is given) or if there are confounding features on the resting ECG (symptom limited treadmill exercise may be used to stress the coronary circulation). At the bottom of the figure are examples of the data obtained with ECG monitoring and specialized imaging procedures. IHD, ischemic heart disease; EBCT, electron beam computed tomography; ECG, electrocardiogram; MR, magnetic resonance; PET, positron emission tomography; ECHO, echocardiography; MIBI, methoxyisobutyl isonitrite; CMR, cardiac magnetic resonance.

A. Lead V_4 at rest (*top*) and after $4^1/_2$ min of exercise (*bottom*). There is 3 mm (0.3 mV) of horizontal ST-segment depression, indicating a positive test for ischemia. *[Modified from BR Chaitman, in E Braunwald et al (eds): Heart Disease, 6th ed. Philadelphia, Saunders, 2001.]*

B. 45-year-old avid jogger who began experiencing classic substernal chest pressure underwent an exercise echo study. With exercise the patient's heart rate increased from 52 to 153 bpm. The left ventricular chamber dilated with exercise, and the septal and apical portions became akinetic to dyskinetic (*red arrow*). These findings are strongly suggestive of a significant flow limiting stenosis in the proximal left anterior descending coronary artery, which was confirmed at coronary angiography. *[Modified from SD Solomon, in E. Braunwald et al (eds): Primary Cardiology, 2d ed. Philadelphia, Saunders, 2003.] (continued)*

FIGURE 237-1 ***(Continued)*** ***C.*** Stress and rest myocardial perfusion SPECT images obtained with Tc99m sestamibi in a patient with chest pain and dyspnea on exertion. The images demonstrate a medium size and severe stress perfusion defect involving the inferolateral and basal inferior walls, showing near complete reversibility, consistent with moderate ischemia in the right coronary artery territory (*red arrows*). *(Images provided by Dr. Marcello Di Carli, Nuclear Medicine Division, Brigham and Women's Hospital, Boston, MA.)*

D. A patient with a prior myocardial infarction presented with recurrent chest discomfort. On CMR cine imaging a large area of anterior akinesia was noted (marked by the arrows in the top left and right images, systolic frame only). This area of akinesia was matched by a larger extent of late gadolinium-DTPA enhancements consistent with a large transmural myocardial infarction (marked by arrows in the middle left and right images). Resting (*bottom left*) and adenosine vasodilating stress (*bottom right*) first-pass perfusion images revealed reversible perfusion abnormality that extends to the inferior septum. This patient was found to have an occluded proximal left anterior descending coronary artery with extensive collateral formation. This case illustrates the utility of different modalities in a CMR examination in characterizing ischemic and infarcted myocardium. CMR, cardiac magnetic resonance; DTPA, diethylenetriamine pentaacetic acid *(Images provided by Dr. Raymond Kwong, Cardiovascular Division, Brigham and Women's Hospital, Boston, MA.)*

E. Stress and rest myocardial perfusion PET images obtained with rubidium-82 in a patient with chest pain on exertion. The images demonstrate a large and severe stress perfusion defect involving the mid and apical anterior, anterolateral, and anteroseptal walls, and the LV apex, showing complete reversibility, consistent with extensive and severe ischemia in the mid left anterior descending coronary artery territory (*red arrows*). *(Images provided by Dr. Marcello Di Carli, Nuclear Medicine Division, Brigham and Women's Hospital, Boston, MA.)*

considered characteristic of ischemia and do not constitute a positive test. Although T-wave abnormalities, conduction disturbances, and ventricular arrhythmias that develop during exercise should be noted, they are also not diagnostic. Negative exercise tests in which the target heart rate (85% of maximal predicted heart rate for age and sex) is not achieved are considered to be nondiagnostic.

When interpreting ECG stress tests, the probability that coronary artery disease (CAD) exists in the patient or population under study (i.e., pretest probability) should be considered. Overall, false-positive or false-negative results occur in one-third of cases. However, a positive result on exercise indicates that the likelihood of CAD is 98% in males >50 years with a history of typical angina pectoris and who develop chest discomfort during the test. The likelihood decreases if the patient has atypical or no chest pain by history and/or during the test.

The incidence of false-positive tests is significantly increased in patients with low probabilities of IHD, such as asymptomatic men under the age of 40 or in premenopausal women with no risk factors for premature atherosclerosis. It is also increased in patients taking cardioactive drugs, such as digitalis and antiarrhythmic agents, or in those with intraventricular conduction disturbances, resting ST-segment and T-wave abnormalities, ventricular hypertrophy, or abnormal serum potassium levels. Obstructive disease limited to the circumflex coronary artery may result in a false-negative stress test since the lateral portion of the heart which this vessel supplies is not well represented on the surface 12-lead ECG. Since the overall sensitivity of exercise stress electrocardiography is only ~75%, a negative result does not exclude CAD, although it makes the likelihood of three-vessel or left main CAD extremely unlikely.

The physician should be present throughout the exercise test, and it is important to measure total duration of exercise, the times to the onset of ischemic ST-segment change and chest discomfort, the external work performed (generally expressed as the stage of exercise), and the internal cardiac work performed, i.e., by the heart rate–blood pressure product. The depth of the ST-segment depression and the time needed for recovery of these ECG changes are also important. Because the risks of exercise testing are small but real—estimated at one fatality and two nonfatal complications per 10,000 tests—equipment for resuscitation should be available. Modified (heart rate–limited rather than symptom-limited) exercise tests can be performed safely in patients as early as 6 days after uncomplicated MI (Table 237-2). Contraindications to exercise stress testing include rest angina within 48 h, unstable rhythm, severe aortic stenosis, acute myocarditis, uncontrolled heart failure, severe pulmonary hypertension, and active infective endocarditis.

The normal response to graded exercise includes progressive increases in heart rate and blood pressure. Failure of the blood pressure to increase or an actual decrease with signs of ischemia during the test is an important adverse prognostic sign, since it may reflect ischemia-induced global LV dysfunction. The development of angina and/or severe (>0.2 mV) ST-segment depression at a low workload, i.e., before completion of stage II of the Bruce protocol, and/or ST-segment depression that persists for >5 min after the termination of exercise increases the specificity of the test and suggests severe IHD and a high risk of future adverse events.

Cardiac Imaging (See also Chap. 222) When the resting ECG is abnormal (e.g., preexcitation syndrome, >1 mm of resting ST-segment depression, left bundle branch block, paced ventricular rhythm), information gained from an exercise test can be enhanced by stress myocardial radionuclide perfusion imaging after the intravenous administration of thallium 201 or technetium 99m (^{99m}Tc) sestamibi during exercise (or a pharmacologic) stress. Recent data also suggest positron emission tomography (PET) imaging (with exercise or pharmacologic stress) using N-13 ammonia or rubidium-82 nuclide as another technique for assessing perfusion. Images obtained immediately after cessation of exercise to detect regional ischemia are compared with those obtained at rest to confirm reversible ischemia and regions of persistent absent uptake that signify infarction.

A sizable fraction of patients who need noninvasive stress testing to identify myocardial ischemia and increased risk of coronary events cannot exercise because of peripheral vascular or musculoskeletal disease, exertional dyspnea, or deconditioning. In these circumstances an intravenous pharmacologic challenge is used in place of exercise. For example, dipyridamole or adenosine can be given to create a coronary "steal" by temporarily increasing flow in nondiseased segments of the coronary vasculature at the expense of diseased segments. Alternatively, a graded incremental infusion of dobutamine may be administered to increase MVO_2. A variety of imaging options are available to accompany these pharmacologic stressors (Fig. 237-1). The development of a transient perfusion defect with a tracer such as radioactive thallium or ^{99m}Tc sestamibi is used to detect myocardial ischemia.

Two-dimensional echocardiography can assess both global and regional wall motion abnormalities of the left ventricle due to MI or persistent ischemia. Stress (exercise or dobutamine) echocardiography may cause the emergence of regions of akinesis or dyskinesis not present at rest. Stress echocardiography, like stress myocardial perfusion imaging, is more sensitive than exercise electrocardiography in the diagnosis of IHD. Cardiac magnetic resonance (CMR) stress testing is also evolving as an alternative to radionuclide, PET, or echocardiographic stress imaging. CMR stress testing performed with dobutamine infusion can be used to assess wall motion abnormalities accompanying ischemia, and myocardial perfusion CMR can be used to provide rather complete ventricular evaluation using multislice MR imaging studies. Ambulatory monitoring of the ECG can assess myocardial ischemia as episodes of ST-segment depression. Echocardiography or radionuclide angiography should be carried out to assess LV function in patients with chronic stable angina and in patients with a history of a prior MI, pathologic Q waves, or clinical evidence of heart failure.

Atherosclerotic plaques become progressively calcified over time, and coronary calcification in general increases with age. For this reason, methods for detecting coronary calcium have been developed as a measure of the presence of coronary atherosclerosis. These methods involve computed tomography (CT) applications that achieve rapid acquisition of images [ultrafast or electron beam (EBCT) and multidetector (MDCT)]. Coronary calcium detected by these imaging techniques is quantified using the Agatston score most commonly, which is based on the area and density of calcification. Although the diagnostic accuracy of this imaging method is high (sensitivity, 90–94%; specificity, 95–97%; negative predictive value, 93–99%), its prognostic utility and its role in the evaluative algorithm of patients with stable angina pectoris have not yet been defined.

CORONARY ARTERIOGRAPHY

(See also Chap. 223) This diagnostic method outlines the lumina of the coronary arteries and can be used to detect or exclude serious coronary obstruction. However, coronary arteriography provides no information regarding the arterial wall, and severe atherosclerosis that does not encroach on the lumen may go undetected. Of note, atherosclerotic plaques characteristically grow progressively in the intima and media of an epicardial coronary artery, at first without encroaching on the lumen, causing an outward bulging of the artery—a process referred to as negative remodeling (Chap. 235). Later in the course of the disease, further growth causes luminal narrowing.

Indications Coronary arteriography is indicated in (1) patients with chronic stable angina pectoris who are severely symptomatic despite medical therapy and who are being considered for revascularization, i.e., a percutaneous coronary intervention (PCI) or coronary artery bypass grafting (CABG); (2) patients with troublesome symptoms that present diagnostic difficulties in whom there is a need to confirm or rule out the diagnosis of IHD; (3) patients with known or possible angina pectoris who have survived cardiac arrest; (4) patients with angina or evidence of ischemia on noninvasive testing with clinical or laboratory evidence of ventricular dysfunction; and (5) patients judged to be at high risk of sustaining coronary events based on signs of severe ischemia on noninvasive testing, regardless of the presence or severity of symptoms (see below).

Examples of other indications include:

1. Patients with chest discomfort suggestive of angina pectoris but a negative or nondiagnostic stress test who require a definitive diagnosis for guiding medical management, alleviating psychological stress, career or family planning, or insurance purposes.
2. Patients who have been admitted repeatedly to the hospital for a suspected acute coronary syndrome (Chaps. 238 and 239) but in whom this diagnosis has not been established and in whom the presence or absence of CAD should be determined.
3. Patients with careers that involve the safety of others (e.g., pilots, firefighters, police) who have questionable symptoms or suspicious or positive noninvasive tests, and in whom there are reasonable doubts about the state of the coronary arteries.
4. Patients with aortic stenosis or hypertrophic cardiomyopathy and angina in whom the chest pain could be due to IHD.
5. Male patients >45 years and females >55 years who are to undergo a cardiac operation, such as valve replacement or repair, and who may or may not have clinical evidence of myocardial ischemia.
6. Patients following myocardial infarction, especially those who are at high risk after MI because of the recurrence of angina or the presence of heart failure, frequent ventricular premature contractions, or signs of ischemia on the stress test.
7. Patients with angina pectoris, regardless of severity, in whom noninvasive testing indicates a high risk of coronary events.
8. Patients in whom coronary spasm or another nonatherosclerotic cause of myocardial ischemia (e.g., coronary artery anomaly, Kawasaki's disease) is suspected.

Noninvasive alternatives to diagnostic coronary arteriography include CT angiography and cardiac MR angiography (Chap. 222). While these new imaging techniques can provide information about obstructive lesions in the epicardial coronary arteries, their exact role in clinical practice has not yet been rigorously defined. Important aspects of their use that should be noted include the substantially higher radiation exposure with CT angiography compared to conventional diagnostic arteriography and the limitations on cardiac MR imposed by cardiac movement during the cardiac cycle, especially at high heart rates.

PROGNOSIS

The principal prognostic indicators in patients known to have IHD are age, the functional state of the left ventricle, the location(s) and severity of coronary artery narrowing, and the severity or activity of myocardial ischemia. Angina pectoris of recent onset, unstable angina (Chap. 238), early postmyocardial infarction angina, and angina that is unresponsive or poorly responsive to medical therapy or is accompanied by symptoms of congestive heart failure all indicate an increased risk for adverse coronary events. The same is true for the physical signs of heart failure, episodes of pulmonary edema, transient third heart sounds, or mitral regurgitation, and for echocardiographic or radioisotopic (or roentgenographic) evidence of cardiac enlargement and reduced (<0.40) ejection fraction.

Most importantly, any of the following signs during noninvasive testing indicate a high risk for coronary events: inability to exercise for 6 min, i.e., stage II (Bruce protocol) of the exercise test; a strongly positive exercise test showing onset of myocardial ischemia at low workloads (≥0.1 mV ST-segment depression before completion of stage II; ≥0.2 mV ST depression at any stage; ST depression for >5 min following the cessation of exercise; a decline in systolic pressure >10 mmHg during exercise; the development of ventricular tachyarrhythmias during exercise); the development of large or multiple perfusion defects or increased lung uptake during stress radioisotope perfusion imaging; and a decrease in LV ejection fraction (LVEF) during exercise on radionuclide ventriculography or during stress echocardiography. Conversely, patients who can complete stage III of the Bruce exercise protocol and have a normal stress perfusion scan or negative stress echocardiographic evaluation are at very low risk of future coronary events.

On cardiac catheterization, elevations of LV end-diastolic pressure and ventricular volume and reduced ejection fraction are the most important signs of LV dysfunction and are associated with a poor prognosis. Patients with chest discomfort but normal LV function and normal coronary arteries have an excellent prognosis. Obstructive lesions of the left main (>50% luminal diameter) or left anterior descending coronary artery proximal to the origin of the first septal artery are associated with a greater risk than are lesions of the right or left circumflex coronary artery because of the greater quantity of myocardium at risk. Atherosclerotic plaques in epicardial arteries with fissuring or filling defects indicate increased risk. These lesions go through phases of inflammatory cellular activity, degeneration, endothelial dysfunction, abnormal vasomotion, platelet aggregation, and fissuring or hemorrhage. These factors can temporarily worsen the stenosis and cause abnormal reactivity of the vessel wall, thus exacerbating the manifestations of ischemia. The recent onset of symptoms, the development of severe ischemia during stress testing (see above), and unstable angina pectoris (Chap. 238) all reflect episodes of rapid progression in coronary lesions.

With any degree of obstructive CAD, mortality is greatly increased when LV function is impaired; conversely, at any level of LV function, the prognosis is influenced importantly by the quantity of myocardium perfused by critically obstructed vessels. Therefore, it is useful to collect all the evidence substantiating past myocardial damage (evidence of MI on ECG, echocardiography, radioisotope imaging, or left ventriculography), residual LV function (ejection fraction and wall motion), and risk of future damage from coronary events (extent of coronary disease and severity of ischemia defined by noninvasive stress testing). The larger the quantity of established myocardial necrosis, the less the heart is able to withstand additional damage and the poorer the prognosis. All the above signs of past damage plus the risk of future damage should be considered indicators of risk.

The greater the number and severity of risk factors for coronary atherosclerosis [advanced age (>75 years), diabetes, morbid obesity, accompanying peripheral and/or cerebrovascular disease, previous MI], the worse the prognosis of the angina patient. Evidence exists that elevated levels of C-reactive protein in the plasma, extensive coronary calcification on EBCT (see above), and increased carotid intimal thickening on ultrasound examination also indicate an increased risk of coronary events.

℞ STABLE ANGINA PECTORIS

Each patient must be evaluated individually with respect to his or her expectations and goals, control of symptoms, and prevention of adverse clinical outcomes, such as MI and premature death. The degree of disability as well as the physical and emotional stress that precipitates angina must be carefully recorded in order to set treatment goals. The management plan should include the following components: (1) explanation of the problem and reassurance about the ability to formulate a treatment plan, (2) identification and treatment of aggravating conditions, (3) recommendations for adaptation of activity as needed, (4) treatment of risk factors that will decrease the occurrence of adverse coronary outcomes, (5) drug therapy for angina, and (6) consideration of revascularization.

EXPLANATION AND REASSURANCE Patients with IHD need to understand their condition and to realize that a long and productive life is possible even though they suffer from angina pectoris or have experienced and recovered from an acute MI. Offering results of clinical trials showing improved outcomes can be of great value when encouraging patients to resume or maintain activity and return to their occupation. A planned program of rehabilitation can encourage patients to lose weight, improve exercise tolerance, and control risk factors with more confidence.

IDENTIFICATION AND TREATMENT OF AGGRAVATING CONDITIONS A number of conditions may either increase oxygen demand or decrease oxygen supply to the myocardium and may precipitate or exacerbate angina in patients with IHD. Aortic valve disease and hypertrophic cardiomyopathy may cause or contribute to angina and should be excluded or treated. Obesity, hypertension, and hyperthyroidism should be treated aggressively in order to reduce the frequency and severity of anginal episodes. Decreased myocardial oxygen supply may be due to reduced oxygenation of the arterial blood (e.g., in pulmonary disease or, when carboxyhemoglobin is present, due to cigarette or cigar smoking) or decreased oxygen-carrying capacity (e.g., in anemia). Correction of these abnormalities, if present, may reduce or even eliminate angina pectoris.

ADAPTATION OF ACTIVITY Myocardial ischemia is caused by a discrepancy between the demand of the heart muscle for oxygen and the ability of the coronary circulation to meet this demand. Most patients can be helped to understand this concept and utilize it in the rational programming of activity. Many tasks that ordinarily evoke angina may be accomplished without symptoms simply by reducing the speed at which they are performed. Patients must appreciate the diurnal variation in their tolerance of certain activities and should reduce their energy requirements in the morning, immediately after meals, and in cold or inclement weather.

On occasion, it may be necessary to recommend a change in employment or residence to avoid physical stress. However, with the exception of manual laborers, most patients with IHD can continue to function merely by allowing more time to complete each task. In some patients, anger and frustration may be the most important factors precipitating myocardial ischemia. If these cannot be avoided, training in stress management may be useful. A treadmill exercise test to determine the approximate heart rate at which ischemic ECG changes or symptoms develop may be helpful in the development of a specific exercise program.

Physical conditioning usually improves the exercise tolerance of patients with angina and exerts substantial psychological benefits. A regular program of isotonic exercise that is within the limits of each patient's threshold for the development of angina pectoris and does not exceed 80% of the heart rate associated with ischemia on exercise testing should be strongly encouraged. Based on the results of an exercise test, the number of METS performed at the onset of ischemia can be estimated (Table 237-2) and a practical exercise prescription can be formulated to permit daily activities that will fall below the ischemic threshold **(Table 237-3)**.

TREATMENT OF RISK FACTORS A *family history* of premature IHD is an important indicator of increased risk and should trigger a search for treatable risk factors such as hyperlipidemia, hypertension, and diabetes mellitus. *Obesity* impairs the treatment of other risk factors and increases the risk of adverse coronary events. In addition, obesity is often accompanied by three other risk factors—diabetes mellitus, hypertension, and hyperlipidemia. The treatment of obesity and these accompanying risk factors is an important component of any management plan. A diet low in saturated and *trans*-unsaturated fatty acids and a caloric intake to achieve optimal body weight is a cornerstone in the management of chronic IHD.

Cigarette smoking accelerates coronary atherosclerosis in both sexes and at all ages and increases the risk of thrombosis, plaque instability, MI,

Source: Modified from WL Haskell: Rehabilitation of the coronary patient, in NK Wenger, HK Hellerstein (eds): *Design and Implementation of Cardiac Conditioning Program*. New York, Churchill Livingstone. 1978.

and death (Chap. 235). In addition, by increasing myocardial oxygen needs and reducing oxygen supply, it aggravates angina. Smoking cessation studies have demonstrated important benefits with a significant decline in the occurrence of these adverse outcomes. The physician's message must be clear and strong and supported by programs that achieve and monitor abstinence (Chap. 390). *Hypertension* (Chap. 241) is associated with increased risk of adverse clinical events from coronary atherosclerosis as well as stroke. In addition, the LV hypertrophy that results from sustained hypertension aggravates ischemia. There is evidence that long-term, effective treatment of hypertension can decrease the occurrence of adverse coronary events. *Diabetes mellitus* (Chap. 338) accelerates coronary and peripheral atherosclerosis and is frequently associated with dyslipidemias and increases in the risk of angina, MI, and sudden coronary death. Aggressive control of the dyslipidemia (target LDL cholesterol <70 mg/dL) and hypertension (target BP 120/80 or less) that are frequently found in diabetic patients is essential, as described below.

DYSLIPIDEMIA The treatment of dyslipidemia is central when aiming for long-term relief from angina, reduced need for revascularization, and reduction in myocardial infarction and death. The control of lipids can be achieved by the combination of a diet low in saturated and *trans*-unsaturated fatty acids, exercise, and weight loss. Frequently, HMG-CoA reductase inhibitors (statins) are required and can lower LDL cholesterol (25–50%), raise HDL cholesterol (5–9%), and lower triglycerides (5–30%). Niacin or fibrates can be used to raise HDL cholesterol and lower triglycerides (Chaps. 235 and 350). Controlled trials with lipid-regulating regimens have shown equal proportional benefit for men, women, the elderly, diabetics, and even smokers.

Compliance with regard to the health-promoting behaviors listed above is generally very poor, and the conscientious physician must not underestimate the major effort required to meet this challenge. Fewer than one-half of patients in the United States discharged from the hospital with proven coronary disease receive treatment for dyslipidemia. Given the proof that treating dyslipidemia brings major benefits, physicians need to secure treatment pathways, monitor compliance, and follow up.

RISK REDUCTION IN WOMEN WITH IHD The incidence of clinical IHD in premenopausal women is very low; however, following the menopause, the atherogenic risk factors increase (e.g., increased LDL, reduced HDL) and the rate of clinical coronary events accelerates to the levels observed in men. Women have not given up cigarette smoking as effectively as have men. Diabetes mellitus, which is more common in women, greatly increases the occurrence of clinical IHD and amplifies the deleterious effects of hypertension, hyperlipidemia, and smoking. Cardiac catheterization and coronary revascularization are often applied more sparingly in women and at a later, and more severe, stage of the disease than in men. When cholesterol lowering, beta blockers after MI, and CABG are applied in the appropriate patient groups, women enjoy the same benefits of improved outcome as do men.

DRUG THERAPY The commonly used drugs for the treatment of angina pectoris are summarized in Tables 237-4–237-6. Pharmacotherapy for IHD is designed to reduce the frequency of anginal episodes and blunt the surge in the patient's heart rate and blood pressure with exertion so that they can perform daily activities without approaching the heart rate–blood pressure threshold that provokes ischemia. Antiplatelet therapy with aspirin is also used to reduce thrombotic events that may occur with destabilization of atherosclerotic plaques.

Nitrates The organic nitrates are a valuable class of drugs in the management of angina pectoris that have been in clinical use for over 125 years **(Table 237-4)**. Their major mechanisms of action include systemic venodilation with concomitant reduction in LV end-diastolic volume and pressure, thereby reducing myocardial wall tension and oxygen requirements; dilation of epicardial coronary vessels; and increased blood flow in collateral vessels. The organic nitrates, when metabolized release nitric oxide (NO) which binds to guanylyl cyclase in vascular smooth-muscle cells, leading to an increase in cyclic guanosine monophosphate, which causes relaxation of vascular smooth muscle. Nitrates also exert antithrombotic activity by NO-dependent activation of platelet guanylyl cyclase and impairment of intraplatelet calcium flux, and platelet activation.

The absorption of these agents is most rapid and complete through the mucous membranes. For this reason, nitroglycerin is most commonly administered sublingually in tablets of 0.4 or 0.6 mg. Patients with angina should be instructed to take the medication both to relieve angina and also approximately 5 min before stress that is likely to induce an episode. The value of this prophylactic use of the drug cannot be overemphasized.

A pulsating feeling in the head or headache is the most common side effect of nitroglycerin and fortunately is only rarely disturbing at the doses usually required to relieve or prevent angina. Postural dizziness has also been reported. Nitroglycerin deteriorates with exposure to air, moisture, and sunlight, so that if the drug neither relieves discomfort nor produces a slight sensation of tingling at the sublingual site of absorption, the preparation may be inactive and a fresh supply should be obtained. If relief is not achieved by rest and within 2 or 3 min after up to three nitroglycerin tablets, the patient should consult a physician or report promptly to a hospital emergency room for evaluation of possible unstable angina or acute MI (Chap. 239).

Nitrates improve exercise tolerance in patients with chronic angina and relieve ischemia in patients with unstable angina as well as in patients with Prinzmetal's variant angina (Chap. 238). A diary of angina and nitroglycerin use may be valuable for detecting changes in the frequency, severity, or threshold for discomfort that may signify the development of unstable angina pectoris and/or herald an impending MI.

Long-Acting Nitrates None of the long-acting nitrates is as effective as sublingual nitroglycerin for the acute relief of angina. These organic nitrate preparations can be swallowed, chewed, or administered as a patch or paste by the transdermal route (Table 237-4). They can provide effective plasma levels for up to 24 h, but the therapeutic response is highly variable. Different preparations and/or administration during the daytime should be tried only to prevent discomfort while avoiding side effects such as headache and dizziness. Individual dose titration is important in order to prevent side effects.

Useful preparations include isosorbide dinitrate (10–60 mg orally bid or tid) or mononitrate (30–120 mg orally qd), nitroglycerin ointment (0.5–2.0 in. qid), or sustained-release transdermal patches (5–25 mg/d). Tolerance with loss of efficacy develops within 12–24 h of continuous exposure to all of the long-acting nitrates. The mechanism of development of nitrate tolerance is incompletely understood, but leading hypotheses include inadequate generation of reduced sulfhydryl groups required for biotransformation to NO, inhibition of mitochondrial aldehyde dehydrogenase (responsible for formation of NO), counterregulatory neurohormonal activation with vasoconstric-

TABLE 237-4 NITROGLYCERIN AND NITRATES FOR PATIENTS WITH ISCHEMIC HEART DISEASE

Compound	Route	Dose	Duration of Effect
Nitroglycerin	Sublingual tablets	0.3–0.6 mg up to 1.5 mg	Approximately 10 min
	Spray	0.4 mg as needed	Similar to sublingual tablets
	Ointment	2% 6 × 6 in; 15 × 15 cm 7.5-40 mg	Effect up to 7 h
	Transdermal	0.2–0.8 mg/h every 12 h	8–12 h during intermittent therapy
	Oral sustained release	2.5–13 mg	4–8 h
	Intravenous	5–200 μg/min	Tolerance may be seen in 7–8 h
Isosorbide dinitrate	Sublingual	2.5–10 mg	Up to 60 min
	Oral	5–80 mg, 2–3 times daily	Up to 8 h
	Spray	1.25 mg daily	2–3 min
	Chewable	5 mg	2–2½ h
	Oral slow release	40 mg 1–2 daily	Up to 8 h
	Intravenous	1.25–5.0 mg/h	Tolerance in 7–8 h
	Ointment	100 mg/24 h	Not effective
Isosorbide mononitrate	Oral	20 mg twice daily 60–240 mg once daily	12–24 h
Pentaerythritol tetranitrate	Sublingual	10 mg as needed	Not known

TABLE 237-5 PROPERTIES OF BETA BLOCKERS IN CLINICAL USE FOR ISCHEMIC HEART DISEASE

Drugs	Selectivity	Partial Agonist Activity	Usual Dose for Angina
Acebutolol	β1	Yes	200–600 mg twice daily
Atenolol	β1	No	50–200 mg/d
Betaxolol	β1	No	10–20 mg/d
Bisoprolol	β1	No	10 mg/d
Esmolol (intravenous)[a]	β1	No	50–300 μg/kg per min
Labetalol[b]	None	Yes	200–600 mg twice daily
Metoprolol	β1	No	50–200 mg twice daily
Nadolol	None	No	40–80 mg/d
Pindolol	None	Yes	2.5–7.5 mg 3 times daily
Propranolol	None	No	80–120 mg twice daily
Timolol	None	No	10 mg twice daily

Note: This list of β blockers that may be used to treat patients with angina pectoris is arranged alphabetically. The agents for which there is the greatest clinical experience include atenolol, metoprolol, and propranolol. It is preferable to use a sustained release formulation that may be taken once daily to improve the patient's compliance with the regimen.

[a]Esmolol is an ultrashort acting β blocker that is administered as a continuous intravenous infusion. Its rapid offset of action makes esmolol an attractive agent to use in patients with relative contraindications to β blockade.

[b]Labetolol is a combined alpha- and β blocker.

Source: Modified from RJ Gibbons et al.

tion and fluid retention, and production of oxygen free radical species that inactivate NO and increase the sensitivity of vascular smooth muscle to circulating vasoconstrictors.

In order to minimize the effects of tolerance, the minimum effective dose should be used and a minimum of 8 h each day kept free of the drug so as to restore any useful response(s).

β-Adrenergic Blockers These drugs represent an important component of the pharmacologic treatment of angina pectoris **(Table 237-5)**. They reduce myocardial oxygen demand by inhibiting the increases in heart rate, arterial pressure, and myocardial contractility caused by adrenergic activation. Beta blockade reduces these variables most strikingly during exercise while causing only small reductions at rest. Long-acting beta-blocking drugs or sustained release formulations offer the advantage of once daily dosage (Table 237-5). The therapeutic aims include relief of angina and ischemia. These drugs can also reduce mortality and reinfarction in patients after MI and are moderately effective antihypertensive agents.

Relative contraindications include asthma and reversible airway obstruction in patients with chronic lung disease, atrioventricular conduction disturbances, severe bradycardia, Raynaud's phenomenon, and a history of mental depression. Side effects include fatigue, reduced exercise tolerance, nightmares, impotence, cold extremities, intermittent claudication, bradycardia (sometimes severe), impaired atrioventricular conduction, LV failure, bronchial asthma, worsening claudication, and intensification of the hypoglycemia produced by oral hypoglycemic agents and insulin. Reducing the dose or even discontinuation may be necessary if these side effects develop and persist. Since sudden discontinuation can intensify ischemia, the doses should be tapered over 2 weeks.

Beta blockers with relative β_1-receptor specificity, such as metoprolol and atenolol, may be preferable in patients with mild bronchial obstruction and insulin-requiring diabetes mellitus.

Calcium Channel Blockers Calcium channel blockers **(Table 237-6)** are coronary vasodilators that produce variable and dose-dependent reductions in myocardial oxygen demand, contractility, and arterial pressure. These combined pharmacologic effects are advantageous and make these agents as effective as beta blockers in the treatment of angina pectoris. They are indicated when beta blockers are contraindicated, poorly tolerated, or ineffective. Verapamil and diltiazem may produce symptomatic disturbances in cardiac conduction and bradyarrhythmias. They also exert negative inotropic actions and are more likely to aggravate LV failure, particularly when used in patients with LV dysfunction, especially if they are also receiving beta blockers. Although useful effects are usually achieved when calcium channel blockers are combined with beta blockers and nitrates, careful individual titrations of the doses are essential with these combinations. Variant (Prinzmetal's) angina responds particularly well to calcium channel blockers (especially members of the dihydropyridine class), supplemented when necessary by nitrates (Chap. 238).

Verapamil should not ordinarily be combined with beta blockers because of the combined effects on heart rate and contractility. Diltiazem can be combined with beta blockers in patients with normal ventricular function and no conduction disturbances. Amlodipine and beta blockers have complementary actions on coronary blood supply and myocardial oxygen demands. While the former decreases blood pressure and dilates coronary arteries, the latter slows heart rate and decreases contractility. Amlodipine and the other second-generation dihydropyridine calcium antagonists (nicardipine, isradipine, long-acting nifedipine, and felodipine) are potent vasodilators and useful in the simultaneous treatment of angina and hypertension. Short-acting dihydropyridines should be avoided because of the risk of precipitating infarction, particularly in the absence of beta blockers.

Choice between Beta Blockers and Calcium Channel Blockers for Initial Therapy Since beta blockers have been shown to improve life expectancy following acute MI (Chaps. 238 and 239) while calcium channel blockers have not, the former may also be preferable in patients with chronic IHD. However, calcium channel blockers are indicated in patients with the following: (1) inadequate responsiveness to the combination of beta blockers and nitrates; many such patients do well with a combination of a beta blocker and a dihydropyridine calcium channel blocker; (2) ad-

TABLE 237-6 CALCIUM CHANNEL BLOCKERS IN CLINICAL USE FOR ISCHEMIC HEART DISEASE

Drugs	Usual Dose	Duration of Action	Side Effects
Dihydropyridines			
Amlodipine	5–10 mg qd	Long	Headache, edema
Felodipine	5–10 mg qd	Long	Headache, edema
Isradipine	2.5–10 mg bid	Medium	Headache, fatigue
Nicardipine	20–40 mg tid	Short	Headache, dizziness, flushing, edema
Nifedipine	Immediate release:[a] 30–90 mg/d orally Slow release: 30–180 mg orally	Short	Hypotension, dizziness, flushing, nausea, constipation, edema
Nisoldipine	20–40 mg qd	Short	Similar to nifedipine
Nondihydropyridines			
Diltiazem	Immediate release: 30–80 mg 4 times daily Slow release: 120–320 mg qd	Short Long	Hypotension, dizziness, flushing, bradycardia, edema
Verapamil	Immediate release: 80–160 mg tid Slow release: 120–480 mg qd	Short Long	Hypotension, myocardial depression, heart failure, edema, bradycardia

Note: This list of calcium channel blockers that may be used to treat patients with angina pectoris is divided into two broad classes, dihydropyridines and nondihydropyridines, and arranged alphabetically within each class. Among the dihydropyridines, the greatest clinical experience has been obtained with amlodipine and nifedipine. After the initial period of dose titration with a short-acting formulation, it is preferable to switch to a sustained release formulation that may be taken once daily to improve patient compliance with the regimen.

[a]May be associated with increased risk of mortality if administered during acute myocardial infarction.

Source: Modified from RJ Gibbons et al.

verse reactions to beta blockers such as depression, sexual disturbances, and fatigue; (3) angina and a history of asthma or chronic obstructive pulmonary disease; (4) sick-sinus syndrome or significant atrioventricular conduction disturbances; (5) Prinzmetal's angina; or (6) symptomatic peripheral arterial disease.

Antiplatelet Drugs Aspirin is an irreversible inhibitor of platelet cyclooxygenase activity and thereby interferes with platelet activation. Chronic administration of 75–325 mg orally per day has been shown to reduce coronary events in asymptomatic adult men, patients with chronic stable angina, and patients with or who have survived unstable angina and MI. There is a dose-dependent increase in bleeding when aspirin is used chronically. It is preferable to use an enteric-coated formulation in the range of 75–162 mg/d. Administration of this drug should be considered in all patients with IHD in the absence of gastrointestinal bleeding, allergy, or dyspepsia. Clopidogrel (300–600 mg loading and 75 mg/d maintenance) is an oral agent that blocks ADP receptor–mediated platelet aggregation. It provides similar benefits as aspirin in patients with stable chronic IHD and may be substituted for aspirin if aspirin causes the side effects listed above. Clopidogrel combined with aspirin reduces death and coronary ischemic events in patients with an acute coronary syndrome (Chap. 238) and also reduces the risk of thrombus formation in patients undergoing implantation of a stent in a coronary artery (Chap. 240). (In order to reduce the risk of gastrointestinal bleeding, it is recommended that a proton pump inhibitor be prescribed to patients taking a combination of clopidogrel and aspirin.) While combined treatment with clopidogrel and aspirin for at least a year is recommended in patients with an acute coronary syndrome and following implantation of a drug-eluting stent, studies have not shown any benefit of the routine addition of clopidogrel to aspirin in patients with chronic stable IHD.

OTHER THERAPIES Angiotensin-converting enzyme (ACE) inhibitors are widely used in the treatment of survivors of MI; patients with hypertension or chronic IHD, including angina pectoris; and those at high risk of vascular disease, such as diabetes. The benefits of ACE inhibitors are most evident in IHD patients at increased risk, especially if diabetes mellitus or LV dysfunction is present, and in those who have not achieved adequate control of blood pressure and LDL cholesterol on beta blockers and statins. However, the routine administration of ACE inhibitors to IHD patients with normal LV function and who have achieved blood pressure and LDL goals on other therapies does not reduce events and therefore is not cost-effective.

Despite treatment with nitrates, beta blockers, or calcium channel blockers, some patients with IHD continue to experience angina, and additional medical therapy is now available to alleviate their symptoms. Ranolazine, a piperazine derivative, was approved for use in January 2006 for patients with chronic angina who continue to be symptomatic despite a standard medical regimen. The mechanism of the antianginal effect of ranolazine is not firmly established, but the leading theory is that the drug inhibits the late inward sodium current (I_{Na}). The benefits of I_{Na} inhibition include limitation of the Na overload of ischemic myocytes and prevention of Ca^{2+} overload via the Na^{+}-Ca^{2+} exchanger. Prevention of Ca^{2+} overload minimizes diastolic tension and blunts the reduction in coronary nutrient flow that results from compression of the intramyocardial arterioles. A dose of 500–1000 mg orally twice daily is usually well tolerated. Ranolazine is contraindicated in patients with hepatic impairment, with conditions or drugs associated with QT_c prolongation, and when drugs that inhibit the CYP3A metabolic system (e.g., ketoconazole, diltiazem, verapamil, macrolide antibiotics, HIV protease inhibitors, and large quantities of grapefruit juice) are being taken by the patient.

Use of nonsteroidal anti-inflammatory drugs (NSAIDs) in patients with IHD may be associated with a small but finite increased risk of MI and mortality. For this reason, they should generally be avoided in IHD patients. If they are required for symptom relief, it is advisable to coadminister aspirin and strive to use the lowest NSAID dose required for the shortest period of time.

Another class of agents that may be considered are potassium channel openers. These agents open ATP-sensitive potassium channels in myocytes, leading to hyperpolarization of the cell membrane and a reduction of free intracellular calcium ions. The major drug in this class is nicorandil, which is typically administered in a dose of 20 mg twice daily orally for prevention of angina. (Nicorandil is not available for use in the United States but is used in several other countries.) Tolerance to nicorandil's anti-anginal effect may develop with chronic dosing, but there is no cross-tolerance to the organic nitrates.

Angina and Heart Failure Transient LV failure with angina can be controlled by the use of nitrates. For patients with established congestive heart failure, the increased LV wall tension raises myocardial oxygen demand. Treatment of congestive heart failure with an angiotensin-converting enzyme inhibitor, diuretic, and digoxin (Chap. 227) reduces heart size, wall tension, and myocardial oxygen demand, which in turn helps to control angina and ischemia. If the symptoms and signs of heart failure are controlled, an effort should be made to use beta blockers not only for angina but because trials in heart failure have shown significant improvement in survival. A trial of the intravenous ultrashort acting beta blocker esmolol may be useful to establish the safety of beta blockade in individual patients. Nocturnal angina can often be relieved by the treatment of heart failure. Nitrates are useful and can simultaneously improve the disturbed hemodynamics of congestive heart failure by vasodilatation, thereby reducing preload, and relieve angina by preventing or reversing myocardial ischemia. The combination of congestive heart failure and angina in patients with IHD usually indicates a poor prognosis and warrants serious consideration of cardiac catheterization and coronary revascularization.

CORONARY REVASCULARIZATION

While the basic management of patients with IHD is medical, as described above, many patients are improved by coronary revascularization procedures. *These interventions should be employed in conjunction with but do not replace the continuing need to modify risk factors and medical therapy.* An algorithm for integrating medical therapy and revascularization options in patients with IHD is shown in Fig. 237-2.

PERCUTANEOUS CORONARY INTERVENTION

(See also Chap. 240) PCI, involving balloon dilatation usually accompanied by coronary stenting, is widely used to achieve revascularization of the myocardium in patients with symptomatic IHD and suitable stenoses of epicardial coronary arteries. Whereas patients with stenosis of the left main coronary artery and those with three-vessel IHD (especially with diabetes and/or impaired LV function) who require revascularization are best treated with CABG, PCI is widely employed in patients with symptoms and evidence of ischemia due to stenoses of one or two vessels, and even in selected patients with three-vessel disease, and may offer many advantages over surgery.

Indications and Patient Selection The most common clinical indication for PCI is angina pectoris, despite medical therapy, accompanied by evidence of ischemia during a stress test. PCI is more effective than medical therapy for the relief of angina. Whereas PCI improves outcomes in patients with unstable angina and MI, the value of this procedure in reducing the occurrence of coronary death and MI in patients with chronic stable angina has not been established. PCI can be used to treat stenoses in native coronary arteries as well as in bypass grafts in patients who have recurrent angina following CABG.

Risks When coronary stenoses are discrete and symmetric, two and even three vessels can be dilated in sequence. However, case selection is essential in order to avoid a prohibitive risk of complications, which are usually due to dissection or thrombosis with vessel occlusion, uncontrolled ischemia, and ventricular failure (Chap. 240). Oral aspirin, clopidogrel, and an antithrombin are given to reduce coronary thrombus formation. Left main coronary artery stenosis is generally regarded as a contraindication to PCI; such patients should be treated with CABG. In rare cases, such as patients with prohibitive surgical risks, PCI of an unprotected left main can be considered, but such a procedure should only be performed by a highly skilled operator; importantly, there are regional differences in the use of this approach internationally.

Efficacy Primary success—i.e., adequate dilation (an increase in luminal diameter >20% to a residual diameter obstruction <50%) with relief of angina—is achieved in >95% of cases. Recurrent stenosis of the dilated vessels occurs in ~20% of cases within 6 months of PCI with bare metal stents, and angina will recur within 6 months in 10% of cas-

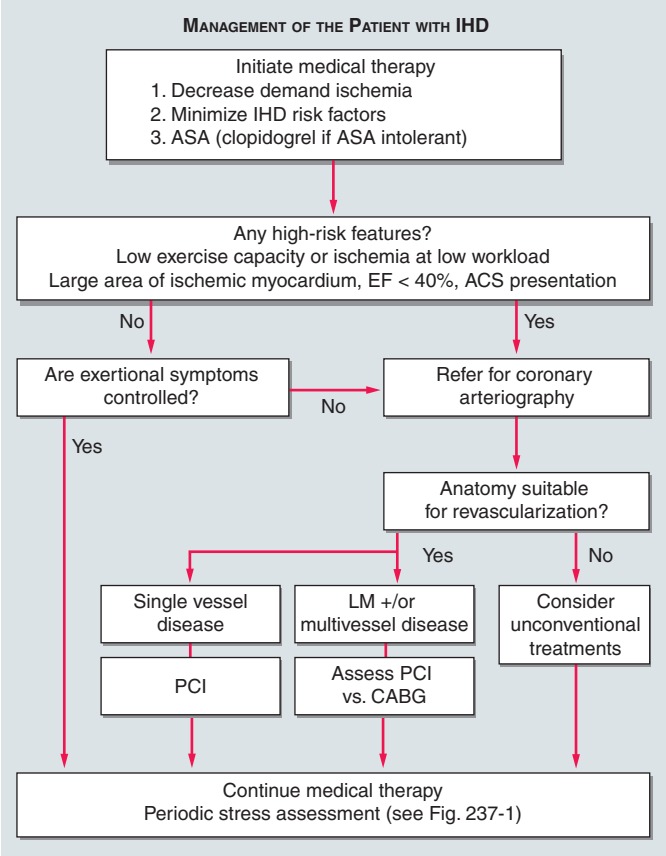

FIGURE 237-2 Algorithm for management of the patient with ischemic heart disease. All patients should receive the core elements of medical therapy as shown at the top of the algorithm. If high-risk features are present, as established by the clinical history, exercise test data, and imaging studies, the patient should be referred for coronary arteriography. Based on the number and location of the diseased vessels and their suitability for revascularization, the patient is treated with either a percutaneous coronary intervention (PCI), coronary artery bypass graft (CABG) surgery, or should be considered for unconventional treatments. See text for further discussion. IHD, ischemic heart disease; ASA, aspirin; EF, ejection fraction; ACS, acute coronary syndrome; LM, left main.

es. Restenosis is more common in patients with diabetes mellitus, arteries with small caliber, incomplete dilation of the stenosis, occluded vessels, obstructed vein grafts, dilation of the left anterior descending coronary artery, and stenoses containing thrombi. In diseased vein grafts, procedural success has been improved by the use of capture devices or filters that prevent embolization, ischemia, and infarction.

It is usual clinical practice to administer aspirin indefinitely and clopidogrel for 1–3 months after the implantation of a bare metal stent. Although aspirin and the antiplatelet drug clopidogrel may help prevent coronary thrombosis during and shortly following PCI with stenting, there is no evidence that these medications reduce the incidence of restenosis. The use of drug-eluting stents that locally deliver antiproliferative drugs such as rapamycin or paclitaxel can reduce restenosis to near zero within the stent and 3–7% at its edges. Advances in PCI, especially the availability of drug-eluting stents, have vastly extended the use of this revascularization option in patients with IHD. Of note, however, the delayed endothelial healing in the region of a drug-eluting stent also extends the period during which the patient is at risk for subacute stent thrombosis. Current recommendations are to administer aspirin indefinitely and clopidogrel daily for at least 1 year after implantation of a drug-eluting stent. When a situation arises where temporary discontinuation of antiplatelet therapy is desirable, the clinical circumstances should be reviewed with the operator who performed the PCI and a coordinated plan should be established for minimizing the risk of late stent thrombus. Central to this plan is the discontinuation of antiplatelet therapy for the shortest acceptable period of time.

Successful PCI produces effective relief of angina in >95% of cases and has been shown to be more effective than medical therapy for up to 2 years. More than one-half of patients with symptomatic IHD who require revascularization can be treated initially by PCI. Successful PCI is less invasive and expensive than CABG, usually requires only 1–2 days in the hospital, and permits savings in the initial cost of care. Successful PCI also allows earlier return to work and the resumption of an active life. However, this economic benefit is reduced over time because of the greater need for follow-up and for repeat procedures.

CORONARY ARTERY BYPASS GRAFTING

Anastomosis of one or both of the internal mammary arteries or a radial artery to the coronary artery distal to the obstructive lesion is carried out. For additional obstructions that cannot be bypassed by an artery, a section of a vein (usually the saphenous) is used to form a connection between the aorta and the coronary artery distal to the obstructive lesion.

Although some indications for CABG are controversial, certain areas of agreement exist:

1. The operation is relatively safe, with mortality rates <1% in patients without serious comorbid disease and normal LV function, and when the procedure is performed by an experienced surgical team.
2. Intraoperative and postoperative mortality increase with the severity of ventricular dysfunction, comorbidities, age >80 years, and lack of surgical experience. The effectiveness and risk of CABG vary widely depending on case selection and the skill and experience of the surgical team.
3. Occlusion of *venous* grafts is observed in 10–20% of patients during the first postoperative year, in approximately 2% per year during 5- to 7-year follow-up, and in 4% per year thereafter. Long-term patency rates are considerably higher for internal mammary and radial artery implantations than saphenous vein grafts. In patients with left anterior descending coronary artery obstruction, survival is better when coronary bypass involves the internal mammary artery rather than a saphenous vein. Graft patency and outcomes are improved by meticulous treatment of risk factors, particularly dyslipidemia.
4. Angina is abolished or greatly reduced in ~90% of patients following complete revascularization. Although this is usually associated with graft patency and restoration of blood flow, the pain may also have been alleviated as a result of infarction of the ischemic segment or a placebo effect. Within 3 years, angina recurs in about one-fourth of patients but is rarely severe.
5. Survival may be improved by operation in patients with stenosis of the left main coronary artery as well as in patients with three- or two-vessel disease with significant obstruction of the proximal left anterior descending coronary artery. The survival benefit is greater in patients with abnormal LV function (ejection fraction <50%). Survival *may* also be improved in the following patients: (1) those with obstructive CAD who have survived sudden cardiac death or sustained ventricular tachycardia; (2) those who have undergone previous CABG and who have multiple saphenous vein graft stenoses, especially of a graft supplying the left anterior descending coronary artery; and (3) those with recurrent stenosis following PCI and high-risk criteria on noninvasive testing.
6. Minimally invasive CABG through a small thoracotomy and/or off-pump surgery can reduce morbidity and shorten convalescence in suitable patients but does not appear to significantly reduce the risk of neurocognitive dysfunction postoperatively.

Indications for CABG are usually based on the severity of symptoms, coronary anatomy, and ventricular function. The ideal candidate is male, is <80 years of age, has no other complicating disease, has troublesome or disabling angina that is not adequately controlled by medical therapy or does not tolerate medical therapy and wishes to lead a more active life, and has severe stenoses of two or three epicardial coronary ar-

teries with objective evidence of myocardial ischemia as a cause of the chest discomfort. Great symptomatic benefit can be anticipated in such patients. Congestive heart failure and/or LV dysfunction, advanced age (>80 years), reoperation, urgent need for surgery, and the presence of diabetes mellitus are all associated with a higher perioperative mortality.

LV dysfunction can be due to noncontractile or hypocontractile segments that are viable but are chronically ischemic (hibernating myocardium). As a consequence of chronic reduction in myocardial blood flow these segments downregulate their contractile function. These can be detected by using radionuclide scans of myocardial perfusion and metabolism, PET, CMR imaging, or delayed scanning with thallium-201; or by improvement of regional functional impairment, provoked by low-dose dobutamine. In such patients, revascularization improves myocardial blood flow, can return function, and can improve survival.

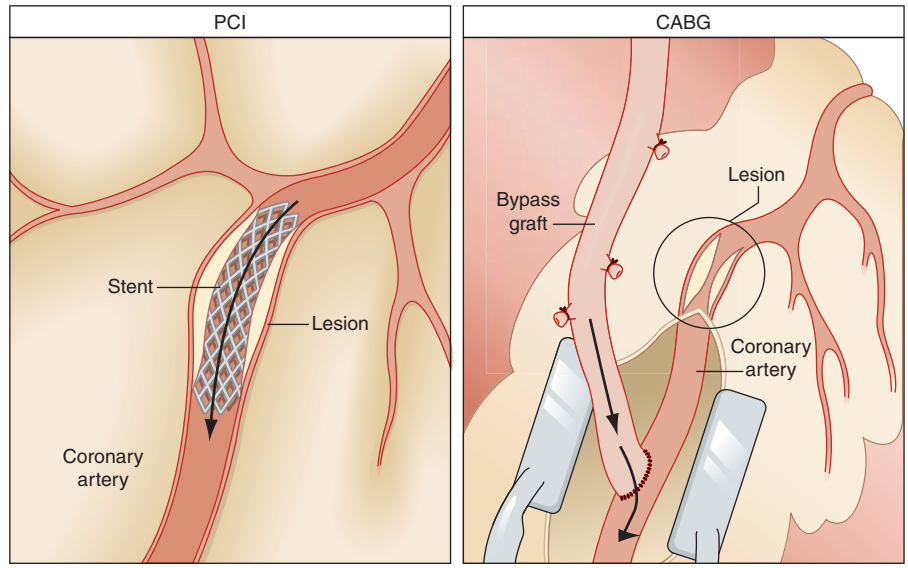

FIGURE 237-3 Difference in the approach to the lesion with percutaneous coronary intervention (PCI) and coronary artery bypass grafting (CABG). PCI is targeted at the "culprit" lesion or lesions, whereas CABG is directed at the epicardial vessel, including the "culprit" lesion or lesions and future culprits, proximal to the insertion of the vein graft, a difference that may account for the superiority of CABG, at least in the intermediate term, in patients with multivessel disease. *(Reproduced from BJ Gersh et al: N Engl J Med 352:2235, 2005.)*

The Choice between PCI and CABG A number of randomized clinical trials have compared PCI and CABG in patients with multivessel CAD who were suitable technically for both procedures. The redevelopment of angina requiring repeat coronary angiography and repeat revascularization is higher with PCI. This is a result of restenosis in the stented segment (a problem largely solved with drug-eluting stents) and the development of new stenoses in unstented portions of the coronary vasculature. It has been argued that PCI with stenting focuses on culprit lesions while a bypass graft to the target vessel also provides a conduit around future culprit lesions proximal to the anastomosis of the graft to the native vessel (Fig. 237-3).

Comparison of mortality rates in patients treated with CABG versus PCI is a complex issue. There is an early increased risk of mortality with CABG, but when considering a longer time horizon, such as 5 years, mortality is lower with CABG compared with PCI.

Based on available evidence, it is now recommended that patients with an unacceptable level of angina despite optimal medical management be considered for coronary revascularization. Patients with single- or two-vessel disease with normal LV function and anatomically suitable lesions are ordinarily advised to undergo PCI (Chap. 240). Patients with three-vessel disease (or two-vessel disease that includes the proximal left descending coronary artery) and impaired global LV function (LVEF <50%) or diabetes mellitus or those with left main coronary artery disease or other lesions unsuitable for catheter-based procedures should be considered for CABG as the initial method of revascularization.

UNCONVENTIONAL TREATMENTS FOR IHD

On occasion clinicians will encounter a patient with persistent disabling angina despite maximally tolerated medical therapy for whom revascularization is not an option (e.g., small diffusely diseased vessels not amenable to stent implantation or acceptable targets for bypass grafting). In such situations unconventional treatments should be considered.

Enhanced external counterpulsation utilizes pneumatic cuffs on the lower extremities to provide diastolic augmentation and systolic unloading of blood pressure in order to decrease cardiac work and oxygen consumption while enhancing coronary blood flow. Clinical trials have shown that regular application improves angina, exercise capacity, and regional myocardial perfusion.

Additional options include *transmyocardial laser revascularization* (to increase intramyocardial channels of blood flow), and the currently experimental approaches of gene and stem cell therapies are under study.

ASYMPTOMATIC (SILENT) ISCHEMIA

Obstructive CAD, acute MI, and transient myocardial ischemia are frequently asymptomatic. During continuous ambulatory ECG monitoring, the majority of ambulatory patients with typical chronic stable angina are found to have objective evidence of myocardial ischemia (ST-segment depression) during episodes of chest discomfort while they are active outside the hospital, but many of these patients have more frequent episodes of asymptomatic ischemia. In addition, there is a large (but as yet unknown) number of totally asymptomatic persons with severe coronary atherosclerosis who exhibit ST-segment changes during activity. Some of these patients exhibit higher thresholds to electrically induced pain, others show higher endorphin levels, and still others may be diabetics with autonomic dysfunction.

Frequent episodes of ischemia (symptomatic and asymptomatic) during daily life appear to be associated with an increased likelihood of adverse coronary events (death and MI). In addition, patients with asymptomatic ischemia after suffering a myocardial infarction are at greater risk for a second coronary event. The widespread use of exercise ECG during routine examinations has also identified some of these heretofore unrecognized patients with asymptomatic CAD. Longitudinal studies have demonstrated an increased incidence of coronary events in asymptomatic patients with positive exercise tests.

℞ ASYMPTOMATIC ISCHEMIA

The management of patients with asymptomatic ischemia must be individualized. Thus, the physician should consider the following: (1) the degree of positivity of the stress test, particularly the stage of exercise at which ECG signs of ischemia appear, the magnitude and number of the ischemic zones of myocardium on imaging, and the change in LVEF which occurs on radionuclide ventriculography or echocardiography during ischemia and/or during exercise; (2) the ECG leads showing a positive response, with changes in the anterior precordial leads indicating a less favorable prognosis than changes in the inferior leads; and (3) the patient's age, occupation, and general medical condition.

Most would agree that an asymptomatic 45-year-old commercial airline pilot with 0.4-mV ST-segment depression in leads V_1 to V_4 during mild exercise should undergo coronary arteriography, whereas the asymptomatic,

sedentary 75-year-old retiree with 0.1-mV ST-segment depression in leads II and III during maximal activity need not. However, there is no consensus about the appropriate procedure in the large majority of patients for whom the situation is less extreme. Asymptomatic patients with silent ischemia, three-vessel CAD, and impaired LV function may be considered appropriate candidates for CABG.

The treatment of risk factors, particularly lipid lowering as described above, and the use of aspirin, beta blockers, and statins have been shown to reduce events and improve outcomes in asymptomatic as well as symptomatic patients with ischemia and proven CAD. While the incidence of asymptomatic ischemia can be reduced by treatment with beta blockers, calcium channel blockers, and long-acting nitrates, it is not clear whether this is necessary or desirable in patients who have not suffered a myocardial infarction.

238 Unstable Angina and Non-ST-Elevation Myocardial Infarction

Christopher P. Cannon, Eugene Braunwald

Patients with ischemic heart disease fall into two large groups: patients with chronic coronary artery disease (CAD) who most commonly present with stable angina (Chap. 237) and patients with acute coronary syndromes (ACSs). The latter group, in turn, is composed of patients with acute myocardial infarction (MI) with ST-segment elevation on their presenting electrocardiogram (STEMI; Chap. 239) and those with unstable angina and non-ST-segment elevation MI (UA/NSTEMI; see Fig. 239-1). Every year in the United States, ~1.3 million patients are admitted to hospitals with UA/NSTEMI as compared with ~300,000 patients with acute STEMI. The relative incidence of UA/NSTEMI compared to STEMI appears to be increasing. Almost one-half of patients with UA/NSTEMI are women, while more than three-fourths of patients with STEMI are men.

DEFINITION

The diagnosis of UA is based largely on the clinical presentation. *Stable* angina pectoris is characterized by chest or arm discomfort that may not be described as pain but is reproducibly associated with physical exertion or stress and is relieved within 5–10 min by rest and/or sublingual nitroglycerin (Chaps. 13 and 237). UA is defined as angina pectoris or equivalent ischemic discomfort with at least one of three features: (1) it occurs at rest (or with minimal exertion), usually lasting >10 min; (2) it is severe and of new onset (i.e., within the prior 4–6 weeks); and/or (3) it occurs with a crescendo pattern (i.e., distinctly more severe, prolonged, or frequent than previously). The diagnosis of NSTEMI is established if a patient with the clinical features of UA develops evidence of myocardial necrosis, as reflected in elevated cardiac biomarkers.

PATHOPHYSIOLOGY

UA/NSTEMI is most commonly caused by a reduction in oxygen supply and/or by an increase in myocardial oxygen demand superimposed on an atherosclerotic coronary plaque, with varying degrees of obstruction. Four pathophysiologic processes that may contribute to the development of UA/NSTEMI have been identified: (1) plaque rupture or erosion with superimposed nonocclusive thrombus, believed to be the most common cause—NSTEMI may occur with downstream embolization of platelet aggregates and/or atherosclerotic debris; (2) dynamic obstruction [e.g., coronary spasm, as in Prinzmetal's variant angina (p. 1531)]; (3) progressive mechanical obstruction [e.g., rapidly advancing coronary atherosclerosis or restenosis following percutaneous coronary intervention (PCI)]; and (4) secondary UA related to increased myocardial oxygen demand and/or decreased supply (e.g., tachycardia, anemia). More than one of these processes may be involved.

Among patients with UA/NSTEMI studied at angiography, approximately 5% have left main stenosis, 15% have three-vessel CAD, 30% have two-vessel disease, 40% have single-vessel disease, and 10% have no critical coronary stenosis; some of the latter have Prinzmetal's variant angina (see below). The "culprit lesion" on angiography may show an eccentric stenosis with scalloped or overhanging edges and a narrow neck. Angioscopy may reveal "white" (platelet-rich) thrombi, as opposed to "red" thrombi, more often seen in patients with acute STEMI. Patients with UA/NSTEMI often have multiple plaques vulnerable to disruption.

CLINICAL PRESENTATION

History and Physical Examination The clinical hallmark of UA/NSTEMI is chest pain, typically located in the substernal region or sometimes in the epigastrium, that radiates to the neck, left shoulder, and left arm (Chap. 13). This discomfort is usually severe enough to be considered painful. Anginal "equivalents" such as dyspnea and epigastric discomfort may also occur, and these appear to occur more often in women. The examination resembles that in patients with stable an-

gina (Chap. 237) and may be unremarkable. If the patient has a large area of myocardial ischemia or a large NSTEMI, the physical findings can include diaphoresis, pale cool skin, sinus tachycardia, a third and/or fourth heart sound, basilar rales, and sometimes hypotension, resembling the findings of large STEMI.

Electrocardiogram In UA, ST-segment depression, transient ST-segment elevation, and/or T-wave inversion occur in 30–50% of patients, depending on the severity of the clinical presentation. In patients with the clinical features of UA, the presence of new ST-segment deviation, even of only 0.05 mV, is an important predictor of adverse outcome. T-wave changes are sensitive for ischemia but less specific, unless they are new, deep T-wave inversions (≥0.3 mV).

Cardiac Biomarkers Patients with UA who have elevated biomarkers of necrosis, such as CK-MB and troponin (a much more specific and sensitive marker of myocardial necrosis), are at increased risk for death or recurrent MI. Elevated levels of these markers distinguish patients with NSTEMI from those with UA. There is a direct relationship between the degree of troponin elevation and mortality. However, in patients *without* a clear clinical history of myocardial ischemia, minor troponin elevations have been reported and can be caused by congestive heart failure, myocarditis, or pulmonary embolism, or they may be false-positive readings. Thus, in patients with an *unclear* history, small troponin elevations may not be diagnostic of an ACS.

DIAGNOSTIC EVALUATION

(See also Chap. 13) Approximately 6–7 million persons per year in the United States present to hospital emergency departments (EDs) with a complaint of chest pain or other symptoms suggestive of ACS. A diagnosis of an ACS is established in 20–25% of such patients. The first step in evaluating patients with possible UA/NSTEMI is to determine the *likelihood* that CAD is the cause of the presenting symptoms. The American College of Cardiology/American Heart Association (ACC/AHA) Guidelines include, among the factors associated with a high likelihood of ACS, a clinical history typical of ischemic discomfort, a history of established CAD by angiography, prior MI, congestive heart failure, new electrocardiographic (ECG) changes, or elevated cardiac biomarkers. Factors associated with an intermediate likelihood of ACS in patients with the clinical features of this condition but without the above high-risk factors are: age >70 years, male gender, diabetes mellitus, known peripheral arterial or cerebrovascular disease, and old ECG abnormalities.

Diagnostic Pathways Four major diagnostic tools are used in the diagnosis of UA/NSTEMI in the ED: the clinical history, the ECG, cardiac markers, and stress testing. The goals are to (1) recognize or exclude MI (using cardiac markers), (2) evaluate for rest ischemia (chest pain at rest, serial or continuous ECGs), and (3) evaluate for significant CAD (using provocative stress testing). Typical pathways begin with assessment of the likelihood that the presenting symptoms are due to ischemia. Patients with a low likelihood of ischemia are usually managed with an ED-based critical pathway (which in some institutions is carried out in a "chest pain unit" (Fig. 238-1). Evaluation of such patients includes clinical monitoring for recurrent ischemic discomfort, serial ECGs, and cardiac markers, typically performed at baseline and at 4–6 h and 12 h after presentation. If new elevations in cardiac markers (CK-MB and/or troponin) or ECG changes are noted, the patient is admitted to the hospital. If the patient remains pain-free and the markers are negative, the patient may go on to stress testing. This may be performed as early as 6 h after presentation in the ED or chest pain center, or on an outpatient basis within 72 h. For most patients, standard treadmill ECG stress testing is used, but for patients with fixed abnormalities on the ECG (e.g., left bundle branch block), perfusion or echocardiographic imaging is used. For patients who cannot walk, pharmacologic stress is used. By demonstrating normal myocardial perfusion, sestamibi or thallium imaging can reduce unnecessary hospitalizations by excluding acute ischemia. CT angiography is used with increasing frequency to exclude obstructive CAD (Chap. 222).

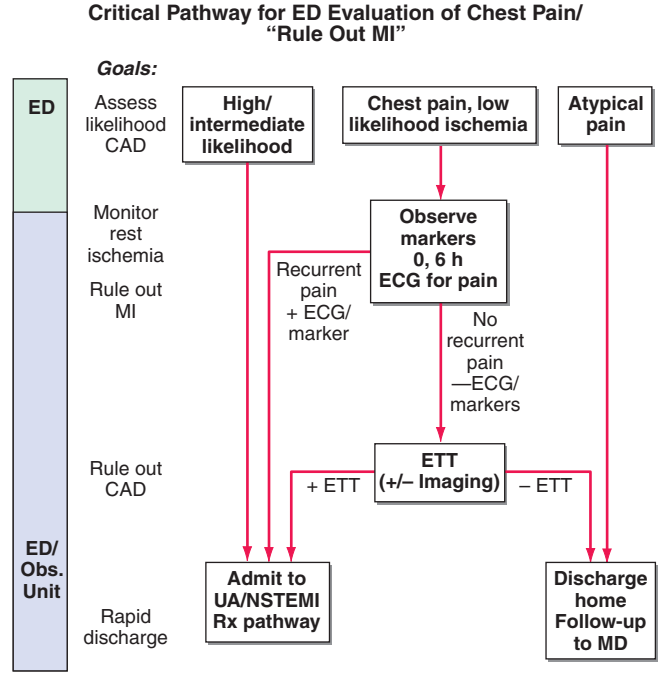

FIGURE 238-1 Diagnostic evaluation of patients presenting with suspected UA/NSTEMI. The first step is to assess the likelihood of coronary artery disease (CAD). Patients at *high* or *intermediate* likelihood are admitted to the hospital. Those with clearly atypical chest pain are sent home. Patients with a *low* likelihood of ischemia enter the pathway and are observed in a monitored bed in the emergency department (ED) or observation unit over a period of 6 h, and 12-lead electrocardiograms are performed if the patient has recurrent chest discomfort. A panel of cardiac markers (e.g., troponin and CK-MB) is drawn at baseline and 6 h later. If the patient develops recurrent pain, has ST-segment or T-wave changes, or has positive cardiac markers, he/she is admitted to the hospital and treated for UA/NSTEMI. If the patient has negative markers and no recurrence of pain, he/she is sent for exercise treadmill testing, with imaging reserved for patients with abnormal baseline electrocardiograms (e.g., left bundle branch block or left ventricular hypertrophy). If positive, the patient is admitted; if negative, the patient is discharged, with follow-up to his/her primary physician. ETT, exercise tolerance test; MI, myocardial infarction. [*Adapted from CP Cannon, E Braunwald, in Heart Disease: A Textbook of Cardiovascular Medicine, 6th ed, E Braunwald et al (eds). Philadelphia, Saunders, 2001.*]

RISK STRATIFICATION AND PROGNOSIS

Patients with documented UA/NSTEMI exhibit a wide spectrum of early (30 days) risk of death, ranging from 1 to 10%, and of new or recurrent infarction of 3–10%. Assessment of "global risk" can be accomplished by clinical risk scoring systems such as that developed from in the Thrombolysis in Myocardial Infarction (TIMI) Trials, which includes seven independent risk factors: age ≥ 65 years, three or more risk factors for CAD, documented CAD at catheterization, development of UA/NSTEMI while on aspirin, more than two episodes of angina within the preceding 24 h, ST deviation ≥0.5 mm, and an elevated cardiac marker (Fig. 238-2). Other risk factors include diabetes mellitus, left ventricular dysfunction, and elevated levels of creatinine, atrial natriuretic peptides, and C-reactive protein.

Early risk assessment (especially using troponin, ST-segment changes, and/or a global risk scoring system) is useful both in predicting the risk of recurrent cardiac events and in identifying those patients who would derive the greatest benefit from antithrombotic therapies more potent than unfractionated heparin, such as low-molecular-weight heparin (LMWH) and glycoprotein (GP)IIb/IIIa inhibitors, and from an early invasive strategy. For example, in the TACTICS-TIMI 18 Trial, an early invasive strategy conferred a 40% reduction in recurrent cardiac events in patients with a positive troponin

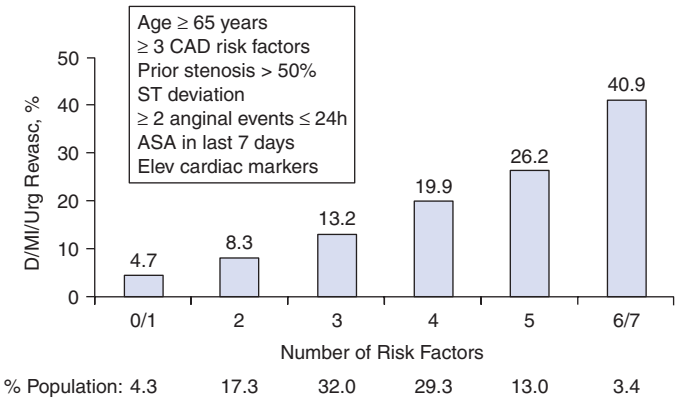

FIGURE 238-2 The TIMI Risk Score for UA/NSTEMI, a simple but comprehensive clinical risk stratification score to identify increasing risk of death, myocardial infarction, or urgent revascularization to day 14. CAD, coronary artery disease; ASA, aspirin. *(Adapted from Antman et al.)*

level, whereas no benefit was observed in those with a negative troponin level.

C-reactive protein, a marker of vascular inflammation, and B-type natriuretic peptide, a marker of increased myocardial wall tension, correlate independently with increased mortality (and, in some studies, recurrent cardiac events) in patients presenting with UA/NSTEMI. Multimarker strategies are now gaining favor both to define the pathophysiologic mechanisms underlying a given patient's presentation more fully and to stratify the patient's risk further.

Rx UNSTABLE ANGINA AND NON-ST ELEVATION MYOCARDIAL INFARCTION

MEDICAL TREATMENT Patients with UA/NSTEMI should be placed at bed rest with continuous ECG monitoring for ST-segment deviation and cardiac rhythm. Ambulation is permitted if the patient shows no recurrence of ischemia (discomfort or ECG changes) and does not develop a biomarker of necrosis for 12–24 h. Medical therapy involves simultaneous anti-ischemic treatment and antithrombotic treatment.

ANTI-ISCHEMIC TREATMENT (Table 238-1) In order to provide relief and prevention of recurrence of chest pain, initial treatment should include bed rest, nitrates, and beta blockers.

Nitrates Nitrates should first be given sublingually or by buccal spray (0.3–0.6 mg) if the patient is experiencing ischemic pain. If pain persists after three doses given 5 min apart, intravenous nitroglycerin (5–10 μg/min using nonabsorbing tubing) is recommended. The rate of the infusion may be increased by 10 μg/min every 3–5 min until symptoms are relieved or systolic

TABLE 238-1 DRUGS COMMONLY USED IN INTENSIVE MEDICAL MANAGEMENT OF PATIENTS WITH UNSTABLE ANGINA AND NON-ST ELEVATION MI

Drug Category	Clinical Condition	When to Avoid[a]	Dosage
Nitrates	Administer intravenously when symptoms are not fully relieved with three sublingual nitroglycerin tablets and initiation of beta-blocker therapy	Hypotension Patient receiving sildenafil or other PDE-5 inhibitor	5–10 μg/min by continuous infusion Titrated up to 75–100 μg/min until relief of symptoms or limiting side effects (headache or hypotension with a systolic blood pressure <90 mmHg or more than 30% below starting mean arterial pressure levels if significant hypertension is present) Topical, oral, or buccal nitrates are acceptable alternatives for patients without ongoing or refractory symptoms
Beta blockers[b]	Unstable angina	PR interval (ECG) >0.24 s 2° or 3° atrioventricular block Heart rate <60 beats/min Blood pressure <90 mmHg Shock Left ventricular failure with congestive heart failure Severe reactive airway disease	Metoprolol[c] 5-mg increments by slow (over 1–2 min IV administration) Repeated every 5 min for a total initial dose of 15 mg Followed in 1–2 h by 25–50 mg by mouth every 6 h If a very conservative regimen is desired, initial doses can be reduced to 1–2 mg Esmolol[c] Starting maintenance dose of 0.1 mg/kg per min IV Titration in increments of 0.05 mg/kg per min every 10–15 min as tolerated by blood pressure until the desired therapeutic response has been obtained, limiting symptoms develop, or a dose of 0.20 mg/kg per min is reached Optional loading dose of 0.5 mg/kg may be given by slow IV administration (2–5 min) for more rapid onset of action
Calcium channel blockers	Patients whose symptoms are not relieved by adequate doses of nitrates and beta blockers or in patients unable to tolerate adequate doses of one or both of these agents or in patients with variant angina	Pulmonary edema Evidence of left ventricular dysfunction (for diltiazem or verapamil)	Dependent on specific agent
Morphine sulfate	Patients whose symptoms are not relieved after three serial sublingual nitroglycerin tablets or whose symptoms recur with adequate anti-ischemic therapy	Hypotension Respiratory depression Confusion Obtundation	2–5 mg IV dose May be repeated every 5–30 min as needed to relieve symptoms and maintain patient comfort

[a]Allergy or prior intolerance is a contraindication for all categories of drugs listed in this chart.
[b]Choice of the specific agent is not as important as ensuring that appropriate candidates receive this therapy. If there are concerns about patient intolerance owing to existing pulmonary disease, especially asthma, left ventricular dysfunction, risk of hypotension or severe bradycardia, initial selection should favor a short-acting agent, such as propranolol or metoprolol or the ultra-short-acting agent esmolol. Mild wheezing or a history of chronic obstructive pulmonary disease should prompt a trial of a short-acting agent at a reduced dose (e.g., 2.5 mg IV metoprolol, 12.5 mg oral metoprolol, or 25 μg/kg per min esmolol as initial doses) rather than complete avoidance of beta-blocker therapy.
[c]Metoprolol and esmolol are two of several beta blockers that may be employed.
Note: Some of the recommendations in this guide suggest the use of agents for purposes or in doses other than those specified by the U.S. Food and Drug Administration. Such recommendations are made after consideration of concerns regarding nonapproved indications. Where made such recommendations are based on more recent clinical trials or expert consensus.
IV, intravenous; aPTT, activated partial thromboplastin time; ECG, electrocardiogram; 2°, second-degree; 3°, third-degree.

TABLE 238-2 CLINICAL USE OF ANTITHROMBOTIC THERAPY

Oral Antiplatelet Therapy	
Aspirin	Initial dose of 162–325 mg nonenteric formulation followed by 75–162 mg/d of an enteric or a nonenteric formulation
Clopidogrel (Plavix)	Loading dose of 300 mg followed by 75 mg/d
Intravenous Antiplatelet Therapy	
Abciximab (ReoPro)	0.25 mg/kg bolus followed by infusion of 0.125 μg/kg per min (maximum 10 μg/min) for 12 to 24 h
Eptifibatide (Integrilin)	180 μg/kg bolus followed by infusion of 2.0 μg/kg per min for 72 to 96 h
Tirofiban (Aggrastat)	0.4 μg/kg per min for 30 min followed by infusion of 0.1 μg/kg per min for 48 to 96 h
Heparins[a]	
Heparin (UFH)	Bolus 60–70 U/kg (maximum 5000 U) IV followed by infusion of 12–15 U/kg per h (initial maximum 1000 U/h) titrated to a PTT 50–70 s
Enoxaparin (Lovenox)	1 mg/kg SC every 12 h; the first dose may be preceded by a 30-mg IV bolus; renal adjustment to 1 mg/kg once daily if creatine Cl < 30 cc/min
Fondaparinux	2.5 mg SQ qd
Bivalirudin	Initial bolus intravenous bolus of 0.1 mg/kg and an infusion of 0.25 mg/kg per hour. Before PCI, an additional intravenous bolus of 0.5 mg/kg was administered, and the infusion was increased to 1.75 mg/kg per hour.

[a]Other LMWH exist beyond those listed.
Note: IV, intravenous; SC, subcutaneously; UFH, unfractionated heparin.
Source: Modified from E Braunwald et al: J Am Coll Cardiol 2000;36:970–1056.

arterial pressure falls to <100 mmHg. Topical or oral nitrates (Chap. 237) can be used once the pain has resolved, or they may replace intravenous nitroglycerin when the patient has been pain-free for 12–24 h. The only absolute contraindications to the use of nitrates are hypotension or the use of sildenafil (Viagra) or other drugs in that class within the previous 24 h.

β-Adrenergic Blockade These agents are the other mainstay of antiischemic treatment. Intravenous beta blockade followed by oral beta blockade targeted to a heart rate of 50–60 beats/min is recommended. Heart rate–slowing calcium channel blockers, e.g., verapamil or diltiazem, are recommended in patients who have persistent or recurrent symptoms after treatment with full-dose nitrates and beta blockers and in patients with contraindications to beta blockade. Additional medical therapy includes angiotensin-converting enzyme (ACE) inhibition and HMG-CoA reductase inhibitors (statins) for long-term secondary prevention.

If pain persists despite intravenous nitroglycerin and beta blockade, morphine sulfate, 1–5 mg intravenously, can be administered every 5–30 min as needed.

ANTITHROMBOTIC THERAPY **(Table 238-2)** This is the other main component of treatment for UA/NSTEMI. Initial treatment should begin with the platelet cyclooxygenase inhibitor aspirin **(Fig. 238-3)**. The typical initial dose is 325 mg daily, with lower doses (75–162 mg daily) recommended for long-term therapy. "Aspirin resistance" has been noted in research studies in 5–10% of patients and more frequently in patients treated with lower doses of aspirin. No clear guidelines are available regarding evaluation or treatment, but the use of higher doses of aspirin and/or a thienopyridine (clopidogrel) appears to be logical in this situation.

The thienopyridine clopidogrel, which blocks the platelet $P2Y_{12}$ (adenosine) receptor (in combination with aspirin), was shown in the CURE trial to confer a 20% relative reduction in cardiovascular death, MI, or stroke, compared with aspirin alone in both low- and high-risk patients with UA/NSTEMI, but to be associated with a moderate (absolute 1%) increase in major bleeding, which is more common in patients who undergo coronary artery bypass grafting. Pretreatment with clopidogrel (a 300 or 600 mg loading dose, followed by 75 mg qd) has also been shown in three studies to reduce adverse outcomes associated with and following PCI and has a Class I, Grade A evidence recommendation in the PCI Guidelines (Chap. 240). Continued benefit of long-term (~1 year) treatment with the combination of clopidogrel and aspirin has been observed both in patients treated conservatively and in those who underwent a PCI. This combination is recommended for all patients with UA/NSTEMI who are not at excessive risk for bleeding.

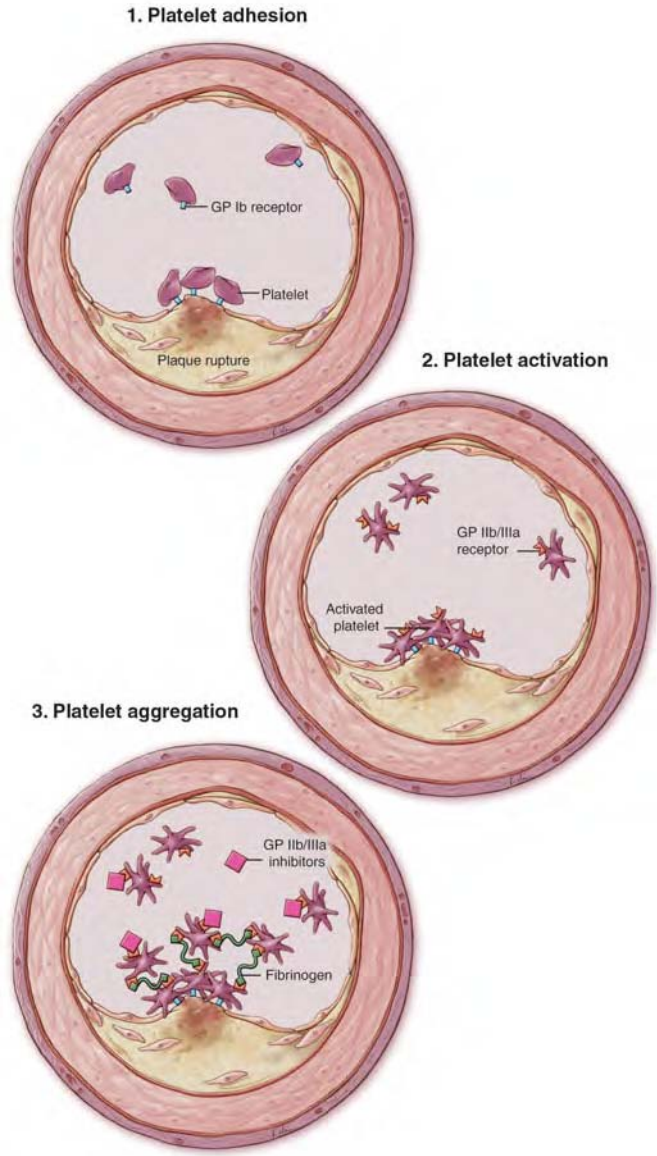

FIGURE 238-3 Platelets initiate thrombosis at the site of a ruptured plaque with denuded endothelium: *platelet adhesion* occurs via (1) the GP 1b receptor in conjunction with von Willebrand factor. This is followed by *platelet activation* (2), which leads to a shape change in the platelet, degranulation of the alpha and dense granules, and expression of glycoprotein IIb/IIIa receptors on the platelet surface with activation of the receptor, such that it can bind fibrinogen. The final step is *platelet aggregation* (3), in which fibrinogen (or von Willebrand factor) binds to the activated GP IIb/IIIa receptors. Aspirin (ASA) and clopidogrel act to decrease platelet activation, whereas the GP IIb/IIIa inhibitors inhibit the final step of platelet aggregation. GP, glycoprotein. [*Modified from CP Cannon, E Braunwald, in Heart Disease: A Textbook of Cardiovascular Medicine, 8th ed, P Libby et al (eds). Philadelphia, Saunders, 2008.*]

Four options are available for anticoagulation therapy to be added to aspirin and clopidogrel. Unfractionated heparin (UFH) is the mainstay of therapy. The LMWH enoxaparin has been shown in several studies to be superior to UFH in reducing recurrent cardiac events, especially in conservatively managed patients. The Factor Xa inhibitor fondaparinux is equivalent for early efficacy compared with enoxaparin but appears to have a lower risk of major bleeding and thus may have the best benefit risk ratio. However, UFH, LMWH, or a direct thrombin inhibitor such as bivalirudin should be used during cardiac catheterization or PCI. Preliminary data indi-

cate that bivalirudin is equivalent (for both efficacy and safety) to either UFH or enoxaparin among patients treated with a GP IIb/IIIa inhibitor, but use of bivalirudin alone had less bleeding than the combination of a heparin and GP IIb/IIIa inhibitor in patients with UA/NSTEMI undergoing PCI.

Intravenous GP IIb/IIIa inhibitors have also been shown to be beneficial in treating UA/NSTEMI. For "upstream" management of high-risk patients in whom an invasive management is intended (i.e., initiating therapy when the patient first presents to the hospital), the small molecule inhibitors eptifibatide and tirofiban show benefit, while the monoclonal antibody abciximab appears not to be effective in patients treated conservatively, (i.e., in those not undergoing coronary angiography or PCI). However, abciximab has been shown to be beneficial in patients with UA/NSTEMI undergoing PCI, even among troponin positive patients pretreated with clopidogrel. The ACC/AHA Guidelines note that these agents can be started either in the ED or during PCI. As with all antithrombotic agents, bleeding is the most important adverse effect of antiplatelet drugs, especially their combination. Thus, patients with a history of bleeding must be screened carefully and given fewer antithrombotic agents.

INVASIVE VERSUS CONSERVATIVE STRATEGY Multiple clinical trials have shown the benefit of an early invasive strategy in high-risk patients, i.e., patients with multiple clinical risk factors, ST-segment deviation, and/or positive biomarkers **(Table 238-3)**. In this strategy, following treatment with anti-ischemic and antithrombotic agents, coronary arteriography is carried out within ~48 h of admission, followed by coronary revascularization (PCI or coronary artery bypass grafting), depending on the coronary anatomy.

In low-risk patients, the outcomes from an invasive strategy are similar to those obtained from a conservative strategy, which consists of anti-ischemic and antithrombotic therapy followed by "watchful waiting," in which coronary arteriography is carried out only if rest pain or ST-segment changes recur or there is evidence of ischemia on a stress test.

LONG-TERM MANAGEMENT

The time of hospital discharge is a "teachable moment" for the patient with UA/NSTEMI, when the physician can review and optimize the medical regimen. Risk factor modification is key, and the physician should discuss with the patient the importance of smoking cessation, achieving optimal weight, daily exercise following an appropriate diet, blood pressure control, tight control of hyperglycemia (for diabetic patients), and lipid management, as recommended for patients with chronic stable angina (Chap. 237).

There is evidence of benefit with long-term therapy with five classes of drugs that are directed at different components of the atherothrombotic process. Beta blockers are appropriate anti-ischemic therapy and may help decrease triggers for MI. Statins (at a high dose, e.g., atorvastatin 80 mg/d) and ACE inhibitors are recommended for long-term plaque stabilization. Antiplatelet therapy, now recommended to be the combination of aspirin and clopidogrel for at least 9–12 months, with aspirin continued thereafter, prevents or reduces the severity of any thrombosis that would occur if a plaque does rupture. Thus, a multifactorial approach to long-term medical therapy is directed at preventing the various components of atherothrombosis. This therapy should be begun early, i.e. within a week of the event, whenever possible.

Observational registries have shown that patients with UA/NSTEMI at high risk, including women and the elderly as well as racial minorities, are less likely to receive evidence-based pharmacologic and interventional therapies with resultant poorer clinical outcomes and quality of life.

PRINZMETAL'S VARIANT ANGINA

In 1959 Prinzmetal et al. described a syndrome of ischemic pain that occurs at rest but not usually with exertion and is associated with transient ST-segment elevation. This syndrome is due to focal spasm of an epicardial coronary artery, leading to severe myocardial ischemia. The exact cause of the spasm is not well defined, but it may be related to hypercontractility of vascular smooth muscle due to vasoconstrictor mitogens, leukotrienes, or serotonin. In some patients it is a manifestation of a vasospastic disorder and is associated with migraine, Raynaud's phenomenon, or aspirin-induced asthma.

TABLE 238-3 CLASS I RECOMMENDATIONS FOR USE OF AN EARLY INVASIVE STRATEGY[a]

Class I (level of evidence: A) indications
Recurrent angina at rest/low-level activity despite Rx
Elevated TnT or TnI
New ST-segment depression
Rec. angina/ischemia with CHF symptoms, rales, MR
Positive stress test
EF < 0.40
Decreased BP
Sustained VT
PCI < 6 months, prior CABG

[a]Any one of the high-risk indicators.
Abbreviations: TnT, troponin T; TnI, troponin I; Rec, recurrent; CHF, congestive heart failure; MR, mitral regurgitation; EF, ejection fraction; BP, blood pressure; VT, ventricular tachycardia; PCI, percutaneous coronary intervention; CABG, coronary artery bypass grafting.
Source: E Braunwald et al: Circulation 106:1893, 2002.

Clinical and Angiographic Manifestations Patients with variant angina are generally younger and have fewer coronary risk factors (with the exception of cigarette smoking) than patients with UA secondary to coronary atherosclerosis. The anginal discomfort is often extremely severe and has usually not progressed from a period of chronic stable angina. Cardiac examination is usually normal in the absence of ischemia.

The clinical diagnosis of variant angina is made with the detection of transient ST-segment *elevation* with rest pain. Many patients also exhibit multiple episodes of asymptomatic ST-segment elevation (*silent ischemia*). Small elevations of CK-MB and troponin may occur in patients with prolonged attacks of variant angina. Exercise testing in patients with variant angina is of limited value because the patients can demonstrate ST elevation, depression, or no ST changes.

Coronary angiography demonstrates transient coronary spasm as the diagnostic hallmark of Prinzmetal's angina. Atherosclerotic plaques, which do not usually cause critical obstruction, in at least one proximal coronary artery occur in the majority of patients, and in them spasm usually occurs within 1 cm of the plaque. Focal spasm is most common in the right coronary artery, and it may occur at one or more sites in one artery or in multiple arteries simultaneously. Ergonovine, acetylcholine, other vasoconstrictor medications, and hyperventilation have been used to provoke and demonstrate focal coronary stenosis to establish the diagnosis. Hyperventilation has also been used to provoke rest angina, ST-segment elevation, and spasm on coronary arteriography.

Rx PRINZMETAL'S VARIANT ANGINA

Nitrates and calcium channel blockers are the main treatments for patients with variant angina. Sublingual or intravenous nitroglycerin often abolishes episodes of variant angina promptly, and long-acting nitrates are useful in preventing recurrences. Calcium antagonists are extremely effective in preventing the coronary artery spasm of variant angina, and they should be prescribed in maximally tolerated doses. Similar efficacy rates have been noted among the various types of calcium antagonists. Prazosin, a selective α-adrenoreceptor blocker, has also been found to be of value in some patients, while aspirin may actually increase the severity of ischemic episodes. The response to beta blockers is variable. Coronary revascularization may be helpful in patients with variant angina who also have discrete, proximal fixed obstructive lesions.

Prognosis Many patients with Prinzmetal's angina pass through an acute, active phase, with frequent episodes of angina and cardiac events during the first 6 months after presentation. Long-term survival at 5 years is excellent (~90–95%). Patients with no or mild fixed coronary obstruction tend to experience a more benign course than do patients with associated severe obstructive lesions. Nonfatal MI occurs in up to 20% of patients by 5 years. Patients with variant angina who develop serious arrhythmias during spontaneous episodes of pain are at a higher risk for

sudden death. In most patients who survive an infarction or the initial 3–6-month period of frequent episodes, the condition stabilizes, and there is a tendency for symptoms and cardiac events to diminish with time.

239 ST-Segment Elevation Myocardial Infarction

Elliott M. Antman, Eugene Braunwald

Acute myocardial infarction (AMI) is one of the most common diagnoses in hospitalized patients in industrialized countries. In the United States, approximately 650,000 patients experience a new AMI and 450,000 experience a recurrent AMI each year. The early (30-day) mortality rate from AMI is ~30%, with more than half of these deaths occurring before the stricken individual reaches the hospital. Although the mortality rate after admission for AMI has declined by ~30% over the past two decades, approximately 1 of every 25 patients who survives the initial hospitalization dies in the first year after AMI. Mortality is approximately fourfold higher in elderly patients (over age 75) compared with younger patients.

When patients with prolonged ischemic discomfort at rest are first seen, the working clinical diagnosis is that they are suffering from an acute coronary syndrome (Fig. 239-1). The 12-lead electrocardiogram (ECG) is a pivotal diagnostic and triage tool since it is at the center of the decision pathway for management. It permits distinction of those patients presenting with ST-segment elevation from those presenting without ST-segment elevation. Serum cardiac biomarkers are obtained to distinguish unstable angina (UA) from non-ST-segment MI (NSTEMI) and to assess the magnitude of an ST-segment elevation MI (STEMI). This chapter focuses on the evaluation and management of patients with STEMI, while Chapter 238 discusses UA/NSTEMI.

PATHOPHYSIOLOGY: ROLE OF ACUTE PLAQUE RUPTURE

STEMI usually occurs when coronary blood flow decreases abruptly after a thrombotic occlusion of a coronary artery previously affected by atherosclerosis. Slowly developing, high-grade coronary artery stenoses do not typically precipitate STEMI because of the development of a rich collateral network over time. Instead, STEMI occurs when a coronary artery thrombus develops rapidly at a site of vascular injury. This injury is produced or facilitated by factors such as cigarette smoking, hypertension, and lipid accumulation. In most cases, STEMI occurs when the surface of an atherosclerotic plaque becomes disrupted (exposing its contents to the blood) and conditions (local or systemic) favor thrombogenesis. A mural thrombus forms at the site of plaque disruption, and the involved coronary artery becomes occluded. Histologic studies indicate that the coronary plaques prone to disruption are those with a rich lipid core and a thin fibrous cap (Chap. 235). After an initial platelet monolayer forms at the site of the disrupted plaque, various agonists (collagen, ADP, epinephrine, serotonin) promote platelet activation. After agonist stimulation of platelets, thromboxane A_2 (a potent local vasoconstrictor) is released, further platelet activation occurs, and potential resistance to fibrinolysis develops.

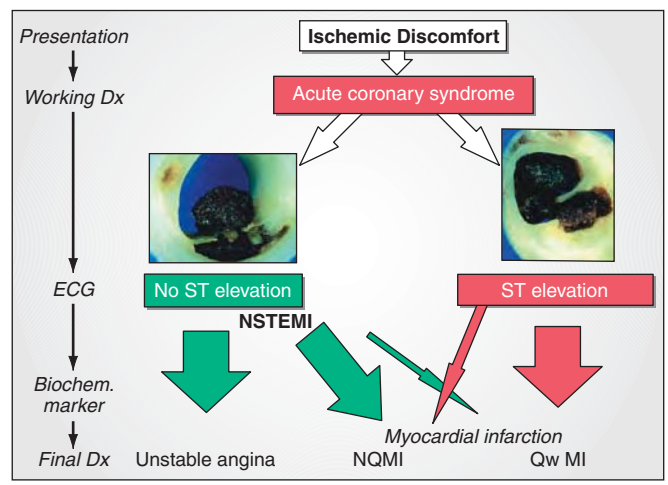

FIGURE 239-1 Acute coronary syndromes. Following disruption of a vulnerable plaque, patients experience ischemic discomfort resulting from a reduction of flow through the affected epicardial coronary artery. The flow reduction may be caused by a completely occlusive thrombus (***right***) or subtotally occlusive thrombus (***left***). Patients with ischemic discomfort may present with or without ST-segment elevation. Of patients with ST-segment elevation, the majority (*wide red arrow*) ultimately develop a Q-wave on the ECG (QwMI), while a minority (*thin red arrow*) do not develop Q-wave and in older literature where said to have sustained a non-Q-wave MI (NQMI). Patients who present without ST-segment elevation are suffering from either unstable angina or a non-ST-segment elevation MI (NSTEMI) (*wide green arrows*), a distinction that is ultimately made on the presence or absence of a serum cardiac marker such as CKMB or a cardiac troponin detected in the blood. The majority of patients presenting with NSTEMI do not develop a Q-wave on the ECG; a minority develop a QwMI *(thin green arrow)*. (*Adapted from CW Hamm et al: Lancet 358:1533, 2001, and MJ Davies: Heart 83:361, 2000; with permission from the BMJ Publishing Group.*)

In addition to the generation of thromboxane A_2, activation of platelets by agonists promotes a conformational change in the glycoprotein IIb/IIIa receptor (Chap. 109). Once converted to its functional state, this receptor develops a high affinity for amino acid sequences on soluble adhesive proteins (i.e., integrins) such as fibrinogen. Since fibrinogen is a multivalent molecule, it can bind to two different platelets simultaneously, resulting in platelet cross-linking and aggregation.

The coagulation cascade is activated on exposure of tissue factor in damaged endothelial cells at the site of the disrupted plaque. Factors

VII and X are activated, ultimately leading to the conversion of prothrombin to thrombin, which then converts fibrinogen to fibrin (Chap. 110). Fluid-phase and clot-bound thrombin participate in an autoamplification reaction leading to further activation of the coagulation cascade. The culprit coronary artery eventually becomes occluded by a thrombus containing platelet aggregates and fibrin strands.

In rare cases STEMI may be due to coronary artery occlusion caused by coronary emboli, congenital abnormalities, coronary spasm, and a wide variety of systemic—particularly inflammatory—diseases. The amount of myocardial damage caused by coronary occlusion depends on (1) the territory supplied by the affected vessel, (2) whether or not the vessel becomes totally occluded, (3) the duration of coronary occlusion, (4) the quantity of blood supplied by collateral vessels to the affected tissue, (5) the demand for oxygen of the myocardium whose blood supply has been suddenly limited, (6) native factors that can produce early spontaneous lysis of the occlusive thrombus, and (7) the adequacy of myocardial perfusion in the infarct zone when flow is restored in the occluded epicardial coronary artery.

Patients at increased risk of developing STEMI include those with multiple coronary risk factors (Chap. 235) and those with unstable angina (Chap. 238). Less common underlying medical conditions predisposing patients to STEMI include hypercoagulability, collagen vascular disease, cocaine abuse, and intracardiac thrombi or masses that can produce coronary emboli.

CLINICAL PRESENTATION

In up to one-half of cases, a precipitating factor appears to be present before STEMI, such as vigorous physical exercise, emotional stress, or a medical or surgical illness. Although STEMI may commence at any time of the day or night, circadian variations have been reported such that clusters are seen in the morning within a few hours of awakening.

Pain is the most common presenting complaint in patients with STEMI. The pain is deep and visceral; adjectives commonly used to describe it are *heavy*, *squeezing*, and *crushing*, although occasionally it is described as stabbing or burning (Chap. 13). It is similar in character to the discomfort of angina pectoris (Chap. 237) but commonly occurs at rest, is usually more severe, and lasts longer. Typically the pain involves the central portion of the chest and/or the epigastrium, and on occasion it radiates to the arms. Less common sites of radiation include the abdomen, back, lower jaw, and neck. The frequent location of the pain beneath the xiphoid and epigastrium and the patients' denial that they may be suffering a heart attack are chiefly responsible for the common mistaken impression of indigestion. The pain of STEMI may radiate as high as the occipital area but not below the umbilicus. It is often accompanied by weakness, sweating, nausea, vomiting, anxiety, and a sense of impending doom. The pain may commence when the patient is at rest, but when it begins during a period of exertion, it does not usually subside with cessation of activity, in contrast to angina pectoris.

The pain of STEMI can simulate pain from acute pericarditis (Chap. 232), pulmonary embolism (Chap. 256), acute aortic dissection (Chap. 242), costochondritis, and gastrointestinal disorders. These conditions should therefore be considered in the differential diagnosis. Radiation of discomfort to the trapezius is not seen in patients with STEMI and may be a useful distinguishing feature that suggests pericarditis is the correct diagnosis. However, *pain is not uniformly present in patients with STEMI.* The proportion of painless STEMIs is greater in patients with diabetes mellitus, and it increases with age. In the elderly, STEMI may present as sudden-onset breathlessness, which may progress to pulmonary edema. Other less common presentations, with or without pain, include sudden loss of consciousness, a confusional state, a sensation of profound weakness, the appearance of an arrhythmia, evidence of peripheral embolism, or merely an unexplained drop in arterial pressure.

PHYSICAL FINDINGS

Most patients are anxious and restless, attempting unsuccessfully to relieve the pain by moving about in bed, altering their position, and stretching. Pallor associated with perspiration and coolness of the extremities occurs commonly. The combination of substernal chest pain persisting for >30 min and diaphoresis strongly suggests STEMI. Although many patients have a normal pulse rate and blood pressure within the first hour of STEMI, about one-fourth of patients with anterior infarction have manifestations of sympathetic nervous system hyperactivity (tachycardia and/or hypertension), and up to one-half with inferior infarction show evidence of parasympathetic hyperactivity (bradycardia and/or hypotension).

The precordium is usually quiet, and the apical impulse may be difficult to palpate. In patients with anterior wall infarction, an abnormal systolic pulsation caused by dyskinetic bulging of infarcted myocardium may develop in the periapical area within the first days of the illness and then may resolve. Other physical signs of ventricular dysfunction include fourth and third heart sounds, decreased intensity of the first heart sound, and paradoxical splitting of the second heart sound (Chap. 220). A transient midsystolic or late systolic apical systolic murmur due to dysfunction of the mitral valve apparatus may be present. A pericardial friction rub is heard in many patients with transmural STEMI at some time in the course of the disease, if they are examined frequently. The carotid pulse is often decreased in volume, reflecting reduced stroke volume. Temperature elevations up to 38°C may be observed during the first week after STEMI. The arterial pressure is variable; in most patients with transmural infarction, systolic pressure declines by approximately 10–15 mmHg from the preinfarction state.

LABORATORY FINDINGS

Myocardial infarction (MI) progresses through the following temporal stages: (1) acute (first few hours–7 days), (2) healing (7–28 days), and (3) healed (≥29 days). When evaluating the results of diagnostic tests for STEMI, the temporal phase of the infarction must be considered. The laboratory tests of value in confirming the diagnosis may be divided into four groups: (1) ECG, (2) serum cardiac biomarkers, (3) cardiac imaging, and (4) nonspecific indices of tissue necrosis and inflammation.

ELECTROCARDIOGRAM

The electrocardiographic manifestations of STEMI are described in Chap. 221. During the initial stage, total occlusion of an epicardial coronary artery produces ST-segment elevation. Most patients initially presenting with ST-segment elevation ultimately evolve Q waves on the ECG (Fig. 239-1; see Fig. 221-13). However, Q waves in the leads overlying the infarct zone may vary in magnitude and even appear only transiently, depending on the reperfusion status of the ischemic myocardium and restoration of transmembrane potentials over time. A small proportion of patients initially presenting with ST-segment elevation will not develop Q waves when the obstructing thrombus is not totally occlusive, obstruction is transient, or if a rich collateral network is present. Among patients presenting with ischemic discomfort but *without* ST-segment elevation, if a serum cardiac biomarker of necrosis (see below) is detected, the diagnosis of NSTEMI is ultimately made (Fig. 239-1). A minority of patients who present initially without ST-segment elevation may develop a Q-wave MI. Previously it was believed that transmural MI is present if the ECG demonstrates Q waves or loss of R waves, and nontransmural MI may be present if the ECG shows only transient ST-segment and T-wave changes. However, electrocardiographic-pathologic correlations are far from perfect and terms such as *Q-wave MI, non-Q-wave MI, transmural MI,* and *nontransmural MI*, have been replaced by STEMI and NSTEMI (Fig. 239-1).

SERUM CARDIAC BIOMARKERS

Certain proteins, called serum cardiac biomarkers, are released from necrotic heart muscle after STEMI. The rate of liberation of specific proteins differs depending on their intracellular location, their molecular weight, and the local blood and lymphatic flow. Cardiac biomarkers become detectable in the peripheral blood once the capacity of the cardiac lymphatics to clear the interstitium of the infarct zone is exceeded and spillover into the venous circulation occurs. The temporal pattern of protein release is of diagnostic importance, but contempo-

rary urgent reperfusion strategies necessitate making a decision (based largely on a combination of clinical and ECG findings) before the results of blood tests have returned from the laboratory. Rapid whole-blood bedside assays for serum cardiac markers are now available and may facilitate management decisions, particularly in patients with nondiagnostic ECGs.

Cardiac-specific troponin T (cTnT) and *cardiac-specific troponin I* (cTnI) have amino acid sequences different from those of the skeletal muscle forms of these proteins. These differences permitted the development of quantitative assays for cTnT and cTnI with highly specific monoclonal antibodies. Since cTnT and cTnI are not normally detectable in the blood of healthy individuals but may increase after STEMI to levels >20 times higher than the upper reference limit (the highest value seen in 99% of a reference population not suffering from MI), the measurement of cTnT or cTnI is of considerable diagnostic usefulness, and they are now the preferred biochemical markers for MI (Fig. 239-2). The cardiac troponins are particularly valuable when there is clinical suspicion of either skeletal muscle injury or a small MI that may be below the detection limit for CK and CKMB measurements, and they are therefore of particular value in distinguishing UA from NSTEMI. Levels of cTnI and cTnT may remain elevated for 7–10 days after STEMI.

Creatine phosphokinase (CK) rises within 4–8 h and generally returns to normal by 48–72 h (Fig. 239-2). An important drawback of total CK measurement is its lack of specificity for STEMI, as CK may be elevated with skeletal muscle disease or trauma, including intramuscular injection. The MB isoenzyme of CK has the advantage over total CK that it is not present in significant concentrations in extracardiac tissue and therefore is considerably more specific. However, cardiac surgery, myocarditis, and electrical cardioversion often result in elevated serum levels of the MB isoenzyme. A ratio (relative index) of CKMB mass:CK activity ≥2.5 suggests but is not diagnostic of a myocardial rather than a skeletal muscle source for the CKMB elevation.

Many hospitals are using cTnT or cTnI rather than CKMB as the routine serum cardiac marker for diagnosis of STEMI, although any of these analytes remains clinically acceptable. It is *not* cost-effective to measure both a cardiac-specific troponin and CKMB at all time points in every patient.

While it has long been recognized that the total quantity of protein released correlates with the size of the infarct, the peak protein concentration correlates only weakly with infarct size. Recanalization of a coronary artery occlusion (either spontaneously or by mechanical or pharmacologic means) in the early hours of STEMI causes earlier and higher peaking (at about 8–12 h after reperfusion) of serum cardiac biomarkers (Fig. 239-2) because of a rapid washout from the interstitium of the infarct zone, quickly overwhelming lymphatic clearance of the proteins.

The *nonspecific reaction* to myocardial injury is associated with polymorphonuclear leukocytosis, which appears within a few hours after the onset of pain and persists for 3–7 days; the white blood cell count often reaches levels of 12,000–15,000/μL. The erythrocyte sedimentation rate rises more slowly than the white blood cell count, peaking during the first week and sometimes remaining elevated for 1 or 2 weeks.

CARDIAC IMAGING

Abnormalities of wall motion on *two-dimensional echocardiography* (Chap. 222) are almost universally present. Although acute STEMI cannot be distinguished from an old myocardial scar or from acute severe ischemia by echocardiography, the ease and safety of the procedure make its use appealing as a screening tool in the Emergency Department setting. When the ECG is not diagnostic of STEMI, early detection of the presence or absence of wall motion abnormalities by echocardiography can aid in management decisions, such as whether the patient should receive reperfusion therapy [e.g., fibrinolysis or a percutaneous coronary intervention (PCI)]. Echocardiographic estimation of left ventricular (LV) function is useful prognostically; detection of reduced function serves as an indication for therapy with an inhibitor of the renin-angiotensin-aldosterone system. Echocardiography may also identify the presence of right ventricular (RV) infarction, ventricular aneurysm, pericardial effusion, and LV thrombus. In addition, Doppler echocardiography is useful in the detection and quantitation of a ventricular septal defect and mitral regurgitation, two serious complications of STEMI.

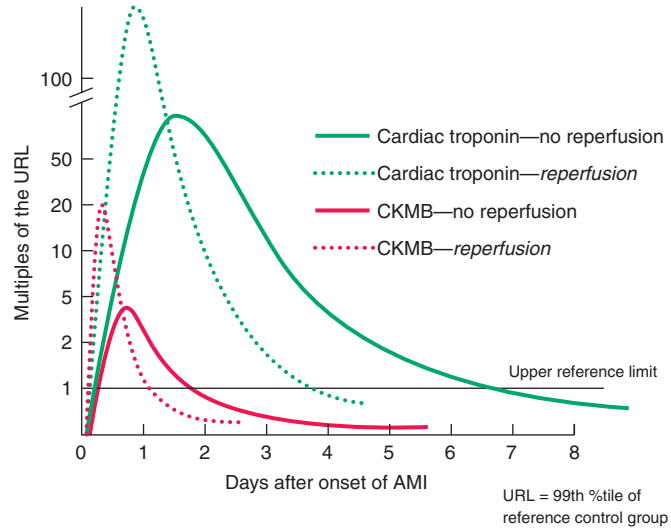

FIGURE 239-2 Typical cardiac biomarkers that are used to evaluate patients with STEMI include the MB isoenzyme of CK (CKMB) and cardiac-specific troponins. The black horizontal line depicts the upper reference limit (URL) for the cardiac biomarker in the clinical chemistry laboratory. The kinetics of release of CKMB and cardiac troponin in patients who do not undergo reperfusion are shown in the solid green and red curves as multiples of the URL. When patients with STEMI undergo reperfusion, as depicted in the dashed green and red curves, the cardiac biomarkers are detected sooner, rise to a higher peak value, but decline more rapidly, resulting in a smaller area under the curve and limitation of infarct size. (*Adapted from JS Alpert et al: J Am Coll Cardiol 36:959, 2000, and AH Wu et al: Clin Chem 45:1104, 1999.*)

Several *radionuclide imaging techniques* (Chap. 222) are available for evaluating patients with suspected STEMI. However, these imaging modalities are used less often than echocardiography because they are more cumbersome and lack sensitivity and specificity in many clinical circumstances. Myocardial perfusion imaging with ^{201}Tl or ^{99m}Tc-sestamibi, which are distributed in proportion to myocardial blood flow and concentrated by viable myocardium (Chap. 237), reveal a defect ("cold spot") in most patients during the first few hours after development of a transmural infarct. Although perfusion scanning is extremely sensitive, it cannot distinguish acute infarcts from chronic scars and thus is not specific for the diagnosis of *acute* MI. Radionuclide ventriculography, carried out with ^{99m}Tc-labeled red blood cells, frequently demonstrates wall motion disorders and reduction in the ventricular ejection fraction in patients with STEMI. While of value in assessing the hemodynamic consequences of infarction and in aiding in the diagnosis of RV infarction when the RV ejection fraction is depressed, this technique is nonspecific, as many cardiac abnormalities other than MI alter the radionuclide ventriculogram.

Myocardial infarction can be detected accurately with high-resolution cardiac magnetic resonance imaging (Chap. 222) using a technique referred to as late enhancement. A standard imaging agent (gadolinium) is administered and images are obtained after a 10-min delay. Since little gadolinium enters normal myocardium where there are tightly packed myocytes, but does percolate into the expanded intercellular region of the infarct zone, there is a bright signal in areas of infarction that appears in stark contrast to the dark areas of normal myocardium.

INITIAL MANAGEMENT

PREHOSPITAL CARE

The prognosis in STEMI is largely related to the occurrence of two general classes of complications: (1) electrical complications (arrhythmias) and (2) mechanical complications ("pump failure"). Most out-

of-hospital deaths from STEMI are due to the sudden development of ventricular fibrillation. The vast majority of deaths due to ventricular fibrillation occur within the first 24 h of the onset of symptoms, and of these, over half occur in the first hour. Therefore, the major elements of prehospital care of patients with suspected STEMI include (1) recognition of symptoms by the patient and prompt seeking of medical attention; (2) rapid deployment of an emergency medical team capable of performing resuscitative maneuvers, including defibrillation; (3) expeditious transportation of the patient to a hospital facility that is continuously staffed by physicians and nurses skilled in managing arrhythmias and providing advanced cardiac life support; and (4) expeditious implementation of reperfusion therapy (Fig. 239-3). The biggest delay usually occurs not during transportation to the hospital but rather between the onset of pain and the patient's decision to call for help. This delay can best be reduced by health care professionals educating the public concerning the significance of chest discomfort and the importance of seeking early medical attention. Regular office visits with patients having a history of or who are at risk for ischemic heart disease are important "teachable moments" for clinicians to review the symptoms of STEMI and the appropriate action plan.

Increasingly, monitoring and treatment are carried out by trained personnel in the ambulance, further shortening the time between the onset of the infarction and appropriate treatment. General guidelines for initiation of fibrinolysis in the prehospital setting include the ability to transmit 12-lead ECGs to confirm the diagnosis, the presence of paramedics in the ambulance, training of paramedics in the interpretation of ECGs and management of STEMI, and online medical command and control that can authorize the initiation of treatment in the field.

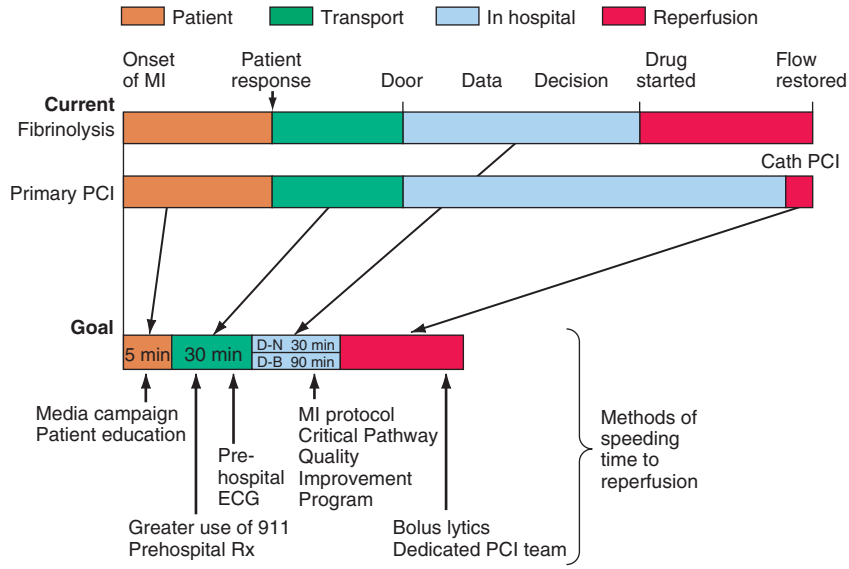

FIGURE 239-3 Major components of time delay between onset of symptoms from STEMI and restoration of flow in the infarct-related artery. Plotted sequentially from left to right are shown the times for patients to recognize symptoms and seek medical attention, transportation to the hospital, in-hospital decision-making, implementation of reperfusion strategy, and restoration of flow once the reperfusion strategy has been initiated. The time to initiate fibrinolytic therapy is the "door-to-needle" (D-N) time; this is followed by the period of time required for pharmacologic restoration of flow. More time is required to move the patient to the catheterization laboratory for a percutaneous coronary interventional (PCI) procedure, referred to as the "door-to-balloon" (D-B) time, but restoration of flow in the epicardial infarct-related artery occurs promptly after PCI. At the bottom are shown a variety of methods for speeding the time to reperfusion along with the goals for the time intervals for the various components of the time delay. (*Adapted from CP Cannon et al: J Thromb Thrombol 1:27, 1994.*)

MANAGEMENT IN THE EMERGENCY DEPARTMENT

In the Emergency Department, the goals for the management of patients with suspected STEMI include control of cardiac discomfort, rapid identification of patients who are candidates for urgent reperfusion therapy, triage of lower-risk patients to the appropriate location in the hospital, and avoidance of inappropriate discharge of patients with STEMI. Many aspects of the treatment of STEMI are initiated in the Emergency Department and then continued during the in-hospital phase of management.

Aspirin is essential in the management of patients with suspected STEMI and is effective across the entire spectrum of acute coronary syndromes (Fig. 239-1). Rapid inhibition of cyclooxygenase-1 in platelets followed by a reduction of thromboxane A_2 levels is achieved by buccal absorption of a chewed 160–325 mg tablet in the Emergency Department. This measure should be followed by daily oral administration of aspirin in a dose of 75–162 mg.

In patients whose arterial O_2 saturation is normal, supplemental O_2 is of limited if any clinical benefit and therefore is not cost-effective. However, when hypoxemia is present, O_2 should be administered by nasal prongs or face mask (2–4 L/min) for the first 6–12 h after infarction; the patient should then be reassessed to determine if there is a continued need for such treatment.

CONTROL OF DISCOMFORT

Sublingual *nitroglycerin* can be given safely to most patients with STEMI. Up to three doses of 0.4 mg should be administered at about 5-min intervals. In addition to diminishing or abolishing chest discomfort, nitroglycerin may be capable of both decreasing myocardial oxygen demand (by lowering preload) and increasing myocardial oxygen supply (by dilating infarct-related coronary vessels or collateral vessels). In patients whose initially favorable response to sublingual nitroglycerin is followed by the return of chest discomfort, particularly if accompanied by other evidence of ongoing ischemia such as further ST-segment or T-wave shifts, the use of intravenous nitroglycerin should be considered. Therapy with nitrates should be avoided in patients who present with low systolic arterial pressure (<90 mmHg) or in whom there is clinical suspicion of right ventricular infarction (inferior infarction on ECG, elevated jugular venous pressure, clear lungs, and hypotension). Nitrates should not be administered to patients who have taken the phosphodiesterase-5 inhibitor sildenafil for erectile dysfunction within the preceding 24 h since it may potentiate the hypotensive effects of nitrates. An idiosyncratic reaction to nitrates, consisting of sudden marked hypotension, sometimes occurs but can usually be reversed promptly by the rapid administration of intravenous atropine.

Morphine is a very effective analgesic for the pain associated with STEMI. However, it may reduce sympathetically mediated arteriolar and venous constriction, and the resulting venous pooling may reduce cardiac output and arterial pressure. These hemodynamic disturbances usually respond promptly to elevation of the legs, but in some patients volume expansion with intravenous saline is required. The patient may experience diaphoresis and nausea, but these events usually pass and are replaced by a feeling of well-being associated with the relief of pain. Morphine also has a vagotonic effect and may cause bradycardia or advanced degrees of heart block, particularly in patients with posteroinferior infarction. These side effects usually respond to atropine (0.5 mg intravenously). Morphine is routinely administered by repetitive (every 5 min) intravenous injection of small doses (2–4 mg) rather than by the subcutaneous administration of a larger quantity, because absorption may be unpredictable by the latter route.

Intravenous *beta blockers* are also useful in the control of the pain of STEMI. These drugs control pain effectively in some patients, presum-

ably by diminishing myocardial O_2 demand and hence ischemia. More important, there is evidence that intravenous beta blockers reduce the risks of reinfarction and ventricular fibrillation (see "Beta-Adrenoceptor Blockers," below). A commonly employed regimen is metoprolol, 5 mg every 2–5 min for a total of 3 doses, provided the patient has a heart rate >60 beats per minute (bpm), systolic pressure >100 mmHg, a PR interval <0.24 s, and rales that are no higher than 10 cm up from the diaphragm. Fifteen minutes after the last intravenous dose, an oral regimen is initiated of 50 mg every 6 h for 48 h, followed by 100 mg every 12 h.

Unlike beta blockers, calcium antagonists are of little value in the acute setting, and there is evidence that short-acting dihydropyridines may be associated with an increased mortality risk.

MANAGEMENT STRATEGIES

The primary tool for screening patients and making triage decisions is the initial 12-lead ECG. When ST-segment elevation of at least 2 mm in two contiguous precordial leads and 1 mm in two adjacent limb leads is present, a patient should be considered a candidate for *reperfusion therapy* (Fig. 239-4). The process of selecting patients for fibrinolysis versus primary PCI (angioplasty, or stenting; Chap. 240) is discussed below. In the absence of ST-segment elevation, fibrinolysis is not helpful, and evidence exists suggesting that it may be harmful.

LIMITATION OF INFARCT SIZE

The quantity of myocardium that becomes necrotic as a consequence of a coronary artery occlusion is determined by factors other than just the site of occlusion. While the central zone of the infarct contains necrotic tissue that is irretrievably lost, the fate of the surrounding ischemic myocardium may be improved by timely restoration of coronary perfusion, reduction of myocardial O_2 demands, prevention of the accumulation of noxious metabolites, and blunting of the impact of mediators of reperfusion injury (e.g., calcium overload and oxygen-derived free radicals). Up to one-third of patients with STEMI may achieve *spontaneous* reperfusion of the infarct-related coronary artery within 24 h and experience improved healing of infarcted tissue. Reperfusion, either pharmacologically (by fibrinolysis) or by PCI, accelerates the opening of infarct-related arteries in those patients in whom spontaneous fibrinolysis ultimately would have occurred and also greatly increases the number of patients in whom restoration of flow in the infarct-related artery is accomplished. Timely restoration of flow in the epicardial infarct–related artery combined with improved perfusion of the downstream zone of infarcted myocardium results in a limitation of infarct size. Protection of the ischemic myocardium by the maintenance of an optimal balance between myocardial O_2 supply and demand through pain control, treatment of congestive heart failure (CHF), and minimization of tachycardia and

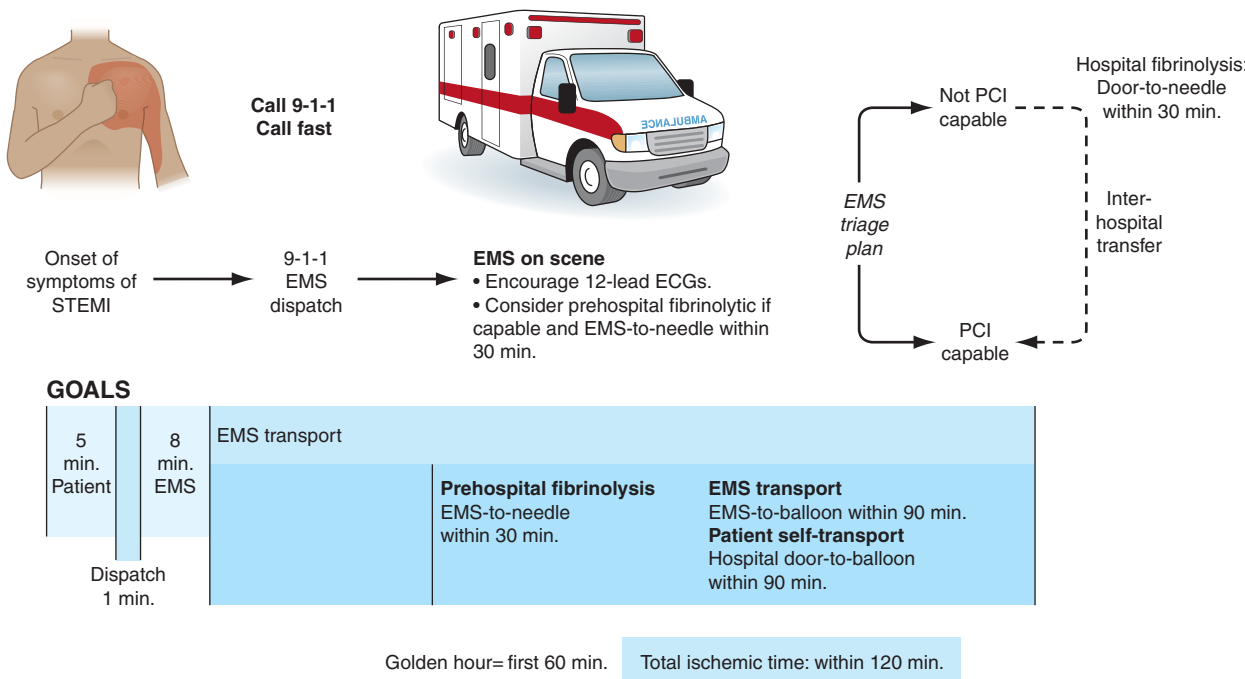

FIGURE 239-4 Options for transportation of patients with STEMI and initial reperfusion treatment. Patient transported by EMS after calling 911: Reperfusion in patients with STEMI can be accomplished by the pharmacologic (fibrinolysis) or catheter-based (primary PCI) approaches. Implementation of these strategies varies based on the mode of transportation of the patient and capabilities at the receiving hospital. Transport time to the hospital is variable from case to case, but the goal is to keep total ischemic time within 120 min. There are three possibilities. (1) If EMS has fibrinolytic capability and the patient qualifies for therapy, prehospital fibrinolysis should be started within 30 min of EMS arrival on scene. (2) If EMS is not capable of administering prehospital fibrinolysis and the patient is transported to a non–PCI-capable hospital, the hospital door-to-needle time should be within 30 min for patients in whom fibrinolysis is indicated. (3) If EMS is not capable of administering prehospital fibrinolysis and the patient is transported to a PCI-capable hospital, the hospital door-to-balloon time should be within 90 min. *Interhospital transfer*: It is also appropriate to consider emergency interhospital transfer of the patient to a PCI-capable hospital for mechanical revascularization if: (1) there is a contraindication to fibrinolysis; (2) PCI can be initiated promptly (within 90 minutes after the patient presented to the initial receiving hospital or within 60 min compared to when fibrinolysis with a fibrin-specific agent could be initiated at the initial receiving hospital); (3) fibrinolysis is administered and is unsuccessful (i.e., "rescue PCI"). Secondary nonemergency interhospital transfer can be considered for recurrent ischemia. *Patient self-transport*: Patient self-transportation is discouraged. If the patient arrives at a non-PCI–capable hospital, the door-to-needle time should be within 30 min. If the patient arrives at a PCI-capable hospital, the door-to-balloon time should be within 90 min. The treatment options and time recommended after first hospital arrival are the same. *(Reproduced with permission from Antman et al: ACC/AHA guidelines for the management of patients with ST-elevation myocardial infarction: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee to Revise the 1999 Guidelines for the Management of Patients with Acute Myocardial Infarction). Available at www.acc.org/clinical/guidelines/stemi/index.pdf.)*

hypertension extends the "window" of time for the salvage of myocardium by reperfusion strategies.

Glucocorticoids and nonsteroidal anti-inflammatory agents, with the exception of aspirin, should be avoided in patients with STEMI. They can impair infarct healing and increase the risk of myocardial rupture, and their use may result in a larger infarct scar. In addition, they can increase coronary vascular resistance, thereby potentially reducing flow to ischemic myocardium.

Primary Percutaneous Coronary Intervention (See also Chap. 240) PCI, usually angioplasty and/or stenting without preceding fibrinolysis, referred to as *primary PCI*, is effective in restoring perfusion in STEMI when carried out on an emergency basis in the first few hours of MI. It has the advantage of being applicable to patients who have contraindications to fibrinolytic therapy (see below) but otherwise are considered appropriate candidates for reperfusion. It appears to be more effective than fibrinolysis in opening occluded coronary arteries and, *when performed by experienced operators [≥75 PCI cases (not necessarily primary) per year] in dedicated medical centers (≥36 primary PCI cases per year)*, is associated with better short-term and long-term clinical outcomes. Compared with fibrinolysis, primary PCI is generally preferred when the diagnosis is in doubt, cardiogenic shock is present, bleeding risk is increased, or symptoms have been present for at least 2–3 h when the clot is more mature and less easily lysed by fibrinolytic drugs. However, PCI is expensive in terms of personnel and facilities, and its applicability is limited by its availability, around the clock, in only a minority of hospitals.

Fibrinolysis If no contraindications are present (see below), fibrinolytic therapy should ideally be initiated within 30 min of presentation (i.e., door-to-needle time ≤30 min). The principal goal of fibrinolysis is prompt restoration of full coronary arterial patency. The fibrinolytic agents tissue plasminogen activator (tPA), streptokinase, tenecteplase (TNK), and reteplase (rPA) have been approved by the U.S. Food and Drug Administration for intravenous use in patients with STEMI. These drugs all act by promoting the conversion of plasminogen to plasmin, which subsequently lyses fibrin thrombi. Although considerable emphasis was first placed on a distinction between more fibrin-specific agents, such as tPA, and non-fibrin-specific agents, such as streptokinase, it is now recognized that these differences are only relative, as some degree of systemic fibrinolysis occurs with the former agents. TNK and rPA are referred to as *bolus fibrinolytics* since their administration does not require a prolonged intravenous infusion.

When assessed angiographically, flow in the culprit coronary artery is described by a simple qualitative scale called the *thrombolysis in myocardial infarction (TIMI) grading system*: grade 0 indicates complete occlusion of the infarct-related artery; grade 1 indicates some penetration of the contrast material beyond the point of obstruction but without perfusion of the distal coronary bed; grade 2 indicates perfusion of the entire infarct vessel into the distal bed but with flow that is delayed compared with that of a normal artery; and grade 3 indicates full perfusion of the infarct vessel with normal flow. The latter is the goal of reperfusion therapy, because full perfusion of the infarct-related coronary artery yields far better results in terms of limiting infarct size, maintenance of LV function, and reduction of both short- and long-term mortality rates. Additional methods of angiographic assessment of the efficacy of fibrinolysis include counting the number of frames on the cine film required for dye to flow from the origin of the infarct-related artery to a landmark in the distal vascular bed (*TIMI frame count*) and determining the rate of entry and exit of contrast dye from the microvasculature in the myocardial infarct zone (*TIMI myocardial perfusion grade*). These methods have an even tighter correlation with outcomes after STEMI than the more commonly employed TIMI flow grade.

Fibrinolytic therapy can reduce the relative risk of in-hospital death by up to 50% when administered within the first hour of the onset of symptoms of STEMI, and much of this benefit is maintained for at least 10 years. When appropriately used, fibrinolytic therapy appears to reduce infarct size, limit LV dysfunction, and reduce the incidence of serious complications such as septal rupture, cardiogenic shock, and malignant ventricular arrhythmias. Since myocardium can be salvaged only before it has been irreversibly injured, the timing of reperfusion therapy, by fibrinolysis or a catheter-based approach, is of extreme importance in achieving maximum benefit. While the upper time limit depends on specific factors in individual patients, it is clear that "every minute counts" and that patients treated within 1–3 h of the onset of symptoms generally benefit most. Although reduction of the mortality rate is more modest, the therapy remains of benefit for many patients seen 3–6 h after the onset of infarction, and some benefit appears to be possible up to 12 h, especially if chest discomfort is still present and ST segments remain elevated. Compared with PCI for STEMI (primary PCI), fibrinolysis is generally the preferred reperfusion strategy for patients presenting in the first hour of symptoms, if there are logistical concerns about transportation of the patient to a suitable PCI center (experienced operator and team with a track record for a "door-to-balloon" time of <2 h), or there is an anticipated delay of at least 1 h between the time that fibrinolysis could be started versus implementation of PCI. Although patients <75 years achieve a greater relative reduction in the mortality rate with fibrinolytic therapy than do older patients, the higher *absolute* mortality rate (15–25%) in the latter results in similar absolute reductions in the mortality rates for both age groups.

tPA and the other relatively fibrin-specific plasminogen activators, rPA and TNK, are more effective than streptokinase at restoring full perfusion—i.e., TIMI grade 3 coronary flow—and have a small edge in improving survival as well. The current recommended regimen of tPA consists of a 15 mg bolus followed by 50 mg intravenously over the first 30 min, followed by 35 mg over the next 60 min. Streptokinase is administered as 1.5 million units (MU) intravenously over 1 h. rPA is administered in a double-bolus regimen consisting of a 10-MU bolus given over 2–3 min, followed by a second 10-MU bolus 30 min later. TNK is given as a single weight-based intravenous bolus of 0.53 mg/kg over 10 s. In addition to the fibrinolytic agents discussed above, pharmacologic reperfusion typically involves adjunctive antiplatelet and antithrombotic drugs, as discussed subsequently.

Alternative pharmacologic regimens for reperfusion combine an intravenous glycoprotein IIb/IIIa inhibitor with a reduced dose of a fibrinolytic agent. Compared with fibrinolytic agents that involve a prolonged infusion (e.g., tPA), such combination reperfusion regimens facilitate the rate and extent of fibrinolysis by inhibiting platelet aggregation, weakening the clot structure, and allowing penetration of the fibrinolytic agent deeper into the clot. However, combination reperfusion regimens have similar efficacy as compared with bolus fibrinolytics and are associated with an increased risk of bleeding, especially in patients >75 years. Therefore, combination reperfusion regimens are not recommended for routine use. Glycoprotein IIb/IIIa inhibitors given alone (i.e., without any fibrinolytic agent) are being investigated as a preparatory pharmacologic regimen in STEMI patients who are referred promptly for PCI—an experimental strategy called *facilitated PCI*. Another experimental strategy that has been proposed but not yet rigorously evaluated is a *pharmacoinvasive* approach where STEMI patients are first treated with a pharmacologic reperfusion regimen followed by routine angiography and PCI after a delay of 12–24 h to minimize the risks of performing PCI while the effects of the lytic agent are still present.

Contraindications and Complications Clear contraindications to the use of fibrinolytic agents include a history of cerebrovascular hemorrhage at any time, a nonhemorrhagic stroke or other cerebrovascular event within the past year, marked hypertension (a reliably determined systolic arterial pressure >180 mmHg and/or a diastolic pressure >110 mmHg) at any time during the acute presentation, suspicion of aortic dissection, and active internal bleeding (excluding menses). While advanced age is associated with an increase in hemorrhagic complications, the benefit of fibrinolytic therapy in the elderly appears to justify its use if no other contraindications are present and the amount of myocardium in jeopardy appears to be substantial.

Relative contraindications to fibrinolytic therapy, which require assessment of the risk:benefit ratio, include current use of anticoagulants (international normalized ratio ≥2), a recent (<2 weeks) invasive or

surgical procedure or prolonged (>10 min) cardiopulmonary resuscitation, known bleeding diathesis, pregnancy, a hemorrhagic ophthalmic condition (e.g., hemorrhagic diabetic retinopathy), active peptic ulcer disease, and a history of severe hypertension that is currently adequately controlled. Because of the risk of an allergic reaction, patients should not receive streptokinase if that agent had been received within the preceding 5 days to 2 years.

Allergic reactions to streptokinase occur in ~2% of patients who receive it. While a minor degree of hypotension occurs in 4–10% of patients given this agent, marked hypotension occurs, although rarely, in association with severe allergic reactions.

Hemorrhage is the most frequent and potentially the most serious complication. Because bleeding episodes that require transfusion are more common when patients require invasive procedures, unnecessary venous or arterial interventions should be avoided in patients receiving fibrinolytic agents. Hemorrhagic stroke is the most serious complication and occurs in ~0.5–0.9% of patients being treated with these agents. This rate increases with advancing age, with patients >70 years experiencing roughly twice the rate of intracranial hemorrhage as those <65 years. Large-scale trials have suggested that the rate of intracranial hemorrhage with tPA or rPA is slightly higher than with streptokinase.

Cardiac catheterization and coronary angiography should be carried out after fibrinolytic therapy if there is evidence of either (1) failure of reperfusion (persistent chest pain and ST-segment elevation >90 min), in which case a *rescue PCI* should be considered; or (2) coronary artery reocclusion (re-elevation of ST segments and/or recurrent chest pain) or the development of recurrent ischemia (such as recurrent angina in the early hospital course or a positive exercise stress test before discharge), in which case an *urgent PCI* should be considered. The potential benefits of routine angiography and *elective* PCI even in asymptomatic patients following administration of fibrinolytic therapy are controversial, but such an approach may have merit given the numerous technological advances that have occurred in the catheterization laboratory and the increasing number of skilled interventionalists. Coronary artery bypass surgery should be reserved for patients whose coronary anatomy is unsuited to PCI but in whom revascularization appears to be advisable because of extensive jeopardized myocardium or recurrent ischemia.

HOSPITAL PHASE MANAGEMENT

CORONARY CARE UNITS

These units are routinely equipped with a system that permits continuous monitoring of the cardiac rhythm of each patient and hemodynamic monitoring in selected patients. Defibrillators, respirators, noninvasive transthoracic pacemakers, and facilities for introducing pacing catheters and flow-directed balloon-tipped catheters are also usually available. Equally important is the organization of a highly trained team of nurses who can recognize arrhythmias; adjust the dosage of antiarrhythmic, vasoactive, and anticoagulant drugs; and perform cardiac resuscitation, including electroshock, when necessary.

Patients should be admitted to a coronary care unit early in their illness when it is expected that they will derive benefit from the sophisticated and expensive care provided. The availability of electrocardiographic monitoring and trained personnel outside the coronary care unit has made it possible to admit lower-risk patients (e.g., those not hemodynamically compromised and without active arrhythmias) to "intermediate care units."

The duration of stay in the coronary care unit is dictated by the ongoing need for intensive care. If symptoms are controlled with oral therapy, patients may be transferred out of the coronary care unit. Also, patients who have a confirmed STEMI but who are considered to be at low risk (no prior infarction and no persistent chest discomfort, CHF, hypotension, or cardiac arrhythmias) may be safely transferred out of the coronary care unit within 24 h.

Activity Factors that increase the work of the heart during the initial hours of infarction may increase the size of the infarct. Therefore, patients with STEMI should be kept at bed rest for the first 12 h. However, in the absence of complications, patients should be encouraged, under supervision, to resume an upright posture by dangling their feet over the side of the bed and sitting in a chair within the first 24 h. This practice is psychologically beneficial and usually results in a reduction in the pulmonary capillary wedge pressure. In the absence of hypotension and other complications, by the second or third day patients typically are ambulating in their room with increasing duration and frequency, and they may shower or stand at the sink to bathe. By day 3 after infarction, patients should be increasing their ambulation progressively to a goal of 185 m (600 ft) at least three times a day.

Diet Because of the risk of emesis and aspiration soon after STEMI, patients should receive either nothing or only clear liquids by mouth for the first 4–12 h. The typical coronary care unit diet should provide ≤30% of total calories as fat and have a cholesterol content of ≤300 mg/d. Complex carbohydrates should make up 50–55% of total calories. Portions should not be unusually large, and the menu should be enriched with foods that are high in potassium, magnesium, and fiber but low in sodium. Diabetes mellitus and hypertriglyceridemia are managed by restriction of concentrated sweets in the diet.

Bowels Bed rest and the effect of the narcotics used for the relief of pain often lead to constipation. A bedside commode rather than a bedpan, a diet rich in bulk, and the routine use of a stool softener such as dioctyl sodium sulfosuccinate (200 mg/d) are recommended. If the patient remains constipated despite these measures, a laxative can be prescribed. Contrary to prior belief, it is safe to perform a gentle rectal examination on patients with STEMI.

Sedation Many patients require sedation during hospitalization to withstand the period of enforced inactivity with tranquillity. Diazepam (5 mg), oxazepam (15–30 mg), or lorazepam (0.5–2 mg), given three or four times daily, is usually effective. An additional dose of any of the above medications may be given at night to ensure adequate sleep. Attention to this problem is especially important during the first few days in the coronary care unit, where the atmosphere of 24-h vigilance may interfere with the patient's sleep. However, sedation is no substitute for reassuring, quiet surroundings. Many drugs used in the coronary care unit, such as atropine, H_2 blockers, and narcotics, can produce delirium, particularly in the elderly. This effect should not be confused with agitation, and it is wise to conduct a thorough review of the patient's medications before arbitrarily prescribing additional doses of anxiolytics.

PHARMACOTHERAPY

ANTITHROMBOTIC AGENTS

The use of antiplatelet and antithrombin therapy during the initial phase of STEMI is based on extensive laboratory and clinical evidence that thrombosis plays an important role in the pathogenesis of this condition. The primary goal of treatment with antiplatelet and antithrombin agents is to establish and maintain patency of the infarct-related artery, in conjunction with reperfusion strategies. A secondary goal is to reduce the patient's tendency to thrombosis and thus the likelihood of mural thrombus formation or deep venous thrombosis, either of which could result in pulmonary embolization. The degree to which antiplatelet and antithrombin therapy achieves these goals partly determines how effectively it reduces the risk of mortality from STEMI.

As noted previously (see "Management in the Emergency Department," above), aspirin is the standard antiplatelet agent for patients with STEMI. The most compelling evidence for the benefits of antiplatelet therapy (mainly with aspirin) in STEMI is found in the comprehensive overview by the Antiplatelet Trialists' Collaboration. Data from nearly 20,000 patients with MI enrolled in 15 randomized trials were pooled and revealed a relative reduction of 27% in the mortality rate, from 14.2% in control patients to 10.4% in patients receiving antiplatelet agents.

Inhibitors of the $P2Y_{12}$ ADP receptor prevent activation and aggregation of platelets. The addition of the $P2Y_{12}$ inhibitor clopidogrel to

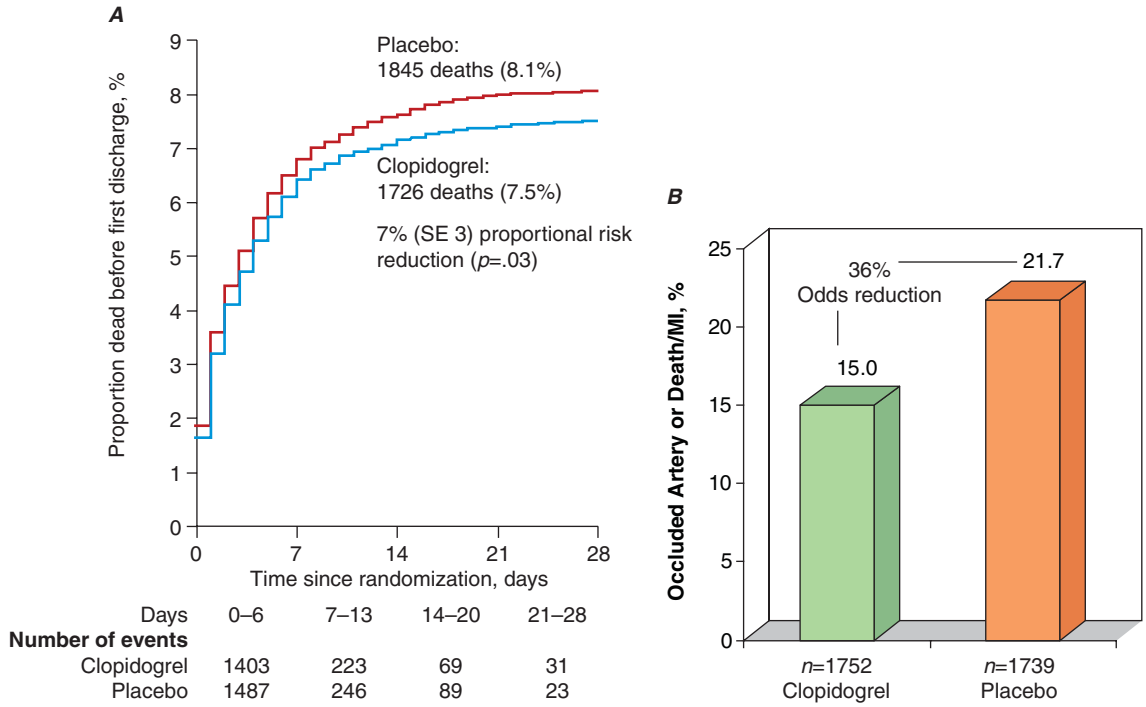

FIGURE 239-5 ***Panel A:*** Effect of the addition of clopidogrel on in-hospital mortality after STEMI. These time-to-event curves show a 0.6% reduction in mortality in the group receiving clopidogrel plus aspirin (*N* = 22,961) compared to placebo plus aspirin (*N* = 22,891) in the COMMIT trial. *(Reproduced with permission from ZM Chen et al: Lancet 366:1607, 2005.)* ***Panel B:*** Effects of the addition of clopidogrel in patients receiving fibrinolysis for STEMI. Patients in the clopidogrel group (*N* = 1752) had a 36% reduction in the odds of dying, sustaining a recurrent infarction, or having an occluded infarct artery compared to the placebo group (*N* = 1739) in the CLARITY-TIMI 28 trial ($p < .001$). *(Adapted from Sabatine MS et al: New Engl J Med 352:1179, 2005.)*

background treatment with aspirin to STEMI patients reduces the risk of clinical events (death, reinfarction, stroke) and in patients receiving fibrinolytic therapy has been shown to prevent reocclusion of a successfully reperfused infarct artery (Fig. 239-5). Glycoprotein IIb/IIIa receptor inhibitors appear useful for preventing thrombotic complications in patients with STEMI undergoing PCI.

The standard antithrombin agent used in clinical practice is unfractionated heparin (UFH). The available data suggest that when UFH is added to a regimen of aspirin and a non-fibrin-specific thrombolytic agent such as streptokinase, additional mortality benefit occurs (about five lives saved per 1000 patients treated). It appears that the immediate administration of intravenous UFH, in addition to a regimen of aspirin and relatively fibrin-specific fibrinolytic agents (tPA, rPA, or TNK), helps to maintain patency of the infarct-related artery. This effect is achieved at the cost of a small increased risk of bleeding. The recommended dose of UFH is an initial bolus of 60 U/kg (maximum 4000 U) followed by an initial infusion of 12 U/kg per hour (maximum 1000 U/h). The activated partial thromboplastin time during maintenance therapy should be 1.5–2 times the control value.

An alternative to UFH for anticoagulation of patients with STEMI are the low-molecular-weight heparin (LMWH) preparations, which are formed by enzymatic or chemical depolymerization to produce saccharide chains of varying length but with a mean molecular weight of about 5000 Da. Advantages of LMWHs include high bioavailability permitting administration subcutaneously, reliable anticoagulation without monitoring, and greater antiXa:IIa activity. Enoxaparin has been shown to significantly reduce the composite endpoints of death/nonfatal reinfarction (Fig. 239-6) and death/nonfatal reinfarction/urgent revascularization compared with UFH in STEMI patients who receive fibrinolysis. Although treatment with enoxaparin is associated with higher rates of serious bleeding, net clinical benefit—a composite endpoint that combines efficacy and safety—strongly favors enoxaparin over UFH.

Patients with an anterior location of the infarction, severe LV dysfunction, heart failure, a history of embolism, two-dimensional echocardiographic evidence of mural thrombus, or atrial fibrillation are at increased risk of systemic or pulmonary thromboembolism. Such individuals should receive full therapeutic levels of antithrombin therapy (LMWH or UFH) while hospitalized, followed by at least 3 months of warfarin therapy.

BETA-ADRENOCEPTOR BLOCKERS

The benefits of beta blockers in patients with STEMI can be divided into those that occur immediately when the drug is given acutely and those that accrue over the long term when the drug is given for secondary pre-

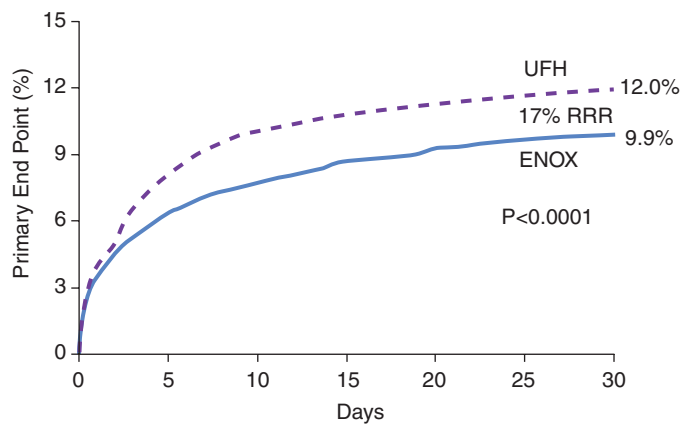

FIGURE 239-6 **Enoxaparin is superior to unfractionated heparin in STEMI patients receiving fibrinolysis.** In the ExTRACT-TIMI 25 trial, patients receiving the low-molecular-weight heparin enoxaparin in addition to a fibrinolytic agent plus aspirin (*N* = 10,256) had a significantly lower rate of the composite endpoint of death or nonfatal reinfarction compared to patients receiving unfractionated heparin in combination with a fibrinolytic plus aspirin (*N* = 10,223). RRR, relative risk reduction. *(Reproduced with permission from EM Antman et al: New Engl J Med 354:1477, 2006.)*

vention after an infarction. Acute intravenous beta blockade improves the myocardial O_2 supply-demand relationship, decreases pain, reduces infarct size, and decreases the incidence of serious ventricular arrhythmias. In patients who undergo fibrinolysis soon after the onset of chest pain, no incremental reduction in mortality rate is seen with beta blockers, but recurrent ischemia and reinfarction are reduced.

Thus, beta blocker therapy after STEMI is useful for most patients (including those treated with an ACE inhibitor) except those in whom it is specifically contraindicated (patients with heart failure or severely compromised LV function, heart block, orthostatic hypotension, or a history of asthma) and perhaps those whose excellent long-term prognosis (defined as an expected mortality rate of <1% per year, patients <55 years, no previous MI, with normal ventricular function, no complex ventricular ectopy, and no angina) markedly diminishes any potential benefit.

INHIBITION OF THE RENIN-ANGIOTENSIN-ALDOSTERONE SYSTEM

Angiotensin-converting enzyme (ACE) inhibitors reduce the mortality rate after STEMI, and the mortality benefits are additive to those achieved with aspirin and beta blockers. The maximum benefit is seen in high-risk patients (those who are elderly or who have an anterior infarction, a prior infarction, and/or globally depressed LV function), but evidence suggests that a short-term benefit occurs when ACE inhibitors are prescribed unselectively to all hemodynamically stable patients with STEMI (i.e., those with a systolic pressure >100 mmHg). The mechanism involves a reduction in ventricular remodeling after infarction (see "Ventricular Dysfunction," below) with a subsequent reduction in the risk of congestive heart failure (CHF). The rate of recurrent infarction may also be lower in patients treated chronically with ACE inhibitors after infarction.

Before hospital discharge, LV function should be assessed with an imaging study. ACE inhibitors should be continued indefinitely in patients who have clinically evident CHF, in patients in whom an imaging study shows a reduction in global LV function or a large regional wall motion abnormality, or in those who are hypertensive.

Angiotensin receptor blockers (ARBs) should be administered to STEMI patients who are intolerant of ACE inhibitors and who have either clinical or radiological signs of heart failure. Long-term aldosterone blockade should be prescribed for STEMI patients without significant renal dysfunction (creatinine ≥2.5 mg/dL in men and ≥2.0 mg/dL in women) or hyperkalemia (potassium ≥5.0 mEq/L) who are already receiving therapeutic doses of an ACE inhibitor, an LV ejection fraction ≤40 percent, and either symptomatic heart failure or diabetes mellitus. A multidrug regimen for inhibiting the renin-angiotensin-aldosterone system has been shown to reduce both heart failure-related and sudden cardiac death-related cardiovascular mortality after STEMI, but has not been as thoroughly explored as ACE inhibitors in STEMI patients.

OTHER AGENTS

Favorable effects on the ischemic process and ventricular remodeling (see below) previously led many physicians to routinely use *intravenous nitroglycerin* (5–10 μg/min initial dose and up to 200 μg/min as long as hemodynamic stability is maintained) for the first 24–48 h after the onset of infarction. However, the benefits of routine use of intravenous nitroglycerin are less in the contemporary era where beta-adrenoceptor blockers and ACE inhibitors are routinely prescribed for patients with STEMI.

Results of multiple trials of different calcium antagonists have failed to establish a role for these agents in the treatment of most patients with STEMI. Therefore, the routine use of calcium antagonists cannot be recommended. Strict control of blood glucose in diabetic patients with STEMI has been shown to reduce the mortality rate. Serum magnesium should be measured in all patients on admission, and any demonstrated deficits should be corrected to minimize the risk of arrhythmias.

COMPLICATIONS AND THEIR MANAGEMENT

VENTRICULAR DYSFUNCTION

After STEMI, the left ventricle undergoes a series of changes in shape, size, and thickness in both the infarcted and noninfarcted segments. This process is referred to as *ventricular remodeling* and generally precedes the development of clinically evident CHF in the months to years after infarction. Soon after STEMI, the left ventricle begins to dilate. Acutely, this results from expansion of the infarct, i.e., slippage of muscle bundles, disruption of normal myocardial cells, and tissue loss within the necrotic zone, resulting in disproportionate thinning and elongation of the infarct zone. Later, lengthening of the noninfarcted segments occurs as well. The overall chamber enlargement that occurs is related to the size and location of the infarct, with greater dilation following infarction of the anterior wall and apex of the left ventricle and causing more marked hemodynamic impairment, more frequent heart failure, and a poorer prognosis. Progressive dilation and its clinical consequences may be ameliorated by therapy with ACE inhibitors and other vasodilators (e.g., nitrates). In patients with an ejection fraction <40%, regardless of whether or not heart failure is present, ACE inhibitors or ARBs should be prescribed (see "Inhibition of the Renin-Angiotensin-Aldosterone System," above).

HEMODYNAMIC ASSESSMENT

Pump failure is now the primary cause of in-hospital death from STEMI. The extent of infarction correlates well with the degree of pump failure and with mortality, both early (within 10 days of infarction) and later. The most common clinical signs are pulmonary rales and S_3 and S_4 gallop sounds. Pulmonary congestion is also frequently seen on the chest roentgenogram. Elevated LV filling pressure and elevated pulmonary artery pressure are the characteristic hemodynamic findings, but these findings may result from a reduction of ventricular compliance (diastolic failure) and/or a reduction of stroke volume with secondary cardiac dilation (systolic failure) (Chap. 227).

A classification originally proposed by Killip divides patients into four groups: class I, no signs of pulmonary or venous congestion; class II, moderate heart failure as evidenced by rales at the lung bases, S_3 gallop, tachypnea, or signs of failure of the right side of the heart, including venous and hepatic congestion; class III, severe heart failure, pulmonary edema; and class IV, shock with systolic pressure <90 mmHg and evidence of peripheral vasoconstriction, peripheral cyanosis, mental confusion, and oliguria. When this classification was established in 1967, the expected hospital mortality rate of patients in these classes was as follows: class I, 0–5%; class II, 10–20%; class III, 35–45%; and class IV, 85–95%. With advances in management, the mortality rate in each class has fallen, perhaps by as much as one-third to one-half.

Hemodynamic evidence of abnormal global LV function appears when contraction is seriously impaired in 20–25% of the left ventricle. Infarction of ≥40% of the left ventricle usually results in cardiogenic shock (Chap. 266). Positioning of a balloon flotation (Swan-Ganz) catheter in the pulmonary artery permits monitoring of LV filling pressure; this technique is useful in patients who exhibit hypotension and/or clinical evidence of CHF. Cardiac output can also be determined with a pulmonary artery catheter. With the addition of intraarterial pressure monitoring, systemic vascular resistance can be calculated as a guide to adjusting vasopressor and vasodilator therapy. Some patients with STEMI have markedly elevated LV filling pressures (>22 mmHg) and normal cardiac indices [2.6–3.6 L/(min/m^2)], while others have relatively low LV filling pressures (<15 mmHg) and reduced cardiac indices. The former patients usually benefit from diuresis, while the latter may respond to volume expansion.

HYPOVOLEMIA This is an easily corrected condition that may contribute to the hypotension and vascular collapse associated with STEMI in some patients. It may be secondary to previous diuretic use, to reduced fluid intake during the early stages of the illness, and/or to vomiting associated with pain or medications. Consequently, hypovolemia should be identified and corrected in patients with STEMI and hypotension before more vigorous forms of therapy are begun. Central venous pressure reflects RV rather than LV filling pressure and is an inadequate guide for adjustment of blood volume, since LV function is almost always affected much more adversely than RV function in patients with STEMI. The optimal LV filling or pulmonary artery wedge

pressure may vary considerably among patients. Each patient's ideal level (generally ~20 mmHg) is reached by cautious fluid administration during careful monitoring of oxygenation and cardiac output. Eventually the cardiac output level plateaus, and further increases in LV filling pressure only increase congestive symptoms and decrease systemic oxygenation without raising arterial pressure.

Rx CONGESTIVE HEART FAILURE

The management of CHF in association with STEMI is similar to that of acute heart failure secondary to other forms of heart disease (avoidance of hypoxemia, diuresis, afterload reduction, inotropic support) (Chap. 227), except that the benefits of digitalis administration to patients with STEMI are unimpressive. By contrast, diuretic agents are extremely effective, as they diminish pulmonary congestion in the presence of systolic and/or diastolic heart failure. LV filling pressure falls and orthopnea and dyspnea improve after the intravenous administration of furosemide or other loop diuretics. These drugs should be used with caution, however, as they can result in a massive diuresis with associated decreases in plasma volume, cardiac output, systemic blood pressure, and hence coronary perfusion. Nitrates in various forms may be used to decrease preload and congestive symptoms. Oral isosorbide dinitrate, topical nitroglycerin ointment, or intravenous nitroglycerin all have the advantage over a diuretic of lowering preload through venodilation without decreasing the total plasma volume. In addition, nitrates may improve ventricular compliance if ischemia is present, as ischemia causes an elevation of LV filling pressure. Vasodilators must be used with caution to prevent serious hypotension. As noted earlier, ACE inhibitors are an ideal class of drugs for management of ventricular dysfunction after STEMI, especially for the long term. (See "Inhibition of the Renin-Angiotensin-Aldosterone System," above.)

CARDIOGENIC SHOCK

Prompt reperfusion, efforts to reduce infarct size, and treatment of ongoing ischemia and other complications of MI appear to have reduced the incidence of cardiogenic shock from 20% to about 7%. Only 10% of patients with this condition present with it on admission, while 90% develop it during hospitalization. Typically, patients who develop cardiogenic shock have severe multivessel coronary artery disease with evidence of "piecemeal" necrosis extending outward from the original infarct zone. **The evaluation and management of cardiogenic shock and severe power failure after STEMI are discussed in detail in Chap. 266.**

RIGHT VENTRICULAR INFARCTION

Approximately one-third of patients with inferior infarction demonstrate at least a minor degree of RV necrosis. An occasional patient with inferoposterior LV infarction also has extensive RV infarction, and rare patients present with infarction limited primarily to the RV. Clinically significant RV infarction causes signs of severe RV failure [jugular venous distention, Kussmaul's sign, hepatomegaly (Chap. 220)] with or without hypotension. ST-segment elevations of right-sided precordial ECG leads, particularly lead V_4R, are frequently present in the first 24 h in patients with RV infarction. Two-dimensional echocardiography is helpful in determining the degree of RV dysfunction. Catheterization of the right side of the heart often reveals a distinctive hemodynamic pattern resembling constrictive pericarditis (steep right atrial "y" descent and an early diastolic dip and plateau in RV waveforms) (Chap. 232). Therapy consists of volume expansion to maintain adequate RV preload and efforts to improve LV performance with attendant reduction in pulmonary capillary wedge and pulmonary arterial pressures.

ARRHYTHMIAS

(See also Chaps. 225 and 226) The incidence of arrhythmias after STEMI is higher in patients seen early after the onset of symptoms. The mechanisms responsible for infarction-related arrhythmias include autonomic nervous system imbalance, electrolyte disturbances, ischemia, and slowed conduction in zones of ischemic myocardium. An arrhythmia can usually be managed successfully if trained personnel and appropriate equipment are available when it develops. Since most deaths from arrhythmia occur during the first few hours after infarction, the effectiveness of treatment relates directly to the speed with which patients come under medical observation. The prompt management of arrhythmias constitutes a significant advance in the treatment of STEMI.

Ventricular Premature Beats Infrequent, sporadic ventricular premature depolarizations occur in almost all patients with STEMI and do not require therapy. Whereas in the past, frequent, multifocal, or early diastolic ventricular extrasystoles (so-called warning arrhythmias) were routinely treated with antiarrhythmic drugs to reduce the risk of development of ventricular tachycardia and ventricular fibrillation, pharmacologic therapy is now reserved for patients with sustained ventricular arrhythmias. Prophylactic antiarrhythmic therapy (either intravenous lidocaine early or oral agents later) is contraindicated for ventricular premature beats in the absence of clinically important ventricular tachyarrhythmias, as such therapy may actually increase the mortality rate. Beta-adrenoceptor blocking agents are effective in abolishing ventricular ectopic activity in patients with STEMI and in the prevention of ventricular fibrillation. As described above (see "Beta-Adrenoceptor Blockers," above), they should be used routinely in patients without contraindications. In addition, hypokalemia and hypomagnesemia are risk factors for ventricular fibrillation in patients with STEMI; the serum potassium concentration should be adjusted to approximately 4.5 mmol/L and magnesium to about 2.0 mmol/L.

Ventricular Tachycardia and Fibrillation Within the first 24 h of STEMI, ventricular tachycardia and fibrillation can occur without prior warning arrhythmias. The occurrence of ventricular fibrillation can be reduced by prophylactic administration of intravenous lidocaine. However, prophylactic use of lidocaine has not been shown to reduce overall mortality from STEMI. In fact, in addition to causing possible noncardiac complications, lidocaine may predispose to an excess risk of bradycardia and asystole. For these reasons, and with earlier treatment of active ischemia, more frequent use of beta-blocking agents, and the nearly universal success of electrical cardioversion or defibrillation, routine prophylactic antiarrhythmic drug therapy *is no longer recommended*.

Sustained ventricular tachycardia that is well tolerated hemodynamically should be treated with an intravenous regimen of amiodarone (bolus of 150 mg over 10 min, followed by infusion of 1.0 mg/min for 6 h and then 0.5 mg/min); or procainamide (bolus of 15 mg/kg over 20–30 min; infusion of 1–4 mg/min); if it does not stop promptly, electroversion should be used (Chap. 226). An unsynchronized discharge of 200–300 J (monophasic wave form; approximately 50% of these energies with biphasic wave forms) is used immediately in patients with ventricular fibrillation or when ventricular tachycardia causes hemodynamic deterioration. Ventricular tachycardia or fibrillation that is refractory to electroshock may be more responsive after the patient is treated with epinephrine (1 mg intravenously or 10 mL of a 1:10,000 solution via the intracardiac route), or amiodarone (a 75–150 mg bolus).

Ventricular arrhythmias, including the unusual form of ventricular tachycardia known as torsades des pointes (Chap. 226), may occur in patients with STEMI as a consequence of other concurrent problems (such as hypoxia, hypokalemia, or other electrolyte disturbances) or of the toxic effects of an agent being administered to the patient (such as digoxin or quinidine). A search for such secondary causes should always be undertaken.

Although the in-hospital mortality rate is increased, the long-term survival is excellent in patients who survive to hospital discharge after *primary* ventricular fibrillation, i.e., ventricular fibrillation that is a primary response to acute ischemia that occurs during the first 48 h and is not associated with predisposing factors such as CHF, shock, bundle branch block, or ventricular aneurysm. This result is in sharp contrast to the poor prognosis for patients who develop ventricular fibrillation *secondary* to severe pump failure. For patients who develop

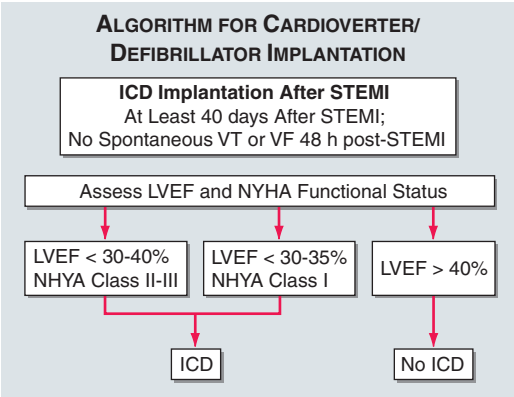

FIGURE 239-7 Algorithm for assessment of need for implantation of a cardioverter/defibrillator. The appropriate management is selected based upon measurement of left ventricular ejection fraction and assessment of the NYHA functional class. Patients with depressed left ventricular function at least 40 days post-STEMI are referred for insertion of an implantable cardioverter/defibrillator (ICD) if the LVEF is <30–40% and they are in NYHA class II–III or if the LVEF is <30–35% and they are in NYHA class I functional status. Patients with preserved left ventricular function (LVEF >40%) do not receive an ICD regardless of NYHA functional class. All patients are treated with medical therapy post-STEMI. *[Adapted from data contained in Zipes DP, Camm AJ, et al: ACC/AHA/ESC 2006 guidelines for management of patients with ventricular arrhythmias and the prevention of sudden cardiac death; a report of the American College of Cardiology/American Heart Association Task Force and the European Society of Cardiology Committee for Practice Guidelines (Writing Committee to Develop Guidelines for Management of Patients with Ventricular Arrhythmias and the Prevention of Sudden Cardiac Death). J Am Coll Cardiol 48:1064, 2006.]*

ventricular tachycardia or ventricular fibrillation late in their hospital course (i.e., after the first 48 h), the mortality rate is increased both in-hospital and during long-term follow-up. Such patients should be considered for electrophysiologic study and implantation of a cardioverter/defibrillator (ICD) (Chap. 226). A more challenging issue is the prevention of sudden cardiac death from ventricular fibrillation late after STEMI in patients who have not exhibited sustained ventricular tachyarrhythmias during their index hospitalization. An algorithm for selection of patients who warrant prophylactic implantation of an ICD is shown in Fig. 239-7.

Accelerated Idioventricular Rhythm Accelerated idioventricular rhythm (AIVR, "slow ventricular tachycardia"), a ventricular rhythm with a rate of 60–100 bpm, occurs in 25% of patients with STEMI. It often occurs transiently during fibrinolytic therapy at the time of reperfusion. For the most part, AIVR is benign and does not presage the development of classic ventricular tachycardia. Most episodes of AIVR do not require treatment if the patient is monitored carefully, as degeneration into a more serious arrhythmia is rare.

Supraventricular Arrhythmias Sinus tachycardia is the most common supraventricular arrhythmia. If it occurs secondary to another cause (such as anemia, fever, heart failure, or a metabolic derangement), the primary problem should be treated first. However, if it appears to be due to sympathetic overstimulation (e.g., as part of a hyperdynamic state), then treatment with a beta blocker is indicated. Other common arrhythmias in this group are atrial flutter and atrial fibrillation, which are often secondary to LV failure. Digoxin is usually the treatment of choice for supraventricular arrhythmias if heart failure is present. If heart failure is absent, beta blockers, verapamil, or diltiazem are suitable alternatives for controlling the ventricular rate, as they may also help to control ischemia. If the abnormal rhythm persists for >2 h with a ventricular rate >120 bpm, or if tachycardia induces heart failure, shock, or ischemia (as manifested by recurrent pain or ECG changes), a synchronized electroshock (100–200 J monophasic wave form) should be used.

Accelerated junctional rhythms have diverse causes but may occur in patients with inferoposterior infarction. Digitalis excess must be ruled out. In some patients with severely compromised LV function, the loss of appropriately timed atrial systole results in a marked reduction of cardiac output. Right atrial or coronary sinus pacing is indicated in such instances.

Sinus Bradycardia Treatment of sinus bradycardia is indicated if hemodynamic compromise results from the slow heart rate. Atropine is the most useful drug for increasing heart rate and should be given intravenously in doses of 0.5 mg initially. If the rate remains <50–60 bpm, additional doses of 0.2 mg, up to a total of 2.0 mg, may be given. Persistent bradycardia (<40 bpm) despite atropine may be treated with electrical pacing. Isoproterenol should be avoided.

Atrioventricular and Intraventricular Conduction Disturbances (See also Chap. 225) Both the in-hospital mortality rate and the post-discharge mortality rate of patients who have complete atrioventricular (AV) block in association with anterior infarction are markedly higher than those of patients who develop AV block with inferior infarction. This difference is related to the fact that heart block in inferior infarction is commonly a result of increased vagal tone and/or the release of adenosine and therefore is transient. In anterior wall infarction, however, heart block is usually related to ischemic malfunction of the conduction system, which is commonly associated with extensive myocardial necrosis.

Temporary electrical pacing provides an effective means of increasing the heart rate of patients with bradycardia due to AV block. However, acceleration of the heart rate may have only a limited impact on prognosis in patients with anterior wall infarction and complete heart block in whom the large size of the infarct is the major factor determining outcome. It should be carried out if it improves hemodynamics. Pacing does appear to be beneficial in patients with inferoposterior infarction who have complete heart block associated with heart failure, hypotension, marked bradycardia, or significant ventricular ectopic activity. A subgroup of these patients, those with RV infarction, often respond poorly to ventricular pacing because of the loss of the atrial contribution to ventricular filling. In such patients, dual-chamber AV sequential pacing may be required.

External noninvasive pacing electrodes should be positioned in a "demand" mode for patients with sinus bradycardia (rate <50 bpm) that is unresponsive to drug therapy, Mobitz II second-degree AV block, third-degree heart block, or bilateral bundle branch block (e.g., right bundle branch block plus left anterior fascicular block). Retrospective studies suggest that permanent pacing may reduce the long-term risk of sudden death due to bradyarrhythmias in the rare patient who develops combined persistent bifascicular and transient third-degree heart block during the acute phase of MI.

OTHER COMPLICATIONS

Recurrent Chest Discomfort Recurrent angina develops in ~25% of patients hospitalized for STEMI. This percentage is even higher in patients who undergo successful fibrinolysis. Since recurrent or persistent ischemia often heralds extension of the original infarct or reinfarction in a new myocardial zone and is associated with a near tripling of mortality after STEMI, patients with these symptoms should be referred for prompt coronary arteriography and mechanical revascularization. Repeat administration of a fibrinolytic agent is an alternative to early mechanical revascularization.

Pericarditis (See also Chap. 232) Pericardial friction rubs and/or pericardial pain are frequently encountered in patients with STEMI involving the epicardium. This complication can usually be managed with aspirin (650 mg four times daily). It is important to diagnose the chest pain of pericarditis accurately, since failure to recognize it may lead to the erroneous diagnosis of recurrent ischemic pain and/or infarct extension, with resulting inappropriate use of anticoagulants, ni-

trates, beta blockers, or coronary arteriography. When it occurs, complaints of pain radiating to either trapezius muscle is helpful since such a pattern of discomfort is typical of pericarditis but rarely occurs with ischemic discomfort. Anticoagulants potentially could cause tamponade in the presence of acute pericarditis (as manifested by either pain or persistent rub) and therefore should not be used unless there is a compelling indication.

Thromboembolism Clinically apparent thromboembolism complicates STEMI in ~10% of cases, but embolic lesions are found in 20% of patients in necropsy series, suggesting that thromboembolism is often clinically silent. Thromboembolism is considered to be an important contributing cause of death in 25% of patients with STEMI who die after admission to the hospital. Arterial emboli originate from LV mural thrombi, while most pulmonary emboli arise in the leg veins.

Thromboembolism typically occurs in association with large infarcts (especially anterior), CHF, and a LV thrombus detected by echocardiography. The incidence of arterial embolism from a clot originating in the ventricle at the site of an infarction is small but real. Two-dimensional echocardiography reveals LV thrombi in about one-third of patients with anterior wall infarction but in few patients with inferior or posterior infarction. Arterial embolism often presents as a major complication, such as hemiparesis when the cerebral circulation is involved or hypertension if the renal circulation is compromised. When a thrombus has been clearly demonstrated by echocardiographic or other techniques or when a large area of regional wall motion abnormality is seen even in the absence of a detectable mural thrombus, systemic anticoagulation should be undertaken (in the absence of contraindications), as the incidence of embolic complications appears to be markedly lowered by such therapy. The appropriate duration of therapy is unknown, but 3–6 months is probably prudent.

Left Ventricular Aneurysm The term *ventricular aneurysm* is usually used to describe *dyskinesis* or local expansile paradoxical wall motion. Normally functioning myocardial fibers must shorten more if stroke volume and cardiac output are to be maintained in patients with ventricular aneurysm; if they cannot, overall ventricular function is impaired. True aneurysms are composed of scar tissue and neither predispose to nor are associated with cardiac rupture.

The complications of LV aneurysm do not usually occur for weeks to months after STEMI; they include CHF, arterial embolism, and ventricular arrhythmias. Apical aneurysms are the most common and the most easily detected by clinical examination. The physical finding of greatest value is a double, diffuse, or displaced apical impulse. Ventricular aneurysms are readily detected by two-dimensional echocardiography, which may also reveal a mural thrombus in an aneurysm.

Rarely, myocardial rupture may be contained by a local area of pericardium, along with organizing thrombus and hematoma. Over time, this *pseudoaneurysm* enlarges, maintaining communication with the LV cavity through a narrow neck. Because a pseudoaneurysm often ruptures spontaneously, it should be surgically repaired if recognized.

POSTINFARCTION RISK STRATIFICATION AND MANAGEMENT

Many clinical and laboratory factors have been identified that are associated with an increase in cardiovascular risk after initial recovery from STEMI. Some of the most important factors include persistent ischemia (spontaneous or provoked), depressed LV ejection fraction (<40%), rales above the lung bases on physical examination or congestion on chest radiograph, and symptomatic ventricular arrhythmias. Other features associated with increased risk include a history of previous MI, age >75, diabetes mellitus, prolonged sinus tachycardia, hypotension, ST-segment changes at rest without angina ("silent ischemia"), an abnormal signal-averaged ECG, nonpatency of the infarct-related coronary artery (if angiography is undertaken), and persistent advanced heart block or a new intraventricular conduction abnormality on the ECG. Therapy must be individualized on the basis of the relative importance of the risk(s) present.

The goal of preventing reinfarction and death after recovery from STEMI has led to strategies to evaluate risk after infarction. In stable patients, submaximal exercise stress testing may be carried out before hospital discharge to detect residual ischemia and ventricular ectopy and to provide the patient with a guideline for exercise in the early recovery period. Alternatively, or in addition, a maximal (symptom-limited) exercise stress test may be carried out 4–6 weeks after infarction. Evaluation of LV function is usually warranted as well. Recognition of a depressed LV ejection fraction by echocardiography or radionuclide ventriculography identifies patients who should receive medications to inhibit the renin-angiotensin-aldosterone system. Patients in whom angina is induced at relatively low workloads, those who have a large reversible defect on perfusion imaging or a depressed ejection fraction, those with demonstrable ischemia, and those in whom exercise provokes symptomatic ventricular arrhythmias should be considered at high risk for recurrent MI or death from arrhythmia (Fig. 239-7). Cardiac catheterization with coronary angiography and/or invasive electrophysiologic evaluation is advised.

Exercise tests also aid in formulating an individualized exercise prescription, which can be much more vigorous in patients who tolerate exercise without any of the above-mentioned adverse signs. Additionally, predischarge stress testing may provide an important psychological benefit, building the patient's confidence by demonstrating a reasonable exercise tolerance.

In many hospitals a cardiac rehabilitation program with progressive exercise is initiated in the hospital and continued after discharge. Ideally, such programs should include an educational component that informs patients about their disease and its risk factors.

The usual duration of hospitalization for an uncomplicated STEMI is about 5 days. The remainder of the convalescent phase may be accomplished at home. During the first 1–2 weeks, the patient should be encouraged to increase activity by walking about the house and outdoors in good weather. Normal sexual activity may be resumed during this period. After 2 weeks, the physician must regulate the patient's activity on the basis of exercise tolerance. Most patients will be able to return to work within 2–4 weeks.

SECONDARY PREVENTION

Various secondary preventive measures are at least partly responsible for the improvement in the long-term mortality and morbidity rates after STEMI. Long-term treatment with an antiplatelet agent (usually aspirin) after STEMI is associated with a 25% reduction in the risk of recurrent infarction, stroke, or cardiovascular mortality (36 fewer events for every 1000 patients treated). An alternative antiplatelet agent that may be used for secondary prevention in patients intolerant of aspirin is clopidogrel (75 mg orally daily). ACE inhibitors or ARBs and, in appropriate patients, aldosterone antagonists should be used indefinitely by patients with clinically evident heart failure, a moderate decrease in global ejection fraction, or a large regional wall motion abnormality to prevent late ventricular remodeling and recurrent ischemic events.

The chronic routine use of oral beta-adrenoceptor blockers for at least 2 years after STEMI is supported by well-conducted, placebo-controlled trials.

Evidence suggests that warfarin lowers the risk of late mortality and the incidence of reinfarction after STEMI. Most physicians prescribe aspirin routinely for all patients without contraindications and add warfarin for patients at increased risk of embolism (see "Thromboembolism," above). Several studies suggest that in patients <75 years a low dose of aspirin (75–81 mg/d) in combination with warfarin administered to achieve an INR >2.0 is more effective than aspirin alone for preventing recurrent MI and embolic cerebrovascular accident. However, there is an increased risk of bleeding and a high rate of discontinuation of warfarin that has limited clinical acceptance of combination antithrombotic therapy. There is increased risk of bleeding when warfarin is added to dual antiplatelet therapy (aspirin and clopidogrel). However, patients who have had a stent implanted and have an indication for anticoagulation should receive dual antiplatelet ther-

apies in combination with warfarin. Such patients should also receive a proton pump inhibitor to minimize the risk of gastrointestinal bleeding and should have regular monitoring of their hemoglobin levels and stool hematest while on combination antithrombotic therapy.

Finally, risk factors for *atherosclerosis* (Chap. 217) should be discussed with the patient, and, when possible, favorably modified.

240 Percutaneous Coronary Intervention

Donald S. Baim*

The introduction of *percutaneous transluminal coronary angioplasty* (PTCA) by Andreas Gruntzig in 1977 established this form of catheter-based therapy as an alternative to bypass surgery for providing coronary revascularization in selected patients. The limitations of early equipment, however, meant that PTCA was applicable to <10% of all coronary revascularization candidates. By 1990, progressive improvements in PTCA equipment led to improved results, expanded indications for use, and an explosive growth in the annual number of PTCA procedures (to ~300,000 in the United States), roughly matching the coronary revascularization provided by surgical bypass operations. Newer interventional devices including atherectomy (plaque removal), stents (plaque scaffolding), and drug-eluting stents were introduced subsequently, further improving the acute success, safety, and long-term durability of percutaneous coronary intervention (PCI). Today, >1 million procedures are performed annually, representing twice the annual number of coronary bypass operations. This dominant role of catheter-based intervention in the treatment of coronary artery disease (CAD) has led to creation of a separate area within the field of cardiovascular diseases known as *interventional cardiology*, with incremental fellowship requirements and Board certification of additional qualification based on training, ongoing experience, and a written examination.

All catheter-based interventions are derivatives of diagnostic cardiac catheterization (Chap. 223), in which catheters are introduced into the arterial circulation by needle puncture, advanced into the heart under fluoroscopic guidance, and used for pressure measurements and injections of radiopaque liquid contrast agents. Interventional procedures differ in that the catheter placed into the ostium of the narrowed coronary artery is then used to advance a flexible, steerable guidewire (diameter < 0.4 mm) down the coronary artery lumen, through the narrowing, and into the vessel beyond. This guidewire then serves as a "rail" over which angioplasty balloons or other therapeutic devices can be advanced and used to enlarge the narrowed segment of coronary artery. Because PCI is performed under local anesthesia and requires only a short (1-day) hospitalization, its use in suitable patients can greatly decrease recovery time and expense compared to coronary bypass surgery.

While not all types of coronary narrowing are well suited to catheter-based intervention, PCI is the treatment of choice for the majority of patients with symptomatic coronary disease. To decide which patients should undergo revascularization (as opposed to continued medical management) and to select which patients should undergo catheter-based rather than surgical revascularization requires a detailed understanding of both clinical and coronary angiographic features, as well as the capabilities of various interventional techniques. The remaining anatomic restrictions relate to dealing with diffuse disease, chronic total occlusions, and bifurcation lesions, but even these challenges are yielding to improved interventional devices and techniques. Deciding between PCI and bypass surgery thus requires balancing the individual patient's coronary anatomy and technical challenges against any factors that limit potential completeness of surgical revascularization or increase its risk (advanced age, poor left ventricular function, and concomitant medical problems). Both patient and physician need to be aware that while catheter-based intervention is done under local anesthesia and has a lower elective mortality rate than bypass surgery (0.4–1.0%, compared to a rate of 1–3%), it is still an invasive procedure whose risks and benefits need to be weighed carefully for each individual patient.

*At the time that Dr. Baim prepared the chapter he was a Professor of Medicine at Harvard Medical School and Senior Physician at Brigham and Women's Hospital. Since then he has assumed the position of Chief Medical and Scientific Officer at Boston Scientific Co.

INDICATIONS

The fundamental indication for PCI is the presence of one or more coronary stenoses thought to be responsible for a clinical syndrome, that warrant revascularization, are approachable by catheter-based techniques, with risks and benefits that compare favorably with those of bypass surgery. For most patients with stable angina, the main goal of either surgical or catheter-based revascularization is the relief of angina rather than improved survival. In patients with multivessel CAD, particularly those with reduced left ventricular function or diabetes, there may also be a survival advantage to surgical revascularization. Trials randomizing patients with multivessel disease in whom either balloon angioplasty or bypass surgery is possible have suggested that the two procedures have essentially equivalent in-hospital and 3- to 5-year mortality rates (except for patients with diabetes mellitus, in whom surgical treatment appears to offer improved 5- to 7-year survival compared to PCI). These trials, however, showed that up to 20% of patients who underwent balloon angioplasty needed a second revascularization procedure to treat renarrowing at the initial treatment site (restenosis). Recent advances in PCI technology (particularly drug-eluting stents) have dramatically reduced the incidence of repeat procedures to treat restenosis to <5%, and have made the durability of symptomatic relief by PCI nearly identical to that of surgery in anatomically suitable patients. Even patients with ostial or mid-shaft left main coronary artery lesions and near normal left ventricular function have 1 year event rates <3% with drug-eluting stenting, although bypass surgery is still the preferred revascularization modality in patients without factors that increase surgical risk.

The current clinical indications for PCI cover the spectrum of ischemic heart disease, from patients with silent ischemia to patients with unstable angina or acute myocardial infarction (MI). The detailed indications are summarized in the recent ACC/AHA guidelines, and the following discussion is thus more conceptual in nature. One clear indication for PCI is moderately *chronic stable angina*, which persists despite medical antianginal therapy and is caused by anatomically suitable lesions (Chap. 237). If multiple severe lesions are present, these can generally be treated during a single procedure. In patients with *acute coronary syndromes*, the benefits of PCI include reduced

death and MI. In *unstable angina* and *non-ST-elevation MI* (STEMI) (Chap. 238), recent studies employing platelet IIb/IIIa receptor blockers and coronary stenting have shown >20% reduction in death or MI at 6 months, with a parallel reduction in hospital readmission, compared to a conservative strategy in which PCI was reserved for strongly positive exercise test results. In patients with *acute STEMI* (Chap. 239), trials comparing thrombolysis to primary angioplasty have consistently shown lower mortality (5.0 vs. 7.0%, $p = .0002$), less non-fatal reinfarction (3.0% vs. 7.0%, $p = .0003$, and less hemorrhagic stroke (0.05% vs. 1%, $p = .0001$), with primary angioplasty (both PTCA and stenting). The current PCI guidelines thus recommend that primary PCI should be performed in patients with STEMI who present within 12 h of symptom onset, if performed in a timely fashion (medical contact-to-balloon or door-to-balloon time within 90 min) by persons skilled in the procedure, working in an appropriate laboratory environment.

As the clinical indications for PCI have broadened, so have its anatomic capabilities. Largely through the introduction of newer interventional devices, PCI has advanced well beyond the treatment of proximal, discrete, subtotal, concentric, non-calcified lesions. Calcified, complex, or diffuse lesions respond well to coronary stent placement, sometimes after pretreatment with rotational atherectomy. Even chronically totally occluded coronary arteries can be crossed and dilated effectively and, when treated with drug-eluting stents, have a 90% long-term patency rate. In addition to lesions in the native coronary tree, obstructions in the saphenous vein bypass grafts can also be dilated successfully to treat recurrent post-bypass angina, making use of distal embolic protection devices to reduce the incidence of peri-procedural MI caused by the tendency of atheroembolic debris to be liberated during stenting of such lesions.

CURRENT TECHNIQUES

While conventional balloon angioplasty (PTCA) offered anatomic versatility and acceptable short- and long-term results, it had limited efficacy in certain anatomic lesion types (e.g., calcified eccentric, ostial, thrombus-containing, or bifurcation lesions). It was also plagued by the problems of elastic recoil (Fig. 240-1), *intimal dissection* (which led to abrupt closure of the dilated segment in 3% of cases requiring emergency bypass surgery), and *restenosis* of 30–40% of the dilated segments within 6 months of initially successful treatment due to a combination of exaggerated neointimal hyperplasia and overall vessel contraction in response to the interventional injury (Fig. 240-2). These problems motivated the development of a number of newer, non-balloon techniques that entered routine clinical practice during the early 1990s. Stents (see below) increased acute procedural success to 98%, reduced the incidence of emergency surgery to 0.1%, and reduced the incidence of restenosis to 15–20%. The incidence of restenosis has been further reduced to 5% by the introduction of drug-eluting stents in 2003. In parallel, improvements in adjunctive pharmacotherapy (especially the acute use of platelet glycoprotein IIb/IIIa receptor blockers, and longer-term thienopyridine, i.e., clopidogrel) use has helped produce significant improvements in procedural safety. In large part, the progressive improvements in PCI results over the past 30 years, and thereby the growth of PCI to become the dominant coronary revascularization modality, lies in the progressive improvements in PCI devices and adjunctive pharmacology.

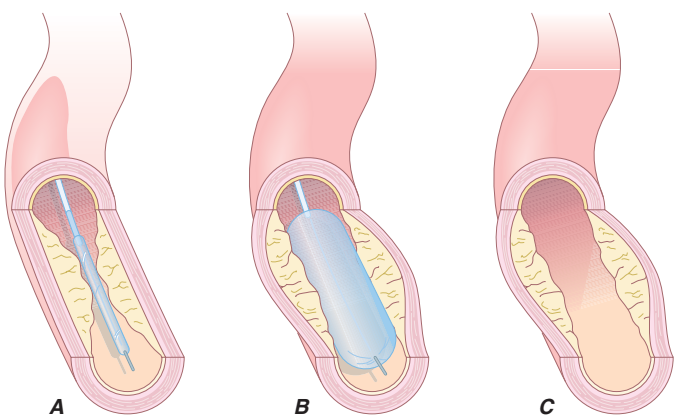

FIGURE 240-1 Proposed mechanism of angioplasty. *A.* Deflated balloon positioned across stenosis. ***B.*** Inflation of the balloon catheter within the stenotic segment causes cracking of the intimal plaque, stretching of the media and adventitia, and expansion of the outer diameter of the vessel. ***C.*** Following balloon deflation, there is partial elastic recoil of the vessel wall, leaving a residual stenosis of 30% and local plaque disruption that would be evident as haziness of the lumen contours on angiography. *[From JT Willerson (ed): Treatment of Heart Diseases, New York, Gower Medical, 1992.]*

FIGURE 240-2 Mechanisms of restenosis. Cross section of a restenotic lesion in the left anterior descending artery 5 months after initial coronary angioplasty shows the original atherosclerotic plaque (AS), the crack in the medial layer induced by the original procedure (star), and the proliferation of fibrocellular tissues (FC) that constitutes the restenotic lesion. In stent restenosis, the mechanism is purely such proliferation, whereas in non-stent interventions such as balloon angioplasty there is frequently also a component due to shrinkage of the overall vessel diameter (unfavorable remodeling) at the treatment site. *(From PW Serruys, et al: Am J Cardiol 54:482, 1984.)*

Stents Stents are metallic scaffolds that are inserted into a diseased vessel segment in their collapsed form and are then deployed by balloon inflation. They overcome two of the principal limitations of balloon dilatation—local dissection of the plaque and elastic recoil of the vessel wall—allowing stents to consistently provide an essentially normal-appearing vessel lumen in the treated segment. In 1994, the first two balloon-expandable stent designs were approved by the U.S. Food and Drug Administration (FDA), with a number of second- and third-generation stent designs introduced subsequently that offered easier delivery into tortuous or distal lesions (Fig. 240-3). In the early experience, metallic stents proved prone to thrombotic occlusion, either acute (<24 h) or subacute (1–14 days with a peak at 6 days), which was ameliorated by greater attention to full initial deployment and the use of dual antiplatelet therapy [aspirin indefinitely, plus the platelet P_2Y_{12}-receptor blockers (ticlopidine or clopidogrel) for 2–4 weeks]. In addition to controlling complications related to abrupt vessel closure, the fact that stenting provided a larger acute luminal area than balloon angioplasty alone reduced the incidence of subsequent restenosis. When in-stent restenosis did occur as the result of excessive neointimal hyperplasia with-

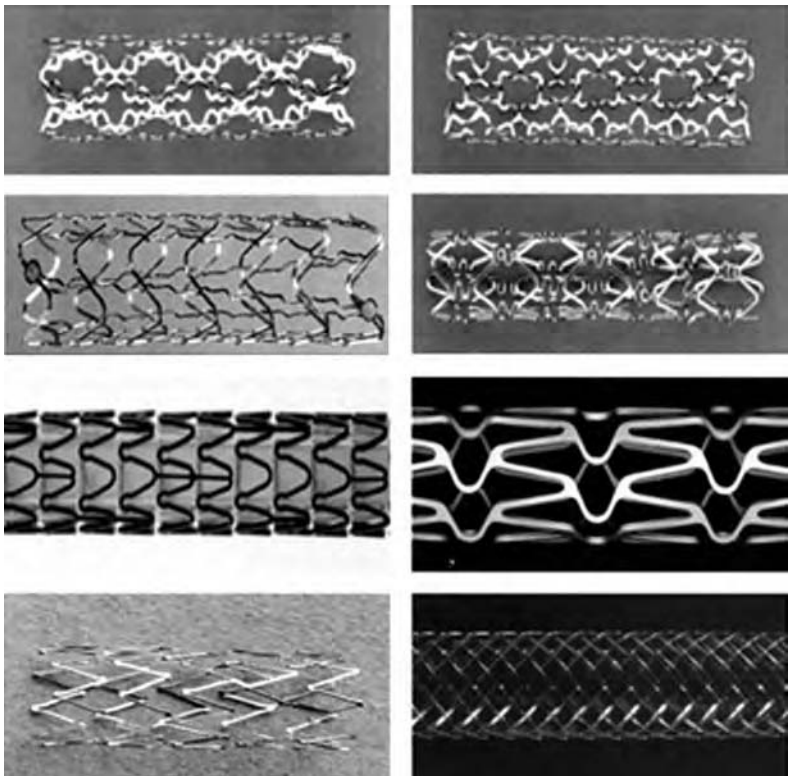

FIGURE 240-3 Examples of various coronary stent designs. Each design is shown in the expanded state. *[Modified from GW Stone. In D Baim (ed). Cardiac Catheterization, Angiography and Intervention, 7th ed, Philadelphia, Lippincott Williams & Wilkins, 2006.]*

in the stent, this could be treated by balloon dilatation followed by catheter-delivered local β or γ radiation (i.e., brachytherapy) to suppress subsequent neointimal regrowth. Despite the limitations of subacute stent thrombosis and in-stent restenosis, the major improvements in outcome led to the dominance of stent placement in catheter-based coronary revascularization, with placement of one or more stents in 85% of all procedures.

Since 2004, the concept of using stents as a local drug delivery platform to favorably modulate the neointimal healing process has entered clinical practice (Fig. 240-4). A wide variety of cytostatic, cytotoxic, and anti-inflammatory and antiproliferative agents have been studied, but current drug-eluting stents utilize either sirolimus (or a derivative thereof) or paclitaxel released from a polymer coating applied to the stent surface. *Sirolimus* is a naturally occurring and immunosuppressive agent that arrests cell proliferation in the G_1 phase, and has been shown to reduce target-vessel failure (target vessel revascularization, death, or MI) to 8.6% vs. 21.0% for bare metal stents. *Paclitaxel* is an inhibitor of microtubules that can arrest cell division at the M phase in high concentrations, but can have cytostatic G_1, anti-migratory, and anti-inflammatory effects on smooth-muscle cells at lower concentrations. It has also been shown to reduce the incidence of ischemia-driven target-vessel revascularization at 12 months, to 7.1% vs. 17.1% for bare metal stents.

Subsequent trials and registries with both drug-eluting stents have supported their use in various vessel sizes and lesion lengths, total occlusions, vein grafts, as well as in patients with diabetes, with target lesion revascularization rates generally in the 4–6% range, and has brought the durability of PCI up to arguably match that of bypass surgery (Fig. 240-5). One consequence of the reduced neointimal hyperplasia with drug-eluting stents, however, is vulnerability to late stent thrombosis, extending to 3 years after implantation, and perhaps even longer. It is thus standard practice to prolong dual antiplatelet therapy (aspirin and clopidogrel) for at least 12 months after placement of a drug-eluting stent, to minimize the small (0.2–0.6% per year) risk of this potentially serious late complication. The risk of late stent thrombosis should always be kept in mind, however, should antiplatelet therapy need to be interrupted for bleeding or a noncardiac surgical procedure within the first year after drug-eluting stent implantation.

Other PCI Technologies Whereas both balloon angioplasty and stent placement enlarge the coronary lumen by displacing plaque, *atherectomy catheters* enlarge the lumen by removing plaque mass from the treated lesion. Several mechanical atherectomy devices were developed in the 1990s, including directional, rotational, extraction, and laser atherectomy. Although each has certain applications, the greater technical difficulty and procedural complications associated with atherectomy compared to stenting has relegated these devices to niche roles (< 5% adjunctive use during current PCI). Various *thrombectomy* devices may be useful when large intracoronary thrombi are present (Fig. 240-6), although their routine use in acute MI PCI has failed to show any benefit in ST-segment resolution or final myocardial infarct size, and in one study their use has been associated with increased adverse events. *Embolic protection devices* (distal filters or occlusion/aspiration devices) may be useful adjuncts during the treatment of saphenous vein graft or other lesions prone to the liberation of debris that may compromise the distal myocardial microcircu-

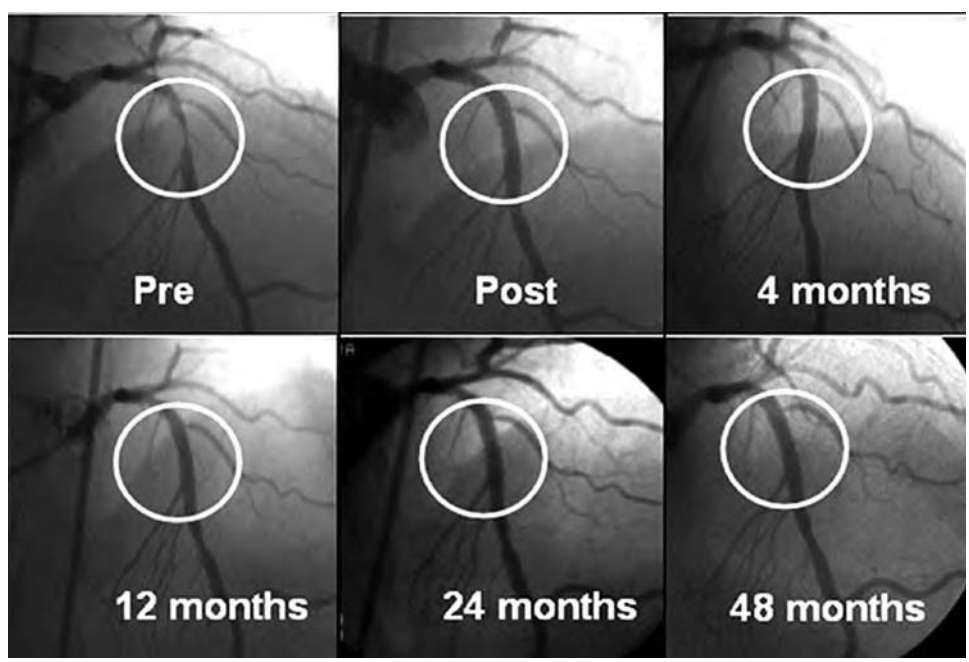

FIGURE 240-4 Long-term results from one of the first patients to receive a sirolimus-eluting stent in the early Sao Paulo experience. A high-grade stenosis in the proximal left anterior descending artery is stented with a single 3.0 mm sirolimus-eluting stent. Serial angiography shows sustained vessel patency with minimal late loss over a 4-year period. *[From GW Stone, in D Baim (ed): Cardiac Catheterization, Angiography and Intervention, 7th ed. Philadelphia, Lippincott Williams & Wilkins, 2006.]*

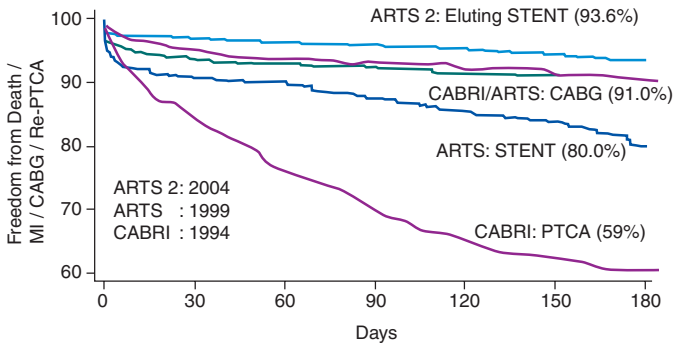

FIGURE 240-5 Improving results of percutaneous coronary intervention (PCI) compared to coronary artery bypass grafting (CABG). In a series of trials spanning a decade from 1994–2004, the 180-day event-free survival of bypass surgery has remained 91%. This was markedly superior to percutaneous transluminal coronary angioplasty (PTCA) in the CABRI trial (32% absolute difference) due to the effect of restenosis. In the ARTS trial, this deficit improved to 11% with the use of bare metal stenting. In the ARTS 2 trial, the event-free survival of drug-eluting stents was actually superior to that of bypass by 2.6%. Although the patient groups are not exactly comparable, the significant improvement in repeat revascularization with the drug-eluting stents may shift the balance further towards PCI. *(Courtesy of Prof. Patrick Serruys; with permission.)*

lation. Again, study of the routine use of distal embolic protection in STEMI has failed to show any improvement in myocardial salvage.

THE PCI PROCEDURE

The procedure begins with percutaneous insertion of an arterial sheath and coronary angiography (Chap. 223). The target lesions for PCI are identified, and the sequencing and strategy for each is planned. Anticoagulation is achieved using either unfractionated heparin [50–70 IU/kg, to an activated clotting time of 250–300 s (slightly less if a glycoprotein IIb/IIIa inhibitor is used concomitantly)] or a direct thrombin inhibitor such as bivalirudin. Aspirin pretreatment (325 mg/d) is begun before the procedure, and clopidogrel loading (300–600 mg) is administered either just before a planned PCI or otherwise at its conclusion. A guiding catheter, which may have the same 6 F (2 mm) outer diameter as a diagnostic coronary angiography catheter but a larger inner lumen to permit balloon and stent advancement, is placed in the involved coronary artery ostium. Under fluoroscopic guidance, a steerable 0.4-mm (0.014-in.) guidewire is advanced across the target stenosis and into the distal vessel beyond, to permit the advancement of a predilating balloon that is ~0.5 mm smaller than the estimated normal caliber of the target vessel, across the lesion. This balloon is inflated with dilute radiographic contrast to a pressure (usually 6–16 atm) to relieve any deformity in the balloon outline and thus partially relieve the stenosis.

If the lesion is heavily calcified, simple balloon predilation may be insufficient, and rotational atherectomy may be required to remove superficial luminal calcification and thereby improve lesion compliance. The guidewire is left in place as the predilating balloon is removed and a drug-eluting stent of appropriate size and length to cover the diseased segment plus a 5-mm margin on either side of the lesion is advanced into position. The angioplasty balloon on which the stent is mounted is then inflated to 14–16 atm to deploy the stent, which can then be further expanded at high pressure with a postdilating balloon as needed. The quality of the result is assessed with repeat angiography (and sometimes intravascular ultrasound) before moving on to treat other significant lesions. Lesions involving bifurcations may be treated either by placing a drug-eluting stent in the main vessel and "rescuing" a compromised branch by balloon dilation, or by any of several strategies to place drug-eluting stents in the main vessel and side branch.
