CSF glucose concentrations <2.2 mmol/L (<40 mg/dL) are abnormal, and a CSF glucose concentration of zero can be seen in bacterial meningitis. Use of the CSF/serum glucose ratio corrects for hyperglycemia that may mask a relative decrease in the CSF glucose concentration. The CSF glucose concentration is low when the CSF/serum glucose ratio is <0.6. A CSF/serum glucose ratio <0.4 is highly suggestive of bacterial meningitis but may also be seen in other conditions, including fungal, tuberculous, and carcinomatous meningitis. It takes from 30 min to several hours for the concentration of CSF glucose to reach equilibrium with blood glucose levels; therefore, administration of 50 mL of 50% glucose (D50) prior to LP, as commonly occurs in emergency room settings, is unlikely to alter CSF glucose concentration significantly unless more than a few hours have elapsed between glucose administration and LP.

A broad-range PCR can detect small numbers of viable and nonviable organisms in CSF and is expected to be useful for making a diagnosis of bacterial meningitis in patients who have been pretreated with oral or parenteral antibiotics and in whom Gram's stain and CSF culture are negative. When the broad-range PCR is positive, a PCR that uses specific bacterial primers to detect the nucleic acid of *S. pneumoniae, N. meningitidis, Escherichia coli, L. monocytogenes, H. influenzae,* and *S. agalactiae* can be obtained based on the clinical suspicion of the meningeal pathogen. The latex agglutination (LA) test for the detection of bacterial antigens of *S. pneumoniae, N. meningitidis, H. influenzae* type b, group B streptococcus, and *E. coli* K1 strains in the CSF has been useful for making a diagnosis of bacterial meningitis but is being replaced by the CSF bacterial PCR assay. The CSF LA test has a *specificity* of 95–100% for *S. pneumoniae* and *N. meningitidis*, so a positive test is virtually diagnostic of bacterial meningitis caused by these organisms. However, the *sensitivity* of the CSF LA test is only 70–100% for detection of *S. pneumoniae* and 33–70% for detection of *N. menin-*

TABLE 376-1 ANTIBIOTICS USED IN EMPIRICAL THERAPY OF BACTERIAL MENINGITIS AND FOCAL CNS INFECTIONS[a]

Indication	Antibiotic
Preterm infants to infants <1 month	Ampicillin + cefotaxime
Infants 1–3 mos	Ampicillin + cefotaxime or ceftriaxone
Immunocompetent children >3 mos and adults <55	Cefotaxime or ceftriaxone + vancomycin
Adults >55 and adults of any age with alcoholism or other debilitating illnesses	Ampicillin + cefotaxime or ceftriaxone + vancomycin
Hospital-acquired meningitis, posttraumatic or postneurosurgery meningitis, neutropenic patients, or patients with impaired cell-mediated immunity	Ampicillin + ceftazidime + vancomycin

Antimicrobial Agent	Total Daily Dose and Dosing Interval	
	Child (>1 month)	Adult
Ampicillin	200 (mg/kg)/d, q4h	12 g/d, q4h
Cefepime	150 (mg/kg)/d, q8h	6 g/d, q8h
Cefotaxime	200 (mg/kg)/d, q6h	12 g/d, q4h
Ceftriaxone	100 (mg/kg)/d, q12h	4 g/d, q12h
Ceftazidime	150 (mg/kg)/d, q8h	6 g/d, q8h
Gentamicin	7.5 (mg/kg)/d, q8h[b]	7.5 (mg/kg)/d, q8h
Meropenem	120 (mg/kg)/d, q8h	3 g/d, q8h
Metronidazole	30 (mg/kg)/d, q6h	1500–2000 mg/d, q6h
Nafcillin	100–200 (mg/kg)/d, q6h	9–12 g/d, q4h
Penicillin G	400,000 (U/kg)/d, q4h	20–24 million U/d, q4h
Vancomycin	60 (mg/kg)/d, q6h	2 g/d, q12h[b]

[a]All antibiotics are administered intravenously; doses indicated assume normal renal and hepatic function.
[b]Doses should be adjusted based on serum peak and trough levels: gentamicin therapeutic level: peak: 5–8 μg/mL; trough: <2 μg/mL; vancomycin therapeutic level: peak: 25–40 μg/mL; trough: 5–15 μg/mL.

gitidis antigens, so a negative test does not exclude infection by these organisms. The Limulus amebocyte lysate assay is a rapid diagnostic test for the detection of gram-negative endotoxin in CSF and thus for making a diagnosis of gram-negative bacterial meningitis. The test has a specificity of 85–100% and a sensitivity approaching 100%. Thus, a positive Limulus amebocyte lysate assay occurs in virtually all patients with gram-negative bacterial meningitis, but false positives may occur.

Almost all patients with bacterial meningitis will have neuroimaging studies performed during the course of their illness. MRI is preferred over CT because of its superiority in demonstrating areas of cerebral edema and ischemia. In patients with bacterial meningitis, diffuse meningeal enhancement is often seen after the administration of gadolinium. Meningeal enhancement is not diagnostic of meningitis but occurs in any CNS disease associated with increased blood-brain barrier permeability.

Petechial skin lesions, if present, should be biopsied. The rash of meningococcemia results from the dermal seeding of organisms with vascular endothelial damage, and biopsy may reveal the organism on Gram's stain.

TABLE 376-2 CEREBROSPINAL FLUID (CSF) ABNORMALITIES IN BACTERIAL MENINGITIS

Opening pressure	>180 mmH_2O
White blood cells	10/μL to 10,000/μL; neutrophils predominate
Red blood cells	Absent in nontraumatic tap
Glucose	<2.2 mmol/L (<40 mg/dL)
CSF/serum glucose	<0.4
Protein	>0.45 g/L (>45 mg/dL)
Gram's stain	Positive in >60%
Culture	Positive in >80%
Latex agglutination	May be positive in patients with meningitis due to *S. pneumoniae*, *N. meningitidis*, *H. influenzae* type b, *E. coli*, group B streptococci
Limulus lysate	Positive in cases of gram-negative meningitis
PCR	Detects bacterial DNA

Note: PCR, polymerase chain reaction.

DIFFERENTIAL DIAGNOSIS

Viral meningoencephalitis, and particularly herpes simplex virus (HSV) encephalitis, can mimic the clinical presentation of bacterial meningitis (see "Encephalitis," below). HSV encephalitis typically presents with headache, fever, altered consciousness, focal neurologic deficits (e.g., dysphasia, hemiparesis), and focal or generalized seizures. The findings on CSF studies, neuroimaging, and electroencephalogram (EEG) distinguish HSV encephalitis from bacterial meningitis. The typical CSF profile with viral CNS infections is a lymphocytic pleocytosis with a normal glucose concentration, in contrast to PMN pleocytosis and hypoglycorrhachia characteristic of bacterial meningitis. MRI abnormalities (other than meningeal enhancement) are not seen in uncomplicated bacterial meningitis. By contrast, in HSV encephalitis, on T2-weighted and fluid-attenuated inversion recovery (FLAIR) MRI images, high signal intensity lesions are seen in the orbitofrontal, anterior, and medial temporal lobes in the majority of patients within 48 h of symptom onset. Some patients with HSV encephalitis have a distinctive periodic pattern on EEG (see below).

Rickettsial disease can resemble bacterial meningitis (Chap. 167). Rocky Mountain spotted fever (RMSF) is transmitted by a tick bite and caused by the bacteria *Rickettsia rickettsii*. The disease may present acutely with high fever, prostration, myalgia, headache, nausea, and vomiting. Most patients develop a characteristic rash within 96 h of the onset of symptoms. The rash is initially a diffuse erythematous maculopapular rash that may be difficult to distinguish from that of meningococcemia. It progresses to a petechial rash, then to a purpuric rash and, if untreated, to skin necrosis or gangrene. The color of the lesions changes from bright red to very dark red, then yellowish-green to black. The rash typically begins in the wrist and ankles and then spreads distally and proximally within a matter of a few hours, involving the palms and soles. Diagnosis is made by immunofluorescent staining of skin biopsy specimens. Ehrlichioses are also transmitted by a tick bite. These are small gram-negative coccobacilli of which two species cause human disease. *Anaplasma phagocytophilum* causes human granulocytic ehrlichiosis (anaplasmosis), and *Ehrlichia chaffeensis* causes human monocytic ehrlichiosis. The clinical and laboratory manifestations of the infections are similar. Patients present with fever, headache, nausea, and vomiting. Twenty percent of patients have a maculopapular or petechial rash. There is laboratory evidence of leukopenia, thrombocytopenia and anemia, and mild to moderate elevations in alanine aminotransferases, alkaline phosphatase, and lactate dehydrogenase. Patients with RMSF and those with ehrlichial infections may have an altered level of consciousness ranging from mild lethargy to coma, confusion, focal neurologic signs, cranial nerve palsies, hyperreflexia, and seizures.

Focal suppurative CNS infections (see below), including subdural and epidural empyema and brain abscess, should also be considered, especially when focal neurologic findings are present. MRI should be performed promptly in all patients with suspected meningitis who have focal features, both to detect the intracranial infection and to search for associated areas of infection in the sinuses or mastoid bones.

A number of noninfectious CNS disorders can mimic bacterial meningitis. Subarachnoid hemorrhage (SAH; Chap. 269) is generally the major consideration. Other possibilities include chemical meningitis due to rupture of tumor contents into the CSF (e.g., from a cystic glioma or craniopharyngioma epidermoid or dermoid cyst); drug-induced hypersensitivity meningitis; carcinomatous or lymphomatous meningitis; meningitis associated with inflammatory disorders such as sarcoid, systemic lupus erythematosus (SLE), and Behçet's syndrome; pituitary apoplexy; and uveomeningitic syndromes (Vogt-Koyanagi-Harada syndrome).

On occasion, subacutely evolving meningitis (Chap. 377) may be considered in the differential diagnosis of acute meningitis. The principal causes include *Mycobacterium tuberculosis* (Chap. 158), *Cryptococcus neoformans* (Chap. 195), *Histoplasma capsulatum* (Chap. 192), *Coccidioides immitis* (Chap. 193), and *Treponema pallidum* (Chap. 162).

℞ ACUTE BACTERIAL MENINGITIS

EMPIRICAL ANTIMICROBIAL THERAPY (Table 376-1) Bacterial meningitis is a medical emergency. The goal is to begin antibiotic therapy

within 60 min of a patient's arrival in the emergency room. Empirical antimicrobial therapy is initiated in patients with suspected bacterial meningitis before the results of CSF Gram's stain and culture are known. *S. pneumoniae* (Chap. 128) and *N. meningitidis* (Chap. 136) are the most common etiologic organisms of community-acquired bacterial meningitis. Due to the emergence of penicillin- and cephalosporin-resistant *S. pneumoniae*, empirical therapy of community-acquired suspected bacterial meningitis in children and adults should include a combination of dexamethasone, a third-generation cephalosporin (e.g., ceftriaxone or cefotaxime) and vancomycin, plus acyclovir, as HSV encephalitis is the leading disease in the differential diagnosis, and doxycycline during tick season to treat tick-borne bacterial infections. Ceftriaxone or cefotaxime provide good coverage for susceptible *S. pneumoniae*, group B streptococci, and *H. influenzae* and adequate coverage for *N. meningitidis*. Cefepime is a broad-spectrum fourth-generation cephalosporin with in vitro activity similar to that of cefotaxime or ceftriaxone against *S. pneumoniae* and *N. meningitidis* and greater activity against *Enterobacter* species and *Pseudomonas aeruginosa*. In clinical trials, cefepime has been demonstrated to be equivalent to cefotaxime in the treatment of penicillin-sensitive pneumococcal and meningococcal meningitis, and it has been used successfully in some patients with meningitis due to *Enterobacter* species and *P. aeruginosa*. Ampicillin should be added to the empirical regimen for coverage of *L. monocytogenes* in individuals <3 months of age, those >55, or those with suspected impaired cell-mediated immunity because of chronic illness, organ transplantation, pregnancy, malignancy, or immunosuppressive therapy. In hospital-acquired meningitis, and particularly meningitis following neurosurgical procedures, staphylococci and gram-negative organisms including *P. aeruginosa* are the most common etiologic organisms. In these patients, empirical therapy should include a combination of vancomycin and ceftazidime, cefepime, or meropenem. Ceftazidime, cefepime, or meropenem should be substituted for ceftriaxone or cefotaxime in neurosurgical patients and in neutropenic patients, as ceftriaxone and cefotaxime do not provide adequate activity against CNS infection with *P. aeruginosa*. Meropenem is a carbapenem antibiotic that is highly active in vitro against *L. monocytogenes*, has been demonstrated to be effective in cases of meningitis caused by *P. aeruginosa*, and shows good activity against penicillin-resistant pneumococci. In experimental pneumococcal meningitis, meropenem was comparable to ceftriaxone and inferior to vancomycin in sterilizing CSF cultures. The number of patients with bacterial meningitis enrolled in clinical trials of meropenem has not been sufficient to definitively assess the efficacy of this antibiotic.

SPECIFIC ANTIMICROBIAL THERAPY

Meningococcal Meningitis (Table 376-3) Although ceftriaxone and cefotaxime provide adequate empirical coverage for *N. meningitidis*, penicillin G remains the antibiotic of choice for meningococcal meningitis caused by susceptible strains. Isolates of *N. meningitidis* with moderate resistance to penicillin have been identified, but patients infected with these strains have still been successfully treated with penicillin. CSF isolates of *N. meningitidis* should be tested for penicillin and ampicillin susceptibility, and if resistance is found, cefotaxime or ceftriaxone should be substituted for penicillin. A 7-day course of intravenous antibiotic therapy is adequate for uncomplicated meningococcal meningitis. The index case and all close contacts should receive chemoprophylaxis with a 2-day regimen of rifampin (600 mg every 12 h for 2 days in adults and 10 mg/kg every 12 h for 2 days in children >1 year). Rifampin is not recommended in pregnant women. Alternatively, adults can be treated with one dose of ciprofloxacin (750 mg), one dose of azithromycin (500 mg), or one intramuscular dose of ceftriaxone (250 mg). Close contacts are defined as those individuals who have had contact with oropharyngeal secretions, either through kissing or by sharing toys, beverages, or cigarettes.

TABLE 376-3 ANTIMICROBIAL THERAPY OF CNS BACTERIAL INFECTIONS BASED ON PATHOGEN[a]

Organism	Antibiotic
Neisseria meningitides	
Penicillin-sensitive	Penicillin G or ampicillin
Penicillin-resistant	Ceftriaxone or cefotaxime
Streptococcus pneumoniae	
Penicillin-sensitive	Penicillin G
Penicillin-intermediate	Ceftriaxone or cefotaxime
Penicillin-resistant	(Ceftriaxone or cefotaxime) + vancomycin
Gram-negative bacilli (except *Pseudomonas* spp.)	Ceftriaxone or cefotaxime
Pseudomonas aeruginosa	Ceftazidime or cefepime or meropenem
Staphylococci spp.	
Methicillin-sensitive	Nafcillin
Methicillin-resistant	Vancomycin
Listeria monocytogenes	Ampicillin + gentamicin
Haemophilus influenzae	Ceftriaxone or cefotaxime
Streptococcus agalactiae	Penicillin G or ampicillin
Bacteroides fragilis	Metronidazole
Fusobacterium spp.	Metronidazole

[a]Doses are as indicated in Table 376-1.

Pneumococcal Meningitis Antimicrobial therapy of pneumococcal meningitis is initiated with a cephalosporin (ceftriaxone, cefotaxime, or cefepime) and vancomycin. All CSF isolates of *S. pneumoniae* should be tested for sensitivity to penicillin and the cephalosporins. Once the results of antimicrobial susceptibility tests are known, therapy can be modified accordingly (Table 376-3). For *S. pneumoniae* meningitis, an isolate of *S. pneumoniae* is considered to be susceptible to penicillin with a minimal inhibitory concentration (MIC) <0.06 μg/mL, to have intermediate resistance when the MIC is 0.1–1.0 μg/mL, and to be highly resistant when the MIC >1.0 μg/mL. Isolates of *S. pneumoniae* that have cephalosporin MICs ≤0.5 μg/mL are considered sensitive to the cephalosporins (cefotaxime, ceftriaxone, cefepime). Those with MICs of 1 μg/mL are considered to have intermediate resistance, and those with MICs ≥2 μg/mL are considered resistant. For meningitis due to pneumococci with cefotaxime or ceftriaxone MICs ≤0.5 μg/mL, treatment with cefotaxime or ceftriaxone is usually adequate. If the MIC >1 μg/mL, vancomycin is the antibiotic of choice. Rifampin can be added to vancomycin for its synergistic effect but is inadequate as monotherapy because resistance develops rapidly when it is used alone. A 2-week course of intravenous antimicrobial therapy is recommended for pneumococcal meningitis.

Patients with *S. pneumoniae* meningitis should have a repeat LP performed 24–36 h after the initiation of antimicrobial therapy to document sterilization of the CSF. Failure to sterilize the CSF after 24–36 h of antibiotic therapy should be considered presumptive evidence of antibiotic resistance. Patients with penicillin- and cephalosporin-resistant strains of *S. pneumoniae* who do not respond to intravenous vancomycin alone may benefit from the addition of intraventricular vancomycin. The intraventricular route of administration is preferred over the intrathecal route because adequate concentrations of vancomycin in the cerebral ventricles are not always achieved with intrathecal administration.

***Listeria* Meningitis** Meningitis due to *L. monocytogenes* is treated with ampicillin for at least 3 weeks (Table 376-3). Gentamicin is often added (2 mg/kg loading dose, then 7.5 mg/kg per day given every 8 h and adjusted for serum levels and renal function). The combination of trimethoprim [10–20 (mg/kg)/d] and sulfamethoxazole [50–100 (mg/kg)/d] given every 6 h may provide an alternative in penicillin-allergic patients.

Staphylococcal Meningitis Meningitis due to susceptible strains of *S. aureus* or coagulase-negative staphylococci is treated with nafcillin (Table 376-3). Vancomycin is the drug of choice for methicillin-resistant staphylococci and for patients allergic to penicillin. In these patients, the CSF should be monitored during therapy. If the CSF is not sterilized after 48 h of intravenous vancomycin therapy, then either intraventricular or intrathecal vancomycin, 20 mg once daily, can be added.

Gram-Negative Bacillary Meningitis The third-generation cephalosporins—cefotaxime, ceftriaxone, and ceftazidime—are equally efficacious for the treatment of gram-negative bacillary meningitis, with the exception of meningitis due to *P. aeruginosa*, which should be treated with ceftazidime, cefepime, or meropenem (Table 376-3). A 3-week course of intravenous antibiotic therapy is recommended for meningitis due to gram-negative bacilli.

ADJUNCTIVE THERAPY The release of bacterial cell-wall components by bactericidal antibiotics leads to the production of the inflammatory cytokines IL-1 and TNF in the subarachnoid space. Dexamethasone exerts its beneficial effect by inhibiting the synthesis of IL-1 and TNF at the level of mRNA, decreasing CSF outflow resistance, and stabilizing the

blood-brain barrier. The rationale for giving dexamethasone 20 min before antibiotic therapy is that dexamethasone inhibits the production of TNF by macrophages and microglia only if it is administered before these cells are activated by endotoxin. Dexamethasone does not alter TNF production once it has been induced. The results of clinical trials of dexamethasone therapy in children, predominantly with meningitis due to *H. influenzae* and *S. pneumoniae*, have demonstrated its efficacy in decreasing meningeal inflammation and neurologic sequelae such as the incidence of sensorineural hearing loss.

A prospective European trial of adjunctive therapy for acute bacterial meningitis in 301 adults found that dexamethasone reduced the number of unfavorable outcomes (15% vs. 25%, $p = .03$) including death (7% vs. 15%, $p = .04$). The benefits were most striking in patients with pneumococcal meningitis. Dexamethasone (10 mg intravenously) was administered 15–20 min before the first dose of an antimicrobial agent, and the same dose was repeated every 6 h for 4 days. These results were confirmed in a second trial of dexamethasone in adults with pneumococcal meningitis. Therapy with dexamethasone should ideally be started 20 min before, or not later than concurrent with, the first dose of antibiotics. It is unlikely to be of significant benefit if started >6 h after antimicrobial therapy has been initiated. Dexamethasone may decrease the penetration of vancomycin into CSF, and it delays the sterilization of CSF in experimental models of *S. pneumoniae* meningitis. As a result, its potential benefit should be carefully weighed when vancomycin is the antibiotic of choice. Alternatively, vancomycin can be administered by the intraventricular route.

INCREASED INTRACRANIAL PRESSURE Emergency treatment of increased ICP includes elevation of the patient's head to 30–45°, intubation and hyperventilation (Pa_{CO_2} 25–30 mmHg), and mannitol. Patients with increased ICP should be managed in an intensive care unit; accurate ICP measurements are best obtained with an ICP monitoring device. **Treatment of increased intracranial pressure is discussed in detail in Chap. 269.**

PROGNOSIS

Mortality is 3–7% for meningitis caused by *H. influenzae*, *N. meningitidis*, or group B streptococci; 15% for that due to *L. monocytogenes*; and 20% for *S. pneumoniae*. In general, the risk of death from bacterial meningitis increases with (1) decreased level of consciousness on admission, (2) onset of seizures within 24 h of admission, (3) signs of increased ICP, (4) young age (infancy) and age >50, (5) the presence of comorbid conditions including shock and/or the need for mechanical ventilation, and (6) delay in the initiation of treatment. Decreased CSF glucose concentration [<2.2 mmol/L (<40 mg/dL)] and markedly increased CSF protein concentration [>3 g/L (>300 mg/dL)] have been predictive of increased mortality and poorer outcomes in some series. Moderate or severe sequelae occur in ~25% of survivors, although the exact incidence varies with the infecting organism. Common sequelae include decreased intellectual function, memory impairment, seizures, hearing loss and dizziness, and gait disturbances.

ACUTE VIRAL MENINGITIS

CLINICAL MANIFESTATIONS

Patients with viral meningitis usually present with headache, fever, and signs of meningeal irritation coupled with an inflammatory CSF profile (see below). The headache of viral meningitis is usually frontal or retroorbital and is often associated with photophobia and pain on moving the eyes. Nuchal rigidity is present in most cases but may be mild and present only near the limit of neck anteflexion. Constitutional signs can include malaise, myalgia, anorexia, nausea and vomiting, abdominal pain, and/or diarrhea. Patients often have mild lethargy or drowsiness; however, profound alterations in consciousness, such as stupor, coma, or marked confusion, are unusual in viral meningitis and suggest the presence of encephalitis or other alternative diagnoses. Similarly, seizures or focal neurologic signs or symptoms or neuroimaging abnormalities indicative of brain parenchymal involvement are not typical of viral meningitis and suggest the presence of encephalitis or another CNS infectious or inflammatory process.

TABLE 376-4 VIRUSES CAUSING ACUTE MENINGITIS AND ENCEPHALITIS IN NORTH AMERICA

Acute Meningitis	
Common	**Less Common**
Enteroviruses (coxsackieviruses, echoviruses, and human enteroviruses 68–71)	Varicella zoster virus
Herpes simplex virus 2	Epstein-Barr virus
Arthropod-borne viruses	Lymphocytic choriomeningitis virus
HIV	
Acute Encephalitis	
Common	**Less Common**
Herpesviruses	Rabies
Herpes simplex virus 1	Eastern equine encephalitis virus
Varicella zoster virus	Western equine encephalitis virus
Epstein-Barr virus	Powassan virus
Arthropod-borne viruses	Cytomegalovirus[a]
La Crosse virus	Enteroviruses[a]
West Nile virus	Colorado tick fever
St. Louis encephalitis virus	Mumps

[a]Immunocompromised host.

ETIOLOGY

Using a variety of diagnostic techniques, including CSF PCR, culture, and serology, a specific viral cause can be found in 75–90% of cases of viral meningitis. The most important agents are enteroviruses, HSV type 2 (HSV-2), and arboviruses (Table 376-4). CSF cultures are positive in 30–70% of patients, the frequency of isolation depending on the specific viral agent. Approximately two-thirds of culture-negative cases of aseptic meningitis have a specific viral etiology identified by CSF PCR testing (see below).

EPIDEMIOLOGY

Viral meningitis is not a nationally reportable disease; however, it has been estimated that the incidence is ~75,000 cases per year. In temperate climates, there is a substantial increase in cases during the summer and early fall months, reflecting the seasonal predominance of enterovirus and arthropod-borne virus (arbovirus) infections, with a peak monthly incidence of about 1 reported case per 100,000 population.

LABORATORY DIAGNOSIS

CSF Examination The most important laboratory test in the diagnosis of viral meningitis is examination of the CSF. The typical profile is a lymphocytic pleocytosis (25–500 cells/μL), a normal or slightly elevated protein concentration [0.2–0.8 g/L (20–80 mg/dL)], a normal glucose concentration, and a normal or mildly elevated opening pressure (100–350 mmH_2O). Organisms are *not* seen on Gram's or acid-fast stained smears or India ink preparations of CSF. Rarely, PMNs may predominate in the first 48 h of illness, especially with infections due to echovirus 9, eastern equine encephalitis (EEE) virus, or mumps. A pleocytosis of polymorphonuclear neutrophils also occurs in 45% of patients with West Nile virus (WNV) meningitis and can persist for a week or longer before shifting to a lymphocytic pleocytosis. Despite these exceptions, the presence of a CSF PMN pleocytosis in a patient with suspected viral meningitis should always prompt consideration of alternative diagnoses, including bacterial meningitis or parameningeal infections. The total CSF cell count in viral meningitis is typically 25–500/μL, although cell counts of several thousand/μL are occasionally seen, especially with infections due to lymphocytic choriomeningitis virus (LCMV) and mumps virus. The CSF glucose concentration is typically normal in viral infections, although it may be decreased in 10–30% of cases due to mumps or LCMV. Rare instances of decreased CSF glucose concentration occur in cases of meningitis due to echoviruses and other enteroviruses, HSV-2, and varicella-zoster virus (VZV). As a rule, a lymphocytic pleocytosis with a low glucose concentration should suggest fungal or tuberculous meningitis, *Listeria* meningoencephalitis, or noninfectious disorders (e.g., sarcoid, neoplastic meningitis).

A number of tests measuring levels of various CSF proteins, enzymes, and mediators—including C-reactive protein, lactic acid, lactate dehydrogenase, neopterin, quinolinate, IL-1β, IL-6, soluble IL-2 receptor, β_2-microglobulin, and TNF—have been proposed as potential discriminators between viral and bacterial meningitis or as markers of specific types of viral infection (e.g., infection with HIV), but they remain of uncertain sensitivity and specificity and are not widely used for diagnostic purposes.

Polymerase Chain Reaction Amplification of Viral Nucleic Acid Amplification of viral-specific DNA or RNA from CSF using PCR amplification has become the single most important method for diagnosing CNS viral infections. In both enteroviral and HSV infections of the CNS, PCR has become the diagnostic procedure of choice and is substantially more sensitive than viral cultures. HSV PCR is also an important diagnostic test in patients with recurrent episodes of "aseptic" meningitis, many of whom have amplifiable HSV DNA in CSF despite negative viral cultures. CSF PCR is also used routinely to diagnose CNS viral infections caused by cytomegalovirus (CMV), Epstein-Barr virus (EBV), VZV, and human herpesvirus 6 (HHV-6). CSF PCR tests are available for WNV but are not as sensitive as CSF IgM. PCR is also useful in the diagnosis of CNS infection caused by *Mycoplasma pneumoniae,* which can mimic viral meningitis and encephalitis.

Viral Culture The sensitivity of CSF cultures for the diagnosis of viral meningitis and encephalitis, in contrast to its utility in bacterial infections, is generally poor. In addition to CSF, specific viruses may also be isolated from throat swabs, stool, blood, and urine. Enteroviruses and adenoviruses may be found in feces; arboviruses, some enteroviruses, and LCMV in blood; mumps and CMV in urine; and enteroviruses, mumps, and adenoviruses in throat washings. During enteroviral infections, viral shedding in stool may persist for several weeks. The presence of enterovirus in stool is not diagnostic and may result from residual shedding from a previous enteroviral infection; it also occurs in some asymptomatic individuals during enteroviral epidemics.

Serologic Studies For some viruses, including many arboviruses such as WNV, serologic studies remain a crucial diagnostic tool. Serum antibody determination is less useful for viruses with high seroprevalence rates in the general population such as HSV, VZV, CMV, and EBV. For viruses with low seroprevalence rates, diagnosis of acute viral infection can be made by documenting seroconversion between acute-phase and convalescent sera (typically obtained after 2–4 weeks) or by demonstrating the presence of virus-specific IgM antibodies. Documentation of synthesis of virus-specific antibodies in CSF, as shown by an increased IgG index or the presence of CSF IgM antibodies, is more useful than serum serology alone and can provide presumptive evidence of CNS infection. Although serum and CSF IgM antibodies generally persist for only a few months after acute infection, there are exceptions to this rule. For example, WNV IgM has been shown to persist in some patients for >1 year following acute infection. Unfortunately, the delay between onset of infection and the host's generation of a virus-specific antibody response often means that serologic data are useful mainly for the retrospective establishment of a specific diagnosis, rather than in aiding acute diagnosis or management.

CSF oligoclonal gamma globulin bands occur in association with a number of viral infections. The associated antibodies are often directed against viral proteins. Oligoclonal bands occur commonly in certain noninfectious neurologic diseases (e.g., multiple sclerosis) and may be found in nonviral infections (e.g., neurosyphilis, Lyme neuroborreliosis).

Other Laboratory Studies All patients with suspected viral meningitis should have a complete blood count and differential, liver and renal function tests, erythrocyte sedimentation rate (ESR) and C-reactive protein, electrolytes, glucose, creatine kinase, aldolase, amylase, and lipase. Neuroimaging studies (MRI, CT) are not necessary in patients with uncomplicated viral meningitis but should be performed in patients with altered consciousness, seizures, focal neurologic signs or symptoms, or atypical CSF profiles.

DIFFERENTIAL DIAGNOSIS

The most important issue in the differential diagnosis of viral meningitis is to consider diseases that can mimic viral meningitis, including (1) untreated or partially treated bacterial meningitis; (2) early stages of meningitis caused by fungi, mycobacteria, or *Treponema pallidum* (neurosyphilis), in which a lymphocytic pleocytosis is common, cultures may be slow growing or negative, and hypoglycorrhachia may not be present early; (3) meningitis caused by agents such as *Mycoplasma*, *Listeria* spp., *Brucella* spp., *Coxiella* spp., *Leptospira* spp., and *Rickettsia* spp.; (4) parameningeal infections; (5) neoplastic meningitis; and (6) meningitis secondary to noninfectious inflammatory diseases, including hypersensitivity meningitis, SLE and other rheumatologic diseases, sarcoidosis, Behçet's syndrome, and the uveomeningitic syndromes.

SPECIFIC VIRAL ETIOLOGIES

Enteroviruses (Chap. 184) are the most common cause of viral meningitis, accounting for >75% of cases in which a specific etiology can be identified. CSF reverse transcriptase PCR (RT-PCR) is the diagnostic procedure of choice and is both sensitive (>95%) and specific (>100%). Enteroviruses are the most likely cause of viral meningitis in the summer months, especially in children (<15 years), although cases occur at reduced frequency year round. Although the incidence of enteroviral meningitis declines with increasing age, some outbreaks have preferentially affected older children and adults. Meningitis outside the neonatal period is usually benign. Patients present with sudden onset of fever; headache; nuchal rigidity; and often constitutional signs, including vomiting, anorexia, diarrhea, cough, pharyngitis, and myalgias. The physical examination should include a careful search for stigmata of enterovirus infection, including exanthemata, hand-foot-mouth disease, herpangina, pleurodynia, myopericarditis, and hemorrhagic conjunctivitis. The CSF profile is typically a lymphocytic pleocytosis (100–1000 cells/μL) with normal glucose and normal or mildly elevated protein concentration. In rare cases, PMNs may predominate during the first 48 h of illness. Treatment is supportive, and patients usually recover without sequelae. Chronic and severe infections can occur in neonates and in individuals with hypo- or agammaglobulinemia.

Arbovirus infections (Chap. 189) occur predominantly in the summer and early fall. Arboviral meningitis should be considered when clusters of meningitis and encephalitis cases occur in a restricted geographic region during the summer or early fall. In WNV epidemics, avian deaths may serve as sentinel infections for subsequent human disease. A history of tick exposure or travel or residence in the appropriate geographic area should suggest the possibility of Colorado tick fever virus or Powassan virus infection, although nonviral tick-borne diseases, including RMSF and Lyme neuroborreliosis, may present similarly. Arbovirus meningoencephalitis is typically associated with a CSF lymphocytic pleocytosis, normal glucose concentration, and normal or mildly elevated protein concentration. However, 40–45% of patients with WNV meningoencephalitis have CSF neutrophilia, which can persist for a week or more. The rarity of hypoglycorrhachia in WNV infection as well as the absence of positive Gram's stains and the negative cultures helps distinguish these patients from those with bacterial meningitis. The presence of increased numbers of plasmacytoid cells or Mollaret-like large mononuclear cells in the CSF may be a clue to the diagnosis of WNV infection. Definitive diagnosis of arboviral meningoencephalitis is based on demonstration of viral-specific IgM in CSF or seroconversion. CSF PCR tests are available for some viruses in selected diagnostic laboratories and at the Centers for Disease Control and Prevention (CDC), but in the case of WNV, sensitivity (~70%) of CSF PCR is less than that of CSF serology.

HSV-2 meningitis (Chap. 172) occurs in ~25% of women and 11% of men at the time of an initial (primary) episode of genital herpes. Of these patients, 20% go on to have recurrent attacks of meningitis. HSV-2 has been increasingly recognized as a major cause of viral meningitis in adults, and overall it is probably second in importance to enteroviruses

as a cause of viral meningitis. Diagnosis of HSV meningitis is usually by HSV CSF PCR as cultures may be negative, especially in patients with recurrent meningitis. Demonstration of intrathecal synthesis of HSV-specific antibody may also be useful in diagnosis, although antibody tests are less sensitive and less specific than PCR and may not become positive until after the first week of infection. In contrast to HSV encephalitis in adults in which >90% of cases are due to HSV-1, the overwhelming majority of HSV meningitis is due to HSV-2. Although a history of or the presence of HSV genital lesions is an important diagnostic clue, many patients with HSV meningitis give no history and have no evidence of active genital herpes at the time of presentation. Most cases of recurrent viral or "aseptic" meningitis, including cases previously diagnosed as Mollaret's meningitis, are likely due to HSV.

VZV meningitis should be suspected in the presence of concurrent chickenpox or shingles. However, it is important to recognize that in some series, up to 40% of VZV meningitis cases have been reported to occur in the absence of rash. The frequency of VZV as a cause of meningitis is extremely variable, ranging from as low as 3% to as high as 20% in different series. Diagnosis is usually based on CSF PCR, although the sensitivity of this test may not be as high as for the other herpesviruses. In patients with negative CSF PCR results, the diagnosis of VZV CNS infection can be made by the demonstration of VZV-specific intrathecal antibody synthesis and/or the presence of VZV CSF IgM antibodies, or by positive CSF cultures.

EBV infections may also produce aseptic meningitis, with or without associated infectious mononucleosis. The presence of atypical lymphocytes in the CSF or peripheral blood is suggestive of EBV infection but may occasionally be seen with other viral infections. EBV is almost never cultured from CSF. Serum and CSF serology can help establish the presence of acute infection, which is characterized by IgM viral capsid antibodies (VCAs), antibodies to early antigens (EA), and the absence of antibodies to EBV-associated nuclear antigen (EBNA). CSF PCR is another important diagnostic test, although positive results may reflect viral reactivation associated with other infectious or inflammatory processes.

HIV meningitis should be suspected in any patient presenting with a viral meningitis with known or suspected risk factors for HIV infection. Meningitis may occur following primary infection with HIV in 5–10% of cases and less commonly at later stages of illness. Cranial nerve palsies, most commonly involving cranial nerves V, VII, or VIII, are more common in HIV meningitis than in other viral infections. Diagnosis can be confirmed by detection of HIV genome in blood or CSF. Seroconversion may be delayed, and patients with negative HIV serologies who are suspected of having HIV meningitis should be monitored for delayed seroconversion. **For further discussion of HIV infection, see Chap. 182.**

Mumps (Chap. 187) should be considered when meningitis occurs in the late winter or early spring, especially in males (male/female ratio 3:1). With the widespread use of the live attenuated mumps vaccine in the United States since 1967, the incidence of mumps meningitis has fallen by >95%. The presence of parotitis, orchitis, oophoritis, pancreatitis, or elevations in serum lipase and amylase are suggestive of mumps meningitis; however, their absence does not exclude the diagnosis. Clinical meningitis occurs in up to 30% of patients with mumps parotitis, and CSF pleocytosis occurs in >50%. Mumps infection confers lifelong immunity, so a documented history of previous infection excludes this diagnosis. Patients with meningitis have a CSF pleocytosis that can exceed 1000 cells/μL in 25%. Lymphocytes predominate in 75%, although CSF neutrophilia occurs in 25%. Hypoglycorrhachia, occurs in 10–30% of patients and may be a clue to the diagnosis when present. Diagnosis is typically made by culture of virus from CSF or by detecting IgM antibodies or seroconversion. CSF PCR is available in some diagnostic and research laboratories. The frequency of mumps meningitis has declined dramatically with the widespread use of the live-attenuated mumps vaccine. Rare cases of vaccine-associated meningitis occur, with a frequency of 10–100/100,000 doses typically 2–4 weeks after vaccination.

LCMV infection (Chap. 189) should be considered when aseptic meningitis occurs in the late fall or winter and in individuals with a history of exposure to house mice (*Mus musculus*), pet or laboratory rodents (e.g., hamsters, rats, mice), or their excreta. Some patients have an associated rash, pulmonary infiltrates, alopecia, parotitis, orchitis, or myopericarditis. Laboratory clues to the diagnosis of LCMV, in addition to the clinical findings noted above, may include the presence of leukopenia, thrombocytopenia, or abnormal liver function tests. Some cases present with a marked CSF pleocytosis (>1000 cells/μL) and hypoglycorrachia (<30%). Diagnosis is based on serology and/or culture of virus from CSF.

℞ ACUTE VIRAL MENINGITIS

Treatment of almost all cases of viral meningitis is primarily symptomatic and includes use of analgesics, antipyretics, and antiemetics. Fluid and electrolyte status should be monitored. Patients with suspected bacterial meningitis should receive appropriate empirical therapy pending culture results (see above). Hospitalization may not be required in immunocompetent patients with presumed viral meningitis and no focal signs or symptoms, no significant alteration in consciousness, and a classic CSF profile (lymphocytic pleocytosis, normal glucose, negative Gram's stain) if adequate provision for monitoring at home and medical follow-up can be ensured. Immunocompromised patients; patients with significant alteration in consciousness, seizures, or the presence of focal signs and symptoms suggesting the possibility of encephalitis or parenchymal brain involvement; and those patients who have an atypical CSF profile should be hospitalized. Oral or intravenous acyclovir may be of benefit in patients with meningitis caused by HSV-1 or -2 and in cases of severe EBV or VZV infection. Data concerning treatment of HSV, EBV, and VZV meningitis are extremely limited. Seriously ill patients should probably receive intravenous acyclovir (15–30 mg/kg per day in three divided doses), which can be followed by an oral drug such as acyclovir (800 mg, five times daily), famciclovir (500 mg tid), or valacyclovir (1000 mg tid) for a total course of 7–14 days. Patients who are less ill can be treated with oral drugs alone. Patients with HIV meningitis should receive highly active antiretroviral therapy (Chap. 182).

Patients with viral meningitis who are known to have deficient humoral immunity (e.g., X-linked agammaglobulinemia) and who are not already receiving either intramuscular gamma globulin or intravenous immunoglobulin (IVIg), should be treated with these agents. Intraventricular administration of immunoglobulin through an Ommaya reservoir has been tried in some patients with chronic enteroviral meningitis who have not responded to intramuscular or intravenous immunoglobulin.

An investigational drug, pleconaril, has shown efficacy against a variety of enteroviral infections and has good oral bioavailability and excellent CNS penetration. Clinical trials in patients with enteroviral meningitis indicated that pleconaril decreased the duration of symptoms compared to placebo. Most cases of enteroviral CNS infection are benign and self-limited and do not require specific antiviral therapy. However, pleconaril treatment might benefit patients with chronic CNS enteroviral infections in the setting of agammaglobulinemia or those who develop poliomyelitis as a complication of polio vaccine administration. Unfortunately, the availability of pleconaril for compassionate-use purposes is currently uncertain.

Vaccination is an effective method of preventing the development of meningitis and other neurologic complications associated with poliovirus, mumps, and measles infection. A live attenuated VZV vaccine (Varivax) is available in the United States. Clinical studies indicate an effectiveness rate of 70–90% for this vaccine, but a booster may be required to maintain immunity. An inactivated varicella vaccine is available for transplant recipients.

PROGNOSIS

In adults, the prognosis for full recovery from viral meningitis is excellent. Rare patients complain of persisting headache, mild mental impairment, incoordination, or generalized asthenia for weeks to months. The outcome in infants and neonates (<1 year) is less certain; intellectual impairment, learning disabilities, hearing loss, and other lasting sequelae have been reported in some studies.

VIRAL ENCEPHALITIS

DEFINITION

In contrast to viral meningitis, where the infectious process and associated inflammatory response are limited largely to the meninges, in

encephalitis the brain parenchyma is also involved. Many patients with encephalitis also have evidence of associated meningitis (meningoencephalitis) and, in some cases, involvement of the spinal cord or nerve roots (encephalomyelitis, encephalomyeloradiculitis).

CLINICAL MANIFESTATIONS

In addition to the acute febrile illness with evidence of meningeal involvement characteristic of meningitis, the patient with encephalitis commonly has an altered level of consciousness (confusion, behavioral abnormalities), or a depressed level of consciousness, ranging from mild lethargy to coma, and evidence of either focal or diffuse neurologic signs and symptoms. Patients with encephalitis may have hallucinations, agitation, personality change, behavioral disorders, and, at times, a frankly psychotic state. Focal or generalized seizures occur in many patients with encephalitis. Virtually every possible type of focal neurologic disturbance has been reported in viral encephalitis; the signs and symptoms reflect the sites of infection and inflammation. The most commonly encountered focal findings are aphasia, ataxia, upper or lower motor neuron patterns of weakness, involuntary movements (e.g., myoclonic jerks, tremor), and cranial nerve deficits (e.g., ocular palsies, facial weakness). Involvement of the hypothalamic-pituitary axis may result in temperature dysregulation, diabetes insipidus, or the development of the syndrome of inappropriate secretion of antidiuretic hormone (SIADH). Despite the clear neuropathologic evidence that viruses differ in the regions of the CNS they injure, it is often impossible to distinguish reliably on clinical grounds alone one type of viral encephalitis (e.g., that caused by HSV) from others (see "Differential Diagnosis," below).

ETIOLOGY

In the United States, there are ~20,000 reported cases of encephalitis per year, although the actual number of cases is likely to be significantly larger. Hundreds of viruses are capable of causing encephalitis, although only a limited subset is responsible for most cases in which a specific cause is identified (Table 376-4). The same organisms responsible for aseptic meningitis are also responsible for encephalitis, although the relative frequencies with which specific organisms cause these two patterns of infection often differ. The most important viruses causing sporadic cases of encephalitis in immunocompetent adults are herpesviruses (HSV, VZV, EBV). Epidemics of encephalitis are caused by arboviruses, which belong to several different viral taxonomic groups including *Alphaviruses* (e.g., EEE virus, western equine encephalitis virus), *Flaviviruses* (e.g., WNV, St. Louis encephalitis virus, Japanese encephalitis virus, Powassan virus), and *Bunyaviruses* (e.g., California encephalitis virus serogroup, LaCrosse virus). Historically, the largest number of cases of arbovirus encephalitis in the United States has been due to St. Louis encephalitis virus and the California encephalitis virus serogroup. However, since 2002, WNV has been responsible for the majority of arbovirus meningitis and encephalitis cases in the United States. The 2003 epidemic was the largest epidemic of arboviral neuroinvasive disease (encephalitis + meningitis) ever recorded in the United States, with 2860 cases and 264 deaths. Since 2003, WNV has accounted for ~1100–1300 cases of neuroinvasive disease per year and 100–120 deaths in the United States. New causes of viral CNS infections are constantly appearing, as evidenced by the recent outbreak of cases of encephalitis in Southeast Asia caused by Nipah virus, a newly identified member of the Paramyxovirus family, and of meningitis in Europe caused by Toscana virus, an arbovirus belonging to the Bunyavirus family.

LABORATORY DIAGNOSIS

CSF Examination CSF examination should be performed in all patients with suspected viral encephalitis unless contraindicated by the presence of severely increased ICP. The characteristic CSF profile is indistinguishable from that of viral meningitis and typically consists of a lymphocytic pleocytosis, a mildly elevated protein concentration, and a normal glucose concentration. A CSF pleocytosis (>5 cells/μL) occurs in >95% of patients with documented viral encephalitis. In rare cases, a pleocytosis may be absent on the initial LP but present on subsequent LPs. Patients who are severely immunocompromised by HIV infection, glucocorticoid or other immunosuppressant drugs, chemotherapy, or lymphoreticular malignancies may fail to mount a CSF inflammatory response. CSF cell counts exceed 500/μL in only about 10% of patients with encephalitis. Infections with certain arboviruses (e.g., EEE virus or California encephalitis virus), mumps, and LCMV may occasionally result in cell counts >1000/μL, but this degree of pleocytosis should suggest the possibility of nonviral infections or other inflammatory processes. Atypical lymphocytes in the CSF may be seen in EBV infection and less commonly with other viruses, including CMV, HSV, and enteroviruses. Increased numbers of plasmacytoid or Mollaret-like large mononuclear cells have been reported in WNV encephalitis. Polymorphonuclear pleocytosis occurs in ~40% of patients with WNV encephalitis. Large numbers of CSF PMNs may be present in patients with encephalitis due to EEE virus, echovirus 9, and, more rarely, other enteroviruses. However, persisting CSF neutrophilia should prompt consideration of bacterial infection, leptospirosis, amebic infection, and noninfectious processes such as acute hemorrhagic leukoencephalitis. About 20% of patients with encephalitis will have a significant number of red blood cells (>500/μL) in the CSF in a nontraumatic tap. The pathologic correlate of this finding may be a hemorrhagic encephalitis of the type seen with HSV; however, CSF red blood cells occur with similar frequency and in similar numbers in patients with nonherpetic focal encephalitides. A decreased CSF glucose concentration is distinctly unusual in viral encephalitis and should suggest the possibility of bacterial, fungal, tuberculous, parasitic, leptospiral, syphilitic, sarcoid, or neoplastic meningitis. Rare patients with mumps, LCMV, or advanced HSV encephalitis may have low CSF glucose concentrations.

CSF PCR CSF PCR has become the primary diagnostic test for CNS infections caused by CMV, EBV, VZV, HHV-6, and enteroviruses (see "Viral Meningitis," above). The sensitivity and specificity of CSF PCRs varies with the virus being tested. The sensitivity (~96%) and specificity (~99%) of HSV CSF PCR is equivalent to or exceeds that of brain biopsy. It is important to recognize that HSV CSF PCR results need to be interpreted after considering the likelihood of disease in the patient being tested, the timing of the test in relationship to onset of symptoms, and the prior use of antiviral therapy. A negative HSV CSF PCR test performed by a qualified laboratory at the appropriate time during illness in a patient with a high likelihood of HSV encephalitis based on clinical and laboratory abnormalities significantly reduces the likelihood of HSV encephalitis but does not exclude it. For example, in a patient with a pretest probability of 35% of having HSV encephalitis, a negative HSV CSF PCR reduces the posttest probability to ~2%, and for a patient with a pretest probability of 60%, a negative test reduces the posttest probability to ~6%. In both situations a positive test makes the diagnosis almost certain (98–99%). There have been several recent reports of initially negative HSV CSF PCR tests that were obtained early (≤72 h) following symptom onset, and that became positive when repeated 1–3 days later. The frequency of positive HSV CSF PCRs in patients with herpes encephalitis also decreases as a function of the duration of illness, with only ~20% of cases remaining positive after ≥14 days. PCR results are generally not affected by ≤1 week of antiviral therapy. In one study, 98% of CSF specimens remained PCR-positive during the first week of initiation of antiviral therapy, but the numbers fell to ~50% by 8–14 days and to ~21% by >15 days after initiation of antiviral therapy.

The sensitivity and specificity of CSF PCR tests for viruses other than herpes simplex have not been definitively characterized. Enteroviral CSF PCR appears to have a sensitivity and specificity of >95%. The specificity of EBV CSF PCR has not been established. Positive EBV CSF PCRs associated with positive tests for other pathogens have been reported and may reflect reactivation of EBV latent in lymphocytes that enter the CNS as a result of an unrelated infectious or inflammatory process. In patients with CNS infection due to VZV, CSF antibody and PCR studies should be considered complementary,

as patients may have evidence of intrathecal synthesis of VZV-specific antibodies and negative CSF PCRs. In the case of WNV infection, CSF PCR appears to be less sensitive (~70% sensitivity) than detection of WNV-specific CSF IgM, although PCR testing remains useful in immunocompromised patients who may not mount an effective anti-WNV antibody response.

CSF Culture Attempts to culture viruses from the CSF in cases of encephalitis are often disappointing. Cultures are negative in >95% of cases of HSV-1 encephalitis.

Serologic Studies and Antigen Detection The basic approach to the serodiagnosis of viral encephalitis is identical to that discussed earlier for viral meningitis. In patients with HSV encephalitis, both antibodies to HSV-1 glycoproteins and glycoprotein antigens have been detected in the CSF. Optimal detection of both HSV antibodies and antigen typically occurs after the first week of illness, limiting the utility of these tests in acute diagnosis. Nonetheless, HSV CSF antibody testing is of value in selected patients whose illness is >1 week in duration and who are CSF PCR–negative for HSV. Demonstration of WNV IgM antibodies is diagnostic of WNV encephalitis as IgM antibodies do not cross the blood-brain barrier, and their presence in CSF is therefore indicative of intrathecal synthesis. Timing of antibody collection may be important as the rate of CSF WNV IgM seropositivity increases by ~10% per day during the first week after illness onset.

MRI, CT, EEG Patients with suspected encephalitis almost invariably undergo neuroimaging studies and often EEG. These tests help identify or exclude alternative diagnoses and assist in the differentiation between a focal, as opposed to a diffuse, encephalitic process. Focal findings in a patient with encephalitis should always raise the possibility of HSV encephalitis. Examples of focal findings include: (1) areas of increased signal intensity in the frontotemporal, cingulate, or insular regions of the brain on T2-weighted, FLAIR, or diffusion-weighted MRI images (Fig. 376-3); (2) focal areas of low absorption, mass effect, and contrast enhancement on CT; or (3) periodic focal temporal lobe spikes on a background of slow or low-amplitude ("flattened") activity on EEG. Approximately 10% of patients with PCR-documented HSV encephalitis will have a normal MRI, although nearly 80% will have abnormalities in the temporal lobe, and an additional 10% in extratemporal regions. The lesions are typically hyperintense on T2-weighted images. CT is less sensitive than MRI and is normal in up to 33% of patients. The addition of FLAIR and diffusion-weighted images to the standard MRI sequences enhances sensitivity. EEG abnormalities occur in >90% of PCR-documented cases of HSV encephalitis; they typically involve the temporal lobes but are often nonspecific. Some patients with HSV encephalitis have a distinctive EEG pattern consisting of periodic, stereotyped, sharp-and-slow complexes originating in one or both temporal lobes and repeating at regular intervals of 2–3 s. The periodic complexes are typically noted between the 2nd and 15th day of the illness and are present in two-thirds of pathologically proven cases of HSV encephalitis.

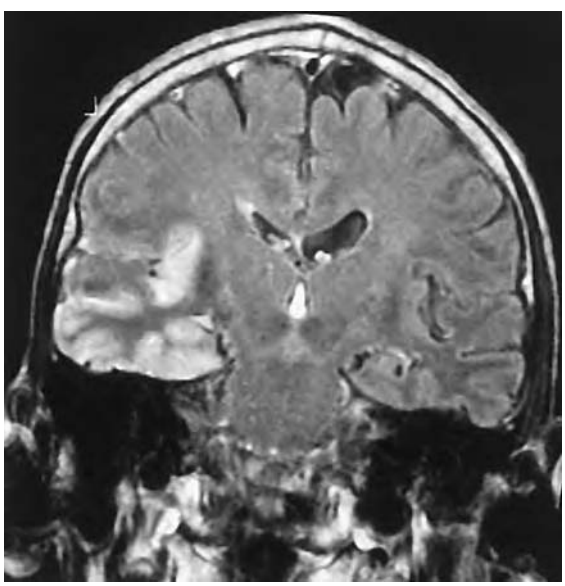

FIGURE 376-3 Coronal FLAIR magnetic resonance image from a patient with herpes simplex encephalitis. Note the area of increased signal in the right temporal lobe (left side of image) confined predominantly to the gray matter. This patient had predominantly unilateral disease; bilateral lesions are more common but may be quite asymmetric in their intensity.

Significant MRI abnormalities are found in only ~50% of patients with WNV encephalitis, a frequency less than that with HSV encephalitis. When present, abnormalities often involve deep brain structures, including the thalamus, basal ganglia, and brainstem, rather than the cortex and may only be apparent on FLAIR images. EEGs typically show generalized slowing that may be more anteriorly prominent rather than the temporally predominant pattern of sharp or periodic discharges more characteristic of HSV encephalitis. Patients with VZV encephalitis may show multifocal areas of hemorrhagic and ischemic infarction reflecting the tendency of this virus to produce a CNS vasculopathy rather than a true encephalitis. Immunocompromised adult patients with CMV often have enlarged ventricles with areas of increased T2 signal on MRI outlining the ventricles and sub-ependymal enhancement on T1-weighted post-contrast images. Table 376-5 highlights specific diagnostic test results in encephalitis that can be useful in clinical decision-making.

Brain Biopsy Brain biopsy is now generally reserved for patients in whom CSF PCR studies fail to lead to a specific diagnosis, who have focal abnormalities on MRI, and who continue to show progressive

TABLE 376-5 USE OF DIAGNOSTIC TESTS IN ENCEPHALITIS

The best test for WNV encephalitis is the *CSF IgM antibody test*. The prevalence of positive CSF IgM tests increases by about 10%/day after illness onset and reaches 70–80% by the end of the first week. Serum WNV IgM can provide evidence for recent WNV infection, but in the absence of other findings does not establish the diagnosis of neuroinvasive disease (meningitis, encephalitis, acute flaccid paralysis).
Approximately 80% of patients with proven HSV encephalitis have *MRI* abnormalities involving the temporal lobes. This percentage likely increases to >90% when FLAIR and DWI MR sequences are also utilized. The absence of temporal lobe lesions on MR reduces the likelihood of HSV encephalitis and should prompt consideration of other diagnostic possibilities.
The *CSF HSV PCR* test may be negative in the first 72 h of symptoms of HSV encephalitis. A repeat study should be considered in patients with an initial early negative PCR in whom diagnostic suspicion of HSV encephalitis remains high and no alternative diagnosis has yet been established.
Detection of *intrathecal synthesis* (increased CSF/serum HSV antibody ratio corrected for breakdown of the blood-brain barrier) of *HSV-specific antibody* may be useful in diagnosis of HSV encephalitis in patients in whom only late (>1 week post-onset) CSF specimens are available and PCR studies are negative. Serum serology alone is of no value in diagnosis of HSV encephalitis due to the high seroprevalence rate in the general population.
Negative *CSF viral cultures* are of no value in excluding the diagnosis of HSV or EBV encephalitis.
VZV CSF IgM antibodies may be present in patients with a negative VZV CSF PCR. Both tests should be performed in patients with suspected VZV CNS disease.
The specificity of *EBV CSF PCR* for diagnosis of CNS infection is unknown. Positive tests may occur in patients with a CSF pleocytosis due to other causes. Detection of EBV CSF IgM or intrathecal synthesis of antibody to VCA supports the diagnosis of EBV encephalitis. Serological studies consistent with acute EBV infection (e.g., IgM VCA, presence of antibodies against EA but not against EBNA) can help support the diagnosis.

Note: CSF, cerebrospinal fluid; IgM, immunoglobulin M; WNV, West Nile virus; HSV, herpes simplex virus; MRI, magnetic resonance imaging; FLAIR, fluid attenuated inversion recovery; DWI, diffusion-weighted imaging; PCR, polymerase chain reaction; EBV, Epstein-Barr virus; VZV, varicella-zoster virus; CNS, central nervous system; VCA, viral capsid antibody; EA, early antigen; EBNA, EBV-associated nuclear antigen.

clinical deterioration despite treatment with acyclovir and supportive therapy.

DIFFERENTIAL DIAGNOSIS

Infection by a variety of other organisms can mimic viral encephalitis. In studies of biopsy-proven HSV encephalitis, common infectious mimics of focal viral encephalitis included mycobacteria, fungi, rickettsia, *Listeria* and other bacteria (including *Bartonella* sp.), and *Mycoplasma*.

Infection caused by the ameba *Naegleria fowleri* can also cause acute meningoencephalitis (primary amebic meningoencephalitis), whereas that caused by *Acanthamoeba* and *Balamuthia* more typically produces subacute or chronic granulomatous amebic meningoencephalitis. *Naegleria* thrive in warm, iron-rich pools of water, including those found in drains, canals, and both natural and human-made outdoor pools. Infection has typically occurred in immunocompetent children with a history of swimming in potentially infected water. The CSF, in contrast to the typical profile seen in viral encephalitis, often resembles that of bacterial meningitis with a neutrophilic pleocytosis and hypoglycorrhachia. Motile trophozoites can be seen in a wet mount of warm, fresh CSF. No effective treatment has been identified, and mortality approaches 100%.

Encephalitis can be caused by the raccoon pinworm *Baylisascaris procyonis*. Clues to the diagnosis include a history of raccoon exposure, and especially of playing in or eating dirt potentially contaminated with raccoon feces. Most patients are children, and many have an associated eosinophilia.

Once nonviral causes of encephalitis have been excluded, the major diagnostic challenge is to distinguish HSV from other viruses that cause encephalitis. This distinction is particularly important because in virtually every other instance the therapy is supportive, whereas specific and effective antiviral therapy is available for HSV, and its efficacy is enhanced when it is instituted early in the course of infection. HSV encephalitis should be considered when clinical features suggesting involvement of the inferomedial frontotemporal regions of the brain are present, including prominent olfactory or gustatory hallucinations, anosmia, unusual or bizarre behavior or personality alterations, or memory disturbance. HSV encephalitis should always be suspected in patients with focal findings on clinical examination, neuroimaging studies, or EEG. The diagnostic procedure of choice in these patients is CSF PCR analysis for HSV. A positive CSF PCR establishes the diagnosis, and a negative test dramatically reduces the likelihood of HSV encephalitis (see above).

The anatomic distribution of lesions may provide an additional clue to diagnosis. Patients with rapidly progressive encephalitis and prominent brainstem signs, symptoms, or neuroimaging abnormalities may be infected by flaviviruses (WNV, St. Louis encephalitis virus, Japanese encephalitis virus), HSV, rabies, or *L. monocytogenes*. Significant involvement of deep gray matter structures, including the basal ganglia and thalamus, should also suggest possible flavivirus infection. These patients may present clinically with prominent movement disorders (tremor, myoclonus) or parkinsonian features. Patients with WNV infection can also present with a poliomyelitis-like acute flaccid paralysis, as can patients infected with enterovirus 71 and, less commonly, other enteroviruses. Acute flaccid paralysis is characterized by the acute onset of a lower motor neuron type of weakness with flaccid tone, reduced or absent reflexes, and relatively preserved sensation. Despite an aggressive World Health Organization poliovirus eradication initiative, >1200 cases of wild-type poliovirus-induced poliomyelitis have been reported worldwide in 2006, with 88% occurring in Nigeria and India and >20 cases each from Somalia, Afghanistan, and Namibia. There have been recent small outbreaks of poliomyelitis associated with vaccine strains of virus that have reverted to virulence through mutation or recombination with circulating wild-type enteroviruses in Hispaniola, China, the Philippines, and Madagascar.

Epidemiologic factors may provide important clues to the diagnosis of viral meningitis or encephalitis. Particular attention should be paid to the season of the year; the geographic location and travel history; and possible exposure to animal bites or scratches, rodents, and ticks. Although transmission from the bite of an infected dog remains the most common cause of rabies worldwide, in the United States very few cases of dog rabies occur, and the most common risk factor is exposure to bats—although a clear history of a bite or scratch is often lacking. The classic clinical presentation of encephalitic (furious) rabies is of fever, fluctuating consciousness, and autonomic hyperactivity. Phobic spasms of the larynx, pharynx, neck muscles, and diaphragm can be triggered by attempts to swallow water (*hydrophobia*) or by inspiration (*aerophobia*). Patients may also present with paralytic (dumb) rabies characterized by acute ascending paralysis. Rabies due to the bite of a bat has a different clinical presentation than classic rabies. Patients present with focal neurologic deficits, myoclonus, seizures, and hallucinations; phobic spasms are not a typical feature. Patients with rabies have a CSF lymphocytic pleocytosis and may show areas of increased T2 signal abnormality in the brainstem, hippocampus, and hypothalamus. Diagnosis can be made by finding rabies virus antigen in brain tissue or in the neural innervation of hair follicles at the nape of the neck. PCR amplification of viral nucleic acid from CSF and saliva or tears may also enable diagnosis. Serology is frequently negative in both serum and CSF in the first week after onset of infection, which limits its acute diagnostic utility. No specific therapy is available, and cases are almost invariably fatal, with isolated survivors having devastating neurologic sequelae.

State public health authorities provide a valuable resource concerning isolation of particular agents in individual regions. Regular updates concerning the number, type and distribution of cases of arboviral encephalitis can be found on the CDC and U.S. Geological Survey (USGS) websites (*http://www.cdc.gov* and *http://diseasemaps.usgs.gov*).

The major noninfectious etiologies that should be included in the differential diagnosis of acute encephalitis are nonvasculitic autoimmune meningoencephalitis, which may or may not be associated with serum antithyroid microsomal and antithyroglobulin antibodies; limbic encephalitis associated with antineuronal antibodies; limbic encephalopathy not associated with cancer; acute disseminated encephalomyelitis and related fulminant demyelinating disorders (Chap. 375); and lymphoma. Finally, Creutzfeldt-Jakob disease (Chap. 378) can rarely present in an explosive fashion mimicking viral encephalitis.

Rx VIRAL ENCEPHALITIS

Specific antiviral therapy should be initiated when appropriate. Vital functions, including respiration and blood pressure, should be monitored continuously and supported as required. In the initial stages of encephalitis, many patients will require care in an intensive care unit. Basic management and supportive therapy should include careful monitoring of ICP, fluid restriction, avoidance of hypotonic intravenous solutions, and suppression of fever. Seizures should be treated with standard anticonvulsant regimens, and prophylactic therapy should be considered in view of the high frequency of seizures in severe cases of encephalitis. As with all seriously ill, immobilized patients with altered levels of consciousness, encephalitis patients are at risk for aspiration pneumonia, stasis ulcers and decubiti, contractures, deep venous thrombosis and its complications, and infections of indwelling lines and catheters.

Acyclovir is of benefit in the treatment of HSV and should be started empirically in patients with suspected viral encephalitis, especially if focal features are present, while awaiting viral diagnostic studies. Treatment should be discontinued in patients found not to have HSV encephalitis, with the possible exception of patients with severe encephalitis due to VZV or EBV. HSV, VZV, and EBV all encode an enzyme, deoxypyrimidine (thymidine) kinase, that phosphorylates acyclovir to produce acyclovir-5′-monophosphate. Host cell enzymes then phosphorylate this compound to form a triphosphate derivative. It is the triphosphate that acts as an antiviral agent by inhibiting viral DNA polymerase and by causing premature termination of nascent viral DNA chains. The specificity of action depends on the fact that uninfected cells do not phosphorylate significant amounts of acyclovir to acyclovir-5′-monophosphate. A second level of specificity is provided by the fact that the acyclovir triphosphate is a more potent inhibitor of viral DNA polymerase than of the analogous host cell enzymes.

Adults should receive a dose of 10 mg/kg of acyclovir intravenously every 8 h (30 mg/kg per day total dose) for a minimum of 14 days. CSF PCR

can be repeated at the completion of the 14-day course, with PCR-positive patients receiving an additional 7 days of treatment, followed by a repeat CSF PCR test. Neonatal HSV CNS infection is less responsive to acyclovir therapy than HSV encephalitis in adults; it is recommended that neonates with HSV encephalitis receive 20 mg/kg of acyclovir every 8 h (60 mg/kg per day total dose) for a minimum of 21 days.

Prior to intravenous administration, acyclovir should be diluted to a concentration ≤7 mg/mL. (A 70-kg person would receive a dose of 700 mg, which would be diluted in a volume of 100 mL.) Each dose should be infused slowly over 1 h rather than by rapid or bolus infusion, to minimize the risk of renal dysfunction. Care should be taken to avoid extravasation or intramuscular or subcutaneous administration. The alkaline pH of acyclovir can cause local inflammation and phlebitis (9%). Dose adjustment is required in patients with impaired renal glomerular filtration. Penetration into CSF is excellent, with average drug levels ~50% of serum levels. Complications of therapy include elevations in blood urea nitrogen and creatinine levels (5%), thrombocytopenia (6%), gastrointestinal toxicity (nausea, vomiting, diarrhea) (7%), and neurotoxicity (lethargy or obtundation, disorientation, confusion, agitation, hallucinations, tremors, seizures) (1%). Acyclovir resistance may be mediated by changes in either the viral deoxypyrimidine kinase or DNA polymerase. To date, acyclovir-resistant isolates have not been a significant clinical problem in immunocompetent individuals. However, there have been reports of clinically virulent acyclovir-resistant HSV isolates from sites outside the CNS in immunocompromised individuals, including those with AIDS.

Oral antiviral drugs with efficacy against HSV, VZV, and EBV, including acyclovir, famciclovir, and valacyclovir, have not been evaluated in the treatment of encephalitis either as primary therapy or as supplemental therapy following completion of a course of parenteral acyclovir. A National Institute of Allergy and Infectious Disease (NIAID)/National Institute of Neurological Disorders and Stroke–sponsored phase III trial of supplemental oral valacyclovir therapy (2 g tid for 3 months) following the initial 14- to 21-day course of therapy with parenteral acyclovir is ongoing in patients with HSV encephalitis; this may help clarify the role of extended oral antiviral therapy.

Ganciclovir and foscarnet, either alone or in combination, are often utilized in the treatment of CMV-related CNS infections, although their efficacy remains unproven. Cidofovir (see below) may provide an alternative in patients who fail to respond to ganciclovir and foscarnet, although data concerning its use in CMV CNS infections is extremely limited.

Ganciclovir is a synthetic nucleoside analogue of 2′-deoxyguanosine. The drug is preferentially phosphorylated by virus-induced cellular kinases. Ganciclovir triphosphate acts as a competitive inhibitor of the CMV DNA polymerase, and its incorporation into nascent viral DNA results in premature chain termination. Following intravenous administration, CSF concentrations of ganciclovir are 25–70% of coincident plasma levels. The usual dose for treatment of severe neurologic illnesses is 5 mg/kg every 12 h given intravenously at a constant rate over 1 h. Induction therapy is followed by maintenance therapy of 5 mg/kg every day for an indefinite period. Induction therapy should be continued until patients show a decline in CSF pleocytosis and a reduction in CSF CMV DNA copy number on quantitative PCR testing (where available). Doses should be adjusted in patients with renal insufficiency. Treatment is often limited by the development of granulocytopenia and thrombocytopenia (20–25%), which may require reduction in or discontinuation of therapy. Gastrointestinal side effects, including nausea, vomiting, diarrhea, and abdominal pain, occur in ~20% of patients. Some patients treated with ganciclovir for CMV retinitis have developed retinal detachment, but the causal relationship to ganciclovir treatment is unclear. Valganciclovir is an orally bioavailable prodrug that can generate high serum levels of ganciclovir, although studies of its efficacy in treating CMV CNS infections are limited.

Foscarnet is a pyrophosphate analogue that inhibits viral DNA polymerases by binding to the pyrophosphate-binding site. Following intravenous infusion, CSF concentrations range from 15 to 100% of coincident plasma levels. The usual dose for serious CMV-related neurologic illness is 60 mg/kg every 8 h administered by constant infusion over 1 h. Induction therapy for 14–21 days is followed by maintenance therapy (60–120 mg/kg per day). Induction therapy may need to be extended in patients who fail to show a decline in CSF pleocytosis and a reduction in CSF CMV DNA copy number on quantitative PCR tests (where available). Approximately one-third of patients develop renal impairment during treatment, which is reversible following discontinuation of therapy in most, but not all, cases. This is often associated with elevations in serum creatinine and proteinuria and is less frequent in patients who are adequately hydrated. Many patients experience fatigue and nausea. Reduction in serum calcium, magnesium, and potassium occur in ~15% of patients and may be associated with tetany, cardiac rhythm disturbances, or seizures.

Cidofovir is a nucleotide analogue that is effective in treating CMV retinitis and equivalent or better than ganciclovir in some experimental models of murine CMV encephalitis, although data concerning its efficacy in human CMV CNS disease are limited. The usual dose is 5 mg/kg intravenously once weekly for 2 weeks, then biweekly for two or more additional doses, depending on clinical response. Patients must be prehydrated with normal saline (e.g., 1 L over 1–2 h) prior to each dose and treated with probenecid (e.g., 1 g 3 h before cidofovir and 1 g 2 and 8 h after cidofovir). Nephrotoxicity is common; the dose should be reduced if renal function deteriorates.

Intravenous ribavirin (15–25 mg/kg per day in divided doses given every 8 h) has been reported to be of benefit in isolated cases of severe encephalitis due to California encephalitis (LaCrosse) virus. Ribavirin might be of benefit for the rare patients, typically infants or young children, with severe adenovirus or rotavirus encephalitis and in patients with encephalitis due to LCMV or other arenaviruses. However, clinical trials are lacking. Hemolysis, with resulting anemia, has been the major side effect limiting therapy.

No specific antiviral therapy of proven efficacy is currently available for treatment of WNV encephalitis. Patients have been treated with α-interferon, ribavirin, WNV-specific antisense oligonucleotides, and an Israeli IVIg preparation that contains high-titer anti-WNV antibody (Omr-IgG-am). WNV chimeric vaccines, in which WNV envelope and premembrane proteins are inserted into the background of another flavivirus, are already undergoing human clinical testing for safety and immunogenicity. Both chimeric and killed inactivated WNV vaccines have been found to be safe and effective in preventing equine WNV infection, and several effective flavivirus vaccines are already in human use, creating optimism that a safe and effective human WNV vaccine can also be developed.

SEQUELAE

There is considerable variation in the incidence and severity of sequelae in patients surviving viral encephalitis. In the case of EEE virus infection, nearly 80% of survivors have severe neurologic sequelae. At the other extreme are infections due to EBV, California encephalitis virus, and Venezuelan equine encephalitis virus, where severe sequelae are unusual. For example, approximately 5–15% of children infected with LaCrosse virus have a residual seizure disorder, and 1% have persistent hemiparesis. Detailed information about sequelae in patients with HSV encephalitis treated with acyclovir is available from the NIAID-CASG trials. Of 32 acyclovir-treated patients, 26 survived (81%). Of the 26 survivors, 12 (46%) had no or only minor sequelae, 3 (12%) were moderately impaired (gainfully employed but not functioning at their previous level), and 11 (42%) were severely impaired (requiring continuous supportive care). The incidence and severity of sequelae were directly related to the age of the patient and the level of consciousness at the time of initiation of therapy. Patients with severe neurologic impairment (Glasgow coma score 6) at initiation of therapy either died or survived with severe sequelae. Young patients (<30 years) with good neurologic function at initiation of therapy did substantially better (100% survival, 62% with no or mild sequelae) compared with their older counterparts (>30 years; 64% survival, 57% no or mild sequelae). Some recent studies using quantitative HSV CSF PCR tests indicate that clinical outcome following treatment also correlates with the amount of HSV DNA present in CSF at the time of presentation. Many patients with WNV infection have acute sequelae, including cognitive impairment; weakness; and hyper- or hypokinetic movement disorders, including tremor, myoclonus, and parkinsonism. Improvement in these symptoms may occur over the subsequent 6–12 months, although detailed clinical studies of the duration and severity of WNV sequelae are not yet available.

SUBACUTE MENINGITIS

CLINICAL MANIFESTATIONS

Patients with subacute meningitis typically have an unrelenting headache, stiff neck, low-grade fever, and lethargy for days to several weeks

before they present for evaluation. Cranial nerve abnormalities and night sweats may be present. **This syndrome overlaps that of chronic meningitis, discussed in detail in Chap. 377.**

ETIOLOGY

Common causative organisms include *M. tuberculosis*, *C. neoformans*, *H. capsulatum*, *C. immitis*, and *T. pallidum*. Initial infection with *M. tuberculosis* is acquired by inhalation of aerosolized droplet nuclei. Tuberculous meningitis in adults does not develop acutely from hematogenous spread of tubercle bacilli to the meninges. Rather, millet seed–size (miliary) tubercles form in the parenchyma of the brain during hematogenous dissemination of tubercle bacilli in the course of primary infection. These tubercles enlarge and are usually caseating. The propensity for a caseous lesion to produce meningitis is determined by its proximity to the subarachnoid space (SAS) and the rate at which fibrous encapsulation develops. Subependymal caseous foci cause meningitis via discharge of bacilli and tuberculous antigens into the SAS. Mycobacterial antigens produce an intense inflammatory reaction that leads to the production of a thick exudate that fills the basilar cisterns and surrounds the cranial nerves and major blood vessels at the base of the brain.

Fungal infections are typically acquired by the inhalation of airborne fungal spores. The initial pulmonary infection may be asymptomatic or present with fever, cough, sputum production, and chest pain. The pulmonary infection is often self-limited. A localized pulmonary fungal infection can then remain dormant in the lungs until there is an abnormality in cell-mediated immunity that allows the fungus to reactivate and disseminate to the CNS. The most common pathogen causing fungal meningitis is *C. neoformans*. This fungus is found worldwide in soil and bird excreta. *H. capsulatum* is endemic to the Ohio and Mississippi River valleys of the central United States and to parts of Central and South America. *C. immitis* is endemic to the desert areas of the southwest United States, northern Mexico, and Argentina.

Syphilis is a sexually transmitted disease that is manifest by the appearance of a painless chancre at the site of inoculation. *T. pallidum* invades the CNS early in the course of syphilis. Cranial nerves VII and VIII are most frequently involved.

LABORATORY DIAGNOSIS

The classic CSF abnormalities in tuberculous meningitis are as follows: (1) elevated opening pressure, (2) lymphocytic pleocytosis (10–500 cells/μL), (3) elevated protein concentration in the range of 1–5 g/L (10–500 mg/dL), and (4) decreased glucose concentration in the range of 1.1–2.2 mmol/L (20–40 mg/dL). *The combination of unrelenting headache, stiff neck, fatigue, night sweats, and fever with a CSF lymphocytic pleocytosis and a mildly decreased glucose concentration is highly suspicious for tuberculous meningitis.* The last tube of fluid collected at LP is the best tube to send for a smear for acid-fast bacilli (AFB). If there is a pellicle in the CSF or a cobweb-like clot on the surface of the fluid, AFB can best be demonstrated in a smear of the clot or pellicle. Positive smears are typically reported in only 10–40% of cases of tuberculous meningitis in adults. Cultures of CSF take 4–8 weeks to identify the organism and are positive in ~50% of adults. Culture remains the "gold standard" to make the diagnosis of tuberculous meningitis. PCR for the detection of *M. tuberculosis* DNA has a sensitivity of 70–80% but is limited at the present time by a high rate of false-positive results.

The characteristic CSF abnormalities in fungal meningitis are a mononuclear or lymphocytic pleocytosis, an increased protein concentration, and a decreased glucose concentration. There may be eosinophils in the CSF in *C. immitis* meningitis. Large volumes of CSF are often required to demonstrate the organism on India ink smear or grow the organism in culture. If spinal fluid examined by LP on two separate occasions fails to yield an organism, CSF should be obtained by high-cervical or cisternal puncture.

The cryptococcal polysaccharide antigen test is a highly sensitive and specific test for cryptococcal meningitis. A reactive CSF cryptococcal antigen test establishes the diagnosis. The detection of the histoplasma polysaccharide antigen in CSF establishes the diagnosis of a fungal meningitis but is not specific for meningitis due to *H. capsulatum*. It may be falsely positive in coccidioidal meningitis. The CSF complement fixation antibody test is reported to have a specificity of 100% and a sensitivity of 75% for coccidioidal meningitis.

The diagnosis of syphilitic meningitis is made when a reactive serum treponemal test [fluorescent treponemal antibody absorption test (FTA-ABS) or microhemagglutination-*T. pallidum* (MHA-TP)] is associated with a CSF lymphocytic or mononuclear pleocytosis and an elevated protein concentration, or when the CSF VDRL (Venereal Disease Research Laboratory) is positive. A reactive CSF FTA-ABS is not definitive evidence of neurosyphilis. The CSF FTA-ABS can be falsely positive from blood contamination. A negative CSF VDRL does not rule out neurosyphilis. A negative CSF FTA-ABS or MHA-TP rules out neurosyphilis.

Rx SUBACUTE MENINGITIS

Empirical therapy of tuberculous meningitis is often initiated on the basis of a high index of suspicion without adequate laboratory support. Initial therapy is a combination of isoniazid (300 mg/d), rifampin (10 mg/kg per day), pyrazinamide (30 mg/kg per day in divided doses), ethambutol (15–25 mg/kg per day in divided doses), and pyridoxine (50 mg/d). If the clinical response is good, pyrazinamide and ethambutol can be discontinued after 8 weeks and isoniazid and rifampin continued alone for the next 6–12 months. A 6-month course of therapy is acceptable, but therapy should be prolonged for 9–12 months in patients who have an inadequate resolution of symptoms of meningitis or who have positive mycobacterial cultures of CSF during the course of therapy. Dexamethasone therapy is recommended for patients who develop hydrocephalus.

Meningitis due to *C. neoformans* is treated with amphotericin B (0.7 mg/kg IV per day) or AmBisome (5 mg/kg per day), plus flucytosine (100 mg/kg per day in four divided doses) for 2 weeks or until CSF culture is sterile. This treatment is followed by an 8–10-week course of fluconazole (400–800 mg/d PO). If the CSF culture is sterile after 10 weeks of acute therapy, the dose of fluconazole is decreased to 200 mg/d for 6 months to a year. Patients with HIV infection may require indefinite maintenance therapy. Meningitis due to *H. capsulatum* is treated with amphotericin B (0.7–1.0 mg/kg per day) for 4–12 weeks. A total dose of 30 mg/kg is recommended. Therapy with amphotericin B is not discontinued until fungal cultures are sterile. After completing a course of amphotericin B, maintenance therapy with itraconazole 200 mg twice daily is initiated and continued for at least 6 months to a year. *C. immitis* meningitis is treated with either high-dose fluconazole (1000 mg daily) as monotherapy or intravenous amphotericin B (0.5–0.7 mg/kg per day) for >4 weeks. Intrathecal amphotericin B (0.25–0.75 mg/d three times weekly) may be required to eradicate the infection. Lifelong therapy with fluconazole (200–400 mg daily) is recommended to prevent relapse. AmBisome (5 mg/kg per day) or amphotericin B lipid complex (5 mg/kg per day) can be substituted for amphotericin B in patients who have or who develop significant renal dysfunction. The most common complication of fungal meningitis is hydrocephalus. Patients who develop hydrocephalus should receive a CSF diversion device. A ventriculostomy can be used until CSF fungal cultures are sterile, at which time the ventriculostomy is replaced by a ventriculoperitoneal shunt.

Syphilitic meningitis is treated with aqueous penicillin G in a dose of 3–4 million units intravenously every 4 h for 10–14 days. An alternative regimen is 2.4 million units of procaine penicillin G intramuscularly daily with 500 mg of oral probenecid four times daily for 10–14 days. Either regimen is followed with 2.4 million units of benzathine penicillin G intramuscularly once a week for 3 weeks. The standard criterion for treatment success is reexamination of the CSF. The CSF should be reexamined at 6-month intervals for 2 years. The cell count is expected to normalize within 12 months, and the VDRL titer to decrease by two dilutions or revert to nonreactive within 2 years of completion of therapy. Failure of the CSF pleocytosis to resolve or an increase in the CSF VDRL titer by two or more dilutions requires retreatment.

CHRONIC ENCEPHALITIS

PROGRESSIVE MULTIFOCAL LEUKOENCEPHALOPATHY

Clinical Features and Pathology Progressive multifocal leukoencephalopathy (PML) is a progressive disorder characterized pathologically

by multifocal areas of demyelination of varying size distributed throughout the brain but sparing the spinal cord and optic nerves. In addition to demyelination, there are characteristic cytologic alterations in both astrocytes and oligodendrocytes. Astrocytes are enlarged and contain hyperchromatic, deformed, and bizarre nuclei and frequent mitotic figures. Oligodendrocytes have enlarged, densely staining nuclei that contain viral inclusions formed by crystalline arrays of JC virus (JCV) particles. Patients often present with visual deficits (45%), typically a homonymous hemianopia; mental impairment (38%) (dementia, confusion, personality change); weakness, including hemi- or monoparesis; and ataxia. Seizures occur in ~20% of patients, predominantly in those with lesions abutting the cortex.

Almost all patients have an underlying immunosuppressive disorder. In recent series, the most common associated conditions were AIDS (80%), hematologic malignancies (13%), transplant recipients (5%), and chronic inflammatory diseases (2%). It has been estimated that up to 5% of AIDS patients will develop PML. There have been three cases of PML occurring in patients being treated for multiple sclerosis and inflammatory bowel disease with natalizimab, a humanized monoclonal antibody that inhibits lymphocyte trafficking into CNS and bowel mucosa by binding to α_4 integrins. Risk in these patients has been estimated at 1 PML case per 1000 treated patients after a mean of 18 months of therapy. The basic clinical and diagnostic features are similar in AIDS and non-AIDS–associated PML.

Diagnostic Studies The diagnosis of PML is frequently suggested by MRI. MRI reveals multifocal asymmetric, coalescing white matter lesions located periventricularly, in the centrum semiovale, in the parietal-occipital region, and in the cerebellum. These lesions have increased signal on T2 and FLAIR images and decreased signal on T1-weighted images. PML lesions are classically nonenhancing (90%) but may rarely show ring enhancement, especially in more immunocompetent patients. PML lesions are not typically associated with edema or mass effect. CT scans, which are less sensitive than MRI for the diagnosis of PML, often show hypodense nonenhancing white matter lesions.

The CSF is typically normal, although mild elevation in protein and/or IgG may be found. Pleocytosis occurs in <25% of cases, is predominantly mononuclear, and rarely exceeds 25 cells/μL. PCR amplification of JCV DNA from CSF has become an important diagnostic tool. The presence of a positive CSF PCR for JCV DNA in association with typical MRI lesions in the appropriate clinical setting is diagnostic of PML, reflecting the assay's relatively high specificity (92–100%); however, sensitivity is variable. In HIV-negative patients and HIV-positive patients not receiving highly active antiviral therapy (HAART), sensitivity is likely 70–90%. In HAART-treated patients, sensitivity may be closer to 60%, reflecting the lower JCV CSF viral load in this relatively more immunocompetent group. Studies with quantitative JCV CSF PCR indicate that patients with low JCV loads (<100 copies/μL) have a generally better prognosis than those with higher viral loads. Patients with negative CSF PCR studies may require brain biopsy for definitive diagnosis. In biopsy or necropsy specimens of brain, JCV antigen and nucleic acid can be detected by immunocytochemistry, in situ hybridization, or PCR amplification. Detection of JCV antigen or genomic material should only be considered diagnostic of PML if accompanied by characteristic pathologic changes, since both antigen and genomic material have been found in the brains of normal patients.

Serologic studies are of no utility in diagnosis due to high basal seroprevalence level (>80%).

Rx PROGRESSIVE MULTIFOCAL LEUKOENCEPHALOPATHY

No effective therapy for PML is available. Intravenous and/or intrathecal cytarabine were not shown to be of benefit in a randomized controlled trial in HIV-associated PML. Another randomized controlled trial of cidofovir in HIV-associated PML also failed to show significant benefit. Some patients with HIV-associated PML have shown disease stabilization and, in rare cases, improvement associated with improvement in their immune status following institution of HAART. In HIV-positive patients treated with HAART, 1-year survival is ~50%, although up to 80% of survivors may have significant neurologic sequelae. HIV-positive patients with higher CD4 counts (>300 mm^3) and low or nondetectable HIV viral loads have a better prognosis than those with lower CD4 counts and higher viral loads.

SUBACUTE SCLEROSING PANENCEPHALITIS (SSPE)

SSPE is a rare chronic, progressive demyelinating disease of the CNS associated with a chronic nonpermissive infection of brain tissue with measles virus. The frequency has been estimated at 1 in 100,000–500,000 measles cases. An average of five cases per year are reported in the United States. The incidence has declined dramatically since the introduction of a measles vaccine. Most patients give a history of primary measles infection at an early age (2 years), which is followed after a latent interval of 6–8 years by the development of progressive neurologic disorder. Some 85% of patients are between 5 and 15 years old at diagnosis. Initial manifestations include poor school performance and mood and personality changes. Typical signs of a CNS viral infection, including fever and headache, do not occur. As the disease progresses, patients develop progressive intellectual deterioration, focal and/or generalized seizures, myoclonus, ataxia, and visual disturbances. In the late stage of the illness, patients are unresponsive, quadriparetic, and spastic, with hyperactive tendon reflexes and extensor plantar responses.

Diagnostic Studies MRI is often normal early, although areas of increased T2 signal develop in the white matter of the brain and brainstem as disease progresses. The EEG may initially show only nonspecific slowing, but with disease progression, patients develop a characteristic periodic pattern with bursts of high-voltage, sharp, slow waves every 3–8 s, followed by periods of attenuated ("flat") background. The CSF is acellular with a normal or mildly elevated protein concentration and a markedly elevated gamma globulin level (>20% of total CSF protein). CSF antimeasles antibody levels are invariably elevated, and oligoclonal antimeasles antibodies are often present. Measles virus can be cultured from brain tissue using special cocultivation techniques. Viral antigen can be identified immunocytochemically, and viral genome can be detected by in situ hybridization or PCR amplification.

Rx SUBACUTE SCLEROSING PANENCEPHALITIS

No definitive therapy for SSPE is available. Treatment with isoprinosine (Inosiplex, 100 mg/kg per day), alone or in combination with intrathecal or intraventricular alpha interferon, has been reported to prolong survival and produce clinical improvement in some patients but has never been subjected to a controlled clinical trial.

PROGRESSIVE RUBELLA PANENCEPHALITIS

This is an extremely rare disorder that primarily affects males with congenital rubella syndrome, although isolated cases have been reported following childhood rubella. After a latent period of 8–19 years, patients develop progressive neurologic deterioration. The manifestations are similar to those seen in SSPE. CSF shows a mild lymphocytic pleocytosis, slightly elevated protein concentration, markedly increased gamma globulin, and rubella virus–specific oligoclonal bands. No therapy is available. Universal prevention of both congenital and childhood rubella through the use of the available live attenuated rubella vaccine would be expected to eliminate the disease.

BRAIN ABSCESS

DEFINITION

A brain abscess is a focal, suppurative infection within the brain parenchyma, typically surrounded by a vascularized capsule. The term *cerebritis* is often employed to describe a nonencapsulated brain abscess.

EPIDEMIOLOGY

A bacterial brain abscess is a relatively uncommon intracranial infection, with an incidence of ~0.3–1.3/100,000 persons per year. Predisposing conditions include otitis media and mastoiditis, paranasal sinusitis, pyogenic infections in the chest or

other body sites, penetrating head trauma or neurosurgical procedures, and dental infections. In immunocompetent individuals the most important pathogens are *Streptococcus* spp. [anaerobic, aerobic, and viridans (40%)], Enterobacteriaceae [*Proteus* spp., *E. coli* sp., *Klebsiella* spp. (25%)], anaerobes [e.g., *Bacteroides* spp., *Fusobacterium* spp. (30%)], and staphylococci (10%). In immunocompromised hosts with underlying HIV infection, organ transplantation, cancer, or immunosuppressive therapy, most brain abscesses are caused by *Nocardia* spp., *Toxoplasma gondii*, *Aspergillus* spp., *Candida* spp., and *C. neoformans*. In Latin America and in immigrants from Latin America, the most common cause of brain abscess is *Taenia solium* (neurocysticercosis). In India and the Far East, mycobacterial infection (tuberculoma) remains a major cause of focal CNS mass lesions.

ETIOLOGY

A brain abscess may develop (1) by direct spread from a contiguous cranial site of infection, such as paranasal sinusitis, otitis media, mastoiditis, or dental infection; (2) following head trauma or a neurosurgical procedure; or (3) as a result of hematogenous spread from a remote site of infection. In up to 25% of cases, no obvious primary source of infection is apparent (cryptogenic brain abscess).

Approximately one-third of brain abscesses are associated with otitis media and mastoiditis, often with an associated cholesteatoma. Otogenic abscesses occur predominantly in the temporal lobe (55–75%) and cerebellum (20–30%). In some series, up to 90% of cerebellar abscesses are otogenic. Common organisms include streptococci, *Bacteroides* spp., *Pseudomonas* spp., *Haemophilus* spp., and Enterobacteriaceae. Abscesses that develop as a result of direct spread of infection from the frontal, ethmoidal, or sphenoidal sinuses and those that occur due to dental infections are usually located in the frontal lobes. Approximately 10% of brain abscesses are associated with paranasal sinusitis, and this association is particularly strong in young males in their second and third decades of life. The most common pathogens in brain abscesses associated with paranasal sinusitis are streptococci (especially *S. milleri*), *Haemophilus* spp., *Bacteroides* spp., *Pseudomonas* spp., and *S. aureus*. Dental infections are associated with ~2% of brain abscesses, although it is often suggested that many "cryptogenic" abscesses are in fact due to dental infections. The most common pathogens in this setting are streptococci, staphylococci, *Bacteroides* spp., and *Fusobacterium* spp.

Hematogenous abscesses account for ~25% of brain abscesses. Hematogenous abscesses are often multiple, and multiple abscesses often (50%) have a hematogenous origin. These abscesses show a predilection for the territory of the middle cerebral artery (i.e., posterior frontal or parietal lobes). Hematogenous abscesses are often located at the junction of the gray and white matter and are often poorly encapsulated. The microbiology of hematogenous abscesses is dependent on the primary source of infection. For example, brain abscesses that develop as a complication of infective endocarditis are often due to viridans streptococci or *S. aureus*. Abscesses associated with pyogenic lung infections such as lung abscess or bronchiectasis are often due to streptococci, staphylococci, *Bacteroides* spp., *Fusobacterium* spp., or Enterobacteriaceae. Abscesses that follow penetrating head trauma or neurosurgical procedures are frequently due to methicillin-resistant *S. aureus* (MRSA), *S. epidermidis*, Enterobacteriaceae, *Pseudomonas* spp., and *Clostridium* spp. Enterobacteriaceae and *P. aeruginosa* are important causes of abscesses associated with urinary sepsis. Congenital cardiac malformations that produce a right-to-left shunt, such as tetralogy of Fallot, patent ductus arteriosus, and atrial and ventricular septal defects, allow bloodborne bacteria to bypass the pulmonary capillary bed and reach the brain. Similar phenomena can occur with pulmonary arteriovenous malformations. The decreased arterial oxygenation and saturation from the right-to-left shunt and polycythemia may cause focal areas of cerebral ischemia, thus providing a nidus for microorganisms that bypassed the pulmonary circulation to multiply and form an abscess. Streptococci are the most common pathogens in this setting.

PATHOGENESIS AND HISTOPATHOLOGY

Results of experimental models of brain abscess formation suggest that for bacterial invasion of brain parenchyma to occur, there must be preexisting or concomitant areas of ischemia, necrosis, or hypoxia in brain tissue. The intact brain parenchyma is relatively resistant to infection. Once bacteria have established infection, brain abscess frequently evolves through a series of stages, influenced by the nature of the infecting organism and by the immunocompetence of the host. The early cerebritis stage (days 1–3) is characterized by a perivascular infiltration of inflammatory cells, which surround a central core of coagulative necrosis. Marked edema surrounds the lesion at this stage. In the late cerebritis stage (days 4–9), pus formation leads to enlargement of the necrotic center, which is surrounded at its border by an inflammatory infiltrate of macrophages and fibroblasts. A thin capsule of fibroblasts and reticular fibers gradually develops, and the surrounding area of cerebral edema becomes more distinct than in the previous stage. The third stage, early capsule formation (days 10–13), is characterized by the formation of a capsule that is better developed on the cortical than on the ventricular side of the lesion. This stage correlates with the appearance of a ring-enhancing capsule on neuroimaging studies. The final stage, late capsule formation (day 14 and beyond), is defined by a well-formed necrotic center surrounded by a dense collagenous capsule. The surrounding area of cerebral edema has regressed, but marked gliosis with large numbers of reactive astrocytes has developed outside the capsule. This gliotic process may contribute to the development of seizures as a sequelae of brain abscess.

CLINICAL PRESENTATION

A brain abscess typically presents as an expanding intracranial mass lesion rather than as an infectious process. Although the evolution of signs and symptoms is extremely variable, ranging from hours to weeks or even months, most patients present to the hospital 11–12 days following onset of symptoms. The classic clinical triad of headache, fever, and a focal neurologic deficit is present in <50% of cases. The most common symptom in patients with a brain abscess is headache, occurring in >75% of patients. The headache is often characterized as a constant, dull, aching sensation, either hemicranial or generalized, and it becomes progressively more severe and refractory to therapy. Fever is present in only 50% of patients at the time of diagnosis, and its absence should not exclude the diagnosis. The new onset of focal or generalized seizure activity is a presenting sign in 15–35% of patients. Focal neurologic deficits including hemiparesis, aphasia, or visual field defects are part of the initial presentation in >60% of patients.

The clinical presentation of a brain abscess depends on its location, the nature of the primary infection if present, and the level of the ICP. Hemiparesis is the most common localizing sign of a frontal lobe abscess. A temporal lobe abscess may present with a disturbance of language (dysphasia) or an upper homonymous quadrantanopia. Nystagmus and ataxia are signs of a cerebellar abscess. Signs of raised ICP—papilledema, nausea and vomiting, and drowsiness or confusion—can be the dominant presentation of some abscesses, particularly those in the cerebellum. Meningismus is not present unless the abscess has ruptured into the ventricle or the infection has spread to the subarachnoid space.

DIAGNOSIS

Diagnosis is made by neuroimaging studies. MRI **(Fig. 376-4)** is better than CT for demonstrating abscesses in the early (cerebritis) stages and is superior to CT for identifying abscesses in the posterior fossa. Cerebritis appears on MRI as an area of low-signal intensity on T1-weighted images with irregular postgadolinium enhancement and as an area of increased signal intensity on T2-weighted images. Cerebritis is often not visualized by CT scan but, when present, appears as an area of hypodensity. On a contrast-enhanced CT scan, a mature brain abscess appears as a focal area of hypodensity surrounded by ring enhancement with surrounding edema (hypodensity). On contrast-enhanced T1-weighted MRI, a mature brain abscess has a capsule that

enhances surrounding a hypodense center and surrounded by a hypodense area of edema. On T2-weighted MRI, there is a hyperintense central area of pus surrounded by a well-defined hypointense capsule and a hyperintense surrounding area of edema. It is important to recognize that the CT and MR appearance, particularly of the capsule, may be altered by treatment with glucocorticoids. The distinction between a brain abscess and other focal CNS lesions such as primary or metastatic tumors may be facilitated by the use of diffusion-weighted imaging sequences on which brain abscesses typically show increased signal and low apparent diffusion coefficient.

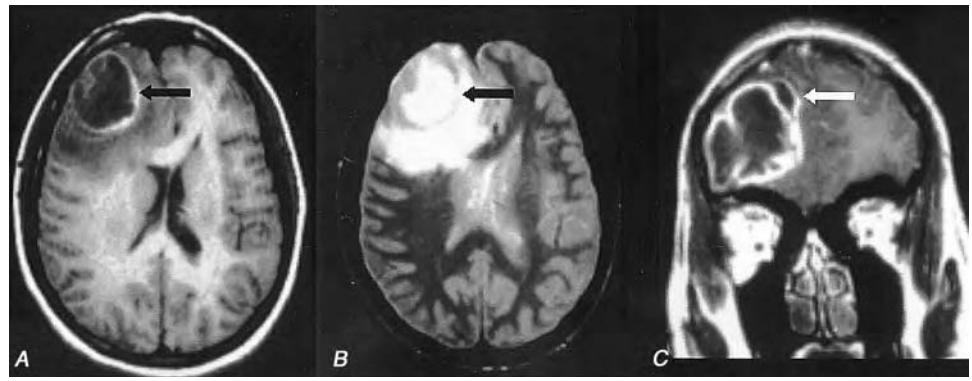

FIGURE 376-4 Pneumococcal brain abscess. Note that the abscess wall has hyperintense signal on the axial T1-weighted MRI (***A***, *black arrow*), hypointense signal on the axial proton density images (***B***, *black arrow*), and enhances prominently after gadolinium administration on the coronal T1-weighted image (***C***). The abscess is surrounded by a large amount of vasogenic edema and has a small "daughter" abscess (***C***, *white arrow*). (*Courtesy of Joseph Lurito, MD; with permission.*)

Microbiologic diagnosis of the etiologic agent is most accurately determined by Gram's stain and culture of abscess material obtained by stereotactic needle aspiration. Aerobic and anaerobic bacterial cultures and mycobacterial and fungal cultures should be obtained. Up to 10% of patients will also have positive blood cultures. LP should not be performed in patients with known or suspected focal intracranial infections such as abscess or empyema; CSF analysis contributes nothing to diagnosis or therapy, and LP increases the risk of herniation.

Additional laboratory studies may provide clues to the diagnosis of brain abscess in patients with a CNS mass lesion. About 50% of patients have a peripheral leukocytosis, 60% an elevated ESR, and 80% an elevated C-reactive protein. Blood cultures are positive in ~10% of cases overall but may be positive in >85% of patients with abscesses due to *Listeria*.

DIFFERENTIAL DIAGNOSIS

Conditions that can cause headache, fever, focal neurologic signs, and seizure activity include brain abscess, subdural empyema, bacterial meningitis, viral meningoencephalitis, superior sagittal sinus thrombosis, and acute disseminated encephalomyelitis. When fever is absent, primary and metastatic brain tumors become the major differential diagnosis. Less commonly, cerebral infarction or hematoma can have an MRI or CT appearance resembling brain abscess.

Rx BRAIN ABSCESS

Optimal therapy of brain abscesses involves a combination of high-dose parenteral antibiotics and neurosurgical drainage. Empirical therapy of community-acquired brain abscess in an immunocompetent patient typically includes a third-generation cephalosporin (e.g., cefotaxime or ceftriaxone) and metronidazole (see Table 376-1 for antibiotic dosages). In patients with penetrating head trauma or recent neurosurgical procedures, treatment should include ceftazidime as the third-generation cephalosporin to enhance coverage of *Pseudomonas* spp. and vancomycin for coverage of staphylococci. Meropenem plus vancomycin also provides good coverage in this setting.

Aspiration and drainage of the abscess under stereotactic guidance are beneficial for both diagnosis and therapy. Empirical antibiotic coverage should be modified based on the results of Gram's stain and culture of the abscess contents. Complete excision of a bacterial abscess via craniotomy or craniectomy is generally reserved for multiloculated abscesses or those in which stereotactic aspiration is unsuccessful.

Medical therapy alone is not optimal for treatment of brain abscess and should be reserved for patients whose abscesses are neurosurgically inaccessible, for patients with small (<2–3 cm) or nonencapsulated abscesses (cerebritis), and patients whose condition is too tenuous to allow performance of a neurosurgical procedure. All patients should receive a minimum of 6–8 weeks of parenteral antibiotic therapy. The role, if any, of supplemental oral antibiotic therapy following completion of a standard course of parenteral therapy has never been adequately studied.

In addition to surgical drainage and antibiotic therapy, patients should receive prophylactic anticonvulsant therapy because of the high risk (~35%) of focal or generalized seizures. Anticonvulsant therapy is continued for at least 3 months after resolution of the abscess, and decisions regarding withdrawal are then based on the EEG. If the EEG is abnormal, anticonvulsant therapy should be continued. If the EEG is normal, anticonvulsant therapy can be slowly withdrawn, with close follow-up and repeat EEG after the medication has been discontinued.

Glucocorticoids should not be given routinely to patients with brain abscesses. Intravenous dexamethasone therapy (10 mg every 6 h) is usually reserved for patients with substantial periabscess edema and associated mass effect and increased ICP. Dexamethasone should be tapered as rapidly as possible to avoid delaying the natural process of encapsulation of the abscess.

Serial MRI or CT scans should be obtained on a monthly or twice-monthly basis to document resolution of the abscess. More frequent studies (e.g., weekly) are probably warranted in the subset of patients who are receiving antibiotic therapy alone. A small amount of enhancement may remain for months after the abscess has been successfully treated.

PROGNOSIS

The mortality of brain abscess has declined in parallel with the development of enhanced neuroimaging techniques, improved neurosurgical procedures for stereotactic aspiration, and improved antibiotics. In modern series, the mortality is typically <15%. Significant sequelae, including seizures, persisting weakness, aphasia, or mental impairment, occur in ≥20% of survivors.

NONBACTERIAL CAUSES OF INFECTIOUS FOCAL CNS LESIONS

ETIOLOGY

Neurocysticercosis is the most common parasitic disease of the CNS worldwide. Humans acquire cysticercosis by the ingestion of food contaminated with the eggs of the parasite *T. solium*. Toxoplasmosis is a parasitic disease caused by *T. gondii* and acquired from the ingestion of undercooked meat and from handling cat feces.

CLINICAL PRESENTATION

The most common manifestation of neurocysticercosis is new-onset partial seizures with or without secondary generalization. Cysticerci may develop in the brain parenchyma and cause seizures or focal neurologic deficits. When present in the subarachnoid or ventricular spaces, cysticerci can produce increased ICP by interference with CSF flow. Spinal cysticerci can mimic the presentation of intraspinal tumors. When the cysticerci first lodge in the brain, they frequently cause little in the way of an inflammatory response. As the cysticercal cyst degenerates, it elicits an inflammatory response that may present clinically as a seizure. Eventually the cyst dies, a process that may take several

years and is typically associated with resolution of the inflammatory response and, often, abatement of seizures.

Primary *toxoplasma* infection is often asymptomatic. However, during this phase parasites may spread to the CNS, where they become latent. Reactivation of CNS infection is almost exclusively associated with immunocompromised hosts, particularly those with HIV infection. During this phase patients present with headache, fever, seizures, and focal neurologic deficits.

DIAGNOSIS

The lesions of neurocysticercosis are readily visualized by MRI or CT scans. Lesions with viable parasites appear as cystic lesions. The scolex can often be visualized on MRI. Lesions may appear as contrast-enhancing lesions surrounded by edema. A very early sign of cyst death is hypointensity of the vesicular fluid on T2-weighted images when compared with CSF. Parenchymal brain calcifications are the most common finding and evidence that the parasite is no longer viable. MRI findings of toxoplasmosis consist of multiple lesions in the deep white matter, the thalamus, and basal ganglia and at the gray-white junction in the cerebral hemispheres. With contrast administration, the majority of the lesions enhance in a ringed, nodular, or homogeneous pattern and are surrounded by edema. In the presence of the characteristic neuroimaging abnormalities of *T. gondii* infection, serum IgG antibody to *T. gondii* should be obtained and, when positive, the patient should be treated.

℞ INFECTIOUS FOCAL CNS LESIONS

Anticonvulsant therapy is initiated when the patient with neurocysticercosis presents with a seizure. There is controversy about whether or not antihelminthic therapy should be given to all patients. Such therapy does not necessarily reduce the risk of seizure recurrence. Cysticerci appearing as cystic lesions or as enhancing lesions in the brain parenchyma or in the subarachnoid space at the convexity of the cerebral hemispheres should be treated with anticysticidal therapy. Cysticidal drugs accelerate the destruction of the parasites, resulting in a faster resolution of the infection. Albendazole and praziquantel are used in the treatment of neurocysticercosis. Approximately 85% of parenchymal cysts are destroyed by a single course of albendazole, and ~75% are destroyed by a single course of praziquantel. The dose of albendazole is 15 mg/kg per day in two doses for 8 days. The dose of praziquantel is 50 mg/kg per day for 15 days, although a number of other dosage regimens are also frequently cited. Antiepileptic therapy can be stopped once the follow-up CT scan shows resolution of the lesion. Long-term antiepileptic therapy is recommended when seizures occur after resolution of edema and resorption or calcification of the degenerating cyst.

CNS toxoplasmosis is treated with a combination of sulfadiazine, 1.5–2.0 g orally qid, plus pyrimethamine, 100 mg orally to load then 75–100 mg orally qd, plus folinic acid, 10–15 mg orally qd. Folinic acid is added to the regimen to prevent megaloblastic anemia. Therapy is continued until there is no evidence of active disease on neuroimaging studies, which typically takes at least 6 weeks, and then the dose of sulfadiazine is reduced to 2–4 g/d and pyrimethamine to 50 mg/d. Clindamycin plus pyrimethamine is an alternative therapy for patients who cannot tolerate sulfadiazine, but the combination of pyrimethamine and sulfadiazine is more effective.

SUBDURAL EMPYEMA

A subdural empyema (SDE) is a collection of pus between the dura and arachnoid membranes (Fig. 376-5).

EPIDEMIOLOGY

SDE is a rare disorder that accounts for 15–25% of focal suppurative CNS infections. Sinusitis is the most common predisposing condition and typically involves the frontal sinuses, either alone or in combination with the ethmoid and maxillary sinuses. Sinusitis-associated empyema has a striking predilection for young males, possibly reflecting sex-related differences in sinus anatomy and development. It has been suggested that SDE may complicate 1–2% of cases of frontal sinusitis severe enough to require hospitalization. As a consequence of this epidemiology, SDE shows an ~3:1 male:female predominance, with 70% of cases occurring in the second and third decades of life. SDE may also develop as a complication of head trauma or neurosurgery. Secondary infection of a subdural effusion may also result in empyema, although secondary infection of hematomas, in the absence of a prior neurosurgical procedure, is rare.

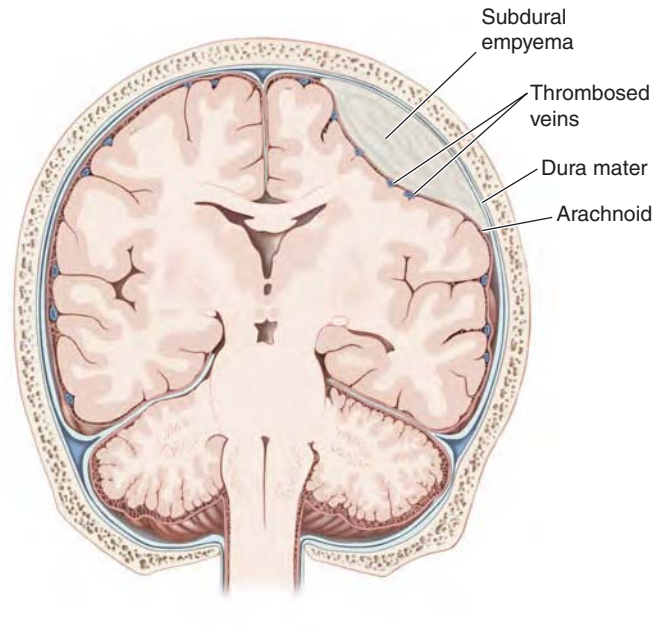

FIGURE 376-5 Subdural empyema.

ETIOLOGY

Aerobic and anaerobic streptococci, staphylococci, Enterobacteriaceae, and anaerobic bacteria are the most common causative organisms of sinusitis-associated SDE. Staphylococci and gram-negative bacilli are often the etiologic organisms when SDE follows neurosurgical procedures or head trauma. Up to one-third of cases are culture-negative, possibly reflecting difficulty in obtaining adequate anaerobic cultures.

PATHOPHYSIOLOGY

Sinusitis-associated SDE develops as a result of either retrograde spread of infection from septic thrombophlebitis of the mucosal veins draining the sinuses or contiguous spread of infection to the brain from osteomyelitis in the posterior wall of the frontal or other sinuses. SDE may also develop from direct introduction of bacteria into the subdural space as a complication of a neurosurgical procedure. The evolution of SDE can be extremely rapid because the subdural space is a large compartment that offers few mechanical barriers to the spread of infection. In patients with sinusitis-associated SDE, suppuration typically begins in the upper and anterior portions of one cerebral hemisphere and then extends posteriorly. SDE is often associated with other intracranial infections, including epidural empyema (40%), cortical thrombophlebitis (35%), and intracranial abscess or cerebritis (>25%). Cortical venous infarction produces necrosis of underlying cerebral cortex and subcortical white matter, with focal neurologic deficits and seizures (see below).

CLINICAL PRESENTATION

A patient with SDE typically presents with fever and a progressively worsening headache. The diagnosis of SDE should always be suspected in a patient with known sinusitis who presents with new CNS signs or symptoms. Patients with underlying sinusitis frequently have symptoms related to this infection. As the infection progresses, focal neurologic deficits, seizures, nuchal rigidity, and signs of increased ICP commonly occur. Headache is the most common complaint at the time of presentation; initially it is localized to the side of the subdural infection, but then it becomes more severe and generalized. Contralat-

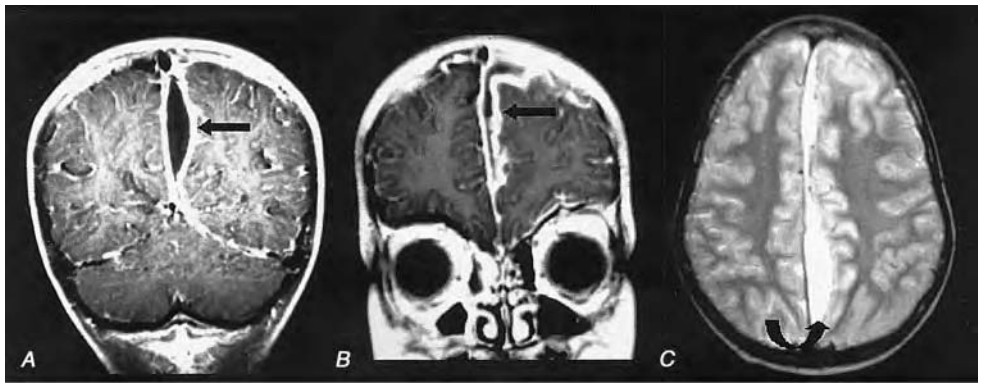

FIGURE 376-6 Subdural empyema. There is marked enhancement of the dura and leptomeninges (***A***, ***B***, *straight arrows*) along the left medial hemisphere. The pus is hypointense on T1-weighted images (***A***, ***B***) but markedly hyperintense on the proton density–weighted (***C***, *curved arrow*) image. *(Courtesy of Joseph Lurito, MD; with permission.)*

eral hemiparesis or hemiplegia is the most common focal neurologic deficit and can occur from the direct effects of the SDE on the cortex or as a consequence of venous infarction. Seizures begin as partial motor seizures that then become secondarily generalized. Seizures may be due to the direct irritative effect of the SDE on the underlying cortex or result from cortical venous infarction (see above). In untreated SDE, the increasing mass effect and increase in ICP cause progressive deterioration in consciousness, leading ultimately to coma.

DIAGNOSIS

MRI (Fig. 376-6) is superior to CT in identifying SDE and any associated intracranial infections. The administration of gadolinium greatly improves diagnosis by enhancing the rim of the empyema and allowing the empyema to be clearly delineated from the underlying brain parenchyma. Cranial MRI is also extremely valuable in identifying sinusitis, other focal CNS infections, cortical venous infarction, cerebral edema, and cerebritis. CT may show a crescent-shaped hypodense lesion over one or both hemispheres or in the interhemispheric fissure. Frequently the degree of mass effect, exemplified by midline shift, ventricular compression, and sulcal effacement, is far out of proportion to the mass of the SDE.

CSF examination should be avoided in patients with known or suspected SDE as it adds no useful information and is associated with the risk of cerebral herniation.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of the combination of headache, fever, focal neurologic signs, and seizure activity that progresses rapidly to an altered level of consciousness includes subdural hematoma, bacterial meningitis, viral encephalitis, brain abscess, superior sagittal sinus thrombosis, and acute disseminated encephalomyelitis. The presence of nuchal rigidity is unusual with brain abscess or epidural empyema and should suggest the possibility of SDE when associated with significant focal neurologic signs and fever. Patients with bacterial meningitis also have nuchal rigidity but do not typically have focal deficits of the severity seen with SDE.

℞ SUBDURAL EMPYEMA

SDE is a medical emergency. Emergent neurosurgical evacuation of the empyema, either through burr-hole drainage or craniotomy, is the definitive step in the management of this infection. Empirical antimicrobial therapy should include a combination of a third-generation cephalosporin (e.g., cefotaxime or ceftriaxone), vancomycin, and metronidazole (see Table 376-1 for dosages). Parenteral antibiotic therapy should be continued for a minimum of 4 weeks. Specific diagnosis of the etiologic organisms is made based on Gram's stain and culture of fluid obtained via either burr holes or craniotomy; the initial empirical antibiotic coverage can be modified accordingly.

PROGNOSIS

Prognosis is influenced by the level of consciousness of the patient at the time of hospital presentation, the size of the empyema, and the speed with which therapy is instituted. Long-term neurologic sequelae, which include seizures and hemiparesis, occur in up to 50% of cases.

EPIDURAL ABSCESS

Cranial epidural abscess is a suppurative infection occurring in the potential space between the inner skull table and dura (Fig. 376-7).

ETIOLOGY AND PATHOPHYSIOLOGY

Epidural abscess is less common than either brain abscess or SDE and accounts for <2% of focal suppurative CNS infections. A cranial epidural abscess develops as a complication of a craniotomy or compound skull fracture or as a result of spread of infection from the frontal sinuses, middle ear, mastoid, or orbit. An epidural abscess may develop contiguous to an area of osteomyelitis, when craniotomy is complicated by infection of the wound or bone flap, or as a result of direct infection of the epidural space. Infection in the frontal sinus, middle ear, mastoid, or orbit can reach the epidural space through retrograde spread of infection from septic thrombophlebitis in the emissary veins that drain these areas or by way of direct spread of infection through areas of osteomyelitis. Unlike the subdural space, the epidural space is really a potential rather than an actual compartment. The dura is normally tightly adherent to the inner skull table, and infection must dissect the dura away from the skull table as it spreads. As a result, epidural abscesses are often smaller than SDEs. Cranial epidural abscesses, unlike brain abscesses, only rarely result from hematogenous spread of infection from extracranial primary sites. The bacteriology of a cranial epidural abscess is similar to that of SDE (see above). The etiologic organisms of an epidural abscess that arises from frontal sinusitis, middle ear infections, or mastoiditis are usually streptococci or anaerobic organisms. Staphylococci or gram-negative organisms are the usual cause of an epidural abscess that develops as a complication of craniotomy or compound skull fracture.

CLINICAL PRESENTATION

Patients present with fever (60%), headache (40%), nuchal rigidity (35%), seizures (10%), and focal deficits (5%). Periorbital edema and Potts puffy tumor, reflecting underlying associated frontal bone osteomyelitis, are present in ~40%. In patients with a recent neurosurgical procedure, wound infection is invariably present, but other symptoms may be subtle and can include altered mental status (45%), fever

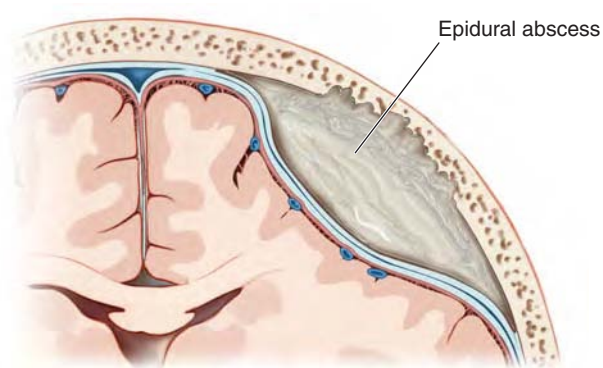

FIGURE 376-7 Cranial epidural abscess is a collection of pus between the dura and the inner table of the skull.

(35%), and headache (20%). The diagnosis should also be considered when fever and headache follow recent head trauma or occur in the setting of frontal sinusitis, mastoiditis, or otitis media.

DIAGNOSIS

Cranial MRI is the procedure of choice to demonstrate a cranial epidural abscess. The sensitivity of CT is limited by the presence of signal artifacts arising from the bone of the inner skull table. The CT appearance of an epidural empyema is that of a lens or crescent-shaped hypodense extraaxial lesion. On MRI, an epidural empyema appears as a lentiform or crescent-shaped fluid collection that is hyperintense compared to CSF on T2-weighted images. On T1-weighted images, the fluid collection has a signal intensity that is intermediate between that of brain tissue and CSF. Following the administration of gadolinium, a significant enhancement of the dura is seen on T1-weighted images. In distinction to subdural empyema, signs of mass effect or other parenchymal abnormalities are uncommon.

℞ EPIDURAL ABSCESS

Immediate neurosurgical drainage is indicated. Empirical antimicrobial therapy, pending the results of Gram's stain and culture of the purulent material obtained at surgery, should include a combination of a third-generation cephalosporin, vancomycin, and metronidazole (Table 376-1). Ceftazidime or meropenem should be substituted for ceftriaxone or cefotaxime in neurosurgical patients. When the organism has been identified, antimicrobial therapy can be modified accordingly. Antibiotics should be continued for at least 3 weeks after surgical drainage.

PROGNOSIS

Mortality is <5% in modern series, and full recovery is the rule in most survivors.

SUPPURATIVE THROMBOPHLEBITIS

DEFINITION

Suppurative intracranial thrombophlebitis is septic venous thrombosis of cortical veins and sinuses. This may occur as a complication of bacterial meningitis; SDE; epidural abscess; or infection in the skin of the face, paranasal sinuses, middle ear, or mastoid.

ANATOMY AND PATHOPHYSIOLOGY

The cerebral veins and venous sinuses have no valves; therefore, blood within them can flow in either direction. The superior sagittal sinus is the largest of the venous sinuses (Fig. 376-8). It receives blood from the frontal, parietal, and occipital superior cerebral veins and the diploic veins, which communicate with the meningeal veins. Bacterial meningitis is a common predisposing condition for septic thrombosis of the superior sagittal sinus. The diploic veins, which drain into the superior sagittal sinus, provide a route for the spread of infection from the meninges, especially in cases where there is purulent exudate near areas of the superior sagittal sinus. Infection can also spread to the superior sagittal sinus from nearby SDE or epidural abscess. Dehydration from vomiting, hypercoagulable states, and immunologic abnormalities, including the presence of circulating antiphospholipid antibodies, also contribute to cerebral venous sinus thrombosis. Thrombosis may extend from one sinus to another, and at autopsy thrombi of different histologic ages can often be detected in several sinuses. Thrombosis of the superior sagittal sinus is often associated with thrombosis of superior cortical veins and small parenchymal hemorrhages.

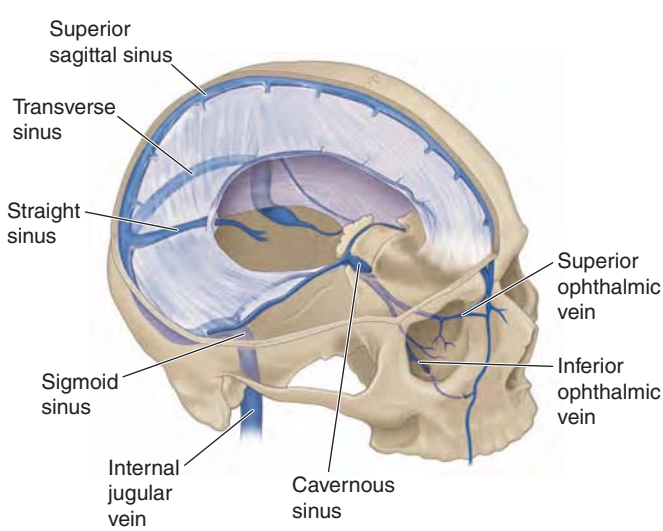

FIGURE 376-8 Anatomy of the cerebral venous sinuses.

The superior sagittal sinus drains into the transverse sinuses (Fig. 376-8). The transverse sinuses also receive venous drainage from small veins from both the middle ear and mastoid cells. The transverse sinus becomes the sigmoid sinus before draining into the internal jugular vein. Septic transverse/sigmoid sinus thrombosis can be a complication of acute and chronic otitis media or mastoiditis. Infection spreads from the mastoid air cells to the transverse sinus via the emissary veins or by direct invasion. The cavernous sinuses are inferior to the superior sagittal sinus at the base of the skull. The cavernous sinuses receive blood from the facial veins via the superior and inferior ophthalmic veins. Bacteria in the facial veins enter the cavernous sinus via these veins. Bacteria in the sphenoid and ethmoid sinuses can spread to the cavernous sinuses via the small emissary veins. The sphenoid and ethmoid sinuses are the most common sites of primary infection resulting in septic cavernous sinus thrombosis.

CLINICAL MANIFESTATIONS

Septic thrombosis of the superior sagittal sinus presents with headache, fever, nausea and vomiting, confusion, and focal or generalized seizures. There may be a rapid development of stupor and coma. Weakness of the lower extremities with bilateral Babinski signs or hemiparesis is often present. When superior sagittal sinus thrombosis occurs as a complication of bacterial meningitis, nuchal rigidity and Kernig's and Brudzinski's signs may be present.

The oculomotor nerve, the trochlear nerve, the abducens nerve, the ophthalmic and maxillary branches of the trigeminal nerve, and the internal carotid artery all pass through the cavernous sinus (see Fig. 371-4). The symptoms of *septic cavernous sinus thrombosis* are fever, headache, frontal and retroorbital pain, and diplopia. The classic signs are ptosis, proptosis, chemosis, and extraocular dysmotility due to deficits of cranial nerves III, IV, and VI; hyperesthesia of the ophthalmic and maxillary divisions of the fifth cranial nerve and a decreased corneal reflex may be detected. There may be evidence of dilated, tortuous retinal veins and papilledema.

Headache and earache are the most frequent symptoms of *transverse sinus thrombosis*. A transverse sinus thrombosis may also present with otitis media, sixth nerve palsy, and retroorbital or facial pain (*Gradinego's syndrome*). Sigmoid sinus and internal jugular vein thrombosis may present with neck pain.

DIAGNOSIS

The diagnosis of septic venous sinus thrombosis is suggested by an absent flow void within the affected venous sinus on MRI and confirmed by magnetic resonance venography, CT angiogram, or the venous phase of cerebral angiography. The diagnosis of thrombophlebitis of intracerebral and meningeal veins is suggested by the presence of intracerebral hemorrhage but requires cerebral angiography for definitive diagnosis.

℞ SUPPURATIVE THROMBOPHLEBITIS

Septic venous sinus thrombosis is treated with antibiotics, hydration, and removal of infected tissue and thrombus in septic lateral or cavernous sinus thrombosis. The choice of antimicrobial therapy is based on the bacteria responsible for the predisposing or associated condition. Optimal duration of therapy is unknown, but antibiotics are usually continued for 6 weeks or until there is radiographic evidence of resolution of thrombosis. Anticoagulation with dose-adjusted heparin has been reported to be beneficial in patients with aseptic venous sinus thrombosis; it is also used in the treatment of sep-

tic venous sinus thrombosis complicating bacterial meningitis in patients who are worsening despite antimicrobial therapy and intravenous fluids. The presence of a small intracerebral hemorrhage from septic thrombophlebitis is not an absolute contraindication to heparin therapy. Successful management of aseptic venous sinus thrombosis has been reported with catheter-directed urokinase therapy and with a combination of intrathrombus recombinant tissue plasminogen activator (rtPA) and intravenous heparin, but there has not been enough experience with these therapies in septic venous sinus thrombosis to make recommendations regarding their use.

377 Chronic and Recurrent Meningitis

Walter J. Koroshetz, Morton N. Swartz

Chronic inflammation of the meninges (pia, arachnoid, and dura) can produce profound neurologic disability and may be fatal if not successfully treated. The condition is most commonly diagnosed when a characteristic neurologic syndrome exists for > 4 weeks and is associated with a persistent inflammatory response in the cerebrospinal fluid (CSF) (white blood cell count >5/μL). The causes are varied, and appropriate treatment depends on identification of the etiology. Five categories of disease account for most cases of chronic meningitis: (1) meningeal infections, (2) malignancy, (3) noninfectious inflammatory disorders, (4) chemical meningitis, and (5) parameningeal infections.

CLINICAL PATHOPHYSIOLOGY

Neurologic manifestations of chronic meningitis (Table 377-1) are determined by the anatomic location of the inflammation and its consequences. Persistent headache with or without stiff neck, hydrocephalus, cranial neuropathies, radiculopathies, and cognitive or personality changes are the cardinal features. These can occur alone or in combination. When they appear in combination, widespread dissemination of the inflammatory process along CSF pathways has occurred. In some cases, the presence of an underlying systemic illness points to a specific agent or class of agents as the probable cause. The diagnosis of chronic meningitis is usually made when the clinical presentation prompts the astute physician to examine the CSF for signs of inflammation. CSF is produced by the choroid plexus of the cerebral ventricles, exits through narrow foramina into the subarachnoid space surrounding the brain and spinal cord, circulates around the base of the brain and over the cerebral hemispheres, and is resorbed by arachnoid villi projecting into the superior sagittal sinus. CSF flow provides a pathway for rapid spread of infectious and other infiltrative processes over the brain, spinal cord, and cranial and spinal nerve roots. Spread from the subarachnoid space into brain parenchyma may occur via the arachnoid cuffs that surround blood vessels that penetrate brain tissue (Virchow-Robin spaces).

TABLE 377-1 SYMPTOMS AND SIGNS OF CHRONIC MENINGITIS

Symptom	Sign
Chronic headache	+/– Papilledema
Neck or back pain	Brudzinski's or Kernig's sign of meningeal irritation
Change in personality	Altered mental status—drowsiness, inattention, disorientation, memory loss, frontal release signs (grasp, suck, snout), perseveration
Facial weakness	Peripheral seventh CN palsy
Double vision	Palsy of CNs III, IV, VI
Visual loss	Papilledema, optic atrophy
Hearing loss	Eighth CN palsy
Arm or leg weakness	Myelopathy or radiculopathy
Numbness in arms or legs	Myelopathy or radiculopathy
Sphincter dysfunction	Myelopathy or radiculopathy Frontal lobe dysfunction (hydrocephalus)
Clumsiness	Ataxia

Note: CN, cranial nerve.

Intracranial Meningitis Nociceptive fibers of the meninges are stimulated by the inflammatory process, resulting in headache or neck or back pain. Obstruction of CSF pathways at the foramina or arachnoid villi may produce *hydrocephalus* and symptoms of raised intracranial pressure (ICP), including headache, vomiting, apathy or drowsiness, gait instability, papilledema, visual loss, impaired upgaze, or palsy of the sixth cranial nerve (CN) (Chap. 371). Cognitive and behavioral changes during the course of chronic meningitis may also result from vascular damage, which may similarly produce seizures, stroke, or myelopathy. Inflammatory deposits seeded via the CSF circulation are often prominent around the brainstem and cranial nerves and along the undersurface of the frontal and temporal lobes. Such cases, termed *basal meningitis*, often present as multiple cranial neuropathies, with visual loss (CN II), facial weakness (CN VII), hearing loss (CN VIII), diplopia (CNs III, IV, and VI), sensory or motor abnormalities of the oropharynx (CNs IX, X, and XII), decreased olfaction (CN I), or facial sensory loss and masseter weakness (CN V).

Spinal Meningitis Injury may occur to motor and sensory roots as they traverse the subarachnoid space and penetrate the meninges. These cases present as multiple radiculopathies with combinations of radicular pain, sensory loss, motor weakness, and sphincter dysfunction. Meningeal inflammation can encircle the cord, resulting in myelopathy. Patients with slowly progressive involvement of multiple cranial nerves and/or spinal nerve roots are likely to have chronic meningitis. Electrophysiologic testing (electromyography, nerve conduction studies, and evoked response testing) may be helpful in determining whether there is involvement of cranial and spinal nerve roots.

Systemic Manifestations In some patients, evidence of systemic disease provides clues to the underlying cause of chronic meningitis. A careful history and physical examination are essential before embarking on a diagnostic workup, which may be costly, prolonged, and associated with risk from invasive procedures. A complete history of travel, sexual practice, and exposure to infectious agents should be sought. Infectious causes are often associated with fever, malaise, anorexia, and signs of localized or disseminated infection outside the nervous system. Infectious causes are of major concern in the immunosuppressed patient, especially in patients with AIDS, in whom chronic meningitis may present without headache or fever. Noninfectious inflammatory disorders often produce systemic manifestations, but meningitis may be the initial manifestation. Carcinomatous meningitis may or may not be accompanied by clinical evidence of the primary neoplasm.

APPROACH TO THE PATIENT: Chronic Meningitis

The occurrence of chronic headache, hydrocephalus, cranial neuropathy, radiculopathy, and/or cognitive decline in a patient should prompt consideration of a lumbar puncture for evidence of meningeal inflammation. On occasion the diagnosis is made when an imaging study (CT or MRI) shows contrast enhancement of the meninges, which is always abnormal with the exception of dural enhancement after lumbar puncture, neurosurgical procedures, or spontaneous CSF leakage. Once chronic meningitis is confirmed by CSF examination, effort is focused on identifying the cause (Tables 377-2 and 377-3) by (1) further analysis of the CSF, (2) diagnosis of an underlying systemic infection or noninfectious inflammatory condition, or (3) pathologic examination of meningeal biopsy specimens.

TABLE 377-2 INFECTIOUS CAUSES OF CHRONIC MENINGITIS

Causative Agent	CSF Formula	Helpful Diagnostic Tests	Risk Factors and Systemic Manifestations
Common Bacterial Causes			
Partially treated suppurative meningitis	Mononuclear or mixed mononuclear-polymorphonuclear cells	CSF culture and Gram stain	History consistent with acute bacterial meningitis and incomplete treatment
Parameningeal infection	Mononuclear or mixed polymorphonuclear-mononuclear cells	Contrast-enhanced CT or MRI to detect parenchymal, subdural, epidural, or sinus infection	Otitis media, pleuropulmonary infection, right-to-left cardiopulmonary shunt for brain abscess; focal neurologic signs; neck, back, ear, or sinus tenderness
Mycobacterium tuberculosis	Mononuclear cells except polymorphonuclear cells in early infection (commonly <500 WBC/μL); low CSF glucose, high protein	Tuberculin skin test may be negative; AFB culture of CSF (sputum, urine, gastric contents if indicated); tuberculostearic acid detection in CSF; identify tubercle bacillus on acid-fast stain of CSF or protein pellicle; PCR	Exposure history; previous tuberculous illness; immunosuppressed or AIDS; young children; fever, meningismus, night sweats, miliary TB on X-ray or liver biopsy; stroke due to arteritis
Lyme disease (Bannwarth's syndrome) *Borrelia burgdorferi*	Mononuclear cells; elevated protein	Serum Lyme antibody titer; Western blot confirmation; (patients with syphilis may have false-positive Lyme titer)	History of tick bite or appropriate exposure history; erythema chronicum migrans skin rash; arthritis, radiculopathy, Bell's palsy, meningoencephalitis–multiple sclerosis-like syndrome
Syphilis (secondary, tertiary) *Treponema pallidum*	Mononuclear cells; elevated protein	CSF VDRL; serum VDRL (or RPR); fluorescent treponemal antibody-absorbed (FTA) or MHA-TP; serum VDRL may be negative in tertiary syphilis	Appropriate exposure history; HIV seropositive individuals at increased risk of aggressive infection; "dementia"; cerebral infarction due to endarteritis
Uncommon Bacterial Causes			
Actinomyces	Polymorphonuclear cells	Anaerobic culture	Parameningeal abscess or sinus tract (oral or dental focus); pneumonitis
Nocardia	Polymorphonuclear; occasionally mononuclear cells; often low glucose	Isolation may require weeks; weakly acid fast	Associated brain abscess may be present
Brucella	Mononuclear cells (rarely polymorphonuclear); elevated protein; often low glucose	CSF antibody detection; serum antibody detection	Intake of unpasteurized dairy products; exposure to goats, sheep, cows; fever, arthralgia, myalgia, vertebral osteomyelitis
Whipple's disease *Tropherema whippelii*	Mononuclear cells	Biopsy of small bowel or lymph node; CSF PCR for *T. whippelii*; brain and meningeal biopsy (with PAS stain and EM examination)	Diarrhea, weight loss, arthralgias, fever; dementia, ataxia, paresis, ophthalmoplegia, oculomasticatory myoclonus
Rare Bacterial Causes			
Leptospirosis (occasionally if left untreated may last 3–4 weeks)			
Fungal Causes			
Cryptococcus neoformans	Mononuclear cells; count not elevated in some patients with AIDS	India ink or fungal wet mount of CSF (budding yeast); blood and urine cultures; antigen detection in CSF	AIDS and immune suppression; pigeon exposure; skin and other organ involvement due to disseminated infection
Coccidioides immitis	Mononuclear cells (sometimes 10–20% eosinophils); often low glucose	Antibody detection in CSF and serum	Exposure history—southwestern US; increased virulence in dark-skinned races
Candida sp.	Polymorphonuclear or mononuclear	Fungal stain and culture of CSF	IV drug abuse; post surgery; prolonged intravenous therapy; disseminated candidiasis
Histoplasma capsulatum	Mononuclear cells; low glucose	Fungal stain and culture of large volumes of CSF; antigen detection in CSF, serum, and urine; antibody detection in serum, CSF	Exposure history—Ohio and central Mississippi River Valley; AIDS; mucosal lesions
Blastomyces dermatitidis	Mononuclear cells	Fungal stain and culture of CSF; biopsy and culture of skin, lung lesions; antibody detection in serum	Midwestern and southeastern USA; usually systemic infection; abscesses, draining sinus, ulcers
Aspergillus sp.	Mononuclear or polymorphonuclear	CSF culture	Sinusitis; granulocytopenia or immunosuppression
Sporothrix schenckii	Mononuclear cells	Antibody detection in CSF and serum; CSF culture	Traumatic inoculation; IV drug use; ulcerated skin lesion

(continued)

TABLE 377-2 INFECTIOUS CAUSES OF CHRONIC MENINGITIS (CONTINUED)

Causative Agent	CSF Formula	Helpful Diagnostic Tests	Risk Factors and Systemic Manifestations
Rare Fungal Causes			
Xylohypha (formerly *Cladosporium*) trichoides and other dark-walled (demateaceous) fungi such as *Curvularia*, *Drechslera*; *Mucor*, *Pseudoallescheria boydii*			
Protozoal Causes			
Toxoplasma gondii	Mononuclear cells	Biopsy or response to empirical therapy in clinically appropriate context (including presence of antibody in serum)	Usually with intracerebral abscesses; common in HIV seropositive patients
Trypanosomiasis *Trypanosoma gambiense*, *T. rhodesiense*	Mononuclear cells, elevated protein	Elevated CSF IgM; identification of trypanosomes in CSF and blood smear	Endemic in Africa; chancre, lymphadenopathy; prominent sleep disorder
Rare Protozoal Causes			
Acanthamoeba sp. causing granulomatous amebic encephalitis and meningoencephalitis in immunocompromised and debilitated individuals			
Helminthic Causes			
Cysticercosis (infection with cysts of *Taenia solium*)	Mononuclear cells; may have eosinophils; glucose level may be low	Indirect hemagglutination assay in CSF; ELISA immunoblotting in serum	Usually with multiple cysts in basal meninges and hydrocephalus; cerebral cysts, muscle calcification
Gnathostoma spinigerum	Eosinophils, mononuclear cells	Peripheral eosinophilia	History of eating raw fish; common in Thailand and Japan; subarachnoid hemorrhage; painful radiculopathy
Angiostrongylus cantonensis	Eosinophils, mononuclear cells	Recovery of worms from CSF	History of eating raw shellfish; common in tropical Pacific regions; often benign
Baylisascaris procyonis (raccoon ascarid)	Eosinophils, mononuclear cells		Infection follows accidental ingestion of *B. procyonis* eggs from raccoon feces; fatal meningoencephalitis
Rare Helminthic Causes			
Trichinella spiralis (trichinosis); *Echinococcus* cysts; *Schistosoma* sp. The former may produce a lymphocytic pleocytosis whereas the latter two may produce an eosinophilic response in CSF associated with cerebral cysts (*Echinococcus*) or granulomatous lesions of brain or spinal cord			
Viral Causes			
Mumps	Mononuclear cells	Antibody in serum	No prior mumps or immunization; may produce meningoencephalitis; may persist for 3–4 weeks
Lymphocytic choriomeningitis	Mononuclear cells	Antibody in serum	Contact with rodents or their excreta; may persist for 3–4 weeks
Echovirus	Mononuclear cells; may have low glucose	Virus isolation from CSF	Congenital hypogammaglobulinemia; history of recurrent meningitis
HIV (acute retroviral syndrome)	Mononuclear cells	p24 antigen in serum and CSF; high level of HIV viremia	HIV risk factors; rash, fever, lymphadenopathy; lymphopenia in peripheral blood; syndrome may persist long enough to be considered as "chronic meningitis"; or chronic meningitis may develop in later stages (AIDS) due to HIV
Herpes simplex (HSV)	Mononuclear cells	PCR for HSV, CMV DNA; CSF antibody for HSV, EBV	Recurrent meningitis due to HSV-2 (rarely HSV-1) often associated with genital recurrences; EBV associated with myeloradiculopathy, CMV with polyradiculopathy

Abbreviations: AFB, acid-fast bacillus; CMV, cytomegalovirus; CSF, cerebrospinal fluid; CT, computed tomography; EBV, Epstein-Barr virus; ELISA, enzyme-linked immunosorbent assay; EM, electron microscopy; FTA, fluorescent treponemal antibody absorption test; HSV, herpes simplex virus; MHA-TP, microhemagglutination assay–*T. pallidum*; MRI, magnetic resonance imaging; PAS, periodic acid–Schiff; PCR, polymerase chain reaction; RPR, rapid plasma reagin test; TB, tuberculosis; VDRL, Venereal Disease Research Laboratories test.

Two clinical forms of chronic meningitis exist. In the first, the symptoms are chronic and persistent, whereas in the second there are recurrent, discrete episodes of illness. In the latter group, all symptoms, signs, and CSF parameters of meningeal inflammation resolve completely between episodes without specific therapy. In such patients, the likely etiologies include herpes simplex virus (HSV) type 2; chemical meningitis due to leakage into CSF of contents from an epidermoid tumor, craniopharyngioma, or cholesteatoma; primary inflammatory conditions, including Vogt-Koyanagi-Harada syndrome, Behçet's syndrome (Chap. 320), systemic lupus erythematosus (SLE; Chap. 313); and drug hypersensitivity with repeated administration of the offending agent.

The epidemiologic history is of considerable importance and may provide direction for selection of laboratory studies. Pertinent features include a history of tuberculosis or exposure to a likely case; past travel to areas endemic for fungal infections (the San Joaquin Valley in California and southwestern states for coccidioidomycosis, midwestern states for histoplasmosis, southeastern states for blastomycosis); travel to the Mediterranean region or ingestion of imported unpasteurized dairy products (*Brucella*); time spent in wooded areas endemic for Lyme disease; exposure to sexually transmitted disease (syphilis); exposure of an immunocompromised host to pigeons and their droppings (*Cryptococcus*); gardening (*Sporothrix schenkii*); ingestion of poorly cooked

TABLE 377-3 NONINFECTIOUS CAUSES OF CHRONIC MENINGITIS

Causative Agents	CSF Formula	Helpful Diagnostic Tests	Risk Factors and Systemic Manifestations
Malignancy	Mononuclear cells, elevated protein, low glucose	Repeated cytologic examination of large volumes of CSF; CSF exam by polarizing microscopy; clonal lymphocyte markers; deposits on nerve roots or meninges seen on myelogram or contrast-enhanced MRI; meningeal biopsy	Metastatic cancer of breast, lung, stomach, or pancreas; melanoma, lymphoma, leukemia; meningeal gliomatosis; meningeal sarcoma; cerebral dysgerminoma; meningeal melanoma or B cell lymphoma
Chemical compounds (may cause recurrent meningitis)	Mononuclear or PMNs, low glucose, elevated protein; xanthochromia from subarachnoid hemorrhage in week prior to presentation with "meningitis"	Contrast-enhanced CT scan or MRI Cerebral angiogram to detect aneurysm	History of recent injection into the subarachnoid space; history of sudden onset of headache; recent resection of acoustic neuroma or craniopharyngioma; epidermoid tumor of brain or spine, sometimes with dermoid sinus tract; pituitary apoplexy
Primary inflammation			
CNS sarcoidosis	Mononuclear cells; elevated protein; often low glucose	Serum and CSF angiotensin-converting enzyme levels; biopsy of extraneural affected tissues or brain lesion/meningeal biopsy	CN palsy, especially of CN VII; hypothalamic dysfunction, especially diabetes insipidus; abnormal chest radiograph; peripheral neuropathy or myopathy
Vogt-Koyanagi-Harada syndrome (recurrent meningitis)	Mononuclear cells		Recurrent meningoencephalitis with uveitis, retinal detachment, alopecia, lightening of eyebrows and lashes, dysacousia, cataracts, glaucoma
Isolated granulomatous angiitis of the nervous system	Mononuclear cells, elevated protein	Angiography or meningeal biopsy	Subacute dementia; multiple cerebral infarctions; recent zoster ophthalmicus
Systemic lupus erythematosus	Mononuclear or PMNs	Anti-DNA antibody, antinuclear antibodies	Encephalopathy; seizures; stroke; transverse myelopathy; rash; arthritis
Behçet's syndrome (recurrent meningitis)	Mononuclear or PMNs, elevated protein		Oral and genital aphthous ulcers; iridocyclitis; retinal hemorrhages; pathergic lesions at site of skin puncture
Chronic benign lymphocytic meningitis	Mononuclear cells		Recovery in 2–6 months, diagnosis by exclusion
Mollaret's meningitis (recurrent meningitis)	Large endothelial cells and PMNs in first hours, followed by mononuclear cells	PCR for herpes; MRI/CT to rule out epidermoid tumor or dural cyst	Recurrent meningitis; exclude HSV-2; rare cases due to HSV-1; occasional case associated with dural cyst
Drug hypersensitivity	PMNs; occasionally mononuclear cells or eosinophils		Exposure to ibuprofen, sulfonamides, isoniazid, tolmetin, ciprofloxacin, phenazopyridine; improvement after discontinuation of drug; recurrent episodes with recurrent exposure
Wegener's granulomatosis	Mononuclear cells	Chest and sinus radiographs; urinalysis; ANCA antibodies in serum	Associated sinus, pulmonary, or renal lesions; CN palsies; skin lesions; peripheral neuropathy
Other: multiple sclerosis, Sjögren's syndrome, neonatal onset multisystemic inflammatory disease (NOMID), and rarer forms of vasculitis (e.g., Cogan's syndrome)			

Abbreviations: ANCA, anti-neutrophil cytoplasmic antibodies; CN, cranial nerve; CSF, cerebrospinal fluid; CT, computed tomography; HSV, herpes simplex virus; MRI, magnetic resonance imaging; PCR, polymerase chain reaction; PMNs, polymorphonuclear cells.

meat or contact with a household cat (*Toxoplasma gondii*); residence in Thailand or Japan (*Gnathostoma spinigerum*), Latin America (*Paracoccidioides brasiliiensis*), or the South Pacific (*Angiostrongylus cantonensis*); rural residence and raccoon exposure (*Baylisascaris procyonis*); and residence in Latin America, the Philippines, or Southeast Asia when eosinophilic meningitis is present (*Taenia solium*).

The presence of focal cerebral signs in a patient with chronic meningitis suggests the possibility of a brain abscess or other parameningeal infection; identification of a potential source of infection (chronic draining ear, sinusitis, right-to-left cardiac or pulmonary shunt, chronic pleuropulmonary infection) supports this diagnosis. In some cases, diagnosis may be established by recognition and biopsy of unusual skin lesions (Behçet's syndrome, cryptococcosis, blastomycosis, SLE, Lyme disease, IV drug use, sporotrichosis, trypanosomiasis) or enlarged lymph nodes (lymphoma, tuberculosis, sarcoid, infection with HIV, secondary syphilis, or Whipple's disease). A careful ophthalmologic examination may reveal uveitis [Vogt-Koyanagi-Harada syndrome, sarcoid, or central nervous system (CNS) lymphoma], keratoconjunctivitis sicca (Sjögren's syndrome), or iridocyclitis (Behçet's syndrome) and is essential to assess visual loss from papilledema. Aphthous oral lesions, genital ulcers, and hypopyon suggest Behçet's syndrome. Hepatosplenomegaly suggests lymphoma, sarcoid, tuberculosis, or brucellosis. Herpetic lesions in the genital area or on the thighs suggests HSV-2 infection. A breast nodule, a suspicious pigmented skin lesion, focal bone pain, or an abdominal mass directs attention to possible carcinomatous meningitis.

IMAGING Once the clinical syndrome is recognized as a potential manifestation of chronic meningitis, proper analysis of the CSF is essential. However, if the possibility of raised ICP exists, a brain imaging study should be performed before lumbar puncture. If ICP is elevated because of a mass lesion, brain swelling, or a block in ventricular CSF outflow (obstructive hydrocephalus), then lumbar puncture carries the potential risk of brain herniation. Obstructive hydrocephalus usually requires direct ventricular drainage of CSF. In patients with open CSF flow pathways, elevated ICP can still occur due to impaired resorption of CSF by arachnoid villi. In such patients, lumbar puncture is usually safe, but repetitive or continuous lumbar drainage may be necessary to prevent relatively sudden death from raised ICP. In some patients, especially with cryptococcal meningitis, fatal levels of raised ICP can occur without enlarged ventricles.

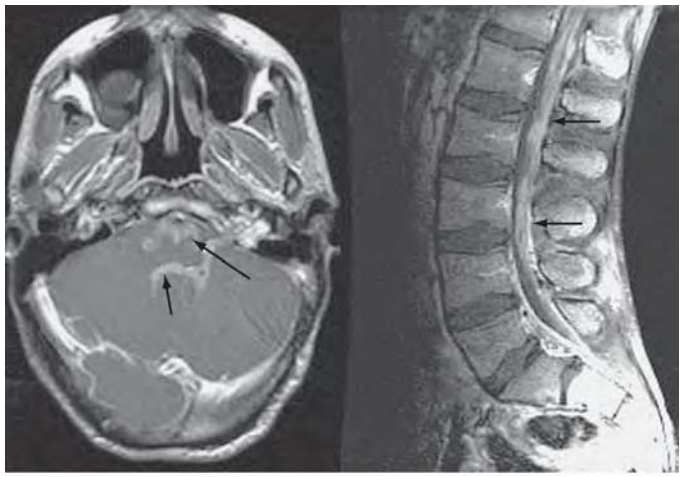

FIGURE 377-1 Primary central nervous system lymphoma. A 24-year-old man, immunosuppressed due to intestinal lymphangiectasia, developed multiple cranial neuropathies. CSF findings consisted of 100 lymphocytes/μL and a protein of 2.5 g/L (250 mg/dL); cytology and cultures were negative. Gadolinium-enhanced T1 MRI revealed diffuse, multifocal meningeal enhancement surrounding the brainstem (***A***), spinal cord and cauda equina (***B***).

Contrast-enhanced MRI or CT studies of the brain and spinal cord can identify meningeal enhancement, parameningeal infections (including brain abscess), encasement of the spinal cord (malignancy or inflammation and infection), or nodular deposits on the meninges or nerve roots (malignancy or sarcoidosis) (Fig. 377-1). Imaging studies are also useful to localize areas of meningeal disease prior to meningeal biopsy.

Cerebral angiography may be indicated in patients with chronic meningitis and stroke to identify cerebral arteritis (granulomatous angiitis, other inflammatory arteritides, or infectious arteritis).

CEREBROSPINAL FLUID ANALYSIS The CSF pressure should be measured and samples sent for bacterial, fungal, and tuberculous culture; Venereal Disease Research Laboratories (VDRL) test; cell count and differential; Gram's stain; and measurement of glucose and protein. Wet mount for fungus and parasites, India ink preparation and culture, culture for fastidious bacteria and fungi, assays for cryptococcal antigen and oligoclonal immunoglobulin bands, and cytology should be performed. Other specific CSF tests (Tables 377-2 and 377-3) or blood tests and cultures should be ordered as indicated on the basis of the history, physical examination, or preliminary CSF results (i.e., eosinophilic, mononuclear, or polymorphonuclear meningitis). Rapid diagnosis may be facilitated by serologic tests and polymerase chain reaction (PCR) testing to identify DNA sequences in the CSF that are specific for the suspected pathogen.

In most categories of chronic (not recurrent) meningitis, mononuclear cells predominate in the CSF. When neutrophils predominate after 3 weeks of illness, the principal etiologic considerations are *Nocardia asteroides*, *Actinomyces israelii*, *Brucella*, *Mycobacterium tuberculosis* (5–10% of early cases only), various fungi (*Blastomyces dermatitidis*, *Candida albicans*, *Histoplasma capsulatum*, *Aspergillus* spp., *Pseudallescheria boydii*, *Cladophialophora bantiana*), and noninfectious causes (SLE, exogenous chemical meningitis). When eosinophils predominate or are present in limited numbers in a primarily mononuclear cell response in the CSF, the differential diagnosis includes parasitic diseases (*A. cantonensis*, *G. spinigerum*, *B. procyonis*, or *Toxocara canis* infection, cysticercosis, schistosomiasis, echinococcal disease, *T. gondii* infection), fungal infections (6–20% eosinophils along with a predominantly lymphocyte pleocytosis, particularly with coccidioidal meningitis), neoplastic disease (lymphoma, leukemia, metastatic carcinoma), or other inflammatory processes (sarcoidosis, hypereosinophilic syndrome).

It is often necessary to broaden the number of diagnostic tests if the initial workup does not reveal the cause. In addition, repeated samples of large volumes of CSF may be required to diagnose certain infectious and malignant causes of chronic meningitis. For instance, lymphomatous or carcinomatous meningitis may be diagnosed by examination of sections cut from a cell block formed by spinning down the sediment from a large volume of CSF. The diagnosis of fungal meningitis may require large volumes of CSF for culture of sediment. If standard lumbar puncture is unrewarding, a cervical cisternal tap to sample CSF near to the basal meninges may be fruitful.

LABORATORY INVESTIGATION In addition to the CSF examination, an attempt should be made to uncover pertinent underlying illnesses. Tuberculin skin test, chest radiograph, urine analysis and culture, blood count and differential, renal and liver function tests, alkaline phosphatase, sedimentation rate, antinuclear antibody, anti-Ro, anti-La antibody and serum angiotensin-converting enzyme level are often indicated. Liver or bone marrow biopsy may be diagnostic in some cases of miliary tuberculosis, disseminated fungal infection, sarcoidosis, or metastatic malignancy. Abnormalities discovered on chest radiograph or chest CT can be pursued by bronchoscopy or transthoracic needle biopsy.

MENINGEAL BIOPSY A meningeal biopsy should be strongly considered in patients who are severely disabled, who need chronic ventricular decompression, or whose illness is progressing rapidly. The activities of the surgeon, pathologist, microbiologist, and cytologist should be coordinated so that a large enough sample is obtained and the appropriate cultures and histologic and molecular studies, including electron-microscopic and PCR studies, are performed. The diagnostic yield of meningeal biopsy can be increased by targeting regions that enhance with contrast on MRI or CT. With current microsurgical techniques, most areas of the basal meninges can be accessed for biopsy via a limited craniotomy. In a series from the Mayo Clinic reported by Cheng et al., MRI demonstrated meningeal enhancement in 47% of patients undergoing meningeal biopsy. Biopsy of an enhancing region was diagnostic in 80% of cases; biopsy of nonenhancing regions was diagnostic in only 9%; sarcoid (31%) and metastatic adenocarcinoma (25%) were the most common conditions identified. Tuberculosis is the most common condition identified in many reports from outside the United States.

APPROACH TO THE ENIGMATIC CASE In approximately one-third of cases, the diagnosis is not known despite careful evaluation of CSF and potential extraneural sites of disease. A number of the organisms that cause chronic meningitis may take weeks to be identified by cultures. In enigmatic cases several options are available, determined by the extent of the clinical deficits and rate of progression. It is prudent to wait until cultures are finalized if the patient is asymptomatic or symptoms are mild and not progressive. Unfortunately, in many cases progressive neurologic deterioration occurs, and rapid treatment is required. Ventricular-peritoneal shunts may be placed to relieve hydrocephalus, but the risk of disseminating the undiagnosed inflammatory process into the abdomen must be considered.

Empirical Treatment Diagnosis of the causative agent is essential because effective therapies exist for many etiologies of chronic meningitis, but if the condition is left untreated, progressive damage to the CNS and cranial nerves and roots is likely to occur. Occasionally, empirical therapy must be initiated when all attempts at diagnosis fail. In general, empirical therapy in the United States consists of antimycobacterial agents, amphotericin for fungal infection, or glucocorticoids for noninfectious inflammatory causes. It is important to direct empirical therapy of lymphocytic meningitis at tuberculosis, particularly if the condition is associated with hypoglycorrhachia and sixth and other CN palsies, since untreated disease is fatal in 4–8 weeks. In the Mayo Clinic series, the most useful empirical therapy was administration of glucocorticoids rather than antituberculous therapy. Carcinomatous or lymphomatous meningitis may be difficult to diagnose initially, but the diagnosis becomes evident with time.

Chronic meningitis is not uncommon in the course of HIV infection. Pleocytosis and mild meningeal signs often occur at the onset of HIV infection, and occasionally low-grade meningitis persists. Toxoplasmosis commonly presents as intracranial abscesses and may also be associated with meningitis. Other important causes of chronic meningitis in AIDS include infection with *Cryptococcus*, *Nocardia*, *Candida*, or other fungi; syphilis; and lymphoma (Fig. 377-1). Toxoplasmosis, cryptococcosis, nocardiosis, and other fungal infections are important etiologic considerations in individuals with immunodeficiency states other than AIDS, including those due to immunosuppressive medications. Because of the increased risk of chronic meningitis and the attenuation of clinical signs of meningeal irritation in immunosuppressed individuals, CSF examination should be performed for any persistent headache or unexplained change in mental state.

378 Prion Diseases

Stanley B. Prusiner, Bruce Miller

Prions are infectious proteins that cause degeneration of the central nervous system (CNS). Prion diseases are disorders of protein conformation, the most common of which in humans is called Creutzfeldt-Jakob disease (CJD). CJD typically presents with dementia and myoclonus, is relentlessly progressive, and generally causes death within a year of onset. Most CJD patients are between 50 and 75 years of age; however, patients as young as 17 and as old as 83 have been recorded.

In mammals, prions reproduce by binding to the normal, *c*ellular isoform of the *p*rion *p*rotein (PrP^C) and stimulating conversion of PrP^C into the disease-causing isoform (PrP^{Sc}). PrP^C is rich in α-helix and has little β-structure, while PrP^{Sc} has less α-helix and a high amount of β-structure (Fig. 378-1). This α-to-β structural transition in the prion protein (PrP) is the fundamental event underlying prion diseases (Table 378-1).

Four new concepts have emerged from studies of prions: (1) Prions are the only known infectious pathogens that are devoid of nucleic acid; all other infectious agents possess genomes composed of either RNA or DNA that direct the synthesis of their progeny. (2) Prion diseases may be manifest as infectious, genetic, and sporadic disorders; no other group of illnesses with a single etiology presents with such a wide spectrum of clinical manifestations. (3) Prion diseases result from the accumulation of PrP^{Sc}, the conformation of which differs substantially from that of its precursor, PrP^C. (4) PrP^{Sc} can exist in a variety of different conformations, each of which seems to specify a particular disease phenotype. How a specific conformation of a PrP^{Sc} molecule is imparted to PrP^C during prion replication to produce nascent PrP^{Sc} with the same conformation is unknown. Additionally, it is unclear what factors determine where in the CNS a particular PrP^{Sc} molecule will be deposited.

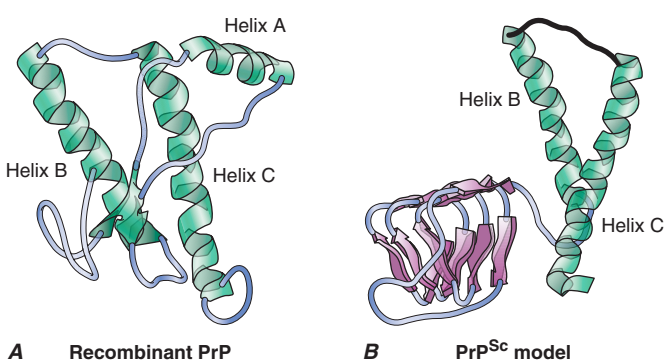

FIGURE 378-1 Structures of prion proteins. *A.* NMR structure of Syrian hamster recombinant (rec) PrP(90–231). Presumably, the structure of the α-helical form of recPrP(90–231) resembles that of PrP^C. recPrP(90–231) is viewed from the interface where PrP^{Sc} is thought to bind to PrP^C. Shown are: α-helices A (residues 144–157), B (172–193), and C (200–227). Flat ribbons depict β-strands S1 (129–131) and S2 (161–163). (***A,*** *from SB Prusiner: N Engl J Med 344:1516, 2006; with permission.)* ***B.*** Structural model of PrP^{Sc}. The 90–160 region has been modeled onto a β-helical architecture while the COOH terminal helices B and C are preserved as in PrP^C. (*Image prepared by C. Govaerts.*)

SPECTRUM OF PRION DISEASES

The sporadic form of CJD is the most common prion disorder in humans. Sporadic CJD (sCJD) accounts for ~85% of all cases of human prion disease, while inherited prion diseases account for 10–15% of all cases (Table 378-2). Familial CJD (fCJD), Gerstmann-Sträussler-Scheinker (GSS) disease, and fatal familial insomnia (FFI) are all dominantly inherited prion diseases that are caused by mutations in the PrP gene.

Although infectious prion diseases account for <1% of all cases and infection does not seem to play an important role in the natural history of these illnesses, the transmissibility of prions is an important biologic feature. *Kuru* of the Fore people of New Guinea is thought to have resulted from the consumption of brains from dead relatives during ritualistic cannibalism. With the cessation of ritualistic cannibalism in the late 1950s, kuru has nearly disappeared, with the ex-

TABLE 378-1 GLOSSARY OF PRION TERMINOLOGY

Prion	*Pro*teinaceous *in*fectious particle that lacks nucleic acid. Prions are composed largely, if not entirely, of PrP^{Sc} molecules. They can cause scrapie in sheep and goats, and related neurodegenerative diseases of humans such as Creutzfeldt-Jakob disease (CJD).
PrP^{Sc}	Disease-causing isoform of the prion protein. This protein is the only identifiable macromolecule in purified preparations of scrapie prions.
PrP^C	Cellular isoform of the prion protein. PrP^C is the precursor of PrP^{Sc}.
PrP 27-30	A fragment of PrP^{Sc}, generated by truncation of the NH_2-terminus by limited digestion with proteinase K. PrP 27-30 retains prion infectivity and polymerizes into amyloid.
PRNP	PrP gene located on human chromosome 20.
Prion rod	An aggregate of prions composed largely of PrP 27-30 molecules. Created by detergent extraction and limited proteolysis of PrP^{Sc}. Morphologically and histochemically indistinguishable from many amyloids.
PrP amyloid	Amyloid containing PrP in the brains of animals or humans with prion disease; often accumulates as plaques.

TABLE 378-2 THE PRION DISEASES

Disease	Host	Mechanism of Pathogenesis
Human		
Kuru	Fore people	Infection through ritualistic cannibalism
iCJD	Humans	Infection from prion-contaminated hGH, dura mater grafts, etc.
vCJD	Humans	Infection from bovine prions
fCJD	Humans	Germ-line mutations in *PRNP*
GSS	Humans	Germ-line mutations in *PRNP*
FFI	Humans	Germ-line mutation in *PRNP* (D178N, M129)
sCJD	Humans	Somatic mutation or spontaneous conversion of PrP^{C} into PrP^{Sc}?
sFI	Humans	Somatic mutation or spontaneous conversion of PrP^{C} into PrP^{Sc}?
Animal		
Scrapie	Sheep, goats	Infection in genetically susceptible sheep
BSE	Cattle	Infection with prion-contaminated MBM
TME	Mink	Infection with prions from sheep or cattle
CWD	Mule deer, elk	Unknown
FSE	Cats	Infection with prion-contaminated beef
Exotic ungulate encephalopathy	Greater kudu, nyala, or oryx	Infection with prion-contaminated MBM

Abbreviations: BSE, bovine spongiform encephalopathy; CJD, Creutzfeldt-Jakob disease; fCJD, familial Creutzfeldt-Jakob disease; iCJD, iatrogenic Creutzfeldt-Jakob disease; sCJD, sporadic Creutzfeldt-Jakob disease; vCJD, variant Creutzfeldt-Jakob disease; CWD, chronic wasting disease; FFI, fatal familial insomnia; sFI, sporadic fatal insomnia; FSE, feline spongiform encephalopathy; GSS, Gerstmann-Sträussler-Scheinker disease; hGH, human growth hormone; MBM, meat and bone meal; TME, transmissible mink encephalopathy.

ception of a few recent patients exhibiting incubation periods of >40 years. Iatrogenic CJD (iCJD) seems to be the result of the accidental inoculation of patients with prions. Variant CJD (vCJD) in teenagers and young adults in Europe is the result of exposure to tainted beef from cattle with bovine spongiform encephalopathy (BSE).

Six diseases of animals are caused by prions (Table 378-2). Scrapie of sheep and goats is the prototypic prion disease. Mink encephalopathy, BSE, feline spongiform encephalopathy, and exotic ungulate encephalopathy are all thought to occur after the consumption of prion-infected foodstuffs. The BSE epidemic emerged in Britain in the late 1980s and was shown to be due to industrial cannibalism. Whether BSE began as a sporadic case of BSE in a cow or started with scrapie in sheep is unknown. The origin of chronic wasting disease (CWD), a prion disease endemic in deer and elk in regions of North America, is uncertain.

EPIDEMIOLOGY

CJD is found throughout the world. The incidence of sCJD is approximately one case per million population, and thus it accounts for about one in every 10,000 deaths. Because sCJD is an age-dependent neurodegenerative disease, its incidence is expected to increase steadily as older segments of populations in developed and developing countries continue to expand. Although many geographic clusters of CJD have been reported, each has been shown to segregate with a PrP gene mutation. Attempts to identify common exposure to some etiologic agent have been unsuccessful for both the sporadic and familial cases. Ingestion of scrapie-infected sheep or goat meat as a cause of CJD in humans has not been demonstrated by epidemiologic studies, although speculation about this potential route of inoculation continues. Of particular interest are deer hunters who develop CJD, because up to 90% of culled deer in some game herds have been shown to harbor CWD prions. Whether prion disease in deer or elk can be passed to cows, sheep, or directly to humans remains unknown. Studies with Syrian hamsters demonstrate that oral infection with prions can occur, but the process is inefficient compared to intracerebral inoculation.

PATHOGENESIS

The human prion diseases were initially classified as neurodegenerative disorders of unknown etiology on the basis of pathologic changes being confined to the CNS. With the transmission of kuru and CJD to apes, investigators began to view these diseases as infectious CNS illnesses caused by slow viruses. Even though the familial nature of a subset of CJD cases was well described, the significance of this observation became more obscure with the transmission of CJD to animals. Eventually the meaning of heritable CJD became clear with the discovery of mutations in the PRNP gene of these patients. The prion concept explains how a disease can manifest as a heritable as well as an infectious illness. Moreover, the hallmark of all prion diseases, whether sporadic, dominantly inherited, or acquired by infection, is that they involve the aberrant metabolism of PrP.

A major feature that distinguishes prions from viruses is the finding that both PrP isoforms are encoded by a chromosomal gene. In humans, the PrP gene is designated *PRNP* and is located on the short arm of chromosome 20. Limited proteolysis of PrP^{Sc} produces a smaller, protease-resistant molecule of ~142 amino acids designated PrP 27-30; PrP^{C} is completely hydrolyzed under the same conditions (Fig. 378-2). In the presence of detergent, PrP 27-30 polymerizes into amyloid. Prion rods formed by limited proteolysis and detergent extraction are indistinguishable from the filaments that aggregate to form PrP amyloid plaques in the CNS. Both the rods and the PrP amyloid filaments found in brain tissue exhibit similar ultrastructural morphology and green-gold birefringence after staining with Congo red dye.

Prion Strains The existence of prion strains raised the question of how heritable biologic information can be enciphered in a molecule other than nucleic acid. Various strains of prions have been defined by incubation times and the distribution of neuronal vacuolation. Subsequently, the patterns of PrP^{Sc} deposition were found to correlate with vacuolation profiles, and these patterns were also used to characterize prion strains.

Persuasive evidence that strain-specific information is enciphered in the tertiary structure of PrP^{Sc} comes from transmission of two different inherited human prion diseases to mice expressing a chimeric human-mouse PrP transgene. In FFI, the protease-resistant fragment of PrP^{Sc} after deglycosylation has a molecular mass of 19 kDa, whereas in fCJD and most sporadic prion diseases, it is 21 kDa (Table 378-3). This difference in molecular mass was shown to be due to different sites of proteolytic cleavage at the NH_2 termini of the two human PrP^{Sc} molecules, reflecting different tertiary structures. These distinct conformations were not unexpected because the amino acid sequences of the PrPs differ.

Extracts from the brains of patients with FFI transmitted disease into mice expressing a chimeric human-mouse PrP transgene and in-

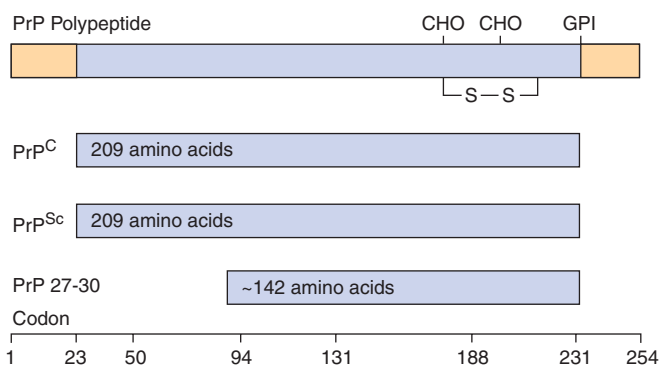

FIGURE 378-2 Prion protein isoforms. Bar diagram of Syrian hamster PrP, which consists of 254 amino acids. After processing of the NH_2 and COOH termini, both PrP^{C} and PrP^{Sc} consist of 209 residues. After limited proteolysis, the NH_2 terminus of PrP^{Sc} is truncated to form PrP 27–30 composed of ~142 amino acids.

TABLE 378-3 DISTINCT PRION STRAINS GENERATED IN HUMANS WITH INHERITED PRION DISEASES AND TRANSMITTED TO TRANSGENIC MICE[a]

Inoculum	Host Species	Host PrP Genotype	Incubation Time [days ± SEM] (n/n_0)	PrP^{Sc} (kDa)
None	Human	FFI(D178N, M129)		19
FFI	Mouse	Tg(MHu2M)	206 ± 7 (7/7)	19

[a] Tg(MHu2M) mice express a chimeric mouse-human PrP gene.

Note: Clinicopathologic phenotype is determined by the conformation of PrP^{Sc} in accord with the results of the transmission of human prions from patients with FFI to transgenic mice. FFI, fatal familial insomnia; fCJD, familial Creutzfeldt-Jakob disease.

duced formation of the 19-kDa PrP^{Sc}, whereas brain extracts from fCJD and sCJD patients produced the 21-kDa PrP^{Sc} in mice expressing the same transgene. On second passage, these differences were maintained, demonstrating that chimeric PrP^{Sc} can exist in two different conformations based on the sizes of the protease-resistant fragments, even though the amino acid sequence of PrP^{Sc} is invariant.

This analysis was extended when patients with sporadic fatal insomnia (sFI) were identified. Although they did not carry a *PRNP* gene mutation, the patients demonstrated a clinical and pathologic phenotype that was indistinguishable from that of patients with FFI. Furthermore, 19-kDa PrP^{Sc} was found in their brains, and on passage of prion disease to mice expressing a chimeric human-mouse PrP transgene, 19-kDa PrP^{Sc} was also found. These findings indicate that the disease phenotype is dictated by the conformation of PrP^{Sc} and not the amino acid sequence. PrP^{Sc} acts as a template for the conversion of PrP^{C} into nascent PrP^{Sc}. On the passage of prions into mice expressing a chimeric hamster-mouse PrP transgene, a change in the conformation of PrP^{Sc} was accompanied by the emergence of a new strain of prions.

New strains of prions were also generated from recombinant (rec) PrP produced in bacteria. In these studies, recPrP was polymerized into amyloid fibrils and inoculated into transgenic mice expressing very high levels of truncated mouse PrP^{C}; about 500 days later, the mice died of prion disease. These "synthetic prions" were found to be much more stable than any prions previously isolated from animals or humans with naturally occurring prion diseases. Surprisingly, studies of synthetic and naturally occurring prions indicate that the incubation time is directly proportional to the stability of the prion. As the stability increases, the incubation time lengthens; thus, less-stable prions replicate more rapidly. These studies also showed that PrP^{Sc} can adopt a continuum of conformational states, each of which enciphers a distinct incubation-time phenotype.

Species Barrier Studies on the role of the primary and tertiary structures of PrP in the transmission of prion disease have given new insights into the pathogenesis of these maladies. The amino acid sequence of PrP encodes the species of the prion, and the prion derives its PrP^{Sc} sequence from the last mammal in which it was passaged. While the primary structure of PrP is likely to be the most important or even sole determinant of the tertiary structure of PrP^{C}, PrP^{Sc} seems to function as a template in determining the tertiary structure of nascent PrP^{Sc} molecules as they are formed from PrP^{C}. In turn, prion diversity appears to be enciphered in the conformation of PrP^{Sc}, and thus prion strains seem to represent different conformers of PrP^{Sc}.

In general, transmission of prion disease from one species to another is inefficient, in that not all intracerebrally inoculated animals develop disease, and those that fall ill do so only after long incubation times that can approach the natural life span of the animal. This "species barrier" to transmission is correlated with the degree of similarity between the amino acid sequences of PrP^{C} in the inoculated host and of PrP^{Sc} in the prion inoculum. The importance of sequence similarity between the host and donor PrP argues that PrP^{C} directly interacts with PrP^{Sc} in the prion conversion process.

SPORADIC AND INHERITED PRION DISEASES

Several different scenarios might explain the initiation of sporadic prion disease: (1) A somatic mutation may be the cause and thus follow a path similar to that for germ-line mutations in inherited disease. In this situation, the mutant PrP^{Sc} must be capable of targeting wild-type PrP^{C}, a process known to be possible for some mutations but less likely for others. (2) The activation barrier separating wild-type PrP^{C} from PrP^{Sc} could be crossed on rare occasions when viewed in the context of a population. Most individuals would be spared while presentations in the elderly with an incidence of ~1 per million would be seen. (3) PrP^{Sc} may be present at very low levels in some normal cells, where it performs some important, as yet unknown, function. The level of PrP^{Sc} in such cells is hypothesized to be sufficiently low as to be not detected by bioassay. In some altered metabolic states, the cellular mechanisms for clearing PrP^{Sc} might become compromised and the rate of PrP^{Sc} formation would then begin to exceed the capacity of the cell to clear it. The third possible mechanism is attractive since it suggests PrP^{Sc} is not simply a misfolded protein, as proposed for the first and second mechanisms, but that it is an alternatively folded molecule with a function. Moreover, the multitude of conformational states that PrP^{Sc} can adopt, as described above, raises the possibility that PrP^{Sc} or another prion-like protein might function in a process like short-term memory where information storage occurs in the absence of new protein synthesis.

More than 30 different mutations resulting in nonconservative substitutions in the human *PRNP* gene have been found to segregate with inherited human prion diseases. Missense mutations and expansions in the octapeptide repeat region of the gene are responsible for familial forms of prion disease. Five different mutations of the *PRNP* gene have been linked genetically to heritable prion disease.

Although phenotypes may vary dramatically within families, specific phenotypes tend to be observed with certain mutations. A clinical phenotype indistinguishable from typical sCJD is usually seen with substitutions at codons 180, 183, 200, 208, 210, and 232. Substitutions at codons 102, 105, 117, 198, and 217 are associated with the GSS variant of prion disease. The normal human PrP sequence contains five repeats of an eight-amino-acid sequence. Insertions from two to nine extra octarepeats frequently cause variable phenotypes ranging from a condition indistinguishable from sCJD to a slowly progressive dementing illness of many years' duration to an early-age-of-onset disorder that is similar to Alzheimer's disease. A mutation at codon 178 resulting in substitution of asparagine for aspartic acid produces FFI if a methionine is encoded at the polymorphic 129 residue on the same allele. Typical CJD is seen if a valine is encoded at position 129 of the same allele.

HUMAN PRNP GENE POLYMORPHISMS

Polymorphisms influence the susceptibility to sporadic, inherited, and infectious forms of prion disease. The methionine/valine polymorphism at position 129 not only modulates the age of onset of some inherited prion diseases but can also determine the clinical phenotype. The finding that homozygosity at codon 129 predisposes to sCJD supports a model of prion production that favors PrP interactions between homologous proteins.

Substitution of the basic residue lysine at position 218 in mouse PrP produced dominant-negative inhibition of prion replication in transgenic mice. This same lysine at position 219 in human PrP has been found in 12% of the Japanese population, and this group appears to be resistant to prion disease. Dominant-negative inhibition of prion replication was also found with substitution of the basic residue arginine

at position 171; sheep with arginine are resistant to scrapie prions but are susceptible to BSE prions that were inoculated intracerebrally.

INFECTIOUS PRION DISEASES

IATROGENIC CJD

Accidental transmission of CJD to humans appears to have occurred with corneal transplantation, contaminated electroencephalogram (EEG) electrode implantation, and surgical procedures. Corneas from donors with inapparent CJD have been transplanted to apparently healthy recipients who developed CJD after prolonged incubation periods. The same improperly decontaminated EEG electrodes that caused CJD in two young patients with intractable epilepsy caused CJD in a chimpanzee 18 months after their experimental implantation.

Surgical procedures may have resulted in accidental inoculation of patients with prions, presumably because some instrument or apparatus in the operating theater became contaminated when a CJD patient underwent surgery. Although the epidemiology of these studies is highly suggestive, no proof for such episodes exists.

Dura Mater Grafts More than 160 cases of CJD after implantation of dura mater grafts have been recorded. All of the grafts were thought to have been acquired from a single manufacturer whose preparative procedures were inadequate to inactivate human prions. One case of CJD occurred after repair of an eardrum perforation with a pericardium graft.

Human Growth Hormone and Pituitary Gonadotropin Therapy The possibility of transmission of CJD from contaminated human growth hormone (hGH) preparations derived from human pituitaries has been raised by the occurrence of fatal cerebellar disorders with dementia in >180 patients ranging in age from 10 to 41 years. These patients received injections of hGH every 2–4 days for 4–12 years. If it is assumed that these patients developed CJD from injections of prion-contaminated hGH preparations, the possible incubation periods range from 4 to 30 years. Even though several investigations argue for the efficacy of inactivating prions in hGH fractions prepared from human pituitaries with 6 *M* urea, it seems doubtful that such protocols will be used for purifying hGH because recombinant hGH is available. Four cases of CJD have occurred in women receiving human pituitary gonadotropin.

VARIANT CJD

The restricted geographic occurrence and chronology of vCJD raised the possibility that BSE prions have been transmitted to humans through the consumption of tainted beef. More than 190 cases of vCJD have occurred, with >90% of these in Britain. vCJD has also been reported in people either living in or originating from France, Ireland, Italy, Netherlands, Portugal, Spain, Saudi Arabia, United States, Canada, and Japan.

Because the number of vCJD cases is still small, it not possible to decide if we are at the beginning of a prion disease epidemic in Europe, similar to those seen for BSE and kuru, or if the number of vCJD cases will remain small. What is certain is that prion-tainted meat should be prevented from entering the human food supply.

The most compelling evidence that vCJD is caused by BSE prions was obtained from experiments in mice expressing the bovine PrP transgene. Both BSE and vCJD prions were efficiently transmitted to these transgenic mice and with similar incubation periods. In contrast to sCJD prions, vCJD prions did not transmit disease efficiently to mice expressing a chimeric human-mouse PrP transgene. Earlier studies with nontransgenic mice suggested that vCJD and BSE might be derived from the same source because both inocula transmitted disease with similar but very long incubation periods.

Attempts to determine the origin of BSE and vCJD prions have relied on passaging studies in mice, some of which are described above, as well as studies of the conformation and glycosylation of PrP^{Sc}. One scenario suggests that a particular conformation of bovine PrP^{Sc} was selected for heat resistance during the rendering process and was then reselected multiple times as cattle infected by ingesting prion-contaminated meat and bone meal (MBM) were slaughtered and their offal rendered into more MBM.

NEUROPATHOLOGY

Frequently the brains of patients with CJD have no recognizable abnormalities on gross examination. Patients who survive for several years have variable degrees of cerebral atrophy.

On light microscopy, the pathologic hallmarks of CJD are spongiform degeneration and astrocytic gliosis. The lack of an inflammatory response in CJD and other prion diseases is an important pathologic feature of these degenerative disorders. Spongiform degeneration is characterized by many 1- to 5-μm vacuoles in the neuropil between nerve cell bodies. Generally the spongiform changes occur in the cerebral cortex, putamen, caudate nucleus, thalamus, and molecular layer of the cerebellum. Astrocytic gliosis is a constant but nonspecific feature of prion diseases. Widespread proliferation of fibrous astrocytes is found throughout the gray matter of brains infected with CJD prions. Astrocytic processes filled with glial filaments form extensive networks.

Amyloid plaques have been found in ~10% of CJD cases. Purified CJD prions from humans and animals exhibit the ultrastructural and histochemical characteristics of amyloid when treated with detergents during limited proteolysis. In first passage from some human Japanese CJD cases, amyloid plaques have been found in mouse brains. These plaques stain with antibodies raised against PrP.

The amyloid plaques of GSS disease are morphologically distinct from those seen in kuru or scrapie. GSS plaques consist of a central dense core of amyloid surrounded by smaller globules of amyloid. Ultrastructurally, they consist of a radiating fibrillar network of amyloid fibrils, with scant or no neuritic degeneration. The plaques can be distributed throughout the brain but are most frequently found in the cerebellum. They are often located adjacent to blood vessels. Congophilic angiopathy has been noted in some cases of GSS disease.

In vCJD, a characteristic feature is the presence of "florid plaques." These are composed of a central core of PrP amyloid, surrounded by vacuoles in a pattern suggesting petals on a flower.

CLINICAL FEATURES

Nonspecific prodromal symptoms occur in about a third of patients with CJD and may include fatigue, sleep disturbance, weight loss, headache, malaise, and ill-defined pain. Most patients with CJD present with deficits in higher cortical function. These deficits almost always progress over weeks or months to a state of profound dementia characterized by memory loss, impaired judgment, and a decline in virtually all aspects of intellectual function. A few patients present with either visual impairment or cerebellar gait and coordination deficits. Frequently the cerebellar deficits are rapidly followed by progressive dementia. Visual problems often begin with blurred vision and diminished acuity, rapidly followed by dementia.

Other symptoms and signs include extrapyramidal dysfunction manifested as rigidity, masklike facies, or choreoathetoid movements; pyramidal signs (usually mild); seizures (usually major motor) and, less commonly, hypoesthesia; supranuclear gaze palsy; optic atrophy; and vegetative signs such as changes in weight, temperature, sweating, or menstruation.

Myoclonus Most patients (~90%) with CJD exhibit myoclonus that appears at various times throughout the illness. Unlike other involuntary movements, myoclonus persists during sleep. Startle myoclonus elicited by loud sounds or bright lights is frequent. It is important to stress that myoclonus is neither specific nor confined to CJD. Dementia with myoclonus can also be due to Alzheimer's disease (AD) (Chap. 365), dementia with Lewy bodies (Chap. 365), cryptococcal encephalitis (Chap. 195), or the myoclonic epilepsy disorder Unverricht-Lundborg disease (Chap. 363).

Clinical Course In documented cases of accidental transmission of CJD to humans, an incubation period of 1.5–2.0 years preceded the development of clinical disease. In other cases, incubation periods of up to 30 years have been suggested. Most patients with CJD live 6–12 months after the onset of clinical signs and symptoms, whereas some live for up to 5 years.

DIAGNOSIS

The constellation of dementia, myoclonus, and periodic electrical bursts in an afebrile 60-year-old patient generally indicates CJD. Clinical abnormalities in CJD are confined to the CNS. Fever, elevated sedimentation rate, leukocytosis in blood, or a pleocytosis in cerebrospinal fluid (CSF) should alert the physician to another etiology to explain the patient's CNS dysfunction.

Variations in the typical course appear in inherited and transmitted forms of the disease. fCJD has an earlier mean age of onset than sCJD. In GSS disease, ataxia is usually a prominent and presenting feature, with dementia occurring late in the disease course. GSS disease typically presents earlier than CJD (mean age 43 years) and is typically more slowly progressive than CJD; death usually occurs within 5 years of onset. FFI is characterized by insomnia and dysautonomia; dementia occurs only in the terminal phase of the illness. Rare sporadic cases have been identified. vCJD has an unusual clinical course, with a prominent psychiatric prodrome that may include visual hallucinations and early ataxia, while frank dementia is usually a late sign of vCJD.

DIFFERENTIAL DIAGNOSIS

Many conditions may mimic CJD superficially. Dementia with Lewy bodies (Chap. 365) is the most common disorder to be mistaken for CJD. It can present in a subacute fashion with delirium, myoclonus, and extrapyramidal features. Other neurodegenerative disorders to consider include AD, frontotemporal dementia, progressive supranuclear palsy, ceroid lipofuscinosis (Chap. 365), and myoclonic epilepsy with Lafora bodies (Chap. 363). The absence of abnormalities on diffusion-weighted and FLAIR MRI will usually distinguish these dementing conditions from CJD.

Hashimoto's encephalopathy, which presents as a subacute progressive encephalopathy with myoclonus and periodic triphasic complexes on the EEG, should be excluded in every case of suspected CJD. It is diagnosed by the finding of high titers of antithyroglobulin or antithyroid peroxidase (antimicrosomal) antibodies in the blood and improves with glucocorticoid therapy. Unlike CJD, fluctuations in severity typically occur in Hashimoto's encephalopathy.

Intracranial vasculitides (Chap. 319) may produce nearly all of the symptoms and signs associated with CJD, sometimes without systemic abnormalities. Myoclonus is exceptional with cerebral vasculitis, but focal seizures may confuse the picture. Prominent headache, absence of myoclonus, stepwise change in deficits, abnormal CSF, and focal white matter changes on MRI or angiographic abnormalities all favor vasculitis.

Paraneoplastic conditions, particularly limbic encephalitis and cortical encephalitis, can also mimic CJD. In many of these patients, dementia appears prior to the diagnosis of a tumor, and in some, no tumor is ever found. Detection of the paraneoplastic antibodies is often the only way to distinguish these cases from CJD.

Other diseases that can simulate CJD include neurosyphilis (Chap. 162), AIDS dementia complex (Chap. 182), progressive multifocal leukoencephalopathy (Chap. 376), subacute sclerosing panencephalitis, progressive rubella panencephalitis, herpes simplex encephalitis, diffuse intracranial tumor (gliomatosis cerebri; Chap. 374), anoxic encephalopathy, dialysis dementia, uremia, hepatic encephalopathy, and lithium or bismuth intoxication.

LABORATORY TESTS

The only specific diagnostic tests for CJD and other human prion diseases measure PrP^{Sc}. The most widely used method involves limited proteolysis that generates PrP 27-30, which is detected by immunoassay after denaturation. The conformation-dependent immunoassay (CDI) is based on immunoreactive epitopes that are exposed in PrP^{C} but buried in PrP^{Sc}. The CDI is extremely sensitive and quantitative and is likely to find wide application in both the post- and antemortem detection of prions. In humans, the diagnosis of CJD can be established by brain biopsy if PrP^{Sc} is detected. If no attempt is made to measure PrP^{Sc}, but the constellation of pathologic changes frequently found in CJD is seen in a brain biopsy, then the diagnosis is reasonably secure (see "Neuropathology," above). Because PrP^{Sc} is not uniformly distributed throughout the CNS, the apparent absence of PrP^{Sc} in a limited sample such as a biopsy does not rule out prion disease. At autopsy, sufficient brain samples should be taken for both PrP^{Sc} immunoassay, preferably by CDI, and immunohistochemistry of tissue sections.

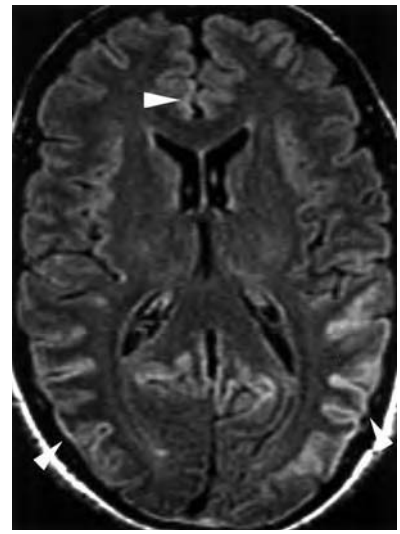

FIGURE 378-3 T2-weighted (FLAIR) MRI showing hyperintensity in the cortex in a patient with sporadic CJD. This so-called "cortical ribboning" along with increased intensity in the basal ganglia on T2 or diffusion-weighted imaging can aid in the diagnosis of CJD.

To establish the diagnosis of either sCJD or familial prion disease, sequencing the *PRNP* gene must be performed. Finding the wild-type *PRNP* gene sequence permits the diagnosis of sCJD if there is no history to suggest infection from an exogenous source of prions. The identification of a mutation in the *PRNP* gene sequence that encodes a nonconservative amino acid substitution argues for familial prion disease.

CT may be normal or show cortical atrophy. MRI is valuable for distinguishing sCJD from most other conditions. On FLAIR sequences and diffusion-weighted imaging, ~90% of patients show increased intensity in the basal ganglia and cortical ribboning **(Fig. 378-3)**. This pattern is not seen with other neurodegenerative disorders but has been seen infrequently with viral encephalitis, paraneoplastic syndromes, or seizures. When the typical MRI pattern is present, in the proper clinical setting, diagnosis is facilitated. However, some cases of sCJD do not show this typical pattern, and other early diagnostic approaches are still needed.

CSF is nearly always normal but may show protein elevation and, rarely, mild pleocytosis. Although the stress protein 14-3-3 is elevated in the CSF of some patients with CJD, similar elevations of 14-3-3 are found in patients with other disorders; thus this elevation is not specific.

The EEG is often useful in the diagnosis of CJD, although only about 60% of individuals show the typical pattern. During the early phase of CJD, the EEG is usually normal or shows only scattered theta activity. In most advanced cases, repetitive, high-voltage, triphasic, and polyphasic sharp discharges are seen, but in many cases their presence is transient. The presence of these stereotyped periodic bursts of <200 ms duration, occurring every 1–2 s, makes the diagnosis of CJD very likely. These discharges are frequently but not always symmetric; there may be a one-sided predominance in amplitude. As CJD progresses, normal background rhythms become fragmentary and slower.

CARE OF CJD PATIENTS

Although CJD should not be considered either contagious or communicable, it is transmissible. The risk of accidental inoculation by aerosols is very small; nonetheless, procedures producing aerosols should be performed in certified biosafety cabinets. Biosafety level 2 practices, containment equipment, and facilities are recommended by the Centers for Disease Control and Prevention and the National Institutes of Health. The primary problem in caring for patients with CJD is the inadvertent infection of health care workers by needle and stab wounds. The transmission of prions through the air has never been document-

ed. Electroencephalographic and electromyographic needles should not be reused after studies on patients with CJD have been performed.

There is no reason for pathologists or other morgue employees to resist performing autopsies on patients whose clinical diagnosis was CJD. Standard microbiologic practices outlined here, along with specific recommendations for decontamination, seem to be adequate precautions for the care of patients with CJD and the handling of infected specimens.

DECONTAMINATION OF CJD PRIONS

Prions are extremely resistant to common inactivation procedures, and there is some disagreement about the optimal conditions for sterilization. Some investigators recommend treating CJD-contaminated materials once with 1 *N* NaOH at room temperature, but we believe this procedure may be inadequate for sterilization. Autoclaving at 134°C for 5 h or treatment with 2 *N* NaOH for several hours is recommended for sterilization of prions. The term *sterilization* implies complete destruction of prions; any residual infectivity can be hazardous. Recent studies show that sCJD prions bound to stainless steel surfaces are resistant to inactivation by autoclaving at 134°C for 2 h; exposure of bound prions to an acidic detergent solution prior to autoclaving rendered prions susceptible to inactivation.

PREVENTION AND THERAPEUTICS

There is no known effective therapy for preventing or treating CJD. The finding that phenothiazines and acridines inhibit PrP^{Sc} formation in cultured cells led to clinical studies of quinacrine in CJD patients. Although quinacrine seems to slow the rate of decline in some CJD patients, no cure of the disease has been observed. In wild-type mice, quinacrine treatment has been ineffective. Recent studies indicate that inhibition of the P-glycoprotein (Pgp) transport system results in substantially increased quinacrine levels in the brains of mice. Whether such an approach can be used to treat CJD remains to be established.

Like the acridines, anti-PrP antibodies have been shown to eliminate PrP^{Sc} from cultured cells. Additionally, such antibodies in mice, either administered by injection or produced from a transgene, have been shown to prevent prion disease when prions are introduced by a peripheral route, such as intraperitoneal inoculation. Unfortunately, the antibodies were ineffective in mice inoculated intracerebrally with prions. Several drugs, including pentosan polysulfate and porphyrin derivatives, delay the onset of disease in animals inoculated intracerebrally with prions if the drugs are given intracerebrally beginning soon after inoculation.

Structure-based drug design predicated on dominant-negative inhibition of prion formation has produced several promising compounds. Modified quinacrine compounds that are more potent than the parent drug have been found. Whether improving the efficacy of such small molecules will provide general methods for developing novel therapeutics for other neurodegenerative disorders, including AD and Parkinson's disease as well as amyotrophic lateral sclerosis (ALS), remains to be established.

SECTION 3 NERVE AND MUSCLE DISORDERS

379 Peripheral Neuropathy

Vinay Chaudhry

Peripheral neuropathy describes disorders of peripheral nerves, including the dorsal or ventral nerve roots; dorsal root ganglia; brachial or lumbosacral plexus; cranial nerves (except I and II); and other sensory, motor, autonomic, or mixed nerves; the term *peripheral* indicates that the disorder is outside the central nervous system (brain and spinal cord). Peripheral neuropathy affects ~2–8% of adults; the incidence increases with age. Evaluation begins with a history focusing on the time course of the illness, symptoms, medical conditions that predispose to neuropathy (e.g., diabetes mellitus, connective tissue disease, nutritional deficiency), toxic exposures (drug or environmental), and family history. Physical examination assesses the function of small sensory fibers (pain and temperature), large sensory fibers (vibration, proprioception, reflex changes), and/or motor nerves (weakness). The distribution of sensory, motor, and reflex changes determines whether the neuropathy is asymmetric or symmetric. Electrodiagnostic studies (EDx) help to classify the neuropathy into one of three major categories: axonal, demyelinating, or neuronal. Focused laboratory tests are then performed based on the history, examination, and EDx. An underlying cause can be identified in ~75% of neuropathies.

APPROACH TO THE PATIENT: Peripheral Neuropathy

A stepwise approach to diagnosis is presented in Fig. 379-1. The following questions should be addressed initially:

1. *Is this a peripheral neuropathy?* The initial symptoms of peripheral neuropathy are often intermittent, and examination can be normal. Patients may present with positive and/or negative symptoms (Table 379-1). In most situations, sensory symptoms precede motor symptoms. Small-fiber neuropathies often present with dysesthesias and paresthesias, terms used interchangeably to describe unpleasant, unusual, or abnormal sensations such as burning or cutting pain, electric shock–like sensations, tingling, pins and needles, formication, prickly feelings such as a limb falling asleep, or cramp-like sensations (Chap. 25). Large-fiber neuropathies can present as numbness, tingling, or a gait disturbance (sensory ataxia). In most cases, the abnormal sensation originates in the toes and feet and ascends proximally to the legs in a stocking distribution. Only when the sensation reaches the level of the knee or thigh do symptoms appear in the hands, producing a length-dependent, or stocking-glove, pattern. Paresthesias that begin in one hand suggest an entrapment neuropathy such as carpal tunnel syndrome.

   Motor symptoms usually have a later onset than sensory symptoms. In long-standing inherited neuropathies, patients may present with isolated weakness of the feet without sensory symptoms; the ankle jerk, the most distal deep tendon reflex, is invariably absent. When confronted with a length-dependent pattern of sensory symptoms, the diagnosis of a peripheral neuropathy is not difficult. However, in cases with pure motor weakness or wasting, localization may be difficult, and in such cases the presence of distal weakness is helpful in differentiating a peripheral neuropathy from muscle or neuromuscular junction disorders, which typical-

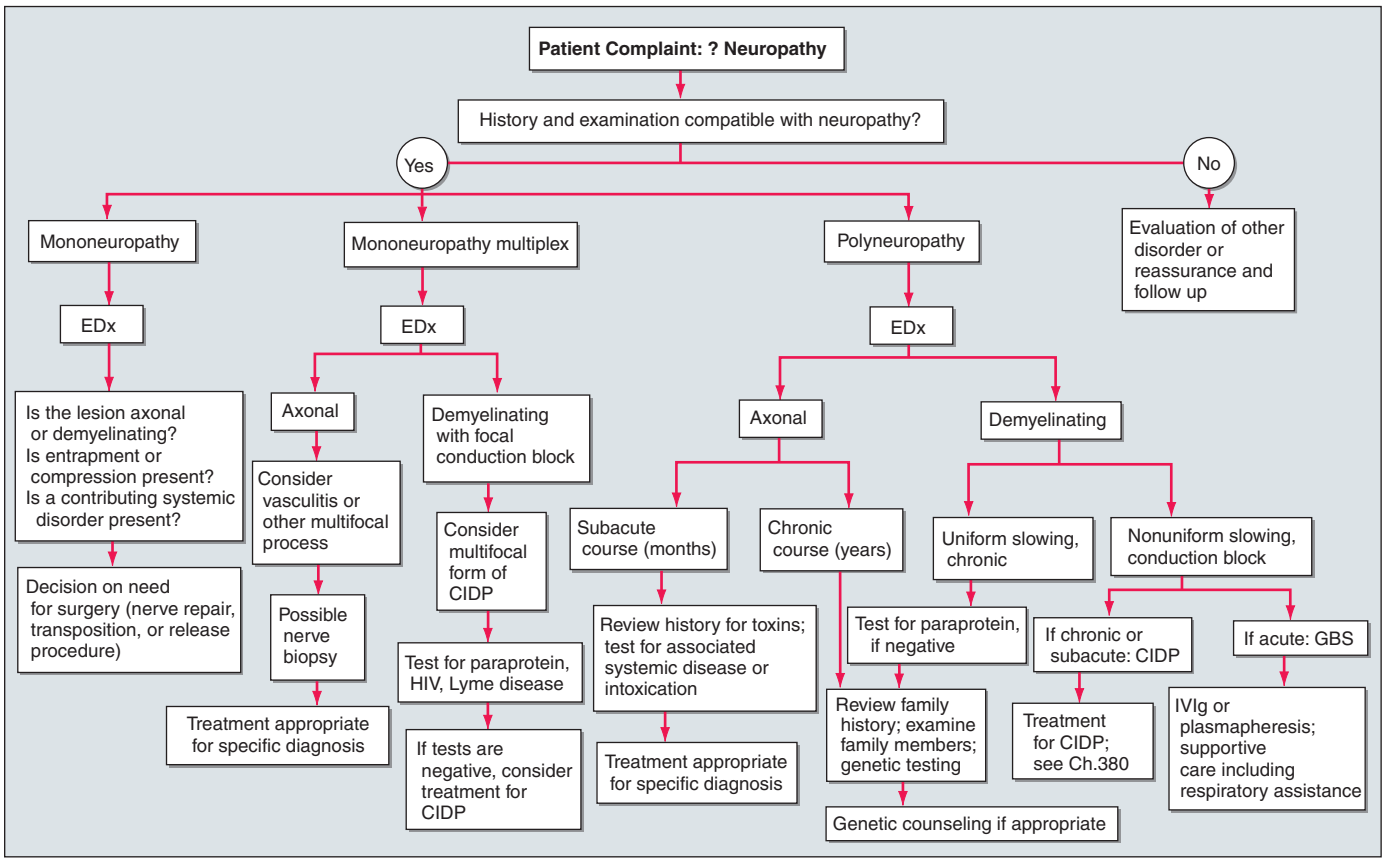

FIGURE 379-1 Approach to the evaluation of peripheral neuropathies. CIDP, chronic inflammatory demyelinating polyradiculoneuropathy; GBS, Guillain-Barré syndrome.

ly present with proximal weakness. Motor neuron disease can also present with distal weakness and wasting; however, the findings are not in the distribution of an individual nerve.

2. *What is its distribution?* Polyneuropathy involves widespread and symmetric dysfunction of the peripheral nerves; mononeuropathy involves a single peripheral nerve; multiple mononeuropathy involves multiple individual peripheral nerves (Table 379-2 and Fig. 379-1). Mononeuropathies are usually due to compression, trauma, or vascular causes. Multiple mononeuropathies (also referred to as mononeuropathy multiplex) can be a result of multiple entrapments, infiltration, or vasculitis. Plexopathies (brachial or lumbosacral) also involve multiple peripheral nerves, in an asymmetric fashion.
3. *Which fibers are affected?* In a polyneuropathy, manifestations can be classified as small-fiber sensory, large-fiber sensory, motor, and/or autonomic (Table 379-3). Often there is overlap, but if there is predominant involvement of one fiber group, the differential diagnosis and evaluation can be narrowed. For example, if a patient has burning pain in the feet, a small-fiber neuropathy is likely and diabetes mellitus is a possible etiology. If a patient has sensory ataxia, large fibers are likely affected and Sjögren's syndrome or a paraneoplastic process should be considered.
4. *What is the anatomic pattern?* Clinical evaluation is often helpful in categorizing a neuropathy as axonal, demyelinating, or neuronal [dorsal root ganglion (DRG)] (Table 379-4). Most axonal neuropathies follow a length-dependent (stocking-glove) pattern with sensory (small fiber more than large fiber) symptoms and signs predominating over motor manifestations; distal reflexes are absent. In contrast, most demyelinating neuropathies affect motor fibers and sensory fibers (large fiber more than small fiber) equally, and areflexia or hyporeflexia is more generalized. DRG lesions involve purely sensory fibers in a non-length-dependent fashion; sensory ataxia and generalized loss of reflexes are usually found. EDx studies are also important in defining the anatomy of a neuropathy.

TABLE 379-1 SYMPTOMS, SIGNS, AND TESTS IN PERIPHERAL NEUROPATHY

Large Fiber	Small Fiber	Motor	Autonomic
Symptoms			
Numbness "Pins and needles" Tingling Poor balance	Pain: burning, shock-like, stabbing, prickling, shooting, lancinating Allodynia	Cramps Weak grip Footdrop Twitching	Decreased or increased sweating Dry eyes, mouth, Erectile dysfunction Gastroparesis/diarrhea Faintness, light-headedness
Signs			
Decreased Vibration Joint-position sense Reflexes	Decreased Pin prick Temperature sensation	Reduced Strength Reflexes	Orthostasis Unequal pupil size
Tests			
NCS-EMG Nerve biopsy LP	Skin biopsy QST Nerve biopsy	NCS-EMG	QSART Tilt table R-R interval Valsalva

Note: NCS-EMG, nerve conduction studies/electromyography; QSART, quantitative sudomotor axon reflex testing; QST, quantitative sensory test; LP, lumbar puncture.

TABLE 379-2 CLASSIFICATION OF NEUROPATHY BY LOCATION

Polyneuropathy
- Fairly symmetric
- Distal stocking-glove
- May or may not be painful
- Sensorimotor
- Symmetrically decreased reflexes

Plexopathy
- Asymmetric
- Painful onset
- Multiple nerves in a single limb
- Rapid onset of weakness, atrophy
- Isolated reflex loss

Multiple Mononeuropathy
- In distribution of single nerve(s)
- Setting: diabetes, pressure, vasculitis
- May or may not be painful
- Isolated reflex loss

Not a Neuropathy
- Upper motor neuron signs (brisk reflexes)
- Prominent bladder and bowel involvement
- Unilateral (arm, leg, face) symptoms
- Sensory level
- Hyperventilation

TABLE 379-3 CLASSIFICATION OF NEUROPATHY BY FIBER TYPE

Small-fiber sensory (painful neuropathies and dissociated sensory loss)
- Hereditary sensory neuropathies (early)
- Lepromatous leprosy
- Diabetic (includes glucose intolerance) small-fiber neuropathy
- Amyloidosis
- Analphalipoproteinemia (Tangier disease)
- Fabry's disease (pain predominates)
- Dysautonomia (Riley-Day syndrome)
- HIV and antiretroviral therapy neuropathy

Large-fiber sensory (ataxic-neuropathies)
- Sjögren's syndrome
- Vitamin B_{12} neuropathy (from dorsal column involvement)
- Cisplatin neuropathy
- Pyridoxine toxicity
- Friedreich's ataxia

Small- and large-fiber: Global sensory loss
- Carcinomatous sensory neuropathy
- Hereditary sensory neuropathies (recessive and dominant)
- Diabetic sensory neuropathy
- Vacor intoxication
- Xanthomatous neuropathy of primary biliary cirrhosis (tabes dorsalis)

Motor-predominant neuropathies
- Immune neuropathies: acute (Guillain-Barré syndrome); relapsing
- Heritable motor-sensory neuropathies
- Acute intermittent porphyria
- Diphtheritic neuropathy
- Lead neuropathy
- Brachial neuritis
- Diabetic lumbosacralplexus neuropathy (diabetic amyotrophy)

Autonomic
- Acute: Acute pandysautonomic neuropathy, botulism, porphyria, GBS, vacore, amiodarone, vincristine
- Chronic: Amyloid, diabetes, Sjögren's, HSAN I and III (Riley-Day), Chagas, paraneoplastic

Note: GBS, Guillain-Barré syndrome; HSAN, hereditary sensory and autonomic neuropathy.

5. *What is the time course?* Rapidly evolving peripheral neuropathies are usually inflammatory [Guillain-Barré syndrome (GBS)] or toxic in origin. Subacute evolution suggests an inflammatory, toxic, or nutritional cause (Table 379-5). Chronic neuropathies, especially those that are long-standing over many years, are usually hereditary, such as Charcot-Marie-Tooth (CMT) disease.
6. *What is the likely etiology?* It is helpful to consider potential etiologies by category: metabolic (diabetes mellitus, renal failure, amyloid, porphyria); infectious [HIV, Lyme disease, cytomegalovirus (CMV), syphilis, leprosy, diphtheria]; immune-mediated [GBS, chronic inflammatory demyelinating neuropathy (CIDP), multifocal motor neuropathy, anti-myelin-associated glycoprotein (MAG) neuropathy]; hereditary (CMT); toxic (HIV drugs, anticancer drugs, alcohol, heavy metals, tick bite); vasculitic (polyarteritis nodosa, Churg-Strauss syndrome, cryoglobulinemia, isolated vasculitis of the peripheral nervous system); paraneoplastic (especially lung); nutritional (vitamin B_{12}, B_1, B_6 deficiencies); and miscellaneous causes (celiac disease, Fabry disease, hypothyroidism).
7. *What tests are indicated?* These may include fasting blood glucose and hemoglobin A_{1C} (HbA_{1C}); serum vitamin B_{12}; tests for systemic vasculitis or collagen vascular disease; measurement of neuropathy-associated autoantibodies; urine screen for heavy metals; spinal fluid analysis; autonomic function testing (Chap. 370); and genetic tests for hereditary neuropathies. An impaired glucose tolerance test is found in more than half of patients with idiopathic sensory neuropathy and is more sensitive than tests of fasting glucose or HbA_{1C}. Diagnostic tests to further characterize the neuropathy include quantitative sensory testing, EDx studies, sural nerve biopsy, and muscle biopsy. Diagnostic tests and procedures are more likely to be informative in patients with asymmetric, motor-predominant, rapid-onset or demyelinating neuropathies than in patients with slowly evolving length-dependent sensory > motor types.
8. *What treatment is appropriate?* Treatment of the underlying disorder, pain management, and supportive care to protect and rehabilitate damaged tissue all need to be considered. Examples of therapies directed at the underlying etiology include glycemic control for diabetic neuropathy, vitamin replacement for B_{12} deficiency, immunosuppression for vasculitis, surgery for entrapment neuropathy, enzyme replacement for Fabry disease, liver or bone marrow transplant for amyloid neuropathy, and treatment for immune-mediated neuropathies (Chap. 380).

Pain management usually begins with tricyclic antidepressants (TCAs) such as amitriptyline, imipramine, and desipramine, which can reduce burning, aching, sharp, throbbing, and stinging (Table 379-6; see also Table 12-1). Duloxetine hydrochloride, a dual reuptake inhibitor of serotonin and norepinephrine, is approved for the management of neuropathic pain from diabetes. Tramadol is also effective for painful diabetic neuropathy. Anticonvulsants such as phenytoin, carbamazepine, clonazepam, gabapentin, topiramate, lamotrigine, and pregabalin are effective for lancinating pains. Topical anesthetic agents including lidocaine, mexiletine, and capsaicin creams provide transient relief for focal neuropathic pain. Narcot-

TABLE 379-4 CLASSIFICATION OF NEUROPATHY BY HISTOPATHOLOGY

	Demyelinating	Axonal	Neuronal
Pattern	Proximal = distal	Distal > proximal; length-dependent	Non-length-dependent; UE, LE, face
Onset	Acute/subacute	Slow evolution	Rapid
Symptoms	Paresthesia and weakness	Dysesthesias and distal weakness	Paresthesias, gait ataxia
Sensory signs	Vibration and proprioception > pain and temperature	Pain and temperature affected > vibration and proprioception	Vibration and proprioception > pain and temperature
Motor	Distal and proximal weakness	Distal weakness	Proprioceptive weakness
DTRs	Areflexia	Distal areflexia	Areflexia
NCS	Velocity affected > amplitude	Amplitudes affected > velocity	Sensory amplitudes affected; radial > sural
Nerve biopsy	Demyelination and remyelination	Axonal degeneration and regeneration	Axonal degeneration but no regeneration
Prognosis	Rapid recovery	Slow recovery	Poor recovery
Causes	GBS, diphtheria, CIDP, DM, MMN	Toxic, metabolic, HIV, CMT2, DM	Sjögren's, cisplatin, pyridoxine

Note: UE, LE, upper, lower extremities; DTRs, deep tendon reflexes; NCS, nerve conduction studies; GBS, Guillain-Barré syndrome; CIDP, chronic inflammatory demyelinating neuropathy; DM, diabetes mellitus; MMN, multifocal motor neuropathy; CMT, Charcot-Marie-Tooth.

TABLE 379-5 CLASSIFICATION OF NEUROPATHY BY TIME COURSE

Acute	
	GBS, porphyria, toxic (triorthocresyl phosphate, vacor, thallium), diphtheria, brachial neuritis
Subacute	
	Toxic (hexacarbon, acrylamid), angiopathic, nutritional, alcoholic
Chronic	
	Diabetic, CIDP, paraneoplastic, paraprotein
Longstanding heritable	
	CMT, Friedreich's ataxia
Recurrent	
	Relapsing CIDP, porphyria, Refsum's disease, HNPP

Note: GBS, Guillain-Barré syndrome; CIDP, chronic inflammatory demyelinating neuropathy; CMT, Charcot-Marie-Tooth (disease); HNPP, hereditary neuropathy with pressure palsies.

ics may be required for severe cases of refractory neuropathic pain. **Treatment of pain is discussed in detail in Chap. 12.**

The role of physical therapy, occupational therapy, and assistive devices (such as a foot brace) should not be overlooked. Trophic changes in a denervated/immobile extremity, combined with recurrent, unnoticed, painless trauma, predisposes to skin ulceration, poor healing, tissue resorption, neurogenic arthropathy, and mutilation; amputation may be required. This unfortunate sequence of events is avoidable with proper care of the denervated areas.

ELECTROPHYSIOLOGIC STUDIES (See Chap. e31)

Electrophysiologic studies serve as an extension of the neurologic examination and thus play an important role in the evaluation of peripheral neuropathies (Chap. e31). The following information should be obtained from nerve conduction studies and electromyography (NCS-EMG):

1. Is the process axonal or demyelinating? This determination is one of the main goals of an NCS-EMG study since approaches to management and prognosis hinge largely on this distinction. In general, axonal processes affect sensory fibers more than motor fibers, whereas equal involvement is characteristic of most demyelinating processes.
2. Are the findings focal or generalized and are they symmetric or asymmetric?
3. Is this a length-dependent neuropathy? A distal axonopathy generally gives rise to length-dependent findings. The order of nerves affected, as measured by sensory NCS, for example, is sural, followed by ulnar, median, and radial. By contrast, a neuronopathy (or ganglionopathy) may affect the radial nerve before the sural or ulnar nerve.
4. How severe is the lesion? The complete absence of a response may reflect complete loss of fibers or complete conduction block.
5. What is the approximate age of the lesion? In axonal processes, the compound muscle action potential amplitudes are lost early (7 days) compared with sensory amplitudes (10 days). In demyelinating lesions it is often useful to follow progression of findings with serial studies (Chap. 380).
6. Is this a hereditary or acquired neuropathy? A uniform slowing of NCS suggests a hereditary neuropathy, although exceptions exist, such as x-linked CMT and hereditary neuropathy with liability to pressure palsies (HNPP).
7. Is there a subclinical neuropathy? In patients receiving chemotherapy or other potentially neurotoxic drugs, directed examination and limited NCS may help the physician adjust therapy before a significant neuropathy develops.
8. What is the prognosis? For both demyelinating and axonal neuropathies, the degree of axonal loss serves as a guide to prognosis.

It is important to recognize that EDx studies have limitations, and that not all patients with neuropathic symptoms will have informative findings.

TABLE 379-6 TREATMENT OF PAINFUL NEUROPATHY

First-Line Therapy
Antidepressants
Tricyclic
Amitriptyline, nortriptyline, imipramine, desimipramine, doxepin (10–150 mg qd)
Serotonin-noradrenaline reuptake inhibitors (SNRI)
Duloxetine (60–120 mg qd)
Venlafaxine (150–225 mg qd)
Antiepileptics
Carbamazepine 100–800 mg qd
Oxcarabazepine 1200–2400 mg qd
Lamotrigine 200–400 mg qd
Topiramate 300–400 mg qd
Gabapentin 900–3600 mg qd
Pregabalin 150–600 mg qd
Valproic acid 1000–1200 mg qd
Second-Line Therapy
Opioids
Oxycodone 40–160 mg qd
Morphine 90–360 mg qd PO
Tramadol 50–400 mg qd
Fentanyl patch 25–75 μg/h q 3 days
Antiarrhythmics
Mexilitine 600–1200 mg qd
Topical
Capsaicin 0.075% topical tid or qid
Lidocaine 5% patch bid
Isosorbide dinitrate spray 30 mg qhs
Others
Clonidine 0.1–2.4 mg qd
Memantine 55 mg qd
Dextromethorphan 400 mg
Levodopa 100 mg tid
Alpha-lipoic acid (thioctic acid) 600 mg
Spinal cord stimulator
Transcutaneous electrical nerve stimulation (TENS)
Alternative
Acupuncture
Pain psychologist/counselor

MONONEUROPATHIES (Table 379-7)

Mononeuropathy refers to disease or damage of a single nerve. The most common causes are compression, entrapment, and trauma. Extrinsic compression usually occurs when a limb is maintained in a fixed position that produces sustained pressure on the nerve. The neuropathy is often reversible if the position is changed. However, if the patient is unable to move (e.g., during anesthesia or with intoxication), permanent injury can result. Intrinsic factors such as arthritis, fluid retention (pregnancy), amyloid, tumors, and diabetes mellitus may make nerves at entrapment sites more susceptible to injury. Often both extrinsic and intrinsic factors contribute to neuropathy, e.g., an anatomically narrowed region coupled with repetitive activity, poor posture or position. Common entrapment neuropathies include the median nerve at the wrist (carpal tunnel), ulnar nerve at the cubital tunnel or in the ulnar groove, lower trunk of the brachial plexus at the thoracic outlet, common peroneal nerve at the fibular head, posterior tibial nerve at the tarsal tunnel, and lateral femoral cutaneous nerve at the inguinal ligament. Symptoms and signs of various entrapment neuropathies are listed in Table 379-7. Histologic changes of subacute compression consist of a mixture of segmental demyelination and Wallerian degeneration reflecting retrograde axonal injury.

Since most entrapped nerves contain both motor and sensory fibers, both types of symptoms occur, usually in the distribution of the affected nerve. Sensory symptoms may include numbness, pins and needles, tingling, prickling, burning, or electric shock sensations. Light touch is often more affected than pinprick, and subtle sensory abnormalities may be revealed by measuring two-point discrimination. Aching and nondescript pain can also occur proximal to the site of nerve compression. In mild cases, no motor symptoms are evident,

TABLE 379-7 MONONEUROPATHIES

	Symptoms	Precipitating Activities	Examination	Electro-Diagnosis	Differential Diagnosis	Treatment
Carpal tunnel syndrome	Numbness, pain or paresthesias in fingers	Sleep or repetitive hand activity	Sensory loss in thumb, second, and third fingers Weakness in thenar muscles; inability to make a circle with thumb and index finger Tinel and Phalen signs	Slowing of sensory and motor conduction across carpal tunnel	C6 radiculopathy	Splint Surgery definitive treatment
Ulnar nerve entrapment at the elbow (UNE)	Numbness or paresthesias in ulnar aspect of hand	Elbow flexion during sleep; elbow resting on desk	Sensory loss in the little finger and ulnar half of ring finger Weakness of the interossei and thumb adductor; claw-hand	Focal slowing of nerve conduction velocity at the elbow	Thoracic outlet syndrome C8-T1 radiculopathy	Elbow pads Avoid further injury Surgery when conservative treatment fails
Ulnar nerve entrapment at the wrist	Numbness or weakness in the ulnar distribution in the hand	Unusual hand activities with tools, bicycling	Like UNE but sensory examination spares dorsum of the hand, and selected hand muscles affected	Prolongation of distal motor latency in the hand	UNE	Avoid precipitating activities
Radial neuropathy at the spiral groove	Wrist drop	Sleeping on arm after inebriation with alcohol—"Saturday night palsy"	Wrist drop with sparing of elbow extension (triceps sparing); finger and thumb extensors paralyzed; sensory loss in radial region of wrist	Early—conduction block along the spiral groove Late—denervation in radial muscles; reduced radial SNAP	Posterior cord lesion; deltoid also weak Posterior interosseous nerve (PIN); isolated finger drop C7 radiculopathy	Splint Spontaneous recovery provided no ongoing injury
Thoracic outlet syndrome	Numbness, paresthesias in medial arm, forearm, hand, and fingers	Lifting heavy objects with the hand	Sensory loss resembles ulnar nerve and motor loss resembles median nerve	Absent ulnar sensory response and reduced median motor response	UNE	Surgery if correctable lesion present
Femoral neuropathy	Buckling of knee, numbness or tingling in thigh/medial leg	Abdominal hysterectomy; lithotomy position; hematoma, diabetes	Wasting and weakness of quadriceps; absent knee jerk; sensory loss in medial thigh and lower leg	EMG of quadriceps, iliopsoas, paraspinal muscles, adductor muscles	L2-4 radiculopathy Lumbar plexopathy	Physiotherapy to strengthen quadriceps and mobilize hip joint Surgery if needed
Obturator neuropathy	Weakness of the leg, thigh numbness	Stretch during hip surgery; pelvic fracture; childbirth	Weakness of hip adductors; sensory loss in upper medial thigh	EMG—denervation limited to hip adductors sparing the quadriceps	L3-4 radiculopathy Lumbar plexopathy	Conservative management Surgery if needed
Meralgia paresthetica	Pain or numbness in the anterior lateral thigh	Standing or walking Recent weight gain	Sensory loss in the pocket of the pant distribution	Sometimes slowing of sensory response can be demonstrated across the inguinal ligament	L2 radiculopathy	Usually resolves spontaneously
Peroneal nerve entrapment at the fibular head	Footdrop	Usually an acute compressive episode identifiable; weight loss	Weak dorsiflexion, eversion of the foot Sensory loss in the anterolateral leg and dorsum of the foot	Focal slowing of nerve conduction across fibular head Denervation in tibialis anterior and peroneus longus muscles	L5 radiculopathy	Foot brace; remove external source of compression
Sciatic neuropathy	Flail foot and numbness in foot	Injection injury; fracture/dislocation of hip; prolonged pressure on hip (comatose patient)	Weakness of hamstring, plantar and dorsiflexion of foot; sensory loss in tibial and peroneal nerve distribution	NCS—abnormal sural, peroneal, and tibial amplitudes EMG—denervation in sciatic nerve distribution sparing glutei and paraspinal	L5-S1 radiculopathies Common peroneal neuropathy (partial sciatic nerve injury) LS plexopathies	Conservative follow up for partial sciatic nerve injuries Brace and physiotherapy Surgical exploration if needed
Tarsal tunnel syndrome	Pain and paresthesias in the sole of the foot but not in the heel	At the end of the day after standing or walking; nocturnal	Sensory loss in the sole of the foot Tinel's sign at tarsal tunnel	Reduced amplitude in sensory or motor components of medial and planter nerves	Polyneuropathy, foot deformity, poor circulation	Surgery if no external cause identified

but in more affected patients, weakness, wasting, or fasciculations may occur. Knowledge of the anatomy of individual nerves is important to be able to localize the site of the lesion to the root, plexus, or nerves or their branches. Sensory testing may occasionally provoke paresthesias. Reflexes are generally unaffected since most entrapped nerves are distal to the deep tendon reflexes typically examined. Percussion of the nerve at the affected site may induce paresthesias (Tinel's sign); however, this may also occur in normal individuals and is not a reliable sign. Placing the limb in a posture known to aggravate the compression may accentuate symptoms (e.g., Phalen's sign evoked by flexing the wrist for carpal tunnel syndrome).

EDx studies confirm the clinical diagnosis and provide information about location, severity, and prognosis. Focal demyelination is detected as a focally reduced nerve conduction velocity along the length of

the sensory and/or motor fibers. Wallerian degeneration is reflected in a reduction of distal amplitudes and as denervation potentials. The latter is associated with a relatively poor prognosis for recovery. Bone or joint abnormalities and soft tissue masses can be revealed by appropriate imaging techniques. MR neurography and ultrasonography are useful in identifying thickening of nerves at sites of compression; these studies are useful for proximal entrapments (brachial plexus, lumbosacral plexus, or sciatic or gluteal nerve lesions).

Rx MONONEUROPATHIES

Treatment for acute and subacute compressive neuropathies consists of identifying and removing extrinsic contributors and the use of splints to avoid further compression. In patients with chronic compressive neuropathies, exacerbating factors should be identified and treated before surgical correction is considered. The use of splints, a change of work habits to avoid activities or movements that precipitate the neuropathy, or anti-inflammatory medication for tenosynovitis may be helpful (see below).

Surgical treatment may be required for management of chronic compressive neuropathies when conservative measures have failed and the site of entrapment is clearly delineated.

MONONEUROPATHY MULTIPLEX

Mononeuropathy multiplex refers to the multifocal involvement of individual peripheral nerves. Although multiple compressive neuropathies can present in this manner, more often an inflammatory cause is responsible, and in such cases the disorder is referred to as *mononeuritis multiplex*. Both systemic (67%) and nonsystemic (33%) vasculitis may present as mononeuritis multiplex; less commonly, vasculitic neuropathy can present as an asymmetric or distal symmetric neuropathy. Among the systemic vasculitides, polyarteritis nodosa, rheumatoid arthritis, systemic lupus erythematosus (SLE), Churg-Strauss syndrome, Wegener's granulomatosis, and hypersensitivity vasculitis should be considered; these are often associated with constitutional symptoms such as fever and weight loss (Chap. 319). The common fibular nerve (previously called the common peroneal nerve) is affected in ~75% of patients with vasculitic neuropathy; symptoms consist of a painful foot drop. The ulnar, median, and radial nerves may also be involved.

Rx MONONEURITIS MULTIPLEX

Therapy of the necrotizing systemic vasculitides can stabilize and in some cases improve the neuropathy. Glucocorticoids [prednisone (1.5 mg/kg per day)] plus a cytotoxic agent (usually oral cyclophosphamide at 2 mg/kg per day) is the treatment of choice (Chap. 319). Aggressive therapy is warranted since the prognosis for survival of untreated patients is poor. Prednisone can be changed to an alternate-day regimen after 1 month to minimize side effects. Once a clinical response is documented, prednisone may be tapered by 5 mg every 2–4 weeks. The cytotoxic agent is usually continued for 1 year. Therapy of hypersensitivity vasculitis is focused primarily upon removal of the offending antigen trigger. Treatment of localized vasculitis restricted to the peripheral nervous system can be less aggressive than for systemic vasculitis because the risk of death from untreated disease is very low. Monotherapy with either oral glucocorticoids or a brief course of cyclophosphamide (3–6 months) may be sufficient. A tissue diagnosis of vasculitis should be obtained before initiating therapy; a positive nerve biopsy helps to justify long-term immunosuppressive treatment, and pathologic confirmation of the diagnosis is often difficult after treatment has commenced.

POLYNEUROPATHIES

DIABETIC NEUROPATHY

Diabetes mellitus is associated with various neuropathy syndromes that differ in their etiology, natural history, and treatment. The overall prevalence of neuropathy is 66% for type 1 and 59% for type 2 diabetes. Neuropathy can be broadly divided into symmetric and asymmetric types, although a great deal of overlap exists between these categories. Symmetric neuropathies may present as small-fiber involvement (e.g., dysesthesias in the feet) or autonomic dysfunction (e.g., sexual impotence), but often both occur together; examination usually reveals additional evidence of large-fiber involvement and of an underlying generalized neuropathy.

The asymmetric neuropathies are divided into those with acute onset and those with gradual onset. Asymmetric abrupt-onset neuropathies include diabetic truncal radiculoneuropathy (DTRN), diabetic lumbosacral radiculoplexus neuropathy (DLSRPN), and oculomotor (third or sixth nerve) neuropathy. These monophasic conditions are thought to be due to vascular causes such as infarction. Neuropathies of more gradual onset are usually caused by entrapment or compression and include median neuropathy at the wrist, ulnar neuropathy at the elbow, peroneal neuropathy at the fibular head, and lateral cutaneous neuropathy at the thigh at the inguinal ligament (meralgia paresthetica).

Symmetric Diabetic Neuropathy By far the most common form of diabetic neuropathy is a length-dependent diabetic sensorimotor polyneuropathy (DSPN). The lifetime prevalence is ~55% for type 1 and 45% for type 2 diabetes. DSPN is a mixed neuropathy with small- and large-fiber sensory, autonomic, and motor nerve involvement in various combinations, although sensory and autonomic symptoms are more prominent than motor ones (Table 379-1). Proposed criteria for the diagnosis of DSPN are two or more of the following: symptoms or signs of neuropathy, abnormal EDx studies, quantitative sensation test abnormalities, heart rate decrease with deep breathing or Valsalva maneuver.

DSPN has an insidious, progressive course. Initial symptoms may consist of numbness, tingling, buzzing, burning, or prickling sensation affecting the toes and feet. Paresthesias ascend up to the legs and then hands in a stocking-glove distribution. Over time, gait disturbance and distal weakness may occur. Painful or insensitive extremities predispose to foot ulcers; amputation is sometimes required. Examination shows a distal sensory loss to pin, temperature, touch, and vibration sense. Ankle reflexes are invariably reduced or absent. Weakness, if present, is mild and involves toe flexors and extensors. The length-dependent pattern of neuropathy is evident in the stocking-glove sensory loss, and some patients also show sensory loss in the anterior abdominal region in a wedge-shaped distribution. Autonomic symptoms including impotence, nocturnal diarrhea, difficulty voiding, abnormalities of sweating, and abnormal fullness after eating and orthostatic hypotension may be present.

The diagnosis of DSPN is usually straightforward, although other contributors to the neuropathy should be excluded, including nutritional (vitamins B_1 and B_{12} and folate deficiencies), toxic (alcohol, vitamin B_6 toxicity), immune-mediated (paraprotein), and inherited causes. An alternative diagnosis should be sought in patients with rapidly progressive or asymmetric weakness, a family history of neuropathy, exposure to toxins, or prior malignancy. A glucose tolerance test is indicated in all patients presenting with neuropathy. EDx studies show mixed findings of axonal loss and demyelination in a length-dependent pattern. Nerve biopsy and lumbar puncture are not necessary unless alternative diagnoses are being considered.

Various hypotheses have been invoked to account for DSPN. Increased neuronal concentrations of glucose induce the conversion of glucose to sorbitol by aldose reductase using NADPH as a coenzyme. Sorbitol decreases levels of *myo*-inositol and phosphoinositides, leading to a decrease in diacylglycerol, protein kinase C, and Na^+, K^+, ATPase activity. This sequence of events leads to axonal loss and demyelination and is the basis of trials using aldose reductase inhibitors and high *myo*-inositol diets. A second hypothesis proposes insufficient blood flow: increased aldose reductase activity results in competitive inhibition of nitric oxide synthetase for NADPH, resulting in decreased nitric oxide and reduced blood flow in the vasa nervorum. Altered metabolism of fatty acids, reduced concentrations of nerve growth factor, and oxidative stress are possible additional contributing factors.

Rx DIABETIC SENSORIMOTOR POLYNEUROPATHY

Treatment consists of strict glucose control, which prevents the neuropathy from worsening; established neuropathy does not usually reverse. Aldose reductase inhibitors to treat and prevent diabetic neuropathy have

been studied in >30 trials. Although controlled trials of the aldose reductase inhibitors sorbinol and tolrestat were found to improve electrophysiologic or morphometric markers of DSPN, any clinically meaningful improvement in pain or sensation has been inconsistent. Treatment with recombinant nerve growth factor was ineffective. Alpha lipoic acid (thioctic acid), an antioxidant, has been shown to improve experimental diabetic neuropathy, and a meta-analysis of clinical trials suggested that the treatment (600 mg/d IV for 3 weeks) is safe and improves symptoms and signs of neuropathy. Pancreatic transplantation can halt progression of DSPN but is a realistic therapy only for patients who have renal failure and are undergoing combined kidney and pancreas transplantation.

Glycemic control is essential for the prevention of diabetic autonomic neuropathy. Once neuropathy is established, few effective treatments exist.

Asymmetric Diabetic Neuropathy • ***CRANIAL NEUROPATHIES*** The oculomotor nerves (in decreasing order of frequency the sixth, third, and rarely fourth nerves) are most often affected. In general, cranial neuropathy occurs in patients over the age of 50 who already have evidence of DSPN. Abducens (sixth) nerve palsy manifests as the sudden onset of painless double vision, and examination shows paralysis of abduction on the affected side (Chap. 29). In a patient with diabetes who has no other clinical findings the diagnosis is straightforward. Spontaneous recovery typically occurs within 3–5 months and no treatment except an eye patch or prism is necessary. Diabetic third nerve palsy is also abrupt in onset but is often heralded by intense retroorbital pain that may be present for several days. Symptoms include double vision, unilateral ptosis, and restriction of medial gaze and upgaze. Unlike compressive etiologies (e.g., aneurysms of the superior cerebellar or posterior communicating arteries), which present with an enlarged ("blown") pupil, the pupil is nearly always spared in diabetic third nerve palsy. This is due to the fact that pupillomotor fibers are present on the outer layers of the third nerve fascicle, and an ischemic lesion tends to involve the center of the fascicle. In atypical cases, such as those with pupillary involvement or without pain, a neuroimaging study, usually MRI or MR angiography (MRA), is indicated to exclude an aneurysm. Most patients improve spontaneously in 3–6 months without any treatment. Symptomatic treatment with eye prisms is often helpful. Idiopathic neuropathy of the facial nerve (seventh; Bell's palsy) is also more common in older diabetics than in nondiabetics. The clinical features and prognosis are similar to the nondiabetic form (Chap. 371).

LIMB MONONEUROPATHIES Diabetics are also susceptible to entrapment neuropathies, including median neuropathy at the wrist (carpal tunnel syndrome), ulnar neuropathy at the elbow, fibular (peroneal) neuropathy at the fibular head, and lateral cutaneous neuropathy at the inguinal ligament (meralgia paresthetica). The special susceptibility of diabetic nerves may be related to endoneurial edema and vascular factors. Patients typically present with several weeks or months of pain, numbness, or weakness in the distribution of the affected nerve. The approach to these entrapments is similar to that in individuals without diabetes. Decompressive surgery may be needed if there is associated weakness, numbness, or pain in the distribution of the affected nerves and if no reversible extrinsic source of compression (position/habits) can be identified.

RADICULOPATHIES AND PLEXOPATHIES *Diabetic truncal radiculoneuropathy* occurs in diabetics in middle or later life, usually in association with underlying DSPN. Patients present with an abrupt onset, typically over days to weeks, of severe pain in the thoracic spine, flank, rib cage, or upper abdomen. The pain is described as burning, stabbing, or beltlike. Contact hyperesthesia is present in the area of pain. Associated, sometimes profound, weight loss is often described; this can also be seen in diabetic amyotrophy (see below). Examination may be normal or may reveal variable sensory loss in the distribution of one or several intercostal nerves and their branches. Anterior abdominal wall weakness may be noted as focal bulging of the weakened region when the patient attempts to sit up. A needle EMG of the affected muscles may confirm denervation in the abdominal or intercostal muscles; the paraspinal muscles may be spared. This finding, and a reduced fiber density measured by skin biopsy from symptomatic regions, suggests that the injury in diabetic truncal radiculoneuropathy is at, or distal to, the sensory ganglion. The differential diagnosis in this elderly population should include herpes zoster infection (without rash) and an abdominal malignancy. Most patients improve spontaneously, although the pain may persist for weeks to months. Pain management may be difficult and includes topical capsaicin and narcotics. The abrupt onset and spontaneous recovery suggest a vascular cause to this syndrome, although an inflammatory etiology can not be excluded.

Diabetic amyotrophy (femoral neuropathy; proximal diabetic neuropathy) occurs in older patients, usually with type 2 diabetes. Patients present with the abrupt onset of severe pain affecting the anterior thigh. Buttock and lower back pain may also be present. The pain is worse at night and is described as burning. Weakness and wasting in the thigh muscles leads to difficulty climbing stairs and walking. Males are more likely to be affected, and weight loss, at times dramatic, is invariably present. Although symptoms may be bilateral, one side is more severely affected than the other. Examination shows prominent wasting of the quadriceps muscle unilaterally with weakness of the knee extensor and hip flexor and, variably, ankle dorsiflexor, accompanied by sensory loss in the thigh and leg in the distribution of the femoral nerve, and a reduced knee jerk on the affected side. The syndrome progresses over weeks to months, then stabilizes and gradually improves. EDx studies show findings of radiculopathy (L2-4), lumbar plexopathy, or femoral neuropathy along with a distal sensorimotor neuropathy. An MRI of the lumbosacral spine and plexus is indicated to exclude a compressive cause. Cerebrospinal fluid (CSF) examination and nerve biopsy should be considered whenever the diagnosis is uncertain. The level of CSF protein is often elevated, and biopsy of the intermediate femoral cutaneous nerve may show microvasculitis. The condition may be quite painful and require opiates for pain control. Treatment with high-dose glucocorticoids or intravenous immunoglobulin (IVIg) has been effective in case reports, although controlled trials have not shown clear benefit. Physiotherapy and orthotic devices are helpful. The prognosis is generally favorable; improvement occurs over several months in most patients treated with symptomatic measures only. A similar condition may also occur in nondiabetic patients.

Uncommon Diabetic Neuropathies *Diabetic neuropathic cachexia* (acute painful neuropathy of diabetes) is an uncommon painful sensory neuropathy occurring in type 1 diabetics in the setting of poor glucose control and weight loss. Manifestations include severe pain in the feet ascending up to the legs and trunk with associated allodynia. Examination may reveal distal sensory loss to pinprick and vibration and reduced or absent ankle jerks. Strength is preserved. EDx studies may show a distal neuropathy. Unlike DSPN, the prognosis is favorable with glucose control. The painful symptoms reverse over months to a year.

Insulin neuritis describes a painful neuropathy seen with initiation of insulin treatment for diabetes. The clinical presentation is similar to the acute painful neuropathy of diabetes, and most patients improve.

A reversible sensory and motor polyneuropathy has been reported in association with diabetic ketoacidosis. Most patients also have upper and lower motor neuron signs, as well as a preexisting neuropathy. The etiology is not clear; critical illness neuropathy may be the underlying cause. Finally, chronic inflammatory demyelinating neuropathy (CIDP) occurs in diabetics; the disease resembles that seen in nondiabetics.

TOXIC INCLUDING CHEMOTHERAPY-INDUCED NEUROPATHIES

Most toxic neuropathies are distal axonal degenerations that develop gradually over time. The causes are varied, including drugs, heavy metals, and industrial and environmental substances (Table 379-8). Novel anticancer drugs and antiretroviral agents are the most common drugs implicated, although over-the-counter medications (especially pyridoxine) can also cause neuropathy. A temporal relationship between introduction of the toxic substance and the onset of neuropathy is usually noted, as is a dose-response relationship. In general, a

TABLE 379-8 TOXIC NEUROPATHIES

	Circumstances of Toxicity	Neuropathy	Comments
Axonopathy			
Nonpharmaceutical toxins			
Acrylamide monomer	Flocculators, grouting agents	Sensory ataxia; large fiber	Numbness, excessive sweating, exfoliative dermatitis
Allyl chloride	Epoxy resin, glycerin	Dysesthesia and distal weakness	
Arsenic (inorganic)	Copper/lead smelting, contaminant in recreational drugs, suicide/homicide (herbicide/insecticide)	S > M; painful; usually subacute or chronic; may be acute following large doses	Skin: hyperkeratosis, "rain-drop" pigmentation of skin, Mees' line in nails
Carbon disulphide	Viscose rayon, cellophane; airborne industrial exposure	SM	Slow NCS
Dimethylaminopropionitrile (DMAPN)	Polyurethane foam	SM	Small-fiber neuropathy with prominent bladder symptoms and impotence
Ethylene oxide	Sterilization of biomedicals		
Hexacarbons (paranodal giant axonal)	Solvents, adhesives Substance abuse (glues and thinners)	SM	Neurofilament swelling of axons; CNS
Lead	Batteries, smelting metal ores, paints	M > S; wrist drop	Burton's line, anemia, basophilic stippling
Mercury (inorganic)	Environmental/workplace	CNS > PNS; neuropathy uncommon	Tremor, insomnia, behavioral change
Methyl bromide	Fumigant, insecticide, refrigerant, fire extinguisher	Variable recovery	Encephalitis, ataxia
Organophosphorus esters	Insecticide, petroleum, plastics	SM	Acute toxicity presents as cholinergic crisis
Thallium (rat poison)	Rodenticides, insecticides	Painful SM	Thallium (alopecia, Mees' line, hyperkeratosis)
Vacor	Rodenticide, suicide	Rapid onset of severe axonopathy and autonomic dysfunction	Diabetic ketoacidosis a feature of acute toxicity
Pharmaceutical agents			
Chloramphenicol	Mean cumulative dose 255 g, duration	S > M	Also optic neuropathy
Colchicine	Chronic dosing at 1.2 mg/d especially in the presence of renal dysfunction	Distal paresthesias and proximal weakness	Also myopathy with elevated serum CK
Dapsone	200–400 mg/d over many months	Pure motor, especially upper limbs	May look like motor neuron disease
Disulfiram	250–500 mg/d after several months used for alcoholism	SM	Difficult to distinguish from alcohol neuropathy
Ethambutol	>20 mg/kg per day over many months	Sensory neuropathy	Also optic neuropathy
Ethionamide	>15 mg/kg	Sensory neuropathy	Limited by GI, dermatologic and CNS side effects
Gold	Controversial, as rheumatoid arthritis can cause neuropathy Not dose dependent	S > M with myokymia	Rash, pruritus
Isoniazid	>5 mg/kg over weeks or about 6 months, depending on acetylator status	Dose-dependent SM neuropathy	Add pyridoxine 50 mg/d when using INH
Metronidazole	Cumulative dose > 30 g	Sensory (small and large fiber)	
Misonidazole	Cumulative dose > 18 g/m^2	Sensory axonopathy	Dose-limiting side effect
Nitrofurantoin	Standard dose of 200 mg/day over a few weeks	Mild SM neuropathy	
Nitrous oxide	Dental surgery, anesthesia, substance abuse	S >> M	Toxic myeloneuropathy resembles cobalamine deficiency
Nucleoside analogues (ddC, ddI, 4dT)	>12.5 mg/kg per day for ddI, 0.02 mg/kg per day for ddC, and 0.5 mg/kg per day for 4dT	Painful sensory neuropathy	Difficult to distinguish from HIV neuropathy
Pyridoxine	>200 mg a day over several months	Length-dependent axonopathy	Neuronopathy at higher doses
Suramin	Peak serum concentration of 350 μg/mL	S > M; may be demyelinating	
Taxol	Cumulative dose of >1500 mg/m^2	S > M	Higher single doses may cause neuronopathy
Thalidomide	100 mg/d for 6 months.	S > M	Thalidomide (brittle nails, palmar erythema)
Vincristine and other vinca alkaloids	Almost all patients	S > M but autonomic fibers also affected	Vacuolar myopathy
Myelinopathy			
Amiodarone	400 mg/day for 6–36 months, serum concentration of 2.4 mg/L	SM; dose-dependent	Tremor
Perhexiline	Not dose-related	S (large fiber) and M, facial, autonomic	Hepatic toxicity
Polychlorinated biphenyls	Plasticizers, electrical insulators	SM	Acne, brown nails
Suramin	Not dose-related	?Demyelinating like subacute GBS	
Trichloroethylene	Dry-cleaning, rubber, degreasing agent	Mainly cranial nerves: trigeminal, facial, oculomotor, optic	Limbs rarely affected
Sensory Neuronopathy			
Platinum compounds, e.g., cisplatin	Cumulative dose more than 900 mg/m^2	Large-fiber sensory	Irreversible
High-dose pyridoxine	Massive parenteral doses in grams over days	Sensory neuronopathy; gait ataxia, pseudoathetosis	May be irreversible
Taxol	Single dose of ≥250 mg/m^2	Sensory ataxia	May be irreversible

Note: S, sensory; M, motor; SM, sensorimotor; NCS, nerve conduction studies; CNS/PNS, central/peripheral nervous system; CK, creatine kinase; GI, gastrointestinal; GBS, Guillain-Barré syndrome; EDx, electrodiagnosis; CSF, cerebrospinal fluid; CMV, cytomegalovirus; DSPN, diabetic sensory polyneuropathy.

lower dose over a longer period of time is less toxic than a higher dose for a short period, even if the eventual cumulative doses are similar. Onset following introduction of the agent and reversal or at least arrest following its removal provide the best evidence of a toxic neuropathy, along with the symptoms and signs typically caused by the suspected agent. The neuropathy may first manifest or may continue to progress after discontinuing the substance; this phenomenon, known as *coasting*, is seen with the platinum cancer drugs, hexacarbons, nucleoside analogue reverse transcriptase inhibitors, and pyridoxine.

Clinical evaluation includes a history focusing on the temporal relationship between exposure and onset of sensory or motor symptoms, comorbid diseases that may cause neuropathy, and symptoms of systemic toxicity. Nerve biopsy occasionally demonstrates pathognomonic features such as osmiophillic Schwann cell inclusions in amiodarone, perhexiline and chloroquine neuropathies, and paranodal giant axonal swellings in hexacarbon neuropathies. Levels of some toxins can be measured in certain tissues: heavy metals such as lead, arsenic, and thallium can be measured in urine; arsenic can be measured in hair or nails. Blood levels of drugs are also useful.

Table 379-8 lists some of the better-documented neurotoxic substances. Awareness of the types of industries in which toxic exposure can occur is important in identifying occupational exposure. Lower dosages and shorter durations of exposure may produce neuropathy in susceptible individuals such as those with underlying inherited neuropathy. An acute onset of neuropathy occurs with drugs such as paclitaxel, suramin, and vacor, and with biologic agents such as ciguatera, puffer fish (tetrodotoxin), and buckthorn. Some toxic agents that otherwise require long-term exposure to produce chronic neuropathy may do so acutely when used at higher doses; examples include arsenic, thallium, and pyridoxine. The combination of two toxic drugs, commonly seen with anticancer therapy (e.g., paclitaxel and cisplatin), may produce greater nerve toxicity than either one alone. Patients with underlying conditions may be predisposed to neuropathy when exposed to some compounds, e.g., vitamin B_{12}–deficient patients who receive nitrous oxide anesthesia, or patients with porphyria who receive barbiturates. Usually, however, toxic neuropathy is subacute in onset, developing over a period of months. Vincristine, amiodarone, nitrofurantoin, isoniazid, dimethylaminopropionitrile (DMAPN), inorganic mercury, and thallium all cause a subacute neuropathy. The insidious onset of a chronic neuropathy occurs with exposure to industrial toxins at low dosages over a prolonged period of time. Examples include acrylamide, allyl chloride, hexacarbons, carbon disulfide, ethylene oxide, lead, and arsenic. In addition to preexisting neuropathy, other host factors, including diabetes, hepatic or renal impairment, and alcohol abuse, may reduce the threshold for neurotoxicity. The neuropathy may be predominantly motor with lead, inorganic mercury, organophosphates, buckthorn, dapsone, and vincristine; small-fiber sensory with DMAPN, thallium, nucleoside analogue reverse transcriptase inhibitors (dideoxycytidine ddC, dideoxyinosine ddI, stavudine d4T), ethionamide, metronidazole, and taxane; or large-fiber sensory with cisplatin, high doses of taxol, pyridoxine, or acrylamide. Autonomic dysfunction can occur with vincristine, vacor, perhexiline, high dose-pyridoxine, and platinum. Other toxins that may involve autonomic nerves include acrylamide (acral and pedal hyperhidrosis), DMAPN (urologic and sexual dysfunction), and hexacarbons (hyperhidrosis and impotence). Some toxic neuropathies also involve the cranial nerves. These include trichloroethylene, which causes acute dysfunction of the cranial nerves V, VII, III, and II; thallium and acute fulminant vacor poisonings, which cause facial diplegia with generalized neuropathy resembling Guillain-Barré syndrome; perhexiline, which causes facial diplegia and perioral numbness; vincristine and paclitaxel, which may be associated with numbness in the trigeminal nerve distribution; and chloramphenicol, ethambutol, and nitrous oxide, all of which may cause optic neuropathy. Asymmetric neuropathy or mononeuritis multiplex is rare but may be seen with lead, which may cause unilateral wrist drop; or with DMAPN, which causes sacral dermatomal sensory loss. Signs of toxicity to kidney, liver, or other organs can in some cases alert the clinician to the possibility that a neuropathy could be toxic in origin.

Cisplatin Cisplatin (*cis*-diaminodichloroplatinum) is a heavy metal used to treat a variety of solid tumors. Cisplatin is toxic to dorsal root ganglia neurons, producing a dose-related large-fiber sensory neuropathy (*neuronopathy*). It also injures hair cells of the cochlea, causing hearing loss. Peripheral neuropathy is the dose-limiting toxicity of cisplatin. A cumulative cisplatin dose of at least 300 mg/m^2 may lead to paresthesias in the extremities and numbness. Lhermitte's sign, an electric shock–like sensation evoked by flexion of the neck, may occur due to retrograde degeneration of axons in the posterior columns of the spinal cord. Patients with preexisting neuropathy and those who receive combination chemotherapy may develop symptoms after lower cumulative doses. Sensory ataxia may be disabling in patients who have severe neuropathy. Small-fiber sensation (e.g., pain and temperature) and strength are generally spared.

Oxaliplatin Oxaliplatin can cause an early acute and a late chronic neuropathy. The acute neuropathy begins during the infusion, within minutes to hours, or within 1–2 days of administration. Patients complain of paresthesias in the hands or feet, mouth, or throat along with myalgias, cramps, or stiffness. Shortness of breath or difficulty swallowing may occur. Symptoms are often triggered by exposure to cold. Neuromyotonia may be seen on EMG. Although this acute toxicity occurs in >90% of patients, it is often self-limited and resolves within days. A channelopathy is thought to be the underlying mechanism. A chronic large-fiber ataxic neuropathy, similar to that caused by cisplatin, occurs with cumulative doses ≥ 780 mg/m^2, generally after eight or nine treatment cycles. Even though the signs and symptoms (paresthesias, distal sensory loss, and loss of reflexes) are similar to those caused by cisplatin, oxaliplatin neuropathy is more likely to be reversible.

Paclitaxel Paclitaxel, a diterpene alkaloid drug, is widely used as a chemotherapeutic agent. Peripheral neuropathy, which can be severe, is the dose-limiting toxicity. A symmetric, length-dependent neuropathy with prominent sensory (large more than small fiber) and minor motor manifestations, is typically present. Preexisting neuropathy is a risk factor. The neuropathy is dose-dependent, and both single and cumulative doses are important. The drug affects microtubule assembly, causing disruption of axonal transport and a "dying back" axonal neuropathy.

Vincristine Vincristine, an alkaloid derived from the perinwinkle plant, vinca rosea, causes a dose-dependent sensorimotor neuropathy. Lower cumulative doses (4–19 mg) cause only reflex changes, while higher doses progressively cause paresthesias, sensory loss (upper extremity more than lower), weakness with footdrop, and hand weakness and clumsiness. Autonomic neuropathy can manifest as cardiac arrhythmias, orthostasis, urinary bladder dysfunction, constipation, or paralytic ileus. Cranial neuropathies have also been described.

Suramin Suramin is a polysulfonated naphthylurea that has been used as an antineoplastic agent and as a treatment for certain parasitic diseases. Suramin causes a length-dependent distal axonal neuropathy in over half of patients and a subacute inflammatory demyelinating neuropathy in ~15% of patients. Neuropathy occurs with peak plasma concentrations > 300 μg/mL.

Thalidomide Peripheral neuropathy remains the dose-limiting toxicity of thalidomide, which causes a length-dependent painful sensory axonal neuropathy; a sensory neuronopathy has also been reported. Peripheral neuropathy occurs in up to 75% of patients and is dose-dependent, rarely occurring with cumulative doses < 20 g, but invariably noted at cumulative doses > 100 g. The risk of neuropathy is minimized at doses ≤ 150 mg/d. Serial sensory action potential measurements are important in the early detection of the neuropathy. Symptoms often, though not always, improve with cessation or dose reduction. The neuropathy develops at a lower dose and is typically more severe in patients with a preexisting diabetic neuropathy.

Bortezomib Bortezomib (Velcade), a novel proteosome inhibitor used in the treatment of multiple myeloma, induces a length-dependent,

sensory more than motor, axonal polyneuropathy that is dose-dependent, increasing with increasing cycles of treatment. Both small- and large-fiber sensory symptoms occur. In a few patients the symptoms stabilize or improve after stopping treatment. A toxic acquired demyelinating neuropathy has also been reported.

℞ TOXIC NEUROPATHIES

Removal of the toxic substance is the most important step. Specific treatments are available for some toxic neuropathies. Treatment for heavy metal toxicity includes chelation therapy: penicillamine or calcium-EDTA for lead toxicity; penicillamine or British anti-Lewisite (BAL) for arsenic toxicity; and potassium chloride or Prussian blue for thallium toxicity. Pyridoxine (10–50 mg/d) can be used to prevent and treat isoniazid neurotoxicity. Niacin and pyridoxine are recommended for ethionamide neurotoxicity. There may be some benefit from the use of neuroprotective agents. Vitamin E (tocopherol) was reported to be neuroprotective in one small, unblinded study, but these results have not been confirmed. Org 2766, glutathione, diethyldithiocarbamate, and amifostine have also been tried without conclusive outcomes. Studies are under way to evaluate the possible efficacy of nerve growth factor.

Prognosis for recovery depends on both the site of pathology and the severity of the neuropathy. Involvement of the dorsal root ganglion is associated with a poor prognosis. Severe axonopathy requires years for recovery. Demyelinating disorders, if detected early, generally are associated with a relatively rapid recovery. Most toxic neuropathies, even if advanced, will at least stabilize, and some will improve, when exposure to the toxic agent is stopped.

NUTRITIONAL NEUROPATHIES

(See also Chap. 71)

Thiamine (Vitamin B_1) (Dry Beriberi) Thiamine deficiency can be a result of inadequate intake, as may occur in alcoholism, anorexia, intentional dieting, starvation, or bulimia. Protracted vomiting, e.g., in patients receiving chemotherapy or in pregnant women with hyperemesis gravidarum, may also cause thiamine deficiency. Neuropathy from thiamine deficiency presents as the acute or subacute onset of paresthesias, dysesthesias, and mild weakness in the legs. On examination a stocking-glove sensory loss, distal weakness in the legs, and loss of ankle jerks is typical. Nerve conduction tests and sural nerve biopsies show axonal degeneration. Erythrocyte transketolase activity is reduced in the blood. Treatment consists of oral thiamine replacement, 100 mg/d. Alcohol-induced neuropathy develops in some patients without any identifiable nutritional deficiencies, suggesting that alcohol itself may cause sensory neuropathy. It predominantly affects small fibers and is painful, but there is considerable overlap with thiamine deficiency neuropathy.

Pyridoxine (Vitamin B_6) A subacute length-dependent axonal neuropathy occurs as a result of pyridoxine deficiency. Causes include dietary deficiency and drugs such as isoniazid, cycloserine, and penicillamine, which act as pyridoxine antagonists by combining to the aldehyde moiety of the vitamin. Dietary deficiency of pyridoxine is uncommon, although the requirement is increased in pregnancy. Measurement of xanthurenic acid after tryptophan loading can help confirm the diagnosis. Treatment consists of oral pyridoxine, 30 mg/d. Pyridoxine supplements are recommended for prophylaxis during pregnancy and for patients taking isoniazid. Overzealous treatment with pyridoxine should be avoided, as high doses of pyridoxine cause a toxic sensory neuronopathy.

Vitamin B_{12} (Cobalamin) Peripheral neuropathy is a minor part of the vitamin B_{12} deficiency syndrome; subacute combined degeneration of the spinal cord is more prominent. Distal sensory loss predominantly involving large-fiber modalities, dysequilibrium, Lhermitte's sign, and the combination of an absent ankle jerk and upgoing toe may be present. Pancytopenia, megaloblastic anemia, and glossitis are other signs. The principal dietary sources of vitamin B_{12} are meat and dairy products; enteric processing and absorption typically occur in the terminal ileum. Common causes of vitamin B_{12} deficiency include inadequate intake, malabsorption (including post-gastrectomy), and pernicious anemia. Borderline vitamin B_{12} deficiency may develop after exposure to nitrous oxide during anesthesia or with chronic recreational use. Diagnosis of vitamin B_{12} deficiency is made by low serum cobalamin levels and raised levels of methylmalonic acid and homocysteine. Autoantibodies to intrinsic factor and gastric parietal cells are present in pernicious anemia. Treatment is with parenteral administration of cobalamin (vitamin B_{12}) (see Chap. 100).

Riboflavin, Nicotinic Acid and Other B-Group Vitamins Riboflavin and nicotinic acid deficiencies have been incriminated in neuropathies, usually in association with deficiencies of other water-soluble vitamins. Peripheral neuropathy may be accompanied by dermatitis, diarrhea, and dementia (pellagra). The diagnosis is made on clinical grounds, and treatment consists of administration of 40–250 mg niacin daily. *Strachan's syndrome* is characterized by a painful sensory neuropathy associated with orogenital dermatitis, amblyopia, and deafness. This syndrome was first reported in Jamaica and later in malnourished field workers and prisoners of war. Distal sensory loss with hyporeflexia at the ankles (peripheral nerve lesion), combined with hyperreflexia at the knees and an ataxic gait (spinal cord involvement), indicate the combined peripheral and central axonal loss that is characteristic of this deficiency state. Treatment with vitamin B complex frequently improves the symptoms.

Vitamin E Deficiency Vitamin E deficiency can occur from fat malabsorption or from abetalipoproteinemia. The clinical features of vitamin E deficiency resemble those of Friedreich's ataxia (Chap. 368), with severe large-fiber loss and a non-length-dependent reduction of sensory nerve action potentials suggestive of dorsal root ganglionopathy. The diagnosis is confirmed by measurement of serum α tocopherol and the ratio of vitamin E to total serum lipids. Treatment consists of administration of α tocopherol (400 mg bid), which may reverse or prevent progression of the sensory neuronopathy.

INFECTIONS AND PERIPHERAL NEUROPATHY

HIV Infection (See also Chap. 182) HIV infection is associated with polyradiculopathies, distal symmetric polyneuropathies, inflammatory demyelinating polyneuropathies, multifocal mononeuropathies, cranial neuropathies, and neuropathies induced by antiretroviral drugs (Table 379-9).

Lumbosacral polyradiculopathies are usually due to CMV infection and occur with advanced HIV/AIDS. These present with pain, incontinence, and rapidly progressive asymmetric lower extremity weakness leading to paraplegia. Saddle anesthesia is always present. Deep tendon reflexes are often preserved. EMG reveals findings of both peripheral neuropathy and lumbosacral radiculopathy. CSF analysis shows pleocytosis with polymorphonuclear cells; polymerase chain reaction for CMV is positive. The differential diagnosis includes GBS; other infections including herpes viruses, treponema, or tuberculosis; and carcinomatous meningoradiculitis from lymphoma. Aggressive and rapid treatment with ganciclovir, foscanet, or cidofovir should be considered.

DISTAL SYMMETRIC POLYNEUROPATHY ASSOCIATED WITH HIV HIV distal sensory symmetric polyneuropathy presents as a painful, predominantly small-fiber neuropathy. This syndrome cannot be distinguished reliably from neuropathy caused by antiretroviral drugs (nucleoside reverse transcriptase inhibitors); its onset with respect to exposure to the offending drugs may be the only clue. It is estimated that ~30% of hospitalized patients with AIDS and 100% of individuals dying with AIDS have evidence of neuropathy. The prevalence is lower in less advanced HIV infection, occurring in only 3% of those with CD4 cell counts > 200/μL. Older age, associated nutritional deficiencies, and toxic exposures are additional risk factors for AIDS-related neuropathy. Most patients present with painful burning, tingling, and numbness in the feet. Symp-

TABLE 379-9 NEUROPATHIES ASSOCIATED WITH HIV INFECTION

HIV Neuropathy	Symptoms and Signs	Typical CD4 Counts, cells/μL	Diagnostic Tests
Distal symmetric polyneuropathy	Painful paresthesias, distal sensory loss, absent ankle jerk	<200	EDx studies Skin biopsy
GBS, CIDP	Progressive weakness, areflexia, numbness	<500; >50	EDx studies CSF studies: elevated protein, variable pleocytosis
Mononeuropathy multiplex (cryoglobulinemia, hepatitis C)	Footdrop, wrist drop, facial weakness	<500; >50	EDx studies, nerve biopsy
CMV polyradiculopathy	Flaccid paraparesis, saddle anesthesia, urinary retention	<50	EDx, CSF studies
Herpes zoster, tuberculosis, lymphoma	Depends on specific etiology	<50	EDx, CSF studies Nerve biopsy
Toxic neuropathy	Similar to DSPN	<500	Eliminate drug: stavudine (d4T), didanosine (ddI), zalcidabine (ddC)

Note: GBS, Guillain-Barré syndrome; CIDP, chronic inflammatory demyelinating polyneuropathy; EDx, electrodiagnosis; CSF, cerebrospinal fluid; CMV, cytomegalovirus; DSPN, diabetic sensory polyneuropathy.

toms are typically bilateral, gradual in onset, and worse at night (features common to all painful neuropathies). Examination usually shows distal loss to pin and temperature sensation and absent or decreased ankle jerk. Weakness is either not detected or is confined to the intrinsic foot muscles. Asymmetric presentations suggest the possibility of vasculitis (nerve biopsy indicated) or an entrapment neuropathy. The possibility of a confounding neuropathy from diabetes, alcohol, nutritional causes, or toxin exposure should always be considered.

Nerve biopsy shows a length-dependent axonal degeneration of sensory fibers, with little evidence of nerve-fiber regeneration. Both large myelinated and unmyelinated nerve fibers are lost. Inflammatory infiltrates of lymphocytes and activated macrophages and reduced numbers of DRG neurons may be seen.

TOXIC NEUROPATHY FROM ANTIRETROVIRAL DRUGS A toxic neuropathy follows exposure to specific dideoxynucleosides (d4T, ddI, and especially ddC), particularly in advanced HIV disease. Sural nerve biopsy shows severe axonal destruction, most prominently in unmyelinated fibers, along with mitochondrial abnormalities. Serum lactate concentrations are elevated and acetylcarnitine levels are reduced as a result of mitochondrial dysfunction. Dideoxynucleosides have also been shown in vitro to inhibit gamma DNA polymerase, whereas zidovudine, lamivudine, and abacavir (drugs that are not associated with neuropathy) have only limited effects on this enzyme.

℞ TOXIC NEUROPATHY FROM ANTIRETROVIRAL DRUGS

Treatment consists of discontinuing the offending dideoxynucleoside and changing the highly active antiretroviral therapy (HAART) regimen, provided that there is another regimen to offer. Failing this, a patient may need to continue the regimen with the addition of pain-modifying drugs. Prescribing patterns have changed in the developed world to limit the use of specific dideoxynucleosides. However, in resource-limited countries, generic antiretroviral combinations typically contain d4T. After discontinuation of a toxic dideoxynucleoside, symptomatic improvement can be expected in most individuals within ~3 months.

Various pain-modifying drugs have been tried without success, including tricyclic antidepressants and anticonvulsants. Lamotrigine was reported to be efficacious in a subgroup of patients in one class I trial, but results of a smaller class II trial were contradictory. Some positive results have been achieved with topical capsaicin or topical lidocaine, especially in patients with symptoms confined to the feet. Patients with severe neuropathies may require narcotic analgesics for pain relief, and long-acting narcotics such as transdermal fentanyl, morphine, or oxycodone preparations are particularly useful. Specific prescribing guidelines should be used, particularly if there is any history of substance abuse. Regenerative strategies, including trials of recombinant human nerve growth factor, have been attempted.

Neuropathies with Lyme Disease (See also Chap. 166) A focal or multifocal radiculoneuropathy may occur with *Borrelia burgdorferi* infection. Subacute cranial neuropathy (especially VII) or painful radiculopathy may occur in the acute phase of Lyme disease, with or without associated meningitis. The radiculitis is dysesthetic or painful and is variable in distribution. CSF pleocytosis with intrathecal production of *B. burgdorferi* antibodies is typical. The radiculitis is dysesthetic or painful and is variable in distribution. Most patients improve either spontaneously or after IV ceftriaxone treatment. In the chronic phase, a mild, chronic distal polyneuropathy (sensory more than motor) has been described; however, the CSF is normal and the association may be coincidental.

Herpes Zoster (See also Chap. 173) Reactivation of varicella zoster virus (VZV) in dorsal root ganglia produces lancinating pain and hyperalgesia in a dermatomal distribution. The pain is followed 3–4 days later by the appearance of a blistering skin rash. The inflammation may at times involve the adjacent motor nerve roots, causing weakness and wasting. Ophthalmoplegic zoster causes weakness in the division of one or more oculomotor nerves; facial zoster causes facial palsy (Ramsay Hunt syndrome); thoracolumbar zoster causes rash and sensory loss in a thoracic or lumbar nerve root. Although pain usually subsides after a few days to a week, it sometimes persists (postherpetic neuralgia). Herpes zoster and postherpetic neuralgia both occur more commonly in the elderly and in immunosuppressed individuals. In the acute setting acyclovir, famciclovir, or valacyclovir are equally effective, although acyclovir must be given five times a day as opposed to three times a day for the other two drugs. Glucocorticoids are of unproven benefit. Treatment of postherpetic neuralgia includes tricyclic antidepressants, duloxetin, gabapentin, pregabalin, oxycodone, morphine sulfate, tramodol, lidocaine patch, and topical capsaicin. A zoster vaccine (Zostavax) has been approved to prevent VZV in elderly patients; the incidence of shingles is reduced by 50% and postherpetic neuralgia by 67%.

Leprous Neuritis (See also Chap. 159) *Mycobacterium leprae* causes mononeuropathy multiplex affecting peripheral nerves in cooler regions of the body, reflecting the predilection for this bacterium to thrive at cooler temperatures. The deformities caused by untreated leprous neuritis have led to the fear and stigma attached to this disease. Although the incidence of leprous neuritis has declined, it remains a leading cause of neuropathy worldwide. Leprosy is classified into tuberculoid, lepromatous, and borderline types; peripheral nerves may be affected in all three types, and involved nerves are often palpably thickened. In tuberculoid leprosy, a single patch of hypesthetic or anesthetic skin may occur in any location. The area is generally hypopigmented, thickened, or red. A mononeuropathy involving a nearby superficial nerve may occur. Lepromatous leprosy produces more widespread skin thickening, hypesthesia, and anhidrosis affecting the pinnae of ears, dorsum of hands or feet, dorsomedial surfaces of the forearm, and anteromedial aspects of the legs. The sensory loss spares the midline of the trunk anteriorly, the groin, axilla, and scalp; these are the warmer regions of the body. The fifth and seventh cranial nerves, greater auricular nerve in the neck, median and ulnar nerves, and peroneal nerves can all be involved. Over the long term, untreated leprosy leads to claw hand deformity (from ulnar and median nerve weakness), footdrop, and inability to close the eyelids due to orbicularis oculi weakness.

CHARCOT-MARIE-TOOTH DISEASE

Clinical Features CMT neuropathy is the most common heritable neuromuscular disorder with an estimated incidence of 17–40 cases per 100,000 (Table 379-10). It is a chronic distal sensory and motor neuropathy presenting as longstanding gait difficulty with frequent tripping, followed by difficulty with buttoning, handling keys, turning door knobs, and opening jars. There is often a history of clumsiness, frequent ankle injuries, inability to jump well or to keep up with other children in races, and being unathletic. In some patients the history suggests a more recent onset. If carefully sought, a family history can often be obtained. Wasting and weakness of the distal muscles of the legs (inverted champagne bottle appearance) with hammer toes and high arched feet (pes cavus) are commonly present, along with steppage gait, distal sensory loss, and distal loss of reflexes. Pes cavus and hammer toes indicate that the neuropathy dates from early life. An inability to walk on the heels or perform tandem gait is often present. The differential diagnosis is limited if there is an early age of onset, a positive family history, and longstanding symptoms. If the EDx findings indicate a demyelinating process, the diagnosis of CMT can be made with confidence, although genetic testing may be needed to confirm the precise genotype. If the EDx findings are axonal, or if the family history is uncertain or negative, CMT becomes a diagnosis of exclusion. Diabetes, as well as nutritional, toxic, endocrine, inflammatory, paraprotein-associated, and infectious causes, may all need to be excluded. Physical examination and EDx studies of at-risk family members can be more useful diagnostically than additional laboratory testing of the patient. Treatment is supportive; patients often need foot braces but rarely, if ever, become wheelchair dependent. CMT does not reduce the life span and only rarely involves respiratory muscles.

TABLE 379-10 FORMS OF CHARCOT-MARIE-TOOTH DISEASE (HEREDITARY MOTOR AND SENSORY NEUROPATHY) AND RELATED DISORDERS

Disorder	Locus	Gene	Inheritance
Charcot-Marie-Tooth Type 1			
(HMSNI)

Abbreviations: HMSN, hereditary motor and sensory neuropathies; *PMP22*, peripheral myelin protein 22; P_0, myelin protein zero; *SIMPLE*, small integral membrane protein of late endosome; *Cx32*, connexin32; *EGR2* (Krox-20) early growth response 2 gene; *GDAP1*, ganglioside-induced differentiation-associated protein-1; *MTMR2*, myotubularin-related protein-2; *SBF2*, SET binding factor 2; *NDRG1*, N-myc downstream regulated gene1; *PRX*, periaxin; *KIF1B*, kinesin family member 1B; *RAB7*, *ras*-associated protein 7; *GARS*, Glycyl-tRNA synthetase; *NEFL*, neurofilament, light polypeptide; *LMNA*, lamin A.

Classification Demyelinating forms of CMT are classified as CMT1, and axonal forms as CMT2. Patients with nerve conduction velocities (NCVs) intermediate between CMT1 and CMT2 are classified as having "intermediate CMT," and most of these cases are X-linked. CMT is usually transmitted as an autosomal dominant trait, but X-linked-dominant CMT is responsible for ~10% of CMT cases. Rare autosomal recessive forms, designated CMT4, tend to have an early onset and are more severe than the dominant types. In total, ~35 different loci and >24 genes have been identified in CMT.

Charcot-Marie-Tooth 1 (CMT1) Demyelinating Neuropathies CMT1 is the most common of the heritable neuropathies; inheritance is autosomal dominant. Distal weakness, wasting, and sensory loss with distal reduction of tendon reflexes and foot deformities occur as with other forms of CMT. The onset is in the first or second decade of life, although patients may not come to attention until much later in life. EDx studies show a pattern of generalized demyelination with NCVs that are uniformly and proportionately slowed in distal, intermediate, and proximal segments of the same nerve on the opposite side, and in adjacent nerves. Findings suggestive of heterogeneous demyelination, such as conduction block or dispersion, are not seen. Electrophysiologic evidence of demyelination may be prominent even in patients who are clinically asymptomatic. Nerve biopsies show evidence of repeated bouts of demyelination and remyelination. Proliferation of Schwann cells occurs in an attempt to remyelinate; the supernumerary Schwann cells are concentrically arranged around demyelinated and remyelinated axons, giving a characteristic "onion bulb" appearance. There is also increased collagen between the layers of Schwann cells leading to palpably thickened nerves.

CMT1 is classified into several genetically distinct subtypes (Table 379-10), all of which are clinically similar. In addition, distinct phenotypes with overlapping genotypes are identified. These include HNPP; infantile-onset or severe childhood forms, which include Déjerine-Sottas syndrome (DSS) and congenital hypomyelinating neuropathies (CHN); and Roussy-Lévy syndrome.

CMT1A This is the most common form; it is associated with the 17p11.2-p12 duplication in the *PMP22* gene expressed by Schwann cells. The duplication involves a large segment of DNA (~1.4 Mb) encoding a 160-amino-acid protein localized to compact myelin in peripheral nerves. CMT1A accounts for up to 90% of CMT1 and 50% of all CMT. Deletion of the *PMP22* gene produces a different phenotype—HNPP (see below). Commercial testing for *PMP22* duplication/deletion is widely available. *PMP22* appears to be important in the initiation of myelin spirals; regulation and growth of Schwann cells; and control of thickness, stability, and maintenance of myelin sheaths.

CMT1B CMT1B accounts for <5% of CMT1 cases. It is due to a mutation in the myelin protein zero (*MPZ*, or P_0) gene. Different mutations in the same gene can produce a wide spectrum of phenotypes including DSS, CHN, or CMT2. P_0 is quantitatively the major structural protein of peripheral nerve myelin and is important in myelin compaction. CMT1B is clinically indistinguishable from CMT1A; a late adult-onset form with footdrop can occur. Genetic testing is available.

CMT1X This is an X-linked dominant form of CMT that can also affect heterozygote females. It is responsible for up to 10% of CMT.

Males are more often affected, and female carriers are usually mildly affected or asymptomatic. Male-to-male transmission does not occur. Onset in males is between the ages of 5 and 20; symptoms include difficulty running, sprained ankles, footdrop, distal wasting, weakness, sensory loss, and reduced reflexes. These features do not distinguish CMT1X from other forms of CMT1. Signs of central nervous system (CNS) involvement, including ataxia, dysarthria, weakness, aphasia, disorientation, and hearing loss, may be present, especially in males. Spontaneously resolving confluent white matter changes may be seen on MRI. NCVs are in an intermediate range, although males have slower conduction velocities (25–45 m/s), which may be nonuniform with conduction block and dispersion. This nonuniform pattern may mimic findings of an acquired disorder such as CIDP. The mutated gene, *GJB1*, encodes the gap junction protein connexin-32, which is expressed at the paranodal regions and at the Schmidt-Lanterman incisures of noncompact myelin.

HEREDITARY NEUROPATHY WITH LIABILITY TO PRESSURE PALSIES This is also called *tomaculous neuropathy*. It is an autosomal dominant disorder that presents as recurrent episodes of focal entrapment neuropathy with attacks of numbness and weakness in peroneal, ulnar, radial, and median nerves (in descending order) or in a brachial plexus distribution. Malposition of a limb or trauma may provoke episodes of neuropathy. Some patients present with a progressive length-dependent polyneuropathy rather than with recurrent mononeuropathies, and others remain entirely asymptomatic. Increased distal latencies in median and peroneal nerves and reduced velocities across the elbow of the ulnar and fibular head segment of the peroneal nerves may be found. Tomaculae are sausage-shaped bodies that indicate segmental demyelination. CMT1A and HNPP are both associated with copy number changes in the *PMP22* gene—a duplication causing CMT1A and deletion causing HNPP. Hence, CMT1A and HNPP are the reciprocal products of unequal crossing-over during meiosis. When HNPP presents as a painless brachial plexus neuropathy, it should be distinguished from brachial plexus neuritis and from hereditary neuralgic amyotrophy, a familial disorder with painful weakness and sensory loss in the brachial plexus distribution. Treatment for HNPP is supportive. Avoiding further compression or trauma to the entrapment sites is preferred over surgical release or transposition.

DÉJERINE-SOTTAS SYNDROME AND CONGENITAL HYPOMYELINATING NEUROPATHY These are severe childhood forms of CMT1. DSS and CHN both present with muscle weakness at birth or infancy, with absent or very slow NCVs. Delayed motor milestones are noted in early childhood. Patients either never ambulate or lose their ability to ambulate in infancy or childhood. NCVs are markedly slow (typically 10 m/s); CSF protein is elevated. Clinically DSS and CHN are indistinguishable. DSS can be either autosomal dominant or recessive; CHN is autosomal recessive. Nerve biopsy can distinguish the two, with DSS showing a thin myelin sheath surrounded by onion bulbs composed of concentric layers of basal lamina (Schwann cells are degenerated leaving the basal lamina), while CHN shows lack of onion bulbs and absent myelin sheaths. DSS may be caused by mutations of *PMP22*, myelin protein zero (*MPZ*), or early growth response gene (*ERG2*); *EGR2* or *MPZ* mutations underlie CHN.

ROUSSY-LÉVY SYNDROME This describes a combination of demyelinating CMT with postural and action tremor. The original family members had the *MPZ* mutation, but mutations in *PMP22* (CMT1A), *MPZ* (CMT1B), or *GJB1* (CMT1X) genes may also cause this syndrome.

Charcot-Marie-Tooth 2 (CMT2) Axonal Neuropathies CMT2, an autosomal dominant neuropathy, is responsible for one-third of CMT disease, although the number of patients is increasing as more genetic abnormalities are being identified. CMT2 has a later age of onset than CMT1; family members may be affected subclinically. Although typical length-dependent sensory and motor loss develops over the years, intrinsic hand weakness and atrophy, present in CMT1, do not develop.

CMT2A (classic CMT2) is caused by mutations in *MFN2* and represents 10% of dominant CMT2; CMT2B is caused by mutations in *RAB7*, a member of the Rab family of *ras*-related GTPases that function in intracellular membrane trafficking; it presents with severe sensory involvement and limb ulcerations. CMT2B overlaps with hereditary sensory neuropathy (HSN) type I with prominent sensory loss and severe sensory loss to touch and pain (see below). CMT2C is associated with vocal cord and respiratory (diaphragm) involvement; the genetic defects have not been identified. CMT2D is an axonal CMT with upper limb predominance associated with mutations in the glycyl-tRNA synthetase gene; predominant hand involvement with atrophy of distal hand muscles in a patient with a positive family history suggests CMT2D.

Autosomal Recessive Forms of CMT Autosomal recessive CMTs account for <10% of inherited neuropathy cases in the Western world but may be more common in regions of the world where consanguinity is common. Several genes have been identified, especially in inbred families. Demyelinating autosomal recessive forms, designated CMT4, are usually characterized by early onset and more severe involvement, with congenital or delayed motor milestones, facial weakness, bulbar weakness, sensorineural deafness, diaphragm weakness, and vocal cord paralysis.

Molecular Testing The phenotype, the inheritance pattern, and electrophysiologic data guide the approach to the diagnosis of an inherited neuropathy. Figure 379-2 summarizes an approach to genetic testing for CMT. If the proband has CMT1, a single nerve study (median motor forearm conduction velocity) in family members is a quick screening tool. However, if the proband has axonal CMT (CMT2), more detailed evaluation of family members may be required. Evaluation for HNPP employs the same molecular test as for the CMT1A duplication. Most CMT1 and CMT2 pedigrees are autosomal dominant. X-linked inheritance should be suspected if males are more often affected, there is no male-to-male transmission, and EDx studies show heterogeneous findings. Sporadic cases are difficult to evaluate since family members may not be available. Testing for the CMT1A duplication/deletion and for *GJB1* mutation can diagnose ~80% of all cases of CMT.

OTHER INHERITED NEUROPATHIES

Hereditary Motor Neuropathies (HMN) The distal HMNs present with distal motor weakness with sparing of sensory fibers. Seven subtypes have been described based on the age of onset and mode of inheritance, which is usually autosomal dominant or recessive. The common HMNs present as footdrop with severe wasting and weakness distally. Some variants may manifest with predominantly upper limb involvement, vocal cord paralysis, or with upper motor neuron signs mimicking amyotrophic lateral sclerosis (Chap. 369); the prognosis is relatively good.

Hereditary Sensory Neuropathies (HSN) HSNs, also called *hereditary sensory and autonomic neuropathies* (HSANs), are a heterogeneous group of disorders affecting the sensory and/or autonomic neurons. The predominant clinical presentation is of progressive distal sensory loss, although some weakness and wasting is also observed. The classification of HSN and HSAN is based on the age of onset and mode of inheritance. Five subtypes are described. The most common is HSN 1 (also called HSAN 1), an autosomal dominant neuropathy presenting with predominant small-fiber sensory involvement with lancinating pain, loss of pain and temperature sensation, and foot ulceration. Of note, CMT2B (see above) also presents with predominantly sensory loss to all modalities and foot ulcerations. HSN 2–5 are all autosomal recessive. HSN 2 presents in the first two decades of life with prominent sensory loss and mutilation in hands and feet. HSN 3 (HSAN 3), also called *Riley-Day syndrome*, has prominent dysautonomia. HSN 4 (HSAN 4) presents with episodic fever, anhidrosis, and reduced response to painful stimuli. HSAN 5 presents with congenital insensitivity to pain; mutations in a sodium channel (SCN1.7) are causative.

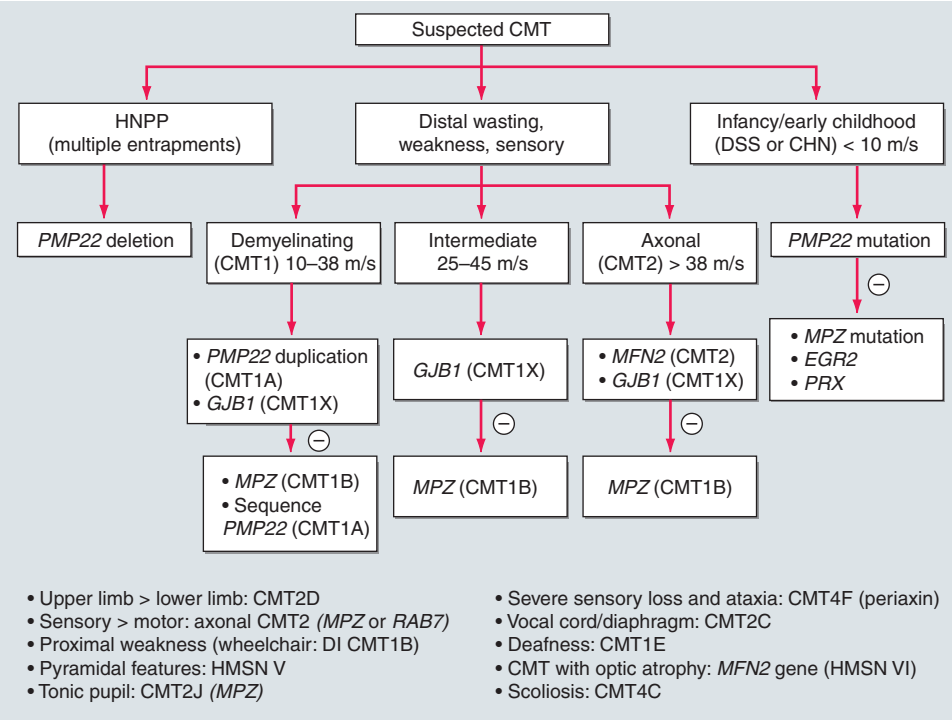

FIGURE 379-2 Diagnostic approach to Charcot-Marie-Tooth disease (CMT). HNPP, hereditary neuropathy with pressure palsies; DSS, Déjerine-Sottas syndrome; CHN, congenital hypomyelinating neuropathy; HMSN, hereditary motor and sensory neuropathy.

Refsum Disease This is an autosomal recessive hypertrophic neuropathy caused by defective oxidation of phytanic acid, a branched-chain fatty acid found in dairy products, beef, lamb, and fish. The onset is in late childhood or adolescence, with a slowly progressive course of a sensorimotor demyelinating neuropathy with sensorineural deafness, cerebellar ataxia, and anosmia. Retinitis pigmentosa presenting as night blindness often precedes the onset of neuropathy. Thickened skin (ichthyosis), syndactyly and shortening of the fourth toe, cardiomyopathy, and cataracts are other features. CSF protein is typically elevated. Abnormally high plasma and urinary levels of phytanic acid are diagnostic. Although a diet low in phytanic acid may prevent the onset of some of the complications, compliance with this diet is usually poor. Plasma exchange and dialysis may be helpful for episodes of worsening.

Familial Amyloid Neuropathy This is an autosomal dominant disorder in which there is extracellular deposition of amyloid in peripheral nerves and other organs (Chap. 324). A painful sensory neuropathy with early involvement of autonomic nerves and cardiomyopathy is typically present. Age of onset can vary from 18–83 years. Small fibers (pain and temperature) are more affected than large fibers (vibration and proprioception); anhidrosis, gastrointestinal disturbances (diarrhea alternating with constipation), impotence, orthostatic intolerance, visual changes, and arrhythmias are additional features. Mutations in transthyretin (FAP 1 and 2), apolipoprotein A1 (FAP 3) or gelosin (FAP 4) are responsible. Transthyretin is most often implicated in peripheral neuropathy. Nearly 100 different mutations have been identified in the *TTR* gene, the most common being the *Val30Met* mutation. Liver transplantation halts disease progression.

Tangier Disease (TD) This is a rare syndrome caused by a severe deficiency of high-density lipoproteins (HDL) in plasma (Chap. 350). Peripheral neuropathy is the most disabling feature of TD and affects ~50% of patients. Three patterns are recognized: a transient or relapsing, often asymmetric neuropathy (including isolated cranial nerve deficits); a slowly progressive symmetric neuropathy most marked in the distal upper limbs (syringomyelia-like); and a slowly progressive symmetric sensory motor neuropathy most marked in the lower limbs. Mononeuropathies involving the oculomotor nerve, long thoracic nerve, or any of the limb nerves may occur. The syringomyelic presentation includes wasting of hand muscles, loss of pain and temperature sensation, and facial diplegia. The length-dependent sensorimotor neuropathy pattern is the least common variant. Deposits of cholesterol esters in tonsils, liver, spleen, rectal mucosa, and cornea lead to the other non-neurologic manifestations of TD. There is no treatment available; a low-cholesterol diet or other dietary changes do not modify the natural history. Gene therapy may be possible in the future.

Porphyric Neuropathy Peripheral neuropathy accompanies the inherited hepatic porphyrias (Chap. 352). The triad of acute neuropathy, psychiatric symptoms, and abdominal involvement are similar in all hepatic porphyrias. Variegate porphyria and hereditary coproporphyria are characterized by additional skin lesions (blisters and bullae) in ~50% of patients. Most patients with porphyria are asymptomatic between attacks. Attacks can occur spontaneously or be precipitated by certain drugs, stress, hormonal factors, and reduced caloric intake. Abdominal pain, constipation, vomiting, and mental changes frequently herald the attacks. Peripheral neuropathy has an acute onset and may be preceded or accompanied by autonomic manifestations such as tachycardia, hypertension, and postural hypotension. The neuropathy is usually subacutely progressive (over 2–4 weeks) with diffuse weakness (often proximal more than distal) and areflexia. Sensory loss is generally mild and may be more prominent proximally in a "bathing trunk" distribution. Porphyric neuropathy should be considered in the differential diagnosis of GBS, the most common cause of rapidly progressive ascending paralysis.

CSF is acellular but the protein level is elevated, similar to that in GBS. Acute attacks are invariably associated with increased urinary excretion of aminolevulinic acid and/or porphobilinogen. Measuring 24-h urinary excretion of porphobilinogen and aminolevulinic acid and 24-h fecal excretion of protoporphyrin and coproporphyrin during a symptomatic period is the most helpful method of determining whether symptoms are due to acute porphyria. Since porphyrins are light sensitive, specimens must be stored in the dark and tested as soon as possible.

Treatment is largely supportive during the acute crisis and includes fluid management, ventilatory support, management of heart rate and blood pressure (autonomic dysfunction), and avoidance of medications that are known to precipitate an acute attack. Oral and IV glucose and heme arginate are the mainstays of treatment (Chap. 352). Recovery from an acute attack may take several months.

Critical Illness Neuropathy See Chap. 269.

SPECIAL PERIPHERAL NEUROPATHY PRESENTATIONS

AUTONOMIC NEUROPATHY

Symptoms may include orthostatic hypotension (syncope, light headedness, dizziness, fatigue, and lethargy), heat intolerance, abnormal (reduced or increased) sweating, constipation, diarrhea, incontinence, sexual dysfunction, dry eyes, dry mouth, or visual blurriness. Autonomic neuropathy is usually a manifestation of a more generalized polyneurop-

athy, as in diabetes, GBS, and alcoholic polyneuropathy, but occasionally syndromes of pure pandysautonomia are encountered. Other causes include amyloidosis and multiple drugs and toxins. **Autonomic neuropathies are discussed in detail in Chap. 370.**

PURE MOTOR NEUROPATHY

Examples of predominantly motor neuropathies include acute inflammatory neuropathies such as GBS; chronic neuropathies such as CIDP and multifocal motor neuropathy (MMN) (Chap. 380); some inherited neuropathies; brachial neuropathy; diabetic lumbosacral radiculoplexus neuropathy (diabetic amyotrophy); and neuropathy due to spinal muscular atrophy, acute intermittent porphyria, diphtheria, lead, and dapsone. Motor neuronopathies include the lower-motor form of amyotrophic lateral sclerosis, poliomyelitis, hereditary spinal muscular atrophies, and an adult variant of hexosaminidase A deficiency (Chap. 369). Neuromuscular junction disorders (e.g., Lambert-Eaton myasthenic syndrome, tick bite paralysis, and other types of toxic neuromuscular blockade) are purely motor and can be recognized and localized electrodiagnostically (Chap. 381).

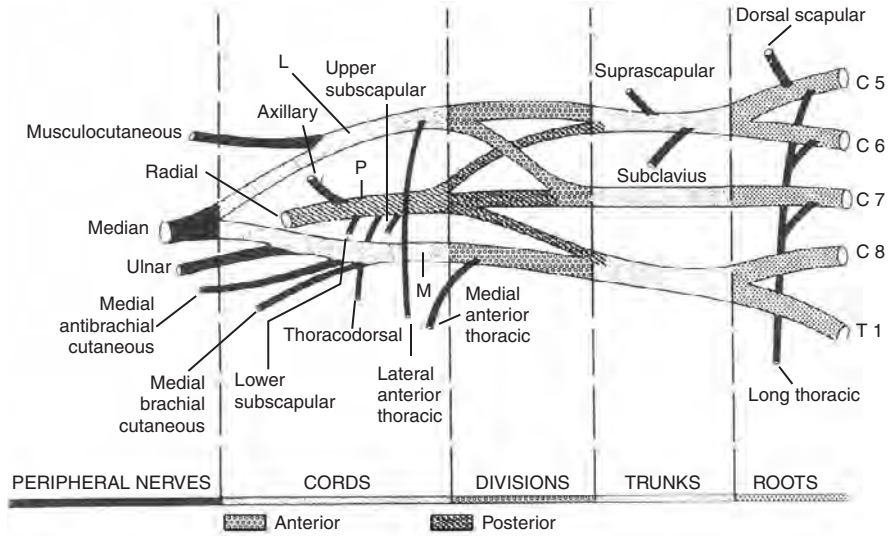

FIGURE 379-3 Brachial plexus anatomy. L, lateral; M, medial; P, posterior. *(From J Goodgold: Anatomical Correlates of Clinical Electromyography. Baltimore, Williams and Wilkins, 1974, p. 126, with permission.)*

PURE SENSORY NEUROPATHY

Causes include Friedreich's ataxia, idiopathic sensory neuropathy, sensory neuropathy associated with Sjögren syndrome, vitamin B_{12} neuropathy (dorsal column involvement is the major factor), pyridoxine toxicity, and cisplatin neuropathy. The most severe and widespread of these pure sensory syndromes exhibit poor or no recovery, suggesting irreversible lesions of nerve cell bodies in dorsal root and trigeminal ganglia (neuronopathy). A painful sensory neuropathy is an early feature of hereditary sensory neuropathies, lepromatous leprosy, diabetic small-fiber neuropathy, amyloidosis, TD, Fabry's disease, and dysautonomia. Global sensory loss can occur with carcinomatous sensory neuropathy, hereditary sensory neuropathies, diabetic sensory neuropathy, vacor intoxication, and xanthomatous neuropathy of primary biliary cirrhosis.

PLEXOPATHY

This refers to disorders of either the brachial or the lumbosacral plexus. *Brachial plexopathy* is a broad term used to define any injury, traumatic or otherwise, to the brachial plexus. Causes include birth injury, trauma, neoplasm, radiation, and familial and immune-mediated processes **(Fig. 379-3; Table 379-11)**. Trauma to the plexus is responsible for up to 70% of brachial plexus lesions; the upper plexus is the most vulnerable. Brachial neuritis (neuralgic amyotrophy; Chap. 16), characterized by sudden onset of pain in the shoulder region followed by weakness and atrophy, is the second most common cause. In this disorder, the shoulder girdle muscles are most frequently affected, and individual peripheral nerves tend to be more commonly involved. Other causes include a cervical rib or band, infiltration by malignant tumor, or prior radiation therapy.

Brachial plexus lesions demonstrate characteristic motor and sensory signs. When the upper parts of the brachial plexus (cervical roots 5–7) are affected, weakness and atrophy of shoulder girdle and upper arm muscles occurs. Injuries to the lower brachial plexus (C8-T1 roots) produce distal arm weakness, atrophy, and focal sensory deficits in the forearm and hand. In general, idiopathic brachial neuritis, irradiation with >60 Gy (6000 rad), and specific types of trauma (arm jerked downward) result in damage to the upper portions of the brachial plexus. In contrast, infiltration by malignant tumor, a cervical rib or band, and specific types of trauma (arm jerked upward) cause damage to the lower brachial plexus.

The *lumbosacral plexus* is formed by the ventral primary rami of L1-S4. Although often considered as a single entity, it can be divided into a lumbar plexus (ventral rami of L1–L4) and a sacral plexus (lumbosacral trunk L4 and L5 and ventral rami of S1–S4) **(Figs. 379-4 and 379-5)**. The femoral and obturator nerves are the main nerves formed from the lumbar plexus, and the sciatic, gluteal, and pudendal nerves

TABLE 379-11 BRACHIAL PLEXUS LESIONS

Site of Injury	Nerves/Nerve Roots	Muscles Affected	Sensory Loss	Common Causes
Upper trunk	C-5 and C-6	Weakness of shoulder abduction (supraspinatus & deltoid), external rotation (infraspinatus) and elbow flexion (biceps)	Small patch of skin overlying the deltoid	Birth injury during difficult delivery (Erb-Duchenne palsy); brachial neuritis, also called neuralgica myotrophy (Parsonage-Turner syndrome)
Lower trunk	C-8 and T-1	Weakness and wasting of small muscles of the hand (claw-hand deformity)	Ulnar border of the hand and inner forearm	Birth injury, especially breech delivery (Déjerine-Klumpke paralysis), compression by cervical rib or band (thoracic outlet syndrome), tumor infiltration
Lateral cord	Musculocutaneous nerve and lateral part of median nerve	Weakness of flexion and pronation of forearm	Radial border of forearm and hand	Trauma, stretch
Medial cord	Medial part of median nerve and ulnar nerve	Weakness and wasting of small muscles of the hand (claw hand deformity)	Ulnar border of the hand and inner forearm	Trauma
Posterior cord	Axillary and radial nerves	Deltoid, extensors of elbow, wrist, and fingers	Outer aspect of upper arm	Trauma, shoulder dislocation

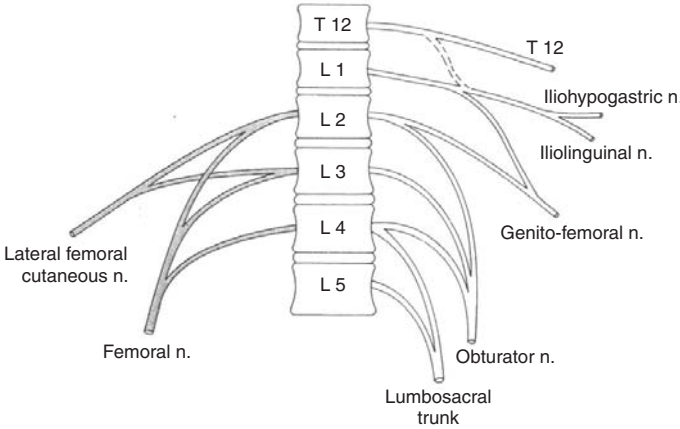

FIGURE 379-4 Lumbar plexus. Posterior divisions are in gray, anterior divisions are in white. *(From J Goodgold: Anatomical Correlates of Clinical Electromyography. Baltimore, Williams and Wilkins, 1974, p. 126, with permission.)*

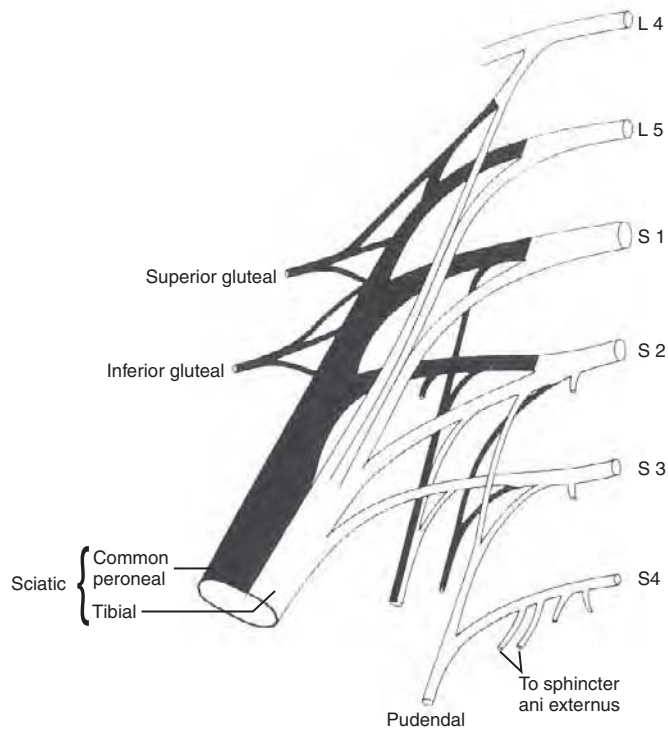

FIGURE 379-5 Lumbosacral plexus. Posterior divisions are in black, anterior divisions are in white. *(From J Goodgold: Anatomical Correlates of Clinical Electromyography. Baltimore, Williams and Wilkins, 1974, p. 126, with permission.)*

are the main nerves formed by the sacral plexus. The lumbosacral plexus courses near the paravertebral psoas muscle and the sacroiliac notch and sacral ala, where it is relatively well protected from injury, unlike its upper extremity counterpart. Disorders affecting the lumbosacral plexus include: trauma, intraoperative damage, retroperitoneal hemorrhage, radiotherapy, neoplastic invasion, diabetes mellitus, pregnancy and labor, retroperitoneal abscess or hemorrhage, abdominal aortic aneurysm, and idiopathic lumbosacral plexopathy (Table 379-12). Most patients present with varying degrees of pain, sensory deficits, and weakness in the lower limbs, generally in an asymmetric distribution. The onset may be acute, subacute, or insidious depending on the etiology; the course may vary from being monophasic, stepwise, or progressive. EDx studies are invaluable aids for diagnosis and localization.

PERIPHERAL NERVE INJURY

Physical damage to peripheral nerves may result from sudden compression, crush, transection, or stretching of a nerve. The mildest form of nerve injury results when a stretch or pressure injury distorts the myelin overlying the nodes of Ranvier and produces focal conduction block. This type of injury, with conduction block but without Wallerian degeneration, is referred to as *neurapraxia,* or *class 1 injury*. This results in a transient sensation of numbness in an extremity, as occurs after lying or sitting in a certain position. Nerve injury that interrupts the axon's continuity and results in Wallerian degeneration of the nerve distal to the lesion is considered moderate or severe. If the endoneurium is preserved, the lesion is considered moderate and is called *axonotmesis*, or *class 2 injury*. If the endoneurium is destroyed, the lesion is considered severe and is called *neurotmesis*. Peripheral nerve lesions are often mixed; neurapraxia and axonotmesis may coexist. Similarly, one fascicle may be completely disrupted while another is only partially affected. If the clinical and electrophysiologic examinations show that the lesion is complete, and if the mechanism of injury is known to be a clean laceration, then surgical repair should be considered within 24 h of the injury. If the mechanism of injury is contusion, stretch, traction, or compression, nerve conduction studies to determine whether the lesion is neurapraxic or axonotmesic should be delayed for 3 weeks. If neurapraxic, a return of function can be expected, provided care is taken to ensure that there is no ongoing compressive injury. If clinical and electrophysiologic examinations (no motor units seen by EMG) fail to reveal evidence of return of function after 3 months, the lesion was most likely neurotmesic, and exploration and surgical repair may need to be undertaken. If the lesion is incomplete, follow-up evaluations should be performed monthly; if no improvement is seen, then surgery may be required. Approximately 80% of closed injuries resolve spontaneously, because these lesions are in continuity. The appearance of an advancing Tinel's sign in the distribution of the injured nerve indicates that the nerve is in continuity and justifies postponement of surgery. The growth rate of regenerating axons is about 2.5 cm/month. The time required for regeneration is dependent on the distance from the site of injury to the first muscle innervated below the lesion. Since this distance is greater for proximal nerve lesions, severe proximal injuries are associated with poor recovery. Brachial plexus injuries during birth carry a better prognosis for spontaneous recovery than do those in adults.

PERIPHERAL NERVE TUMORS

Peripheral nerve tumors, which can present as peripheral neuropathy, are mostly benign and can arise in any nerve trunk or nerve twig. Although peripheral nerve tumors can occur anywhere in the body, including the spinal roots and cauda equina, many are subcutaneous in location and present as a soft swelling, sometimes with a purplish discoloration of the skin. Symptoms can include tingling or pain when the lesion is touched. Diagnostic studies may include imaging (CT/MRI),

TABLE 379-12 LUMBOSACRAL PLEXUS LESIONS

Site	Nerve Roots	Muscles	Sensory Loss	Common Causes
Upper plexus	L-2, L-3, L4	Weakness of thigh flexion (psoas), thigh adduction, and knee extension (quadriceps)	Anterior thigh and medial leg; absent knee jerk	Diabetic amyotrophy; abdominal surgery—either directly/retraction, or due to positioning; lumbosacral plexitis
Lower plexus	L-4, L-5, S-1, and S-2	Weakness of thigh extension (glutei), knee flexion (hamstrings), foot dorsiflexion and plantar flexion	Posterior thigh, lateral leg, and entire foot; absent ankle jerk	Lumbosacral plexitis, perioperative, cancer infiltration, radiation

EMG and nerve conduction studies, and tumor biopsy. Two major categories of peripheral nerve tumors are recognized: neurilemmoma (schwannoma) and neurofibroma. Neurilemmomas are usually solitary and grow in the nerve sheath, rendering the tumor relatively easy to dissect free. In contrast, neurofibromas tend to be multiple and grow in the endoneurial substance, which renders them difficult to dissect. They may undergo malignant changes. Neurofibromas are the hallmark of von Recklinghausen's neurofibromatosis (NF1) (Chap. 374).

380 Guillain-Barré Syndrome and Other Immune-Mediated Neuropathies

Stephen L. Hauser, Arthur K. Asbury

GUILLAIN-BARRÉ SYNDROME

Guillain-Barré syndrome (GBS) is an acute, frequently severe, and fulminant polyradiculoneuropathy that is autoimmune in nature. It occurs year-round at a rate of about one case per million per month, or ~3500 cases per year in the United States and Canada. Males are at 1.5-fold higher risk for GBS than females, and in western countries adults are more frequently affected than children.

Clinical Manifestations GBS manifests as rapidly evolving areflexic motor paralysis with or without sensory disturbance. The usual pattern is an ascending paralysis that may be first noticed as rubbery legs. Weakness typically evolves over hours to a few days and is frequently accompanied by tingling dysesthesias in the extremities. The legs are usually more affected than the arms, and facial diparesis is present in 50% of affected individuals. The lower cranial nerves are also frequently involved, causing bulbar weakness with difficulty handling secretions and maintaining an airway; the diagnosis in these patients may initially be mistaken for brainstem ischemia. Pain in the neck, shoulder, back, or diffusely over the spine is also common in the early stages of GBS, occurring in ~50% of patients. Most patients require hospitalization, and almost 30% require ventilatory assistance at some time during the illness. Fever and constitutional symptoms are absent at the onset and, if present, cast doubt on the diagnosis. Deep tendon reflexes attenuate or disappear within the first few days of onset. Cutaneous sensory deficits (e.g., loss of pain and temperature sensation) are usually relatively mild, but functions subserved by large sensory fibers, such as deep tendon reflexes and proprioception, are more severely affected. Bladder dysfunction may occur in severe cases but is usually transient. If bladder dysfunction is a prominent feature and comes early in the course, diagnostic possibilities other than GBS should be considered, particularly spinal cord disease. Once clinical worsening stops and the patient reaches a plateau (almost always within 4 weeks of onset), further progression is unlikely.

Autonomic involvement is common and may occur even in patients whose GBS is otherwise mild. The usual manifestations are loss of vasomotor control with wide fluctuation in blood pressure, postural hypotension, and cardiac dysrhythmias. These features require close monitoring and management and can be fatal. Pain is another common feature of GBS; in addition to the acute pain described above, a deep aching pain may be present in weakened muscles that patients liken to having overexercised the previous day. Other pains in GBS include dysesthetic pain in the extremities as a manifestation of sensory nerve fiber involvement. These pains are self-limited and often respond to standard analgesics (Chap. 12).

Several subtypes of GBS are recognized, as determined primarily by electrodiagnostic and pathologic distinctions (Table 380-1). These include the axonal variants, which are often clinically severe—either acute motor axonal neuropathy (AMAN) or acute motor sensory axonal neuropathy (AMSAN). In addition, a range of limited or regional GBS syndromes are also encountered. Notable among these is the Miller Fisher syndrome (MFS; Table 380-1), which presents as rapidly evolving ataxia and areflexia of limbs without weakness, and ophthalmoplegia, often with pupillary paralysis. The MFS variant accounts for ~5% of all GBS cases and is strongly associated with antibodies to the ganglioside GQ1b (see "Immunopathogenesis," below). Other regional variants of GBS include (1) pure sensory forms; (2) ophthalmoplegia with anti-GQ1b antibodies as part of severe motor-sensory GBS; (3) GBS with severe bulbar and facial paralysis, sometimes associated with antecedent cytomegalovirus (CMV) infection and anti-GM2 antibodies; and (4) acute pandysautonomia (Chap. 370).

Antecedent Events Approximately 70% of cases of GBS occur 1–3 weeks after an acute infectious process, usually respiratory or gastrointestinal. Culture and seroepidemiologic techniques show that 20–30% of all cases occurring in North America, Europe, and Australia are preceded by infection or reinfection with *Campylobacter jejuni*. A similar proportion is preceded by a human herpes virus infection, often CMV or Epstein-Barr virus. Other viruses and also *Mycoplasma pneumoniae* have been identified as agents involved in antecedent infections, as have recent immunizations. The swine influenza vaccine, administered widely in the United States in 1976, is the most notable example; influenza vaccines in use from 1992–1994, however, resulted in only one additional case of GBS per million persons vaccinated. Older-type rabies vaccine, prepared in nervous system tissue, is implicated as a trigger of GBS in developing countries where it is still used; the mechanism is presumably immunization against neural antigens. GBS also occurs more frequently than can be attributed to chance alone in patients with lymphoma (including Hodgkin's disease), in HIV-seropositive individuals, and in patients with systemic lupus erythematosus (SLE). *C. jejuni* has also been implicated in summer outbreaks of AMAN among children and young adults exposed to chickens in rural China.

Immunopathogenesis Several lines of evidence support an autoimmune basis for acute inflammatory demyelinating polyneuropathy (AIDP), the most common and best-studied type of GBS; the concept extends to all of the subtypes of GBS (Table 380-1).

It is likely that both cellular and humoral immune mechanisms contribute to tissue damage in AIDP. T cell activation is suggested by

TABLE 380-1 SUBTYPES OF GUILLAIN-BARRÉ SYNDROME (GBS)

Subtype	Features	Electrodiagnosis	Pathology
Acute inflammatory demyelinating polyneuropathy (AIDP)	Adults affected more than children; 90% of cases in western world; recovery rapid; anti-GM1 antibodies (<50%)	Demyelinating	First attack on Schwann cell surface; widespread myelin damage, macrophage activation, and lymphocytic infiltration; variable secondary axonal damage
Acute motor axonal neuropathy (AMAN)	Children and young adults; prevalent in China and Mexico; may be seasonal; recovery rapid; anti-GD1a antibodies	Axonal	First attack at motor nodes of Ranvier; macrophage activation, few lymphocytes, frequent periaxonal macrophages; extent of axonal damage highly variable
Acute motor sensory axonal neuropathy (AMSAN)	Mostly adults; uncommon; recovery slow, often incomplete; closely related to AMAN	Axonal	Same as AMAN, but also affects sensory nerves and roots; axonal damage usually severe
M. Fisher syndrome (MFS)	Adults and children; uncommon; ophthalmoplegia, ataxia, and areflexia; anti-GQ1b antibodies (90%)	Demyelinating	Few cases examined; resembles AIDP

the finding that elevated levels of cytokines and cytokine receptors are present in serum [interleukin (IL) 2, soluble IL-2 receptor] and in cerebrospinal fluid (CSF) (IL-6, tumor necrosis factor α, interferon-γ). AIDP is also closely analogous to an experimental T cell–mediated immunopathy designated *experimental allergic neuritis* (EAN); EAN is induced in laboratory animals by immune sensitization against protein fragments derived from peripheral nerve proteins, and in particular against the P2 protein. Based on analogy to EAN, it was initially thought that AIDP was likely to be primarily a T cell–mediated disorder; however, abundant data now suggest that autoantibodies directed against nonprotein determinants may be central to many cases.

Circumstantial evidence suggests that all GBS results from immune responses to nonself antigens (infectious agents, vaccines) that misdirect to host nerve tissue through a resemblance-of-epitope (molecular mimicry) mechanism (Fig. 380-1). The neural targets are likely to be glycoconjugates, specifically gangliosides (Table 380-2; Fig. 380-2). Gangliosides are complex glycosphingolipids that contain one or more sialic acid residues; various gangliosides participate in cell-cell interactions (including those between axons and glia), modulation of receptors, and regulation of growth. They are typically exposed on the plasma membrane of cells, rendering them susceptible to an antibody-mediated attack. Gangliosides and other glycoconjugates are present in large quantity in human nervous tissues and in key sites, such as nodes of Ranvier. Antiganglioside antibodies, most frequently to GM1, are common in GBS (20–50% of cases), particularly in those preceded by *C. jejuni* infection. Furthermore, isolates of *C. jejuni* from stool cultures of patients with GBS have surface glycolipid structures that antigenically cross react with gangliosides, including GM1, concentrated in human nerves. Another line of evidence is derived from experience in Europe with parenteral use of purified bovine brain gangliosides for treatment of various neuropathic disorders. Between 5 and 15 days after injection some recipients developed acute motor axonal GBS with high titers of anti-GM1 antibodies that recognized epitopes at nodes of Ranvier and motor endplates. Experimentally, anti-GM1 antibodies can trigger complement-mediated injury at paranodal axon-glial junctions, disrupting the clustering of sodium channels and likely contributing to conduction block (see "Pathophysiology," below).

Anti-GQ1b IgG antibodies are found in >90% of patients with MFS (Table 380-2; Fig. 380-2), and titers of IgG are highest early in the course. Anti-GQ1b antibodies are not found in other forms of GBS unless there is extraocular motor nerve involvement. A possible explanation for this association is that extraocular motor nerves are enriched in GQ1b gangliosides in comparison to limb nerves. In addition, a monoclonal anti-GQ1b antibody raised against *C. jejuni* isolated from a patient with MFS blocked neuromuscular transmission experimentally.

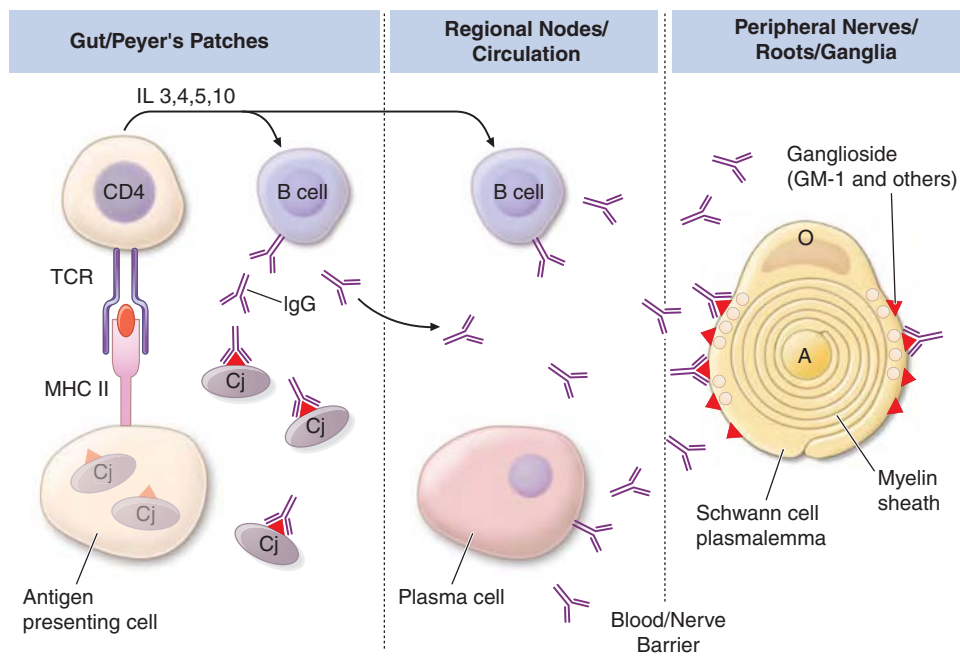

FIGURE 380-1 Postulated immunopathogenesis of GBS associated with *C. jejuni* infection. B cells recognize glycoconjugates on *C. jejuni* (Cj) (triangles) that cross-react with ganglioside present on Schwann cell surface and subjacent peripheral nerve myelin. Some B cells, activated via a T cell–independent mechanism, secrete primarily IgM (not shown). Other B cells (upper left side) are activated via a partially T cell–dependent route and secrete primarily IgG; T cell help is provided by CD4 cells activated locally by fragments of Cj proteins that are presented on the surface of antigen-presenting cells (APC). A critical event in the development of GBS is the escape of activated B cells from Peyer's patches into regional lymph nodes. Activated T cells probably also function to assist in opening of the blood-nerve barrier, facilitating penetration of pathogenic autoantibodies. The earliest changes in myelin (right) consist of edema between myelin lamellae and vesicular disruption (shown as circular blebs) of the outermost myelin layers. These effects are associated with activation of the C5b-C9 membrane attack complex and probably mediated by calcium entry; it is possible that the macrophage cytokine tumor necrosis factor (TNF) also participates in myelin damage. B, B cell; MHC II, class II major histocompatibility complex molecule; TCR, T cell receptor; A, axon; O, oligodendrocyte.

TABLE 380-2 PRINCIPAL ANTI-GLYCOLIPID ANTIBODIES IMPLICATED IN IMMUNE NEUROPATHIES

Clinical Presentation	Antibody Target	Usual Isotype
Acute Immune Neuropathies (Guillain-Barré Syndrome)		
Acute inflammatory demyelinating polyneuropathy (AIDP)	No clear patterns GM1 most common	IgG (polyclonal)
Acute motor axonal neuropathy (AMAN)	GD1a, GM1, GM1b, GalNAc–GD1a (<50% for any)	IgG (polyclonal)
Miller Fisher syndrome (MFS)	GQ1b (>90%)	IgG (polyclonal)
Acute pharyngeal cervicobrachial neuropathy (APCBN)	GT1a (? Most)	IgG (polyclonal)
Chronic Immune Neuropathies		
Chronic inflammatory demyelinating polyneuropathy (CIDP) (75%)	Po in some	No clear pattern
CIDPa (MGUS associated) (25%)	Neural binding sites	IgG, IgA (monoclonal)
Chronic sensory > motor neuropathy	SPGP, SGLPG (on MAG) (50%) Uncertain (50%)	IgM (monoclonal) IgM (monoclonal)
Multifocal motor neuropathy (MMN)	GM1, GalNAc–GD1a, others (25–50%)	IgM (polyclonal, monoclonal)
Chronic sensory ataxic neuropathy	GD1b, GQ1b, and other b-series gangliosides	IgM (monoclonal)

Note: MGUS, monoclonal gammopathy of undetermined significance; MAG, myelin-associated glycoprotein.
Source: Modified from HJ Willison, N Yuki: Brain 125:2591, 2002.

Taken together, these observations provide strong but still inconclusive evidence that autoantibodies play an important pathogenic role in GBS. Although anti-ganglioside antibodies have been studied most intensively, other antigenic targets may also be important. One report identified IgG antibodies against Schwann cells and neurons (nerve growth cone region) in some GBS cases. Proof that these antibodies are pathogenic requires that they be capable of mediating disease following direct passive transfer to naïve hosts; this has not yet been demonstrated, although one case of apparent maternal-fetal transplacental transfer of GBS has been described.

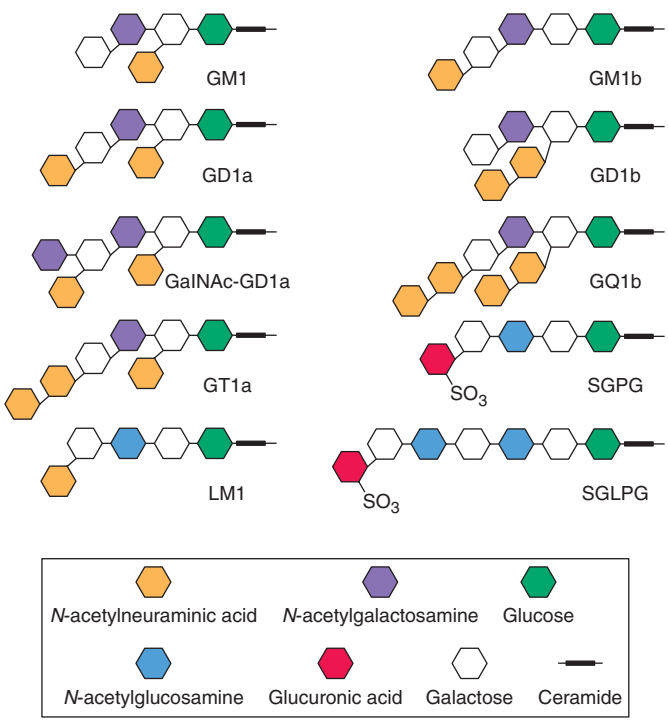

FIGURE 380-2 Glycolipids implicated as antigens in immune-mediated neuropathies. (*Modified from HJ Willison, N Yuki: Brain 125:2591, 2002.*)

In ADEM, an early step in the induction of tissue damage appears to be complement deposition along the outer surface of the Schwann cell. Activation of complement initiates a characteristic vesicular disintegration of the myelin sheath, and also leads to recruitment of activated macrophages, which participate in damage to myelin and axons. In AMAN, the pattern is different in that complement is deposited along with IgG at the nodes of Ranvier along large motor axons.

Pathophysiology In the demyelinating forms of GBS, the basis for flaccid paralysis and sensory disturbance is conduction block. This finding, demonstrable electrophysiologically, implies that the axonal connections remain intact. Hence, recovery can take place rapidly as remyelination occurs. In severe cases of demyelinating GBS, secondary axonal degeneration usually occurs; its extent can be estimated electrophysiologically. More secondary axonal degeneration correlates with a slower rate of recovery and a greater degree of residual disability. When a severe primary axonal pattern is encountered electrophysiologically, the implication is that axons have degenerated and become disconnected from their targets, specifically the neuromuscular junctions, and must therefore regenerate for recovery to take place. In motor axonal cases in which recovery is rapid, the lesion is thought to be localized to preterminal motor branches, allowing regeneration and reinnervation to take place quickly. Alternatively, in mild cases, collateral sprouting and reinnervation from surviving motor axons near the neuromuscular junction may begin to reestablish physiologic continuity with muscle cells over a period of several months.

Laboratory Features CSF findings are distinctive, consisting of an elevated CSF protein level [1–10 g/L (100–1000 mg/dL)] without accompanying pleocytosis. The CSF is often normal when symptoms have been present for ≤48 h; by the end of the first week the level of protein is usually elevated. A transient increase in the CSF white cell count (10–100/μL) occurs on occasion in otherwise typical GBS; however, a sustained CSF pleocytosis suggests an alternative diagnosis (viral myelitis) or a concurrent diagnosis such as unrecognized HIV infection. Electrodiagnostic features are mild or absent in the early stages of GBS and lag behind the clinical evolution. In cases with demyelination (Table 380-1), prolonged distal latencies, conduction velocity slowing, evidence of conduction block, and temporal dispersion of compound action potential are the usual features. In cases with primary axonal pathology, the principal electrodiagnostic finding is reduced amplitude of compound action potentials without conduction slowing or prolongation of distal latencies.

Diagnosis GBS is a descriptive entity. The diagnosis is made by recognizing the pattern of rapidly evolving paralysis with areflexia, absence of fever or other systemic symptoms, and characteristic antecedent events (Table 380-3). Other disorders that may enter into the differential diagnosis include acute myelopathies (especially with prolonged back pain and sphincter disturbances); botulism (pupillary reactivity lost early); diphtheria (early oropharyngeal disturbances); Lyme polyradiculitis and other tick-borne paralyses; porphyria (abdominal pain, seizures, psychosis); vasculitic neuropathy (check erythrocyte sedimentation rate, described below); poliomyelitis (fever and meningismus common); CMV polyradiculitis (in immunocompromised patients); critical illness neuropathy; neuromuscular disorders such as myasthenia gravis; poisonings with organophosphates, thallium, or arsenic; tick paralysis; paralytic shellfish poisoning; or severe hypophosphatemia (rare). Laboratory tests are helpful primarily to exclude mimics of GBS. Electrodiagnostic features may be minimal, and the CSF protein level may not rise until the end of the first week. If the diagnosis is strongly suspected, treatment should be initiated without waiting for evolution of the characteristic electrodiagnostic and CSF

TABLE 380-3 DIAGNOSTIC CRITERIA FOR GUILLAIN-BARRÉ SYNDROME

Required

1. Progressive weakness of 2 or more limbs due to neuropathy[a]
2. Areflexia
3. Disease course <4 weeks
4. Exclusion of other causes [e.g., vasculitis (polyarteritis nodosa, systemic lupus erythematosus, Churg-Strauss syndrome), toxins (organophosphates, lead), botulism, diphtheria, porphyria, localized spinal cord or cauda equina syndrome]

Supportive

1. Relatively symmetric weakness
2. Mild sensory involvement
3. Facial nerve or other cranial nerve involvement
4. Absence of fever
5. Typical CSF profile (acellular, increase in protein level)
6. Electrophysiologic evidence of demyelination

[a]Excluding M. Fisher and other variant syndromes.
Source: Modified from AK Asbury, DR Cornblath: Ann Neurol 27:S21, 1990.

findings to occur. Both tau and 14-3-3 protein levels are reported to be elevated early (during the first few days of symptoms) in some cases of GBS. Tau increases in CSF may reflect axonal damage and predict a residual deficit. GBS patients with risk factors for HIV or with CSF pleocytosis should have a serologic test for HIV.

℞ GUILLAIN-BARRÉ SYNDROME

In the vast majority of patients with GBS, treatment should be initiated as soon after diagnosis as possible. Each day counts; ~2 weeks after the first motor symptoms, immunotherapy is no longer effective. Either high-dose intravenous immune globulin (IVIg) or plasmapheresis can be initiated, as they are equally effective. A combination of the two therapies is not significantly better than either alone. IVIg is often the initial therapy chosen because of its ease of administration and good safety record. IVIg is administered as five daily infusions for a total dose of 2 g/kg body weight. There is some evidence that GBS autoantibodies are neutralized by anti-idiotypic antibodies present in IVIg preparations, perhaps accounting for the therapeutic effect. A course of plasmapheresis usually consists of ~40–50 mL/kg plasma exchange (PE) four times over a week. Meta-analysis of randomized clinical trials indicates that treatment reduces the need for mechanical ventilation by nearly half (from 27% to 14% with PE), and increases the likelihood of full recovery at 1 year (from 55% to 68%). In patients who are treated early in the course of GBS and improve, relapse may occur in the second or third week. Brief retreatment with the original therapy is usually effective. Glucocorticoids have not been found to be effective in GBS. Occasional patients with very mild forms of GBS, especially those who appear to have already reached a plateau when initially seen, may be managed conservatively without IVIg or PE.

In the worsening phase of GBS, most patients require monitoring in a critical care setting, with particular attention to vital capacity, heart rhythm, blood pressure, nutrition, deep vein thrombosis prophylaxis, cardiovascular status, early consideration (after 2 weeks of intubation) of tracheotomy, and chest physiotherapy. As noted, ~30% of patients with GBS require ventilatory assistance, sometimes for prolonged periods of time (several weeks or longer). Frequent turning and assiduous skin care are important, as are daily range-of-motion exercises to avoid joint contractures and daily reassurance as to the generally good outlook for recovery.

Prognosis and Recovery Approximately 85% of patients with GBS achieve a full functional recovery within several months to a year, although minor findings on examination (such as areflexia) may persist. The mortality rate is <5% in optimal settings; death usually results from secondary pulmonary complications. The outlook is worst in patients with severe proximal motor and sensory axonal damage. Such axonal damage may be either primary or secondary in nature (see "Pathophysiology," above), but in either case successful regeneration cannot occur. Other factors that worsen the outlook for recovery are advanced age, a fulminant or severe attack, and a delay in the onset of treatment. Between 5 and 10% of patients with typical GBS have one or more late relapses; such cases are then classified as chronic inflammatory demyelinating polyneuropathy (CIDP).

CHRONIC INFLAMMATORY DEMYELINATING POLYNEUROPATHY

CIDP is distinguished from GBS by its chronic course. In other respects, this neuropathy shares many features with the common demyelinating form of GBS, including elevated CSF protein levels and the electrodiagnostic findings of acquired demyelination. Most cases occur in adults, and males are affected slightly more often than females. The incidence of CIDP is lower than that of GBS, but due to the protracted course the prevalence is greater.

Clinical Manifestations Onset is usually gradual, sometimes subacute; in a few, the initial attack is indistinguishable from that of GBS. An acute-onset form of CIDP should be considered when GBS deteriorates >9 weeks after onset or relapses at least three times. Symptoms are both motor and sensory in most cases. Weakness of the limbs is usually symmetric but can be strikingly asymmetric. There is considerable variability from case to case. Some patients experience a chronic progressive course, whereas others, usually younger patients, have a relapsing and remitting course. Some have only motor findings, and a small proportion present with a relatively pure syndrome of sensory ataxia. Tremor occurs in ~10% and may become more prominent during periods of subacute worsening or improvement. A small proportion have cranial nerve findings, including external ophthalmoplegia. CIDP tends to ameliorate over time with treatment; the result is that many years after onset nearly 75% of patients have reasonable functional status. Death from CIDP is uncommon.

Diagnosis The diagnosis rests on characteristic clinical, CSF, and electrophysiologic findings. The CSF is usually acellular with an elevated protein level, sometimes several times normal. Electrodiagnostically, variable degrees of conduction slowing, prolonged distal latencies, temporal dispersion of compound action potentials, and conduction block are the principal features. In particular, the presence of conduction block is a certain sign of an acquired demyelinating process. Evidence of axonal loss, presumably secondary to demyelination, is present in >50% of patients. Serum protein electrophoresis with immunofixation is indicated to search for monoclonal gammopathy and associated conditions (see "Monoclonal Gammopathy of Undetermined Significance," below). In all patients with presumptive CIDP, it is also reasonable to exclude vasculitis, collagen vascular disease (especially SLE), chronic hepatitis, HIV infection, and diabetes mellitus. Other associated conditions include inflammatory bowel disease and Hodgkin's lymphoma.

Pathogenesis Although there is evidence of immune activation in CIDP, the precise mechanisms of pathogenesis are unknown. Biopsy typically reveals little inflammation and onion-bulb changes (imbricated layers of attenuated Schwann cell processes surrounding an axon) that result from recurrent demyelination and remyelination (Fig. 380-1). The response to therapy suggests that CIDP is immune-mediated; CIDP responds to glucocorticoids, whereas GBS does not. Passive transfer of demyelination into experimental animals has been accomplished using IgG purified from the serum of some patients with CIDP, lending support for a humoral autoimmune pathogenesis. Although the target antigen or antigens in CIDP have not yet been identified, the myelin protein Po has been implicated as a potential autoantigen in some patients. It is also of interest that a CIDP-like illness developed spontaneously in the nonobese diabetic (NOD) mouse when the immune co-stimulatory molecule B7-2 (CD86) was genetically deleted; this suggests that CIDP can result from altered triggering of T cells by antigen-presenting cells.

Approximately 25% of patients with clinical features of CIDP also have a monoclonal gammopathy of undetermined significance (MGUS).

Cases associated with monoclonal IgA or IgG usually respond to treatment as favorably as cases without a monoclonal gammopathy. Patients with IgM monoclonal gammopathy tend to have more sensory findings, a more protracted course, and may have a less satisfactory response to treatment, although this is an area of controversy.

Rx CHRONIC INFLAMMATORY DEMYELINATING POLYNEUROPATHY

Most authorities initiate treatment for CIDP when progression is rapid or walking is compromised. If the disorder is mild, management can be expectant, awaiting spontaneous remission. Controlled studies have shown that high-dose IVIg, PE, and glucocorticoids are all more effective than placebo. Initial therapy is usually with IVIg, administered as 0.4 g/kg body weight daily for 5 days; most patients require periodic re-treatment at ~6-week intervals. PE, which appears to be as effective as IVIg, is initiated at two to three treatments per week for 6 weeks; periodic re-treatment may also be required. Treatment with glucocorticoids is another option (60–80 mg prednisone PO daily for 1–2 months, followed by a gradual dose reduction of 10 mg per month as tolerated), but long-term adverse effects including bone demineralization, gastrointestinal bleeding, and cushingoid changes are problematic. Anecdotal experience suggested that glucocorticoids might be harmful to some patients with a purely motor form of CIDP, thus glucocorticoids should probably be avoided when sensory findings are absent. Approximately one-half of patients with CIDP fail to respond adequately to the initial therapy chosen; a different treatment should then be tried. Patients who fail therapy with IVIg, PE, and glucocorticoids may benefit from treatment with immunosuppressive agents such as azathioprine, methotrexate, cyclosporine, and cyclophosphamide, either alone or as adjunctive therapy. Early experience with anti-CD20 (rituximab) has also shown promise. Use of these therapies requires periodic reassessment of their risks and benefits.

MULTIFOCAL MOTOR NEUROPATHY

Multifocal motor neuropathy (MMN) is a distinctive but uncommon neuropathy that presents as slowly progressive motor weakness and atrophy evolving over years in the distribution of selected nerve trunks, associated with sites of persistent focal motor conduction block in the same nerve trunks. Sensory fibers are relatively spared. The arms are affected more frequently than the legs, and >75% of all patients are male. Some cases have been confused with lower motor neuron forms of amyotrophic lateral sclerosis (Chap. 369). Approximately 50% of patients present with high titers of polyclonal IgM antibody to the ganglioside GM1. It is uncertain how this finding relates to the discrete foci of persistent motor conduction block, but high concentrations of GM1 gangliosides are normal constituents of nodes of Ranvier in peripheral nerve fibers. Pathology reveals demyelination and mild inflammatory changes at the sites of conduction block.

Most patients with MMN respond to high-dose IVIg (dosages as for CIDP, above); periodic re-treatment is required in more than half of responders to maintain the benefit. Some refractory patients have responded to cyclophosphamide. Glucocorticoids and PE are not effective.

NEUROPATHIES WITH MONOCLONAL GAMMOPATHY

MULTIPLE MYELOMA

Clinically overt polyneuropathy occurs in ~5% of patients with the commonly encountered type of multiple myeloma, which exhibits either lytic or diffuse osteoporotic bone lesions. These neuropathies are sensorimotor, are usually mild and slowly progressive but may be severe, and generally do not reverse with successful suppression of the myeloma. In most cases, electrodiagnostic and pathologic features are consistent with a process of axonal degeneration.

In contrast, myeloma with osteosclerotic features, although representing only 3% of all myelomas, is associated with polyneuropathy in one-half of cases. These neuropathies, which may also occur with solitary plasmacytoma, are distinct because they (1) are usually demyelinating in nature; (2) often respond to radiation therapy or removal of the primary lesion; (3) are associated with different monoclonal proteins and light chains (almost always lambda as opposed to primarily kappa in the lytic type of multiple myeloma); and (4) may occur in association with other systemic findings including thickening of the skin, hyperpigmentation, hypertrichosis, organomegaly, endocrinopathy, anasarca, and clubbing of fingers. These are features of the POEMS syndrome (*p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy, *M* protein, and *s*kin changes). The pathogenesis of this uncommon syndrome and the explanation for its association with lambda light chains are unknown. Treatment of the neuropathy is best directed at the osteosclerotic myeloma using surgery, radiotherapy, or chemotherapy, as indicated.

Neuropathies are also encountered in other systemic conditions with gammopathy including Waldenström's macroglobulinemia, primary systemic amyloidosis, and cryoglobulinemic states (mixed essential cryoglobulinemia, some cases of hepatitis C).

MONOCLONAL GAMMOPATHY OF UNDETERMINED SIGNIFICANCE

Chronic polyneuropathies occurring in association with MGUS are usually associated with the immunoglobulin isotypes IgG, IgA, and IgM. From a clinical standpoint, many of these patients are indistinguishable from patients with CIDP without monoclonal gammopathy (see "Chronic Inflammatory Demyelinating Polyneuropathy," above), and their response to immunosuppressive agents is also similar. An exception is the syndrome of IgM kappa monoclonal gammopathy associated with an indolent, longstanding, sometimes static sensory neuropathy, frequently with tremor and sensory ataxia. Most patients are male and over age 50. In the majority, the monoclonal IgM immunoglobulin binds to a normal peripheral nerve constituent, myelin-associated glycoprotein (MAG), found in the paranodal regions of Schwann cells. Binding appears to be specific for a polysaccharide epitope that is also found in other normal peripheral nerve myelin glycoproteins, P0 and PMP22, and also in other normal nerve-related glycosphingolipids (Fig. 380-1). In the MAG-positive cases, IgM paraprotein is incorporated into the myelin sheaths of affected patients and widens the spacing of the myelin lamellae, thus producing a distinctive ultrastructural pattern. Demyelination and remyelination are the hallmarks of the lesions. The chronic demyelinating neuropathy appears to result from a destabilization of myelin metabolism rather than activation of an immune response. Therapy with chlorambucil, or cyclophosphamide combined with glucocorticoids or PE, often results in improvement of the neuropathy associated with a prolonged reduction in the levels in the circulating paraprotein; chronic use of these alkylating agents is associated with significant risks. Recent preliminary data also suggest that anti-CD20 (rituximab) therapy may be effective. In a small proportion of patients (30% at 10 years), MGUS will in time evolve into frankly malignant conditions such as multiple myeloma or lymphoma.

VASCULITIC NEUROPATHY

Peripheral nerve involvement is common in polyarteritis nodosa (PAN), appearing in half of all cases clinically and in 100% of cases at postmortem studies (Chap. 319). The most common pattern is multifocal (asymmetric) motor-sensory neuropathy (mononeuropathy multiplex) due to ischemic lesions of nerve trunks and roots; however, some cases of vasculitic neuropathy present as a distal, symmetric sensorimotor polyneuropathy. Symptoms of neuropathy are a common presenting complaint in patients with PAN. The electrodiagnostic findings are those of an axonal process. Small- to medium-sized arteries of the vasa nervorum, particularly the epineural vessels, are affected in PAN, resulting in a widespread ischemic neuropathy. A high frequency of neuropathy occurs in allergic angiitis and granulomatosis (Churg-Strauss syndrome).

Systemic vasculitis should always be considered when a subacute or chronically evolving mononeuropathy multiplex occurs in conjunction with constitutional symptoms (fever, anorexia, weight loss, loss of energy, malaise, and nonspecific pains). Diagnosis of suspected vascu-

litic neuropathy is made by a combined nerve and muscle biopsy, with serial section or skip-serial techniques (Chap. 379).

Approximately one-third of biopsy-proven cases of vasculitic neuropathy are "nonsystemic" in that the vasculitis appears to affect only peripheral nerves. Constitutional symptoms are absent, and the course is more indolent than that of PAN. The erythrocyte sedimentation rate may be elevated, but other tests for systemic disease are negative. Nevertheless, clinically silent involvement of other organs is likely, and vasculitis is frequently found in muscle biopsied at the same time as nerve.

Vasculitic neuropathy may also be seen as part of the vasculitis syndrome occurring in the course of other connective tissue disorders (Chap. 319). The most frequent is rheumatoid arthritis, but ischemic neuropathy due to involvement of vasa nervorum may also occur in mixed cryoglobulinemia, Sjögren's syndrome, Wegener's granulomatosis, hypersensitivity angiitis, and progressive systemic sclerosis. Management of these neuropathies, including the "nonsystemic" vasculitic neuropathy, consists of treatment of the underlying condition as well as the aggressive use of glucocorticoids and other immunosuppressant drugs. One reasonable starting regimen is daily prednisone (initial dose 1 mg/kg per day PO with a gradual taper after 1 month) plus IV pulse (or daily oral) cyclophosphamide for 3–6 months.

ANTI-HU PARANEOPLASTIC NEUROPATHY

This uncommon immune-mediated disorder manifests as a sensory neuronopathy (i.e., selective damage to sensory nerve bodies in dorsal root ganglia). The onset is often asymmetric with dysesthesias and sensory loss in the limbs that soon progress to affect all limbs, the torso, and face. Marked sensory ataxia, pseudoathetosis, and inability to walk, stand, or even sit unsupported are frequent features and are secondary to the extensive deafferentation. Subacute sensory neuronopathy may be idiopathic, but more than half of cases are paraneoplastic, primarily related to lung cancer, and most of those are small cell lung cancer (SCLC). Diagnosis of the underlying SCLC requires awareness of the association, paraneoplastic testing, and often PET scanning for the tumor. The target antigens are a family of RNA binding proteins (HuD, HuC, and Hel-N1) that in normal tissues are only expressed by neurons. The same proteins are usually expressed by SCLC, triggering in some patients an immune response characterized by antibodies and cytotoxic T cells that cross-react with the Hu proteins of the dorsal root ganglion neurons, resulting in immune-mediated neuronal destruction. An encephalomyelitis may accompany the sensory neuronopathy and presumably has the same pathogenesis. Neurologic symptoms usually precede, by ≤ 6 months, the identification of SCLC. The sensory neuronopathy runs its course in a few weeks or months and stabilizes, leaving the patient disabled. Most cases are unresponsive to treatment with glucocorticoids, IVIg, PE, or immunosuppressant drugs.

381 Myasthenia Gravis and Other Diseases of the Neuromuscular Junction

Daniel B. Drachman

Myasthenia gravis (MG) is a neuromuscular disorder characterized by weakness and fatigability of skeletal muscles. The underlying defect is a decrease in the number of available acetylcholine receptors (AChRs) at neuromuscular junctions due to an antibody-mediated autoimmune attack. Treatment now available for MG is highly effective, although a specific cure has remained elusive.

PATHOPHYSIOLOGY

In the neuromuscular junction (Fig. 381-1), acetylcholine (ACh) is synthesized in the motor nerve terminal and stored in vesicles (quanta). When an action potential travels down a motor nerve and reaches the nerve terminal, ACh from 150–200 vesicles is released and combines with AChRs that are densely packed at the peaks of postsynaptic folds. The structure of the AChR has been fully elucidated; it consists of five subunits (2α, 1β, 1δ, and 1γ or ε) arranged around a central pore. When ACh combines with the binding sites on the α subunits of the AChR, the channel in the AChR opens, permitting the rapid entry of cations, chiefly sodium, which produces depolarization at the end-plate region of the muscle fiber. If the depolarization is sufficiently large, it initiates an action potential that is propagated along the muscle fiber, triggering muscle contraction. This process is rapidly terminated by hydrolysis of ACh by acetylcholinesterase (AChE), which is present within the synaptic folds, and by diffusion of ACh away from the receptor.

In MG, the fundamental defect is a decrease in the number of available AChRs at the postsynaptic muscle membrane. In addition, the postsynaptic folds are flattened, or "simplified." These changes result in decreased efficiency of neuromuscular transmission. Therefore, although ACh is released normally, it produces small end-plate potentials that may fail to trigger muscle action potentials. Failure of transmission at many neuromuscular junctions results in weakness of muscle contraction.

The amount of ACh released per impulse normally declines on repeated activity (termed *presynaptic rundown*). In the myasthenic patient, the decreased efficiency of neuromuscular transmission combined with the normal rundown results in the activation of fewer and fewer muscle fibers by successive nerve impulses and hence increasing weakness, or *myasthenic fatigue*. This mechanism also accounts for the decremental response to repetitive nerve stimulation seen on electrodiagnostic testing.

The neuromuscular abnormalities in MG are brought about by an autoimmune response mediated by specific anti-AChR antibodies. The anti-AChR antibodies reduce the number of available AChRs at neuromuscular junctions by three distinct mechanisms: (1) accelerated turnover of AChRs by a mechanism involving cross-linking and rapid endocytosis of the receptors; (2) blockade of the active site of the AChR, i.e., the site that normally binds ACh; and (3) damage to the postsynaptic muscle membrane by the antibody in collaboration with complement. An immune response to muscle-specific kinase (MuSK) can also result in myasthenia gravis, possibly by interfering with AChR

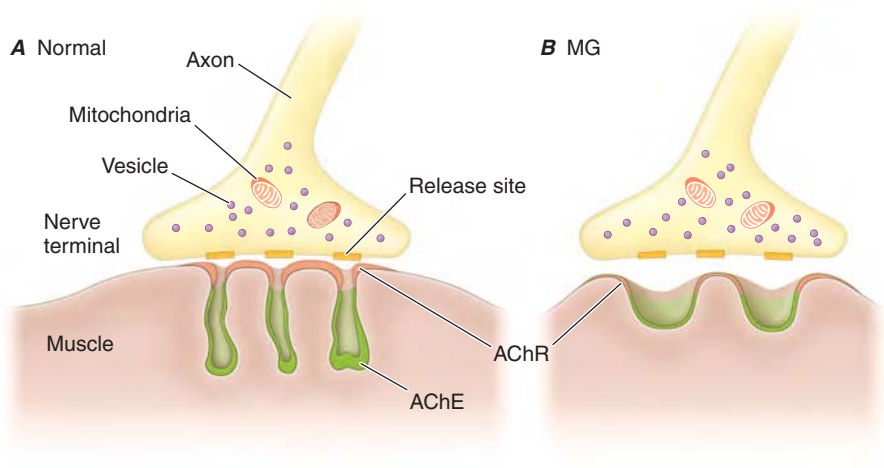

FIGURE 381-1 Diagrams of (*A*) normal and (*B*) myasthenic neuromuscular junctions. AChE, acetylcholinesterase. See text for description of normal neuromuscular transmission. The MG junction demonstrates a normal nerve terminal; a reduced number of AChRs (stippling); flattened, simplified postsynaptic folds; and a widened synaptic space. *(Modified from DB Drachman: N Engl J Med 330:1797, 1994; with permission.)*

clustering. The pathogenic antibodies are IgG and are T cell dependent. Thus, immunotherapeutic strategies directed against T cells are effective in this antibody-mediated disease.

How the autoimmune response is initiated and maintained in MG is not completely understood. However, the thymus appears to play a role in this process. The thymus is abnormal in ~75% of patients with MG; in ~65% the thymus is "hyperplastic," with the presence of active germinal centers detected histologically, though the hyperplastic thymus is not necessarily enlarged. An additional 10% of patients have thymic tumors (thymomas). Muscle-like cells within the thymus (myoid cells), which bear AChRs on their surface, may serve as a source of autoantigen and trigger the autoimmune reaction within the thymus gland.

CLINICAL FEATURES

MG is not rare, having a prevalence of 1–7 in 10,000. It affects individuals in all age groups, but peaks of incidence occur in women in their twenties and thirties and in men in their fifties and sixties. Overall, women are affected more frequently than men, in a ratio of ~3:2. The cardinal features are *weakness* and *fatigability* of muscles. The weakness increases during repeated use (fatigue) and may improve following rest or sleep. The course of MG is often variable. Exacerbations and remissions may occur, particularly during the first few years after the onset of the disease. Remissions are rarely complete or permanent. Unrelated infections or systemic disorders often lead to increased myasthenic weakness and may precipitate "crisis" (see below).

The distribution of muscle weakness often has a characteristic pattern. The cranial muscles, particularly the lids and extraocular muscles, are often involved early in the course of MG, and diplopia and ptosis are common initial complaints. Facial weakness produces a "snarling" expression when the patient attempts to smile. Weakness in chewing is most noticeable after prolonged effort, as in chewing meat. Speech may have a nasal timbre caused by weakness of the palate or a dysarthric "mushy" quality due to tongue weakness. Difficulty in swallowing may occur as a result of weakness of the palate, tongue, or pharynx, giving rise to nasal regurgitation or aspiration of liquids or food. Bulbar weakness is especially prominent in MuSK antibody–positive MG. In ~85% of patients, the weakness becomes generalized, affecting the limb muscles as well. If weakness remains restricted to the extraocular muscles for 3 years, it is likely that it will not become generalized, and these patients are said to have *ocular MG*. The limb weakness in MG is often proximal and may be asymmetric. Despite the muscle weakness, deep tendon reflexes are preserved. If weakness of respiration becomes so severe as to require respiratory assistance, the patient is said to be in *crisis*.

DIAGNOSIS AND EVALUATION

(Table 381-1) The diagnosis is suspected on the basis of weakness and fatigability in the typical distribution described above, without loss of reflexes or impairment of sensation or other neurologic function. The suspected diagnosis should always be confirmed definitively before treatment is undertaken; this is essential because (1) other treatable conditions may closely resemble MG, and (2) the treatment of MG may involve surgery and the prolonged use of drugs with adverse side effects.

Antibodies to AChR or MuSK As noted above, anti-AChR antibodies are detectable in the serum of ~85% of all myasthenic patients but in only about 50% of patients with weakness confined to the ocular muscles. The presence of anti-AChR antibodies is virtually diagnostic of MG, but a negative test does not exclude the disease. The measured level of anti-AChR antibody does not correspond well with the severity of MG in different patients. However, in an individual patient, a treatment-induced fall in the antibody level often correlates with clinical improvement. Antibodies to MuSK have been found to be present in ~40% of AChR antibody-negative patients with generalized MG, and their presence is a useful diagnostic test in these patients. MuSK antibodies are rarely present in AChR antibody-positive patients or in patients with MG limited to ocular muscles. These antibodies may interfere with clustering of AChRs at neuromuscular junctions, as MuSK is known to do during early development. There is also evidence that MG patients without demonstrable antibodies to either AChR or MuSK have other—as yet undefined—antibodies that impair neuromuscular transmission.

Electrodiagnostic Testing Repetitive nerve stimulation often provides helpful diagnostic evidence of MG. Anti-AChE medication is stopped 6–24 h before testing. It is best to test weak muscles or proximal muscle groups. Electric shocks are delivered at a rate of two or three per second to the appropriate nerves, and action potentials are recorded from the muscles. In normal individuals, the amplitude of the evoked muscle action potentials does not change at these rates of stimulation.

TABLE 381-1 DIAGNOSIS OF MYASTHENIA GRAVIS (MG)

History
Diplopia, ptosis, weakness
Weakness in characteristic distribution
Fluctuation and fatigue: worse with repeated activity, improved by rest
Effects of previous treatments
Physical examination
Ptosis, diplopia
Motor power survey: quantitative testing of muscle strength
Forward arm abduction time (5 min)
Vital capacity
Absence of other neurologic signs
Laboratory testing
Anti-AChR radioimmunoassay: ~85% positive in generalized MG; 50% in ocular MG; definite diagnosis if positive; negative result does not exclude MG. ~40% of AChR antibody-negative patients with generalized MG have anti-MuSK antibodies.
Repetitive nerve stimulation; decrement of >15% at 3 Hz: highly probable
Single-fiber electromyography: blocking and jitter, with normal fiber density; confirmatory, but not specific
Edrophonium chloride (Tensilon) 2 mg + 8 mg IV; highly probable diagnosis if unequivocally positive
For ocular or cranial MG: exclude intracranial lesions by CT or MRI

Note: AChR, acetylcholine receptor; MuSK, muscle-specific tyrosine kinase.

TABLE 381-2 THE CONGENITAL MYASTHENIC SYNDROMES

Type	Clinical Features	Electrophysiology	Genetics	End-Plate Effects	Treatment
Slow channel	Most common; weak forearm extensors; onset 2d to 3d decade; variable severity	Repetitive muscle response on nerve stimulation; prolonged channel opening and MEPP duration	Autosomal dominant; α, β, ε AChR mutations	Excitotoxic end-plate myopathy; decreased AChRs; postsynaptic damage	Quinidine: decreases end-plate damage; made worse by anti-AChE
Low-affinity fast channel	Onset early; moderately severe; ptosis, EOM involvement; weakness and fatigue	Brief and infrequent channel openings; opposite of slow channel syndrome	Autosomal recessive; may be heteroallelic	Normal end-plate structure	3,4-DAP; anti-AChE
Severe AChR deficiencies	Early onset; variable severity; fatigue; typical MG features	Decremental response to repetitive nerve stimulation; decreased MEPP amplitudes	Autosomal recessive; ε mutations most common; many different mutations	Increased length of end plates; variable synaptic folds	Anti-AChE; ?3,4-DAP
AChE deficiency	Early onset; variable severity; scoliosis; may have normal EOM, absent pupillary responses	Decremental response to repetitive nerve stimulation	Mutant gene for AChE's collagen anchor	Small nerve terminals; degenerated junctional folds	Worse with anti-AChE drugs

Abbreviations: AChR, acetylcholine receptor; AChE, acetylcholinesterase; EOM, extraocular muscles; MEPP, miniature end-plate potentials; 3,4-DAP, 3-4-diaminopyridine.

However, in myasthenic patients there is a rapid reduction of >10–15% in the amplitude of the evoked responses. As a further test, a single dose of edrophonium may be given to prevent or diminish this decremental response.

Anticholinesterase Test Drugs that inhibit the enzyme AChE allow ACh to interact repeatedly with the limited number of AChRs, producing improvement in the strength of myasthenic muscles. Edrophonium is used most commonly for diagnostic testing because of the rapid onset (30 s) and short duration (~5 min) of its effect. An objective end-point must be selected to evaluate the effect of edrophonium, such as weakness of extraocular muscles, impairment of speech, or the length of time that the patient can maintain the arms in forward abduction. An initial IV dose of 2 mg of edrophonium is given. If definite improvement occurs, the test is considered positive and is terminated. If there is no change, the patient is given an additional 8 mg IV. The dose is administered in two parts because some patients react to edrophonium with side effects such as nausea, diarrhea, salivation, fasciculations, and rarely with severe symptoms of syncope or bradycardia. Atropine (0.6 mg) should be drawn up in a syringe, ready for IV administration if these symptoms become troublesome.

False-positive tests occur in occasional patients with other neurologic disorders, such as amyotrophic lateral sclerosis, and in placeboreactors. False-negative or equivocal tests may also occur. In some cases it is helpful to use a longer-acting drug such as neostigmine (15 mg PO), since this permits more time for detailed evaluation of strength. The edrophonium test is now reserved for patients with clinical findings that are suggestive of MG but who have negative antibody and electrodiagnostic test results.

Inherited Myasthenic Syndromes The congenital myasthenic syndromes (CMS) comprise a heterogeneous group of disorders of the neuromuscular junction that are not autoimmune but rather are due to genetic mutations in which virtually any component of the neuromuscular junction may be affected. Alterations in function of the presynaptic nerve terminal or in the various subunits of the AChR or AChE have been identified in the various forms of CMS. These disorders share many of the clinical features of autoimmune MG, including weakness and fatigability of skeletal muscles, in some cases involving extraocular muscles (EOMs), lids, and proximal muscles, similar to the distribution in autoimmune MG. CMS should be suspected when symptoms of myasthenia have begun in infancy or childhood and AChR antibody tests are consistently negative. Features of four of the most common forms of CMS are summarized in Table 381-2. Although clinical features and electrodiagnostic and pharmacologic tests may suggest the correct diagnosis, molecular analysis is required for precise elucidation of the defect; this may lead to helpful treatment as well as genetic counseling. In the forms that involve the AChR, a wide variety of mutations have been identified in each of the subunits, but the ε subunit is affected in ~75% of these cases. In most of the recessively inherited forms of CMS, the mutations are heteroallelic; that is, different mutations affecting each of the two alleles are present.

Differential Diagnosis Other conditions that cause weakness of the cranial and/or somatic musculature include the nonautoimmune CMS discussed above, drug-induced myasthenia, Lambert-Eaton myasthenic syndrome (LEMS), neurasthenia, hyperthyroidism, botulism, intracranial mass lesions, and progressive external ophthalmoplegia. Treatment with penicillamine (used for scleroderma or rheumatoid arthritis) may result in true autoimmune MG, but the weakness is usually mild, and recovery occurs within weeks or months after discontinuing its use. Aminoglycoside antibiotics or procainamide can cause exacerbation of weakness in myasthenic patients; very large doses can cause neuromuscular weakness in normal individuals.

LEMS is a presynaptic disorder of the neuromuscular junction that can cause weakness similar to that of MG. The proximal muscles of the lower limbs are most commonly affected, but other muscles may be involved as well. Cranial nerve findings, including ptosis of the eyelids and diplopia, occur in up to 70% of patients and resemble features of MG. However, the two conditions are readily distinguished, since patients with LEMS have depressed or absent reflexes, experience autonomic changes such as dry mouth and impotence, and have incremental rather than decremental responses on repetitive nerve stimulation. LEMS is caused by autoantibodies directed against P/Q type calcium channels at the motor nerve terminals, which can be detected in ~85% of LEMS patients by radioimmunoassay. These autoantibodies result in impaired release of ACh from nerve terminals. Most patients with LEMS have an associated malignancy, most commonly small cell carcinoma of the lung, which may express calcium channels that stimulate the autoimmune response. The diagnosis may signal the presence of a tumor long before it would otherwise be detected, permitting early removal. Treatment of LEMS involves plasmapheresis and immunosuppression, as for MG. 3,4-Diaminopyridine (3,4-DAP) and pyridostigmine may also be symptomatically helpful. 3,4-DAP acts by blocking potassium channels, which results in prolonged depolarization of the motor nerve terminals and thus enhances ACh release. Pyridostigmine prolongs the action of ACh, allowing repeated interactions with AChRs.

Botulism is due to a potent bacterial toxin produced by *Clostridium botulinum*. The toxin interferes with the release of acetylcholine from the presynaptic neuromuscular junction, thereby interfering with neuromuscular transmission. The most common form is food-borne botulism from ingestion of food containing toxin; in wound and intestinal botulism spores germinate and give rise to organisms that produce toxin. Patients present with bulbar weakness (e.g., diplopia, dysarthria, dysphagia), but lack sensory symptoms and signs; deep tendon reflexes are preserved early in the disease course. Weakness generalizes to the limbs and may result in respiratory failure; reflexes may be diminished as the disease progresses. Mentation is normal. Autonomic findings include paralytic ileus, constipation, urinary retention, dilated or poorly reactive pupils, and dry mouth. The demonstration of toxin in serum by bioassay is definitive, but may be negative. Nerve conduction studies reveal findings of presynaptic neuromuscular blockade with reduced compound muscle action potentials (CMAPs) that increase in amplitude following high frequency repetitive stimulation. Treatment may include intubation for airway protection, ventilatory support, or aggressive inpatient supportive care (e.g., nutrition, DVT prophylaxis). Equine antitoxin is given rapidly before the results of laboratory studies are available. The prognosis is better among patients with type B infection who are under the age of 60 years. A vaccine is available for highly exposed individuals.

Neurasthenia is the historic term for a myasthenia-like fatigue syndrome without an organic basis. These patients may present with subjective symptoms of weakness and fatigue, but muscle testing usually reveals the "jerky release" or "give-away weakness" characteristic of nonorganic disorders; the complaint of fatigue in these patients means tiredness or apathy rather than decreasing muscle power on repeated effort. Hyperthyroidism is readily diagnosed or excluded by tests of thyroid function, which should be carried out routinely in patients with suspected MG. Abnormalities of thyroid function (hyper- or hypothyroidism) may increase myasthenic weakness. Botulism can cause myasthenic-like weakness, but the pupils are often dilated, and repetitive nerve stimulation gives an incremental response. Diplopia resembling that in MG may occasionally be due to an intracranial mass lesion that compresses nerves to the EOMs (e.g., sphenoid ridge meningioma), but MRI of the head and orbits usually reveals the lesion.

Progressive external ophthalmoplegia is a rare condition resulting in weakness of the EOMs, which may be accompanied by weakness of the proximal muscles of the limbs and other systemic features. Most patients with this condition have mitochondrial disorders that can be detected on muscle biopsy (Chap. 382).

Search for Associated Conditions (Table 381-3) Myasthenic patients have an increased incidence of several associated disorders. Thymic abnormalities occur in ~75% of patients, as noted above. Neoplastic change (thymoma) may produce enlargement of the thymus, which is detected by CT or MRI scanning of the anterior mediastinum. A thymic shadow on CT scan may normally be present through young adulthood, but enlargement of the thymus in a patient >40 years old is highly suspicious of thymoma. Hyperthyroidism occurs in 3–8% of patients and may aggravate the myasthenic weakness. Thyroid function tests should be obtained in all patients with suspected MG. Because of the association of MG with other autoimmune disorders, blood tests for rheumatoid factor and antinuclear antibodies should also be carried out. Chronic infection of any kind can exacerbate MG and should be sought carefully. Finally, measurements of ventilatory function are valuable because of the frequency and seriousness of respiratory impairment in myasthenic patients.

Because of the side effects of glucocorticoids and other immunosuppressive agents used in the treatment of MG, a thorough medical investigation should be undertaken, searching specifically for evidence of chronic or latent infection (such as tuberculosis or hepatitis), hypertension, diabetes, renal disease, and glaucoma.

TABLE 381-3 DISORDERS ASSOCIATED WITH MYASTHENIA GRAVIS AND RECOMMENDED LABORATORY TESTS

Associated disorders
Disorders of the thymus: thymoma, hyperplasia
Other autoimmune disorders: Hashimoto's thyroiditis, Graves' disease, rheumatoid arthritis, lupus erythematosus, skin disorders, family history of autoimmune disorder
Disorders or circumstances that may exacerbate myasthenia gravis: hyperthyroidism or hypothyroidism, occult infection, medical treatment for other conditions (see Table 381-4)
Disorders that may interfere with therapy: tuberculosis, diabetes, peptic ulcer, gastrointestinal bleeding, renal disease, hypertension, asthma, osteoporosis, obesity
Recommended laboratory tests or procedures
CT or MRI of mediastinum
Tests for lupus erythematosus, antinuclear antibody, rheumatoid factor, antithyroid antibodies
Thyroid-function tests
PPD skin test
Chest radiography
Fasting blood glucose measurement, hemoglobin A1c
Pulmonary-function tests
Bone densitometry in older patients

Note: PPD, purified protein derivative.

MYASTHENIA GRAVIS

The prognosis has improved strikingly as a result of advances in treatment; virtually all myasthenic patients can be returned to full productive lives with proper therapy. The most useful treatments for MG include anticholinesterase medications, immunosuppressive agents, thymectomy, and plasmapheresis or intravenous immunoglobulin (IVIg) **(Fig. 381-2)**.

ANTICHOLINESTERASE MEDICATIONS Anticholinesterase medication produces at least partial improvement in most myasthenic patients, although improvement is complete in only a few. Pyridostigmine is the most widely used anticholinesterase drug. As a rule, the beneficial action of oral pyridostigmine begins within 15–30 min and lasts for 3–4 h, but individual responses vary. Treatment is begun with a moderate dose, e.g., 30–60 mg three to four times daily. The frequency and amount of the dose should be tailored to the patient's individual requirements throughout the day. For example, patients with weakness in chewing and swallowing may benefit by taking the medication before meals so that peak strength coincides with mealtimes. Long-acting pyridostigmine may occasionally be useful to get the patient through the night but should never be used for daytime medication because of variable absorption. The maximum useful dose of pyridostigmine rarely exceeds 120 mg every 3–6 h during daytime. Overdosage with anticholinesterase medication may cause increased weakness and other side effects. In some patients, muscarinic side effects of the anticholinesterase medication (diarrhea, abdominal cramps, salivation, nausea) may limit the dose tolerated. Atropine/diphenoxylate or loperamide is useful for the treatment of gastrointestinal symptoms.

THYMECTOMY Two separate issues should be distinguished: (1) surgical removal of thymoma, and (2) thymectomy as a treatment for MG. Surgical removal of a thymoma is necessary because of the possibility of local tumor spread, although most thymomas are histologically benign. In the absence of a tumor, the available evidence suggests that up to 85% of patients experience improvement after thymectomy; of these, ~35% achieve drug-free remission. However, the improvement is typically delayed for months to years. The advantage of thymectomy is that it offers the possibility of long-term benefit, in some cases diminishing or eliminating the need for continuing medical treatment. In view of these potential benefits and of the negligible risk in skilled hands, thymectomy has gained widespread acceptance in the treatment of MG. It is the consensus that thymectomy should be carried out in all patients with generalized MG who are between the ages of puberty and at least 55 years. Whether thymectomy should be recommended in children, in adults >55 years of age, and in patients with weakness limited to the ocular muscles is still a matter of debate. There is also evidence that patients with MuSK antibody–positive MG may not respond to thymectomy. Thymectomy must be carried out in a hospital where it is performed regularly and where the staff is experienced in the pre- and postoperative management, anesthesia, and surgical techniques of total thymectomy.

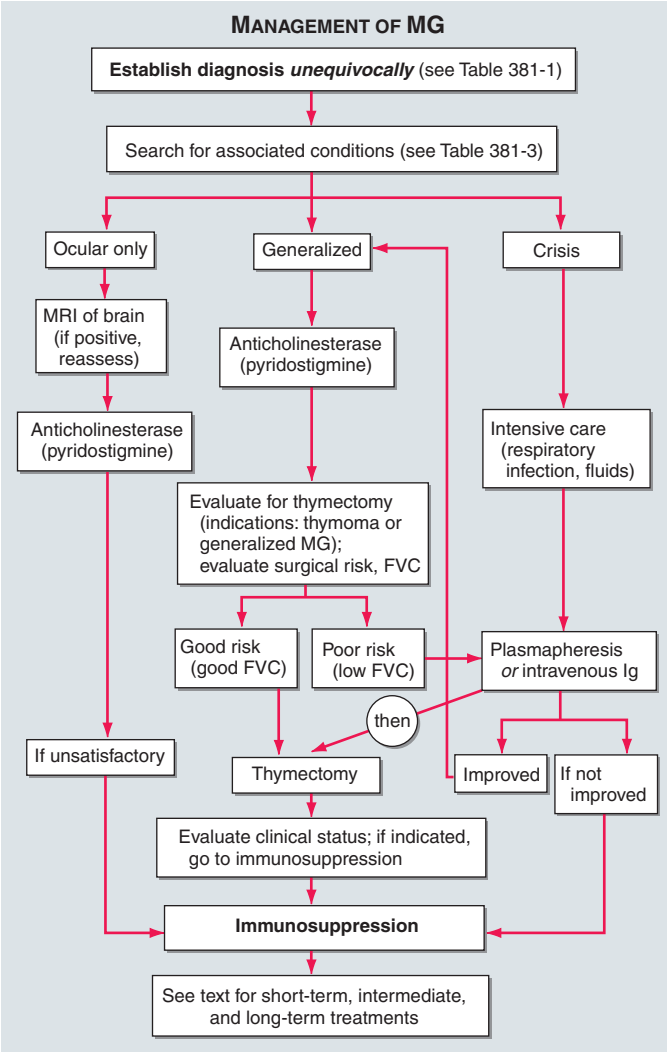

FIGURE 381-2 Algorithm for the management of myasthenia gravis. FVC, forced vital capacity.

IMMUNOSUPPRESSION Immunosuppression using glucocorticoids, azathioprine, and other drugs is effective in nearly all patients with MG. The choice of drugs or other immunomodulatory treatments should be guided by the relative benefits and risks for the individual patient and the urgency of treatment. It is helpful to develop a treatment plan based on short-term, intermediate-term, and long-term objectives. For example, if immediate improvement is essential either because of the severity of weakness or because of the patient's need to return to activity as soon as possible, IVIg should be administered or plasmapheresis should be undertaken. For the intermediate term, glucocorticoids and cyclosporine or tacrolimus generally produce clinical improvement within a period of 1–3 months. The beneficial effects of azathioprine and mycophenolate mofetil usually begin after many months (up to a year), but these drugs have advantages for the long-term treatment of patients with MG. For the occasional patient with MG that is genuinely refractory to optimal treatment with conventional immunosuppressive agents, a course of high-dose cyclophosphamide may induce long-lasting (possibly permanent) benefit by "rebooting" the immune system. At high doses, cyclophosphamide eliminates mature lymphocytes, but hematopoietic precursors (stem cells) are spared, because they express the enzyme aldehyde dehydrogenase, which hydrolyzes cyclophosphamide. At present, this procedure is reserved for refractory patients and should be administered only in a facility fully familiar with this approach.

Glucocorticoid Therapy Glucocorticoids, when used properly, produce improvement in myasthenic weakness in the great majority of patients. To minimize adverse side effects, prednisone should be given in a single dose rather than in divided doses throughout the day. The initial dose should be relatively low (15–25 mg/d) to avoid the early weakening that occurs in about one-third of patients treated initially with a high-dose regimen. The dose is increased stepwise, as tolerated by the patient (usually by 5 mg/d at 2- to 3-day intervals), until there is marked clinical improvement or a dose of 50–60 mg/d is reached. This dose is maintained for 1–3 months and then is gradually modified to an alternate-day regimen over the course of an additional 1–3 months; the goal is to reduce the dose on the "off day" to zero or to a minimal level. Generally, patients begin to improve within a few weeks after reaching the maximum dose, and improvement continues to progress for months or years. The prednisone dosage may gradually be reduced, but usually months or years may be needed to determine the minimum effective dose, and close monitoring is required. Few patients are able to do without immunosuppressive agents entirely. Patients on long-term glucocorticoid therapy must be followed carefully to prevent or treat adverse side effects. The most common errors in glucocorticoid treatment of myasthenic patients include (1) insufficient persistence—improvement may be delayed and gradual; (2) too early, too rapid, or excessive tapering of dosage; and (3) lack of attention to prevention and treatment of side effects. **The management of patients treated with glucocorticoids is discussed in Chap. 336.**

Other Immunosuppressive Drugs Mycophenolate mofetil, azathioprine, cyclosporine, tacrolimus, and occasionally cyclophosphamide are effective in many patients, either alone or in various combinations.

Mycophenolate mofetil has become one of the most widely used drugs in the treatment of MG because of its effectiveness and relative lack of side effects. A dose of 1–1.5 g bid is recommended. Its mechanism of action involves inhibition of purine synthesis by the de novo pathway. Since lymphocytes lack the alternative salvage pathway that is present in all other cells, mycophenolate inhibits proliferation of lymphocytes but not proliferation of other cells. It does not kill or eliminate preexisting autoreactive lymphocytes, and therefore clinical improvement may be delayed for many months to a year, until the preexisting autoreactive lymphocytes die spontaneously. The advantage of mycophenolate lies in its relative lack of adverse side effects, with only occasional production of diarrhea and rare development of leukopenia. This drug has become the choice for long-term treatment of myasthenic patients. Unfortunately, the cost of mycophenolate is still very high (~$6400 U.S. annually for 1g bid).

Until recently, azathioprine has been the most widely used of these drugs because of its relative safety in most patients and long track record. Its therapeutic effect may add to that of glucocorticoids and/or allow the glucocorticoid dose to be reduced. However, up to 10% of patients are unable to tolerate azathioprine because of idiosyncratic reactions consisting of flulike symptoms of fever and malaise, bone marrow depression, or abnormalities of liver function. An initial dose of 50 mg/d should be used to test for adverse side effects. If this dose is tolerated, it is increased gradually until the white blood count falls to ~3000–4000/μL. In patients who are receiving glucocorticoids concurrently, leukocytosis precludes the use of this measure. A reduction of the lymphocyte count to <1000/μL and/or an increase of the mean corpuscular volume of red blood cells may be used as indications of adequacy of azathioprine dosage. The typical dosage range is 2–3 mg/kg total body weight. The beneficial effect of azathioprine takes at least 3–6 months to begin and even longer to peak. In patients taking azathioprine, allopurinol should never be used to treat hyperuricemia, because the two drugs share a common degradation pathway; the result may be severe bone marrow depression due to increased effects of the azathioprine.

The calcineurin inhibitors cyclosporine and tacrolimus (FK506) are approximately as effective as azathioprine and are being used increasingly in the management of MG. Their beneficial effect appears more rapidly than that of azathioprine. Either drug may be used alone, but they are usually used as an adjunct to glucocorticoids to permit reduction of the glucocorticoid dose. The usual dose of cyclosporine is 4–5 mg/kg per day, and the average dose of tacrolimus is 0.1 mg/kg per day, given in two equally divided doses (to minimize side effects). Side effects of these drugs include hypertension and nephrotoxicity, which must be closely monitored. "Trough" blood levels are measured 12 h after the evening dose. The therapeutic range for cyclosporine is 150–200 ng/L, and for tacrolimus it is 5–15 ng/L.

Cyclophosphamide is reserved for occasional patients refractory to the other drugs (see above for discussion of high-dose cyclophosphamide treatment).

PLASMAPHERESIS AND INTRAVENOUS IMMUNOGLOBULIN Plasmapheresis has been used therapeutically in MG. Plasma, which contains the pathogenic antibodies, is mechanically separated from the blood cells, which are returned to the patient. A course of five exchanges (3–4 L

per exchange) is generally administered over a 10- to 14-day period. Plasmapheresis produces a short-term reduction in anti-AChR antibodies, with clinical improvement in many patients. It is useful as a temporary expedient in seriously affected patients or to improve the patient's condition prior to surgery (e.g., thymectomy).

The indications for the use of IVIg are the same as those for plasma exchange: to produce rapid improvement to help the patient through a difficult period of myasthenic weakness or prior to surgery. This treatment has the advantages of not requiring special equipment or large-bore venous access. The usual dose is 2 g/kg, which is typically administered over 5 days (400 mg/kg per day). If tolerated, the course of IVIg can be shortened to administer the entire dose over a 3-day period. Improvement occurs in ~70% of patients, beginning during treatment, or within a week, and continuing for weeks to months. The mechanism of action of IVIg is not known; the treatment has no consistent effect on the measurable amount of circulating AChR antibody. Adverse reactions are generally not serious but include headache, fluid overload, and rarely aseptic meningitis or renal failure. IVIg should rarely be used as a long-term treatment in place of rationally managed immunosuppressive therapy. Unfortunately, there is a tendency for physicians unfamiliar with immunosuppressive treatments to rely on repeated IVIg infusions, which are inconvenient, usually produce only intermittent benefit, and are costly. The intermediate and long-term treatment of myasthenic patients requires other methods of therapy outlined earlier in this chapter.

MANAGEMENT OF MYASTHENIC CRISIS Myasthenic crisis is defined as an exacerbation of weakness sufficient to endanger life; it usually consists of respiratory failure caused by diaphragmatic and intercostal muscle weakness. Crisis rarely occurs in properly managed patients. Treatment should be carried out in intensive care units staffed with teams experienced in the management of MG, respiratory insufficiency, infectious disease, and fluid and electrolyte therapy. The possibility that deterioration could be due to excessive anticholinesterase medication ("cholinergic crisis") is best excluded by temporarily stopping anticholinesterase drugs. The most common cause of crisis is intercurrent infection. This should be treated immediately, because the mechanical and immunologic defenses of the patient can be assumed to be compromised. The myasthenic patient with fever and early infection should be treated like other immunocompromised patients. Early and effective antibiotic therapy, respiratory assistance, and pulmonary physiotherapy are essentials of the treatment program. As discussed above, plasmapheresis or IVIg is frequently helpful in hastening recovery.

DRUGS TO AVOID IN MYASTHENIC PATIENTS Many drugs have been reported to have adverse effects in patients with MG **(Table 381-4)**. However, not all patients react adversely to all these drugs. Conversely, not all "safe" drugs can be used with impunity in patients with MG. As a rule, the listed drugs should be avoided *whenever possible*, and myasthenic patients should be followed closely when *any new drug* is introduced.

TABLE 381-4 DRUGS WITH INTERACTIONS IN MYASTHENIA GRAVIS (MG)

Drugs That May Exacerbate MG
Antibiotics
Aminoglycosides: e.g., streptomycin, tobramycin, kanamycin
Quinolones: e.g., ciprofloxacin, levofloxacin, ofloxacin, gatifloxacin
Macrolides: e.g., erythromycin, azithromycin, telithromycin
Nondepolarizing muscle relaxants for surgery
D-Tubocurarine (curare), pancuronium, vecuronium, atracurium
Beta-blocking agents
Propranalol, atenolol, metoprolol
Local anesthetics and related agents
Procaine, xylocaine in large amounts
Procainamide (for arrhythmias)
Botulinum toxin
Botox exacerbates weakness
Quinine derivatives
Quinine, quinidine, chloroquine, mefloquine (Lariam)
Magnesium
Decreases ACh release
Penicillamine
May cause MG
Drugs with Important Interactions in MG
Cyclosporine
Broad range of drug interactions, which may raise or lower cyclosporine levels.
Azathioprine
Avoid allopurinol—combination may result in myelosuppression.

Myasthenia Gravis Worksheet

History				
General	Normal	Good	Fair	Poor
Diplopia	None	Rare	Occasional	Constant
Ptosis	None	Rare	Occasional	Constant

FIGURE 381-3 Abbreviated interval assessment form for use in evaluating treatment for myasthenia gravis.

PATIENT ASSESSMENT

In order to evaluate the effectiveness of treatment as well as drug-induced side effects, it is important to assess the patient's clinical status systematically at baseline and on repeated interval examinations. Because of the variability of symptoms of MG, the interval history and physical findings on examination must be taken into account. The most useful clinical tests include forward arm abduction time (up to a full 5 min), forced vital capacity, range of eye movements, and time to development of ptosis on upward gaze. Manual muscle testing or, preferably, quantitative dynamometry of limb muscles, especially proximal muscles, is also important. An interval form can provide a succinct summary of the patient's status and a guide to treatment results; an abbreviated form is shown in **Fig. 381-3**. A progressive reduction in the patient's AChR antibody level also provides clinically valuable confirmation of the effectiveness of treatment; conversely, a rise in AChR antibody levels during tapering of immunosuppressive medication may predict clinical exacerbation. For reliable quantitative measurement of AChR antibody levels, it is best to compare antibody levels from prior frozen serum aliquots with current serum samples in simultaneously run assays.

382 Muscular Dystrophies and Other Muscle Diseases

Robert H. Brown, Jr., Anthony A. Amato, Jerry R. Mendell

Skeletal muscle diseases, or myopathies, are disorders with structural changes or functional impairment of muscle. These conditions can be differentiated from other diseases of the motor unit (e.g., lower motor neuron or neuromuscular junction pathologies) by characteristic clinical and laboratory findings. **Myasthenia gravis and related disorders are discussed in Chap. 381; dermatomyositis, polymyositis, and inclusion body myositis are discussed in Chap. 383.**

CLINICAL FEATURES

The most common clinical findings of a myopathy are proximal, symmetric limb weakness (arms or legs) with preserved reflexes and sensation. An associated sensory loss suggests injury to peripheral nerve or the central nervous system (CNS) rather than myopathy. On occasion, disorders affecting the motor nerve cell bodies in the spinal cord (anterior horn cell disease), the neuromuscular junction, or peripheral nerves can mimic findings of myopathy.

Muscle Weakness Symptoms of muscle weakness can be either intermittent or persistent. Disorders causing *intermittent weakness* (Fig. 382-1) include myasthenia gravis, periodic paralyses (hypokalemic, hyperkalemic, and paramyotonia congenita), and metabolic energy deficiencies of glycolysis (especially myophosphorylase deficiency) and fatty acid utilization (carnitine palmitoyltransferase deficiency and some mitochondrial myopathies). The states of energy deficiency cause activity-related muscle breakdown accompanied by myoglobinuria, appearing as light-brown- to dark-brown-colored urine.

Most muscle disorders cause *persistent weakness* (Fig. 382-2). In the majority of these, including most types of muscular dystrophy, polymyositis, and dermatomyositis, the proximal muscles are weaker than the distal and are symmetrically affected, and the facial muscles are spared, a pattern referred to as *limb-girdle*. The differential diagnosis is more restricted for other patterns of weakness. Facial weakness (difficulty with eye closure and impaired smile) and scapular winging (Fig. 382-3) are characteristic of facioscapulohumeral dystrophy. Facial and distal limb weakness associated with hand grip myotonia is virtually diagnostic of myotonic dystrophy. When other cranial nerve muscles are weak, causing ptosis or extraocular muscle weakness, the most important disorders to consider include neuromuscular junction disorders, oculopharyngeal muscular dystrophy, mitochondrial myopathies, or some of the congenital myopathies (Table 382-1). A pathognomonic pattern characteristic of inclusion body myositis is atrophy and weakness of the flexor forearm (e.g., wrist and finger flexors) and quadriceps muscles that is often asymmetric. Less frequently, but important diagnostically, is the presence of a dropped head syndrome indicative of selective neck extensor muscle weakness. The most important neuromuscular diseases associated with this pattern of weakness include myasthenia gravis, amyotrophic lateral sclerosis, late-onset nemaline myopathy, hyperparathyroidism, focal myositis, and some forms of inclusion body myopathy. A final pattern, recognized because of preferential distal extremity weakness, is typical of a unique category of muscular dystrophy, the distal myopathies.

It is important to examine functional capabilities to help disclose certain patterns of weakness (Table 382-2). The Gowers' sign (Fig. 382-4) is particularly useful. Observing the gait of an individual may disclose a lordotic posture caused by combined trunk and hip weakness, frequently exaggerated by toe walking (Fig. 382-5). A waddling gait is caused by the inability of weak hip muscles to prevent hip drop or hip dip. Hyperextension of the knee (genu recurvatum or back-kneeing) is characteristic of quadriceps muscle weakness; and a steppage gait, due to footdrop, accompanies distal weakness.

Any disorder causing muscle weakness may be accompanied by *fatigue*, referring to an inability to maintain or sustain a force (pathologic fatigability). This condition must be differentiated from asthenia, a type of fatigue caused by excess tiredness or lack of energy. Associated symptoms may help differentiate asthenia and pathologic fatigability. Asthenia is often accompanied by a tendency to avoid physical activities, complaints of daytime sleepiness, necessity for frequent naps, and difficulty concentrating on activities such as reading. There may be feelings of overwhelming stress and depression. Thus, asthenia is not a myopathy. In contrast, pathologic fatigability occurs in disorders of neuromuscular transmission and in disorders altering energy production, including defects in glycolysis, lipid metabolism, or mitochondrial energy production. Pathologic fatigability also occurs in chronic myopathies because of difficulty accomplishing a task with less muscle. Pathologic fatigability is accompanied by abnormal clinical or lab-

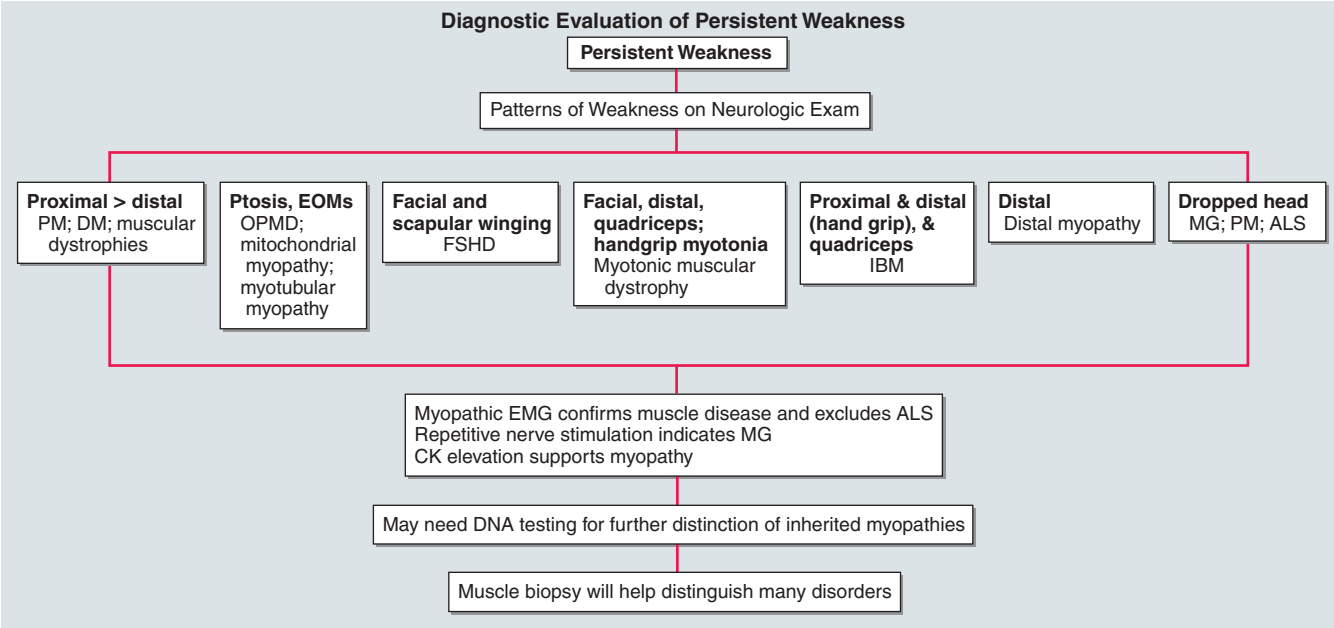

FIGURE 382-2 Diagnostic evaluation of persistent weakness. Examination reveals one of seven patterns of weakness. The pattern of weakness in combination with the laboratory evaluation leads to a diagnosis. EOM, extraocular muscles; OPMD, oculopharyngeal muscular dystrophy; FSHD, facioscapulohumeral dystrophy; IBM, inclusion body myositis; DM, dermatomyositis; PM, polymyositis; MG, myasthenia gravis; ALS, amyotrophic lateral sclerosis; CK, creatine kinase.

oratory findings. Fatigue without those supportive features almost never indicates a primary muscle disease.

Muscle Pain (Myalgias), Cramps, and Stiffness Muscle pain can be associated with cramps, spasms, contractures, and stiff or rigid muscles. In distinction, true myalgia (muscle aching), which can be localized or generalized, may be accompanied by weakness, tenderness to palpation, or swelling. Certain drugs cause true myalgia (Table 382-3).

There are two painful muscle conditions of particular importance, neither of which is associated with muscle weakness. *Fibromyalgia* is a common, yet poorly understood type of myofascial pain syndrome. Patients complain of severe muscle pain and tenderness and have specific painful trigger points, sleep disturbances, and easy fatigability. Serum creatine kinase (CK), erythrocyte sedimentation rate (ESR), electromyography (EMG), and muscle biopsy are normal (Chap. 329). *Polymyalgia rheumatica* occurs mainly in patients >50 years and is characterized by stiffness and pain in the shoulders, lower back, hips, and thighs (Chap. 319). The ESR is elevated, while serum CK, EMG, and muscle biopsy are normal. Temporal arteritis, an inflammatory disorder of medium- and large-sized arteries, usually involving one or more branches of the carotid artery, may accompany polymyalgia rheumatica. Vision is threatened by ischemic optic neuritis. Glucocorticoids can relieve the myalgias and protect against visual loss.

Localized muscle pain is most often traumatic. A common cause of sudden abrupt-onset pain is a ruptured tendon, which leaves the muscle belly appearing rounded and shorter in appearance compared to the normal side. The biceps brachii and Achilles tendons are particularly vulnerable to rupture. Infection or neoplastic infiltration of the muscle is a rare cause of localized muscle pain.

A *muscle cramp* or *spasm* is a painful, involuntary, localized, muscle contraction with a visible or palpable hardening of the muscle. Cramps are abrupt in onset, short in duration, and may cause abnormal posturing of the joint. The EMG shows firing of motor units, reflecting an origin from spontaneous neural discharge. Muscle cramps often occur in neurogenic disorders, especially motor neuron disease (Chap. 369), radiculopathies, and polyneuropathies (Chap. 379), but are not a feature of most primary muscle diseases. Duchenne muscular dystrophy is an exception since calf muscle complaints are a common complaint. Muscle cramps are also common during pregnancy.

FIGURE 382-5 Lordotic posture, exaggerated by standing on toes, associated with trunk and hip weakness.

A *muscle contracture* is different from a muscle cramp. In both conditions, the muscle becomes hard, but a contracture is associated with energy failure in glycolytic disorders. The muscle is unable to relax after an active muscle contraction. The EMG shows electrical silence. Confusion is created because contracture also refers to a muscle that cannot be passively stretched to its proper length (fixed contracture) because of fibrosis. In some muscle disorders, especially in Emery-Dreifuss muscular dystrophy and Bethlem myopathy, fixed contractures occur early and represent distinctive features of the disease.

Muscle stiffness can refer to different phenomena. Some patients with inflammation of joints and periarticular surfaces feel stiff. This condition is different from the disorders of hyperexcitable motor nerves causing stiff or rigid muscles. In *stiff-person syndrome* spontaneous discharges of the motor neurons of the spinal cord cause involuntary muscle contractions mainly involving the axial (trunk) and proximal lower extremity muscles. The gait becomes stiff and labored, with hyperlordosis of the lumbar spine. Superimposed episodic muscle spasms are precipitated by sudden movements, unexpected noises, and emotional upset. The muscles relax during sleep. Serum antibodies against glutamic acid decarboxylase are present in approximately two-thirds of cases. In *neuromyotonia* (*Isaacs' syndrome*) there is hyperexcitability of the peripheral nerves manifesting as continuous muscle fiber activity. *Myokymia* (groups of fasciculations associated with continuous undulations of muscle) and impaired muscle relax-

ation are the result. Muscles of the leg are stiff, and the constant contractions of the muscle cause increased sweating of the extremities. This peripheral nerve hyperexcitability is antibody-mediated, targeted against voltage-gated potassium channels. The site of origin of the spontaneous nerve discharges is principally in the distal portion of the motor nerves.

Myotonia is a condition of prolonged muscle contraction followed by slow muscle relaxation. It always follows muscle activation (action myotonia), usually voluntary, but may be elicited by mechanical stimulation (percussion myotonia) of the muscle. Myotonia typically causes difficulty in releasing objects after a firm grasp. In myotonic muscular dystrophy type 1 (DM1), distal weakness usually accompanies myotonia, whereas in DM2 proximal muscles are more affected; thus the related term *proximal myotonic myopathy* (PROMM) is used to describe this condition. Myotonia also occurs with *myotonia congenita* (a chloride channel disorder), but in this condition muscle weakness is not prominent. Myotonia may also be seen in individuals with sodium channel mutations (*hyperkalemic periodic paralysis* or *potassium-sensitive myotonia*). Another sodium channelopathy, *paramyotonia congenita,* also is associated with muscle stiffness. In contrast to other disorders associated with myotonia in which the myotonia is eased by repetitive activity, paramyotonia congenita is named for a paradoxical phenomenon whereby the myotonia worsens with repetitive activity.

Muscle Enlargement and Atrophy In most myopathies muscle tissue is replaced by fat and connective tissue, but the size of the muscle is usually not affected. However, in many limb-girdle muscular dystrophies (and particularly the dystrophinopathies) enlarged calf muscles are typical. The enlargement represents true muscle hypertrophy, thus the term "pseudohypertrophy" should be avoided when referring to these patients. The calf muscles remain very strong even late in the course of these disorders. Muscle enlargement can also result from infiltration by sarcoid granulomas, amyloid deposits, bacterial and parasitic infections, and focal myositis. In contrast, muscle atrophy is characteristic of other myopathies. In dysferlinopathies (LGMD2B) there is a predilection for early atrophy of the gastrocnemius muscles. Atrophy of the humeral muscles is characteristic of facioscapulohumeral muscular dystrophy.

LABORATORY EVALUATION

A limited battery of tests can be used to evaluate a suspected myopathy. Nearly all patients require serum enzyme level measurements and electrodiagnostic studies as screening tools to differentiate muscle disorders from other motor unit diseases. The other tests described—DNA studies, the forearm exercise test, and muscle biopsy—are used to diagnose specific types of myopathies.

Serum Enzymes CK is the preferred muscle enzyme to measure in the evaluation of myopathies. Damage to muscle causes the CK to leak from the muscle fiber to the serum. The MM isoenzyme predominates in skeletal muscle, while CK-MB is the marker for cardiac muscle. Serum CK can be elevated in normal individuals without provocation, presumably on a genetic basis or after strenuous activity, minor trauma (including the EMG needle), a prolonged muscle cramp, or a generalized seizure. Aspartate aminotransferase (AST), alanine aminotransferase (ALT), aldolase, and lactic dehydrogenase (LDH) are enzymes sharing an origin in both muscle and liver. Problems arise when the levels of these enzymes are found to be elevated in a routine screening battery, leading to the erroneous assumption that liver disease is present when in fact muscle could be the cause. An elevated γ-glutamyl transferase (GGT) helps to establish a liver origin since this enzyme is not found in muscle.

Electrodiagnostic Studies EMG, repetitive nerve stimulation, and nerve conduction studies (**Chap. e31**) are essential methods for evaluation of the patient with suspected muscle disease. In combination they provide the information necessary to differentiate myopathies from neuropathies and neuromuscular junction diseases. Routine nerve conduction studies are typically normal in myopathies but reduced amplitudes of compound muscle action potentials may be seen in atrophied muscles. The needle EMG may reveal irritability on needle placement suggestive of a necrotizing myopathy (inflammatory myopathies, dystrophies, toxic myopathies, myotonic myopathies), whereas a lack of irritability is characteristic of long-standing myopathic disorders (muscular dystrophies, endocrine myopathies, disuse atrophy, and many of the metabolic myopathies). In addition, the EMG may demonstrate myotonic discharges that will narrow the differential diagnosis **(Table 382-4)**. Another important EMG finding is the presence of short-duration, small-amplitude, polyphasic motor unit action potentials (MUAPs). Such MUAPs can be seen in both myopathic and neuropathic disorders; however, the recruitment or firing pattern is different. In myopathies, the MUAPs fire early but at a normal rate to compensate for the loss of individual muscle fibers, whereas in neurogenic disorders the MUAPs fire faster. The EMG is usually normal in steroid or disuse myopathy, both of which are associated with type 2 fiber atrophy; this is because the EMG preferentially assesses the physiologic function of type 1 fibers. The EMG can also be invaluable in helping to choose an appropriately affected muscle to sample for biopsy.

DNA Analysis This now serves as an important tool for the definitive diagnosis of many muscle disorders. Nevertheless, there are a number of limitations in currently available molecular diagnostics. For example, in Duchenne and Becker dystrophies, two-thirds of patients have deletion or duplication mutations that are easy to detect, while the remainder have point mutations that are much more difficult to find. For patients without identifiable gene defects, the muscle biopsy remains the main diagnostic tool.

Forearm Exercise Test In myopathies with intermittent symptoms, and especially those associated with myoglobinuria, there may be a defect in glycolysis. Many variations of the forearm exercise test exist. For safety, the test should not be performed under ischemic conditions to avoid an unnecessary insult to the muscle, causing rhabdomyolysis. The test is performed by placing a small indwelling catheter into an antecubital vein. A baseline blood sample is obtained for lactic acid and ammonia. The forearm muscles are exercised by asking the patient to vigorously open and close the hand for 1 min. Blood is then obtained at intervals of 1, 2, 4, 6, and 10 min for comparison with the baseline sample. A three- to fourfold rise of lactic acid is typical. The simultaneous measurement of ammonia serves as a control, since it should also rise with exercise. In patients with myophosphorylase deficiency or other glycolytic defects, the lactic acid rise will be absent or below normal, while the rise in ammonia will reach control values. If there is lack of effort, neither lactic acid nor ammonia will rise. Patients with selective failure to increase ammonia may have myoadenylate deaminase deficiency. This condition has been reported to be a cause of myoglobinuria, but deficiency of this enzyme in asymptomatic individuals makes interpretation controversial.

Muscle Biopsy Muscle biopsy is an important step in establishing the diagnosis of a suspected myopathy. The biopsy is usually obtained from a

TABLE 382-5 PROGRESSIVE MUSCULAR DYSTROPHIES

Type	Inheritance	Defective Gene/Protein	Onset Age	Clinical Features	Other Organ Systems Involved
Duchenne	XR	Dystrophin	Before 5 years	Progressive weakness of girdle muscles Unable to walk after age 12 Progressive kyphoscoliosis Respiratory failure in 2d or 3d decade	Cardiomyopathy Mental impairment
Becker	XR	Dystrophin	Early childhood to adult	Progressive weakness of girdle muscles Able to walk after age 15 Respiratory failure may develop by 4th decade	Cardiomyopathy
Limb-girdle	AD/AR	Several (Tables 382-6, 382-7)	Early childhood to early adult	Slow progressive weakness of shoulder and hip girdle muscles	± Cardiomyopathy
Emery-Dreifuss	XR/AD	Emerin/Lamins A/C	Childhood to adult	Elbow contractures, humeral and peroneal weakness	Cardiomyopathy
Congenital	AR	Several	At birth or within first few months	Hypotonia, contractures, delayed milestones Progression to respiratory failure in some; static course in others	CNS abnormalities (hypomyelination, malformation) Eye abnormalities
Myotonic[a] (DM1, DM2)	AD	DM1: Expansion CTG repeat DM2: Expansion CCTG repeat	Usually 2d decade May be infancy if mother affected (DM1 only)	Slowly progressive weakness of face, shoulder girdle, and foot dorsiflexion Preferential proximal weakness in DM2	Cardiac conduction defects Mental impairment Cataracts Frontal baldness Gonadal atrophy
Facioscapulohumeral	AD	Deletion, distal 4q	Before age 20	Slowly progressive weakness of face, shoulder girdle, and foot dorsiflexion	Deafness Coats' (eye) disease
Oculopharyngeal	AD	Expansion, poly-A RNA binding protein	5th to 6th decade	Slowly progressive weakness of extraocular, pharyngeal, and limb muscles	—

[a] Two forms of myotonic dystrophy, DM1 and DM2, have been identified. Many features overlap (see text).

quadriceps or biceps brachii muscle, less commonly from a deltoid muscle. Evaluation includes a combination of techniques—light microscopy, histochemistry, immunocytochemistry with a battery of antibodies, and electron microscopy. Not all techniques are needed for every case. A specific diagnosis can be established in many disorders. A combination of stains to identify mononuclear cells (polymyositis), complement (dermatomyositis), and amyloid (inclusion body myositis) helps to distinguish the inflammatory myopathies. In addition, the congenital myopathies have distinctive light and electron microscopy features essential for diagnosis. Mitochondrial and metabolic (e.g., myophosphorylase and acid maltase deficiencies) myopathies also demonstrate distinctive histochemical and electron-microscopic profiles. Biopsied muscle tissue can be sent for metabolic enzyme or mitochondrial DNA analyses. A battery of antibodies is available for the identification of missing components of the dystrophin-glycoprotein complex and related proteins to help diagnose specific types of muscular dystrophies. Western blot analysis on muscle specimens can be performed to determine whether specific muscle proteins are reduced in quantity or are of abnormal size.

HEREDITARY MYOPATHIES

Muscular dystrophy refers to a group of hereditary progressive diseases each with unique phenotypic and genetic features (Tables 382-5, 382-6, and 382-7).

DUCHENNE MUSCULAR DYSTROPHY

This X-linked recessive disorder, sometimes also called *pseudohypertrophic muscular dystrophy*, has an incidence of ~30 per 100,000 live-born males.

Clinical Features Duchenne dystrophy is present at birth, but the disorder usually becomes apparent between ages 3 and 5. The boys fall frequently and have difficulty keeping up with friends when playing. Running, jumping, and hopping are invariably abnormal. By age 5, muscle weakness is obvious by muscle testing. On getting up from the floor, the patient uses his hands to climb up himself [Gowers' maneuver (Fig. 382-4)]. Contractures of the heel cords and iliotibial bands become apparent by age 6, when toe walking is associated with a lordotic posture. Loss of muscle strength is progressive, with predilection for proximal limb muscles and the neck flexors; leg involvement is more severe than arm involvement. Between ages 8 and 10 walking may require the use of braces; joint contractures and limitations of hip flexion, knee, elbow, and wrist extension are made worse by prolonged sitting. By age 12, most patients are wheelchair dependent. Contrac-

TABLE 382-6 AUTOSOMAL DOMINANT LIMB-GIRDLE MUSCULAR DYSTROPHIES (LGMDS)

Disease	Clinical Features	Laboratory Features	Locus or Gene
LGMD1A	Onset 3d to 4th decade Muscle weakness affects distal limb muscles, vocal cords, and pharyngeal muscles	Serum CK 2 × normal EMG mixed myopathy/neuropathy NCS normal	Myotilin
LGMD1B	Onset 1st or 2d decade Proximal lower limb weakness and cardiomyopathy with conduction defects Some cases indistinguishable from Emery-Dreifuss muscular dystrophy with joint contractures	Serum CK 3–5 × normal NCS normal EMG myopathic	Lamin A/C
LGMD1C	Onset in early childhood Proximal weakness Gowers' sign, calf hypertrophy Exercise-related muscle cramps	Serum CK 4–25 × normal NCS normal EMG myopathic	Caveolin-3
LGMD1D	Onset 3d to 5th decade Proximal muscle weakness Cardiomyopathy and arrhythmias	Serum CK 2–4 × normal NCS normal EMG myopathic	Linked to chromosome 7q Gene unidentified
LGMD1E	Childhood onset Proximal muscle weakness	Serum CK usually normal NCS normal EMG myopathic	Linked to chromosome 6q23 Gene unidentified

Abbreviations: CK, creatine kinase; NCS, nerve conduction studies; EMG, electromyography.

TABLE 382-7 AUTOSOMAL RECESSIVE LIMB-GIRDLE MUSCULAR DYSTROPHIES (LGMDS)

Disease	Clinical Features	Laboratory Features	Locus or Gene
LGMD2A	Onset 1st or 2d decade Tight heel cords Contractures at elbows, wrists, and fingers; rigid spine in some Proximal and distal weakness	Serum CK 3–15 × normal NCS normal EMG myopathic	Calpain-3
LGMD2B	Onset 2d or 3d decade Proximal muscle weakness at onset, later distal (calf) muscles affected Miyoshi myopathy is variant of LGMD2B with calf muscles affected at onset	Serum CK 3–100 × normal NCS normal EMG myopathic Inflammation on muscle biopsy may simulate polymyositis	Dysferlin
LGMD2C–F	Onset in childhood to teenage yrs Clinical condition similar to Duchenne and Becker muscular dystrophies Cardiomyopathy uncommon Cognitive function normal	Serum CK 5–100 × normal NCS normal EMG myopathic	γ, α, β, δ sarcoglycans
LGMD2G	Onset age 10 to 15 Proximal and distal muscle weakness	Serum CK 3–17 × normal NCS normal EMG myopathic	Telethonin
LGMD2H	Onset 1st to 3d decade Proximal muscle weakness	Serum CK 2–25 × normal NCS normal EMG myopathic	TRIM32 gene
LGMD2I	Onset 1st to 3d decade Clinical condition similar to Duchenne or Becker dystrophies Cardiomyopathy (some not all) Cognitive function normal	Serum CK 10–30 × normal NCS normal EMG myopathic	Fukutin-related protein
LGMD2J[a]	Onset 1st to 3d decade Proximal lower limb weakness Mild distal weakness Progressive weakness causes loss of ambulation	Serum CK 1.5–2 × normal NCS normal EMG myopathic	Titin

[a]Tibial muscular dystrophy is a form of titin deficiency with only distal muscle weakness (see Table 382-8).
Abbreviations: CK, creatine kinase; NCS, nerve conduction studies; EMG, electromyography.

tures become fixed, and a progressive scoliosis often develops that may be associated with pain. The chest deformity with scoliosis impairs pulmonary function, which is already diminished by muscle weakness. By age 16 to 18, patients are predisposed to serious, sometimes fatal pulmonary infections. Other causes of death include aspiration of food and acute gastric dilation.

A cardiac cause of death is uncommon despite the presence of a cardiomyopathy in almost all patients. Congestive heart failure seldom occurs except with severe stress such as pneumonia. Cardiac arrhythmias are rare. The typical electrocardiogram (ECG) shows an increase net RS in lead V_1; deep, narrow Q waves in the precordial leads; and tall right precordial R waves in V_1. Intellectual impairment in Duchenne dystrophy is common; the average intelligence quotient (IQ) is ~1 SD below the mean. Impairment of intellectual function appears to be nonprogressive and affects verbal ability more than performance.

Laboratory Features Serum CK levels are invariably elevated to between 20 and 100 times normal. The levels are abnormal at birth but decline late in the disease because of inactivity and loss of muscle mass. EMG demonstrates features typical of myopathy. The muscle biopsy shows muscle fibers of varying size as well as small groups of necrotic and regenerating fibers. Connective tissue and fat replace lost muscle fibers. A definitive diagnosis of Duchenne dystrophy can be established on the basis of dystrophin deficiency in a biopsy of muscle tissue or mutation analysis on peripheral blood leukocytes, as discussed below.

Duchenne dystrophy is caused by a mutation of the gene that encodes dystrophin, a 427-kDa protein localized to the inner surface of the sarcolemma of the muscle fiber. The dystrophin gene is >2000 kb in size and thus is one of the largest identified human genes. It is localized to the short arm of the X chromosome at Xp21. The most common gene mutation is a deletion. The size varies but does not correlate with disease severity. Deletions are not uniformly distributed over the gene but rather are most common near the beginning (5′ end) and middle of the gene. Less often, Duchenne dystrophy is caused by a gene duplication or point mutation. Identification of a specific mutation allows for an unequivocal diagnosis, makes possible accurate testing of potential carriers, and is useful for prenatal diagnosis.

A diagnosis of Duchenne dystrophy can also be made by Western blot analysis of muscle biopsy specimens, revealing abnormalities on the quantity and molecular weight of dystrophin protein. In addition, immunocytochemical staining of muscle with dystrophin antibodies can be used to demonstrate absence or deficiency of dystrophin localizing to the sarcolemmal membrane. Carriers of the disease may demonstrate a mosaic pattern, but dystrophin analysis of muscle biopsy specimens for carrier detection is not reliable.

Pathogenesis Dystrophin is part of a large complex of sarcolemmal proteins and glycoproteins (Fig. 382-6). Dystrophin binds to F-actin at its amino terminus and to β-dystroglycan at the carboxyl terminus. β-Dystroglycan complexes to α-dystroglycan, which binds to laminin in the extracellular matrix (ECM). Laminin has a heterotrimeric molecular structure arranged in the shape of a cross with one heavy chain and two light chains, β1 and γ1. The laminin heavy chain of skeletal muscle is designated laminin α2. Collagen proteins IV and VI are also found in the ECM. Like β-dystroglycan, the transmembrane sarcoglycan proteins also bind to dystrophin; these five proteins (designated α- through ε-sarcoglycan) complex tightly with each other. More recently, other membrane proteins implicated in muscular dystrophy have been found to be loosely affiliated with constituents of the dystrophin complex. These include caveolin-3, α_7 integrin, and collagen VI.

The dystrophin-glycoprotein complex appears to confer stability to the sarcolemma, although the function of each individual component of the complex is incompletely understood. Deficiency of one member of the complex may cause abnormalities in other components. For example, a primary deficiency of dystrophin (Duchenne dystrophy) may lead to secondary loss of the sarcoglycans and dystroglycan. The primary loss of a single sarcoglycan (see "Limb-Girdle Muscular Dystrophy," below) results in a secondary loss of other sarcoglycans in the membrane without uniformly affecting dystrophin. In either instance, disruption of the dystrophin-glycoprotein complexes weakens the sarcolemma, causing membrane tears and a cascade of events leading to muscle fiber necrosis. This sequence of events occurs repeatedly during the life of a patient with muscular dystrophy.

Rx DUCHENNE MUSCULAR DYSTROPHY

Glucocorticoids, administered as prednisone in a dose of 0.75 mg/kg per day, significantly slow progression of Duchenne dystrophy for up to 3 years. Some patients cannot tolerate glucocorticoid therapy; weight gain and increased risk of fractures in particular represent a significant deterrent for some boys. As in other recessively inherited dystrophies presumed to arise from loss of function of a critical muscle gene, there is optimism that Duchenne disease may benefit from novel therapies that either replace the defective gene or missing protein or implement downstream corrections (e.g., skipping mutated exons or reading through mutations that introduce stop codons).

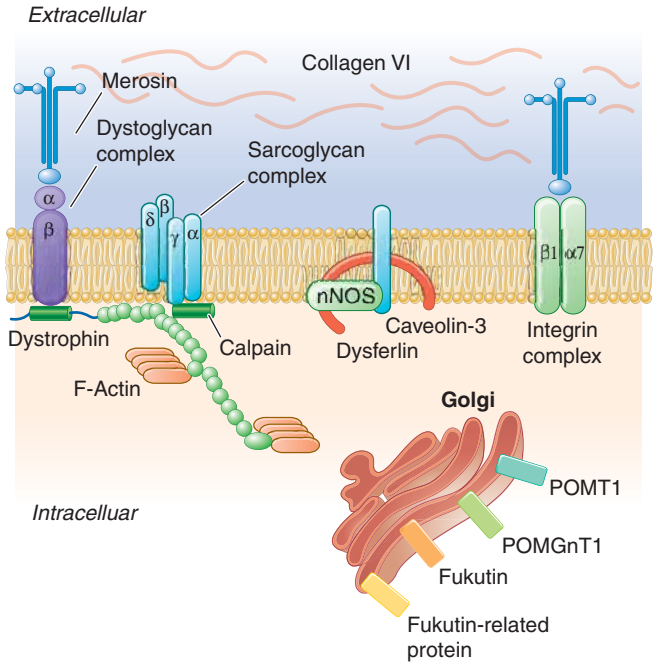

FIGURE 382-6 Selected muscular dystrophy–associated proteins in the cell membrane and Golgi complex. Dystrophin localizes to the cytoplasmic face of the muscle cell membrane. It complexes with two transmembrane protein complexes, the dystroglycans and the sarcoglycans. The dystroglycans bind to the extracellular matrix protein merosin, which is also complexed with β_1 and α_7 integrins (Tables 382-5, 382-6, 382-7). Dysferlin complexes with caveolin-3 (which binds to neuronal nitric oxide synthase, or nNOS) but not with the dystrophin-associated proteins or the integrins. In each of four congenital dystrophies, there is loss of function of different Golgi-associated proteins: POMT1, POMGnT1, Fukutin, and Fukutin-related protein.

BECKER MUSCULAR DYSTROPHY

This less severe form of X-linked recessive muscular dystrophy results from allelic defects of the same gene responsible for Duchenne dystrophy. Becker muscular dystrophy is ~10 times less frequent than Duchenne, with an incidence of about 3 per 100,000 live-born males.

Clinical Features The pattern of muscle wasting in Becker muscular dystrophy closely resembles that seen in Duchenne. Proximal muscles, especially of the lower extremities, are prominently involved. As the disease progresses, weakness becomes more generalized. Significant facial muscle weakness is not a feature. Hypertrophy of muscles, particularly in the calves, is an early and prominent finding.

Most patients with Becker dystrophy first experience difficulties between ages 5 and 15 years, although onset in the third or fourth decade or even later can occur. By definition, patients with Becker dystrophy walk beyond age 15, while patients with Duchenne dystrophy are typically in a wheelchair by the age of 12. Patients with Becker dystrophy have a reduced life expectancy, but most survive into the fourth or fifth decade.

Mental retardation may occur in Becker dystrophy, but it is not as common as in Duchenne. Cardiac involvement occurs in Becker dystrophy and may result in heart failure; some patients manifest with only heart failure. Other less common presentations are asymptomatic hyper-CK-emia, myalgias without weakness, and myoglobinuria.

Laboratory Features Serum CK levels, results of EMG, and muscle biopsy findings closely resemble those in Duchenne dystrophy. The diagnosis of Becker muscular dystrophy requires Western blot analysis of muscle biopsy samples demonstrating a reduced amount or abnormal size of dystrophin or mutation analysis of DNA from peripheral blood leukocytes. Genetic testing reveals deletions or duplications of the dystrophin gene in 65% of patients with Becker dystrophy, approximately the same percentage as in Duchenne dystrophy. In both Becker and Duchenne dystrophies, the size of the DNA deletion does not predict clinical severity; however, in ~95% of patients with Becker dystrophy, the DNA deletion does not alter the translational reading frame of messenger RNA. These "in-frame" mutations allow for production of some dystrophin, which accounts for the presence of altered rather than absent dystrophin on western blot analysis.

Rx BECKER MUSCULAR DYSTROPHY

The use of glucocorticoids has not been adequately studied in Becker dystrophy.

LIMB-GIRDLE MUSCULAR DYSTROPHY

The syndrome of limb-girdle muscular dystrophy (LGMD) represents more than one disorder. Both males and females are affected, with onset ranging from late in the first decade to the fourth decade. The LGMDs typically manifest with progressive weakness of pelvic and shoulder girdle musculature. Respiratory insufficiency from weakness of the diaphragm may occur, as may cardiomyopathy.

A systematic classification of LGMD is based on autosomal dominant (LGMD1) and autosomal recessive (LGMD2) inheritance. Superimposed on the backbone of LGMD1 and LGMD2, the classification employs a sequential alphabetical lettering system (LGMD1A, LGMD2A, etc.). Disorders receive letters in the order in which they are found to have chromosomal linkage. This results in an ever-expanding list of conditions. Presently there are 5 autosomal dominant and 10 autosomal recessive disorders, summarized in Tables 382-6 and 382-7. None of the conditions is as common as the dystrophinopathies; however, prevalence data for the LGMDs have not been systematically gathered for any large heterogeneous population. In referral-based clinical populations, Fukutin-related protein (FKRP) deficiency (LGMD2I), calpainopathies (LGMD2A), and to a lesser extent dysferlinopathies (LGMD2B) have emerged as the most common disorders.

EMERY-DREIFUSS MUSCULAR DYSTROPHY

There are two genetically distinct forms of Emery-Dreifuss muscular dystrophy (EDMD). One is inherited as an X-linked disorder, while the other is autosomal dominant. The latter is classified under the rubric of LGMD1B, but clinically the conditions are closely related.

Clinical Features Prominent contractures can be recognized in early childhood and teenage years, often preceding muscle weakness. The contractures persist throughout the course of the disease and are present at the elbows, ankles, and neck. Muscle weakness affects humeral and peroneal muscles at first and later spreads to a limb-girdle distribution. The cardiomyopathy is potentially life threatening and may result in sudden death. A spectrum of atrial rhythm and conduction defects includes atrial fibrillation and paralysis and atrioventricular heart block. Some patients have a dilated cardiomyopathy. Female carriers of the X-linked variant may have cardiac manifestations that become clinically significant.

Laboratory Features Serum CK may be elevated two- to tenfold. EMG is myopathic. Muscle biopsy shows nonspecific dystrophic features. Immunohistochemistry reveals absent emerin staining of myonuclei in X-lined EDMD. ECGs demonstrate atrial and atrioventricular rhythm disturbances.

X-linked EDMD arises from defects in the emerin gene encoding a nuclear envelope protein. The autosomal dominant disease is caused by mutations of the *LMNA* gene on chromosome 1q21.2 encoding the lamin proteins A and C. These proteins are alternatively spliced products of the *LMNA* gene that are essential components of the filamentous network underlying the inner nuclear membrane. Loss of structural integrity of the nuclear envelope from defects in emerin or lamin A/C accounts for overlapping phenotypes (Fig. 382-7).

Rx EMERY-DREIFUSS MUSCULAR DYSTROPHY

Supportive care should be offered for neuromuscular disability, including ambulatory aids, if necessary. Stretching of contractures is difficult. Man-

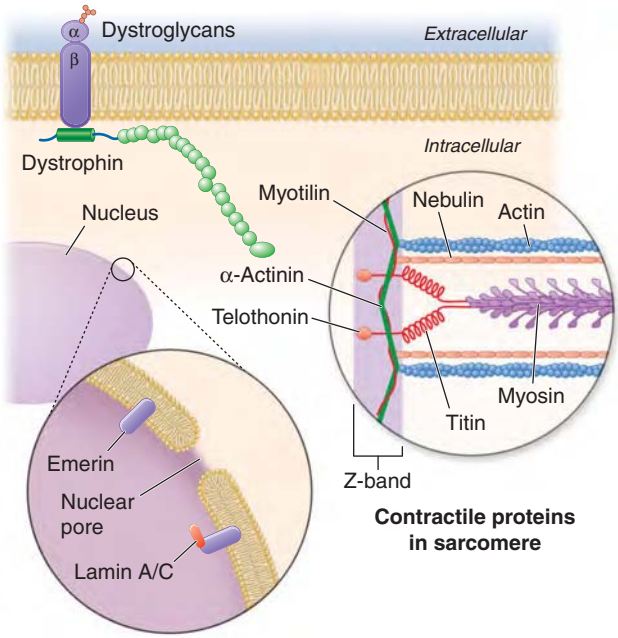

FIGURE 382-7 Selected muscular dystrophy–associated proteins in the nuclear membrane and sarcomere. As shown in the exploded view, emerin and lamin A/C are constituents of the inner nuclear membrane. Several dystrophy-associated proteins are represented in the sarcomere including titin, nebulin, calpain, telethonin, actinin, and myotilin. The position of the dystrophin-dystroglycan complex is also illustrated.

agement of cardiomyopathy and arrhythmias (e.g., early use of a cardiac pacemaker) may be life saving.

CONGENITAL MUSCULAR DYSTROPHY (CMD)

This is not one entity but rather a group of disorders with varying degrees of muscle weakness, central nervous system impairment, and eye abnormalities.

Clinical Features As a group, CMDs present at birth or in the first few months of life with hypotonia and proximal or generalized muscle weakness. Calf muscle hypertrophy is seen in some patients. Facial muscles may be weak, but other cranial nerve–innervated muscles are spared (e.g., extraocular muscles are normal). Most patients have joint contractures of varying degrees at elbows, hips, knees, and ankles. Contractures present at birth are referred to as *arthrogryposis*. Respiratory failure may be seen in some cases.

The CNS is affected in some forms of CMD. In merosin and FKRP deficiency, cerebral hypomyelination may be seen by MRI, though only a small number of patients have mental retardation and seizures. Three forms of congenital muscular dystrophy have severe brain impairment. These include Fukuyama congenital muscular dystrophy (FCMD), muscle-eye-brain (MEB) disease, and Walker-Warburg syndrome (WWS). Patients are severely disabled in all three of these conditions. In MEB disease and WWS, but not in FCMD, ocular abnormalities impair vision. WWS is the most severe congenital muscular dystrophy, causing death by 1 year of age.

Laboratory Features Serum CK is markedly elevated in all of these conditions. The EMG is myopathic and muscle biopsies show nonspecific dystrophic features. Merosin, or laminin α2 chain (a basal lamina protein), is deficient surrounding muscle fibers in merosin deficiency. Skin biopsies can also demonstrate defects in laminin α2 chain. In the other disorders (FKRP deficiency, FCMD, MEB disease, WWS) there is abnormal alpha-dystroglycan staining in muscle. In merosin deficiency, cerebral hypomyelination is common, and a host of brain malformations are seen in FCMD, MEB disease, and WWS.

All forms of CMD are inherited as autosomal recessive disorders. Chromosomal linkage and specific gene defects are presented in Table 382-11 online. With the exception of merosin, the other gene defects affect posttranslational glycosylation of alpha-dystroglycan. This abnormality is thought to impair binding with merosin and leads to weakening of the dystrophin-glycoprotein complex, instability of the muscle membrane, and/or abnormalities in muscle contraction. CMDs with brain and eye phenotypes probably involve defective glycosylation of additional proteins, accounting for the more extensive phenotypes.

Rx CONGENITAL MUSCULAR DYSTROPHY

There is no specific treatment for CMD. Proper wheelchair seating is important. Management of epilepsy and cardiac manifestations is necessary for some patients.

MYOTONIC DYSTROPHY

Myotonic dystrophy is also known as *dystrophia myotonica* (DM). The condition is composed of at least two clinical disorders with overlapping phenotypes and distinct molecular genetic defects: myotonic dystrophy type 1 (DM1), the classic disease originally described by Steinert, and myotonic dystrophy type 2 (DM2), also called *proximal myotonic myopathy* (PROMM).

Clinical Features The clinical expression of myotonic dystrophy varies widely and involves many systems other than muscle. Affected patients have a typical "hatchet-faced" appearance due to temporalis, masseter, and facial muscle atrophy and weakness. Frontal baldness is also characteristic of the disease. Neck muscles, including flexors and sternocleidomastoids, and distal limb muscles are involved early. Weakness of wrist extensors, finger extensors, and intrinsic hand muscles impairs function. Ankle dorsiflexor weakness may cause footdrop. Proximal muscles remain stronger throughout the course, although preferential atrophy and weakness of quadriceps muscles occur in many patients. Palatal, pharyngeal, and tongue involvement produce a dysarthric speech, nasal voice, and swallowing problems. Some patients have diaphragm and intercostal muscle weakness, resulting in respiratory insufficiency.

Myotonia, which usually appears by age 5 years, is demonstrable by percussion of the thenar eminence, the tongue, and wrist extensor muscles. Myotonia causes a slow relaxation of hand grip after a forced voluntary closure. Advanced muscle wasting makes myotonia more difficult to detect.

Cardiac disturbances occur commonly in patients with DM1. ECG abnormalities include first-degree heart block and more extensive conduction system involvement. Complete heart block and sudden death can occur. Congestive heart failure occurs infrequently but may result from cor pulmonale secondary to respiratory failure. Mitral valve prolapse also occurs commonly. Other associated features include intellectual impairment, hypersomnia, posterior subcapsular cataracts, gonadal atrophy, insulin resistance, and decreased esophageal and colonic motility.

Congenital myotonic dystrophy is a more severe form of DM1 and occurs in ~25% of infants of affected mothers. It is characterized by severe facial and bulbar weakness, transient neonatal respiratory insufficiency, and mental retardation.

DM2, or PROMM, has a distinct pattern of muscle weakness affecting mainly proximal muscles. Other features of the disease overlap with DM1, including cataracts, testicular atrophy, insulin resistance, constipation, hypersomnia, and cognitive defects. Cardiac conduction defects occur but are less common, and the hatchet face and frontal baldness are less consistent features. A very striking difference is the failure to clearly identify a congenital form of DM2.

Laboratory Features The diagnosis of myotonic dystrophy can usually be made on the basis of clinical findings. Serum CK levels may be normal or mildly elevated. EMG evidence of myotonia is present in most

cases of DM1 but may be more patchy in DM2. Muscle biopsy shows muscle atrophy, which selectively involves type 1 fibers in 50% of cases, and ringed fibers in DM1 but not in DM2. Typically, numerous internalized nuclei can be seen in individual muscle fibers as well as atrophic fibers with pyknotic nuclear clumps in both DM1 and DM2. Necrosis of muscle fibers and increased connective tissue, common in other muscular dystrophies, are less apparent in myotonic dystrophy.

DM1 and DM2 are both autosomal dominant disorders. New mutations do not appear to contribute to the pool of affected individuals. DM1 is transmitted by an intronic mutation consisting of an unstable expansion of a CTG trinucleotide repeat in a serine-threonine protein kinase gene (named *DMPK*) on chromosome 19q13.3. An increase in the severity of the disease phenotype in successive generations (genetic anticipation) is accompanied by an increase in the number of trinucleotide repeats. A similar type of mutation has been identified in fragile X syndrome (Chap. 62). The unstable triplet repeat in myotonic dystrophy can be used for prenatal diagnosis. Congenital disease occurs almost exclusively in infants born to affected mothers; it is possible that sperm with greatly expanded triplet repeats do not function well.

DM2 is caused by a DNA expansion mutation consisting of a CCTG repeat in intron 1 of the *ZNF9* gene located at chromosome 3q13.3-q24. The gene is believed to encode an RNA binding protein expressed in many different tissues, including skeletal and cardiac muscle.

The DNA expansions in DM1 and DM2 almost certainly impair muscle function by a toxic gain of function of the mutant mRNA. In both DM1 and DM2, the mutant RNA appears to form intranuclear inclusions composed of aberrant RNA. These RNA inclusions sequester RNA binding proteins essential for proper splicing of a variety of other mRNAs. This leads to abnormal transcription of multiple proteins in a variety of tissues/organ systems, in turn causing the systemic manifestations of DM1 and DM2.

Rx MYOTONIC DYSTROPHY

The myotonia in DM1 rarely warrants treatment, though some patients with DM2 are significantly bothered by the discomfort related to the associated muscle stiffness. Phenytoin and mexiletine are the preferred agents for the occasional patient who requires an antimyotonia drug; other agents, particularly quinine and procainamide, may worsen cardiac conduction. A cardiac pacemaker should be considered for patients with unexplained syncope, advanced conduction system abnormalities with evidence of second-degree heart block, or trifascicular conduction disturbances with marked prolongation of the PR interval. Molded ankle-foot orthoses help prevent footdrop in patients with distal lower extremity weakness. Excessive daytime somnolence with or without sleep apnea is not uncommon. Sleep studies, noninvasive respiratory support (BiPAP), and treatment with modafinil may be beneficial.

FACIOSCAPULOHUMERAL (FSH) MUSCULAR DYSTROPHY

This form of muscular dystrophy has a prevalence of ~1 in 20,000. It is distinct from a similar disorder known as scapuloperoneal dystrophy.

Clinical Features The condition typically has an onset in childhood or young adulthood. In most cases, facial weakness is the initial manifestation, appearing as an inability to smile, whistle, or fully close the eyes. Weakness of the shoulder girdles, rather than the facial muscles, usually brings the patient to medical attention. Loss of scapular stabilizer muscles makes arm elevation difficult. Scapular winging (Fig. 382-3) becomes apparent with attempts at abduction and forward movement of the arms. Biceps and triceps muscles may be severely affected, with relative sparing of the deltoid muscles. Weakness is invariably worse for wrist extension than for wrist flexion, and weakness of the anterior compartment muscles of the legs may lead to footdrop.

In most patients, the weakness remains restricted to facial, upper extremity, and distal lower extremity muscles. In 20% of patients, weakness progresses to involve the pelvic girdle muscles, and severe functional impairment and possible wheelchair dependency result.

Characteristically, patients with FSH dystrophy do not have involvement of other organ systems, although labile hypertension is common, and there is an increased incidence of nerve deafness. *Coats' disease*, a disorder consisting of telangiectasia, exudation, and retinal detachment, also occurs.

Laboratory Features The serum CK level may be normal or mildly elevated. EMG usually indicates a myopathic pattern. The muscle biopsy shows nonspecific features of a myopathy. A prominent inflammatory infiltrate, which is often multifocal in distribution, is present in some biopsy samples. The cause or significance of this finding is unknown.

An autosomal dominant inheritance pattern with almost complete penetrance has been established, but each family member should be examined for the presence of the disease, since ~30% of those affected are unaware of involvement. FSH dystrophy is caused by deletions of tandem 3.3-kb repeats at 4q35. The deletion reduces the number of repeats to a fragment of <35 kb in most patients. This mutation may result in an overexpression of upstream genes and a loss of DNA binding of a multiprotein complex mediating transcriptional repression of 4q35 genes. The mutation permits carrier detection and prenatal diagnosis. Most sporadic cases represent new mutations.

Rx FACIOSCAPULOHUMERAL MUSCULAR DYSTROPHY

No specific treatment is available; ankle-foot orthoses are helpful for footdrop. Scapular stabilization procedures improve scapular winging but may not improve function.

OCULOPHARYNGEAL DYSTROPHY

This form of muscular dystrophy represents one of several disorders characterized by progressive external ophthalmoplegia, which consists of slowly progressive ptosis and limitation of eye movements with sparing of pupillary reactions for light and accommodation. Patients usually do not complain of diplopia, in contrast to patients having conditions with a more acute onset of ocular muscle weakness (e.g., myasthenia gravis).

Clinical Features Oculopharyngeal muscular dystrophy has a late onset; it usually presents in the fourth to sixth decade with ptosis and/or dysphagia. The extraocular muscle impairment is less prominent in the early phase but may be severe later. The swallowing problem may become debilitating and result in pooling of secretions and repeated episodes of aspiration. Mild weakness of the neck and extremities also occurs.

Laboratory Features The serum CK level may be two to three times normal. Myopathic EMG findings are typical. On biopsy, muscle fibers are found to contain rimmed vacuoles, which by electron microscopy are shown to contain membranous whorls, accumulation of glycogen, and other nonspecific debris related to lysosomes. A distinct feature of oculopharyngeal dystrophy is the presence of tubular filaments, 8.5 nm in diameter, in muscle cell nuclei.

Oculopharyngeal dystrophy has an autosomal dominant inheritance pattern with complete penetrance. The incidence is high in French-Canadians and in Spanish-American families of the southwestern United States. Large kindreds of Italian and of eastern European Jewish descent have been reported. The molecular defect in oculopharyngeal muscular dystrophy is a subtle expansion of a modest polyalanine repeat tract in a poly-RNA binding protein (PABP2) in muscle.

Rx OCULOPHARYNGEAL DYSTROPHY

Dysphagia can cause inanition, making oculopharyngeal muscular dystrophy a potentially life-threatening disease. Cricopharyngeal myotomy may improve swallowing, although it does not prevent aspiration. Eyelid crutches can improve vision when ptosis obstructs vision; candidates for ptosis surgery must be carefully selected—those with severe facial weakness are not suitable.

DISTAL MYOPATHIES

A group of muscle diseases, the distal myopathies, are notable for their preferential distal distribution of muscle weakness in contrast to most

TABLE 382-8 DISTAL MYOPATHIES

Disease	Clinical Features	Laboratory Features	Inheritance/Locus or Gene
Welander distal myopathy	Onset in fifth decade Weakness begins in hands Slow progression with spread to distal lower extremities Lifespan normal	Serum CK 2–3 × normal EMG myopathic NCS normal Muscle biopsy shows dystrophic features	AD Chromosome 2p13
Tibial muscular dystrophy (Udd)	Onset 4th to 8th decade Distal lower extremity weakness (tibial distribution) Upper extremities usually normal Lifespan normal	Serum CK 2–4 × normal EMG myopathic NCS normal Muscle biopsy shows dystrophic features Titin absent in M-line of muscle	AD Titin
Markesbery-Griggs distal myopathy	Onset 4th to 8th decade Distal lower extremity weakness (tibial distribution) with progression to distal arms and proximal muscles	Serum CK is usually mildly elevated EMG reveals irritative myopathy Muscle biopsies demonstrate rimmed vacuoles and features of myofibrillar myopathy	AD Z-band alternatively spliced PDX motif-containing protein (ZASP)
Laing distal myopathy	Onset childhood to 3d decade Distal lower extremity weakness (tibial distribution) and neck flexors affected early	Serum CK is normal or slightly elevated Muscle biopsies do not show rimmed vacuoles Large deposits of myosin heavy chain are seen in type 1 muscle fibers	AD Myosin heavy chain 7
Nonaka distal myopathy (autosomal recessive hereditary inclusion body myopathy)	Onset 2d to 3d decade Lower extremity distal weakness Mild distal upper limb weakness may be present early Progression to other muscles sparing quadriceps Ambulation may be lost in 10–15 years	Serum CK 3–10 × normal EMG myopathic NCS normal Dystrophic features on muscle biopsy plus rimmed vacuoles and 15- to 19-nm filaments within vacuoles	AR*GNE* gene: UDP-*N*-acetylglucosamine 2-epimerase/*N*-acetylmannosamine kinase Allelic to hereditary inclusion body myopathy
Miyoshi myopathy	Onset 2d to 3d decade Lower extremity weakness in posterior compartment muscles Progression leads to weakness in other muscle groups Ambulation lost after 10–15 years in about one-third of cases	Serum CK 20–100 × normal EMG myopathic NCS normal Muscle biopsy shows nonspecific dystrophic features often with prominent inflammatory cell infiltration; no rimmed vacuoles	AR Allelic to LGMD2B (see Table 382-7) Dysferlin
Myofibrillar myopathies	Onset from early childhood to late adult life Weakness may be distal, proximal, or generalized Cardiomyopathy and respiratory involvement is not uncommon	Serum CKs can be normal or moderately elevated EMG is myopathic and often associated with myopathic discharges Muscle biopsy demonstrates abnormal accumulation of desmin and other proteins, rimmed vacuoles, and myofibrillar degeneration	Genetically heterogeneous AD: Myotilin (also known as LGMD 1A) ZASP (see Markesbery-Griggs distal myopathy) Filamin-C Desmin Alpha B crystallin AR: Desmin Selenoprotein N1

Abbreviations: CK, creatine kinase; AD, autosomal dominant; AR, autosomal recessive; EMG, electromyography; NCS, nerve conduction studies.

muscle conditions associated with proximal weakness. The major distal myopathies are summarized in Table 382-8.

Clinical Features *Welander, Udd,* and *Markesbery-Griggs distal myopathies* are all late-onset, dominantly inherited disorders of distal limb muscles, usually beginning after age 40 years. Welander distal myopathy preferentially involves the wrist and finger extensors, whereas the others are associated with anterior tibial weakness leading to progressive footdrop. *Laing distal myopathy* is also a dominantly inherited disorder heralded by tibial weakness; however, it is distinguished by onset in childhood or early adult life. *Nonaka distal myopathy* and *Miyoshi myopathy* are distinguished by autosomal recessive inheritance and onset in the late teens or twenties. Nonaka myopathy entails anterior tibial weakness, whereas Miyoshi myopathy is unique in that gastrocnemius muscles are preferentially affected at onset. Finally, the *myofibrillar myopathies* (MFM) are a clinically and genetically heterogeneous group of disorders that can be associated with prominent distal weakness; they can be inherited in an autosomal dominant or recessive pattern.

Confounding these clinical features is the observation that proximal muscles can be affected as each of these disorders progresses (less so for Welander disease than the others). In contrast to many other inherited muscle diseases, the distal myopathies are for the most part limited to skeletal muscle.

Laboratory Features Serum CK level is particularly helpful in diagnosing Miyoshi myopathy since it is very elevated. In the other conditions serum CK is only slightly increased. EMGs are myopathic. In the myofibrillar myopathies (MFM), myotonic or pseudomyotonic discharges are common. Muscle biopsy shows nonspecific dystrophic features and, with the exception of Laing and Nonaka distal myopathies, often shows rimmed vacuoles. MFM is associated with the accumulation of dense inclusions, as well as amorphous material best seen on Gomori trichrome and myofibrillar disruption on electron microscopy. Immune staining sometimes demonstrates accumulation of desmin and other proteins in MFM, large deposits of myosin heavy chain in the subsarcolemmal region of type 1 muscle fibers in Laing myopathy, and reduced or absent dysferlin in Miyoshi myopathy.

The affected genes and their gene products are listed in Table 382-8. The gene for Welander disease awaits identification.

Rx DISTAL MYOPATHIES

Occupational therapy is offered for loss of hand function; ankle-foot orthoses can support distal lower limb muscles. The MFMs can be associated with cardiomyopathy (congestive heart failure or arrhythmias) and respiratory failure that may require medical management.

CONGENITAL MYOPATHIES

These rare disorders are distinguished from muscular dystrophies by the presence of specific histochemical and structural abnormalities in muscle. Although primarily disorders of infancy or childhood, three forms that may present in adulthood are described here: central core disease, nemaline (rod) myopathy, and centronuclear (myotubular) myopathy. Other types, such as minicore myopathy (multi-minicore disease), fingerprint body myopathy, and sarcotubular myopathy, are not discussed.

CENTRAL CORE DISEASE

Patients with central core disease may have decreased fetal movements and breech presentation. Hypotonia and delay in motor milestones, particularly in walking, are common. Later in childhood, patients develop problems with stair climbing, running, and getting up from the floor. On examination, there is mild facial, neck-flexor, and proximal-extremity muscle weakness. Legs are more affected than arms. Skeletal abnormalities include congenital hip dislocation, scoliosis, and pes cavus; clubbed feet also occur. Most cases are nonprogressive, but exceptions are well documented. Susceptibility to malignant hyperthermia must be considered as a potential risk factor for patients with central core disease.

The serum CK level is usually normal. Needle EMG demonstrates a myopathic pattern. Muscle biopsy shows fibers with single or multiple central or eccentric discrete zones (*cores*) devoid of oxidative enzymes. Cores occur preferentially in type 1 fibers and represent poorly aligned sarcomeres associated with Z disk streaming.

Autosomal dominant inheritance is characteristic; sporadic cases also occur. The disease is caused by point mutations of the ryanodine receptor gene on chromosome 19q, encoding the calcium-release channel of the sarcoplasmic reticulum of skeletal muscle; mutations of this gene also account for some cases of inherited malignant hyperthermia (Chap. 17). Malignant hyperthermia is an allelic condition; C-terminal mutations of the *RYR1* gene predispose to this complication.

Specific treatment is not required, but establishing a diagnosis of central core disease is extremely important because these patients have a known predisposition to malignant hyperthermia during anesthesia.

NEMALINE MYOPATHY

The term *nemaline* refers to the distinctive presence in muscle fibers of rods or threadlike structures (Greek *nema*, "thread"). Nemaline myopathy is clinically heterogeneous. A severe neonatal form presents with hypotonia and feeding and respiratory difficulties, leading to early death. Nemaline myopathy usually presents in infancy or childhood with delayed motor milestones. The course is nonprogressive or slowly progressive. The physical appearance is striking because of the long, narrow facies, high-arched palate, and open-mouthed appearance due to a prognathous jaw. Other skeletal abnormalities include pectus excavatum, kyphoscoliosis, pes cavus, and clubfoot deformities. Facial and generalized muscle weakness, including respiratory muscle weakness, is common. An adult-onset disorder with progressive proximal weakness may be seen. Myocardial involvement is occasionally present in both the childhood and adult-onset forms. The serum CK level is usually normal or slightly elevated. The EMG demonstrates a myopathic pattern. Muscle biopsy shows clusters of small rods (nemaline bodies), which occur preferentially, but not exclusively, in the sarcoplasm of type 1 muscle fibers. Occasionally, the rods are also apparent in myonuclei. The muscle often shows type 1 muscle fiber predominance. Rods originate from the Z disk material of the muscle fiber.

Five genes have been associated with nemaline myopathy. All code for thin filament–associated proteins, suggesting disturbed assembly or interplay of these structures as a pivotal mechanism. Mutations of the nebulin (*NEB*) gene account for most cases, including both severe neonatal and early childhood forms, inherited as autosomal recessive disorders. Neonatal and childhood cases, inherited as predominantly autosomal dominant disorders, are caused by mutations of the skeletal muscle α-actinin (*ACTA1*) gene. In milder forms of the disease with autosomal dominant inheritance, mutations have been identified in both the slow α-tropomyosin (*TPM3*) and β-tropomyosin (*TPM2*) genes accounting for <3% of cases. Muscle troponin T (*TNNT1*) gene mutations appear to be limited to the Amish population in North America. No specific treatment is available.

CENTRONUCLEAR (MYOTUBULAR) MYOPATHY

Three distinct variants of centronuclear myopathy occur. A neonatal form, also known as *myotubular myopathy*, presents with severe hypotonia and weakness at birth. The late infancy–early childhood form presents with delayed motor milestones. Later, difficulty with running and stair climbing becomes apparent. A marfanoid, slender body habitus, long narrow face, and high-arched palate are typical. Scoliosis and clubbed feet may be present. Most patients exhibit progressive weakness, some requiring wheelchairs. Progressive external ophthalmoplegia with ptosis and varying degrees of extraocular muscle impairment are characteristic of both the neonatal and the late-infantile forms. A third variant, the late childhood–adult form, has an onset in the second or third decade. Patients have full extraocular muscle movements and rarely exhibit ptosis. There is mild, slowly progressive limb weakness that may be distally predominant [some of these patients have been classified as having Charcot-Marie-Tooth disease type 2 (CMT2; Chap. 379)].

Normal or slightly elevated CK levels occur in each of the forms. Nerve conduction studies may reveal reduced amplitudes of distal compound muscle action potentials, in particular in adult-onset cases that resemble CMT2. EMG studies often give distinctive results, showing positive sharp waves and fibrillation potentials, complex and repetitive discharges, and rarely myotonic discharges. Muscle biopsy specimens in longitudinal section demonstrate rows of central nuclei, often surrounded by a halo. In transverse sections, central nuclei are found in 25–80% of muscle fibers.

A gene for the neonatal form of centronuclear myopathy has been localized to Xq28; this gene encodes myotubularin, a protein tyrosine phosphatase. Missense, frameshift, and splice-site mutations predict loss of myotubularin function in affected individuals. Carrier identification and prenatal diagnosis are possible. The inheritance pattern for the late infancy–early childhood disorder is probably autosomal recessive, and for the late childhood–adult form is probably autosomal dominant. No specific treatment is available. Some of the autosomal dominant late-onset cases, which are allelic to a form of CMT2, are associated with mutations in the gene that encodes dynamin-2.

DISORDERS OF MUSCLE ENERGY METABOLISM

There are two principal sources of energy for skeletal muscle—fatty acids and glucose. Abnormalities in either glucose or lipid utilization can be associated with distinct clinical presentations that can range from an acute, painful syndrome with rhabdomyolysis and myoglobinuria to a chronic, progressive muscle weakness simulating muscular dystrophy.

GLYCOGEN STORAGE AND GLYCOLYTIC DEFECTS

Disorders of Glycogen Storage Causing Progressive Weakness • *α-GLUCOSIDASE, OR ACID MALTASE, DEFICIENCY (POMPE'S DISEASE)* Three clinical forms of α-glucosidase, or acid maltase, deficiency (*type II glycogenosis*) can be distinguished. The infantile form is the most common, with onset of symptoms in the first 3 months of life. Infants develop severe muscle weakness, cardiomegaly, hepatomegaly, and respiratory insufficiency. Glycogen accumulation in motor neurons of the spinal cord and brainstem contributes to muscle weakness. Death usually occurs

by 1 year of age. In the childhood form, the picture resembles muscular dystrophy. Delayed motor milestones result from proximal limb muscle weakness and involvement of respiratory muscles. The heart may be involved, but the liver and brain are unaffected. The adult form usually begins in the third or fourth decade but can present as late as the seventh decade. Respiratory failure and diaphragmatic weakness are often initial manifestations, heralding progressive proximal muscle weakness. The heart and liver are not involved.

The serum CK level is 2 to 10 times normal in infantile or childhood-onset Pompe disease but can be normal in adult-onset cases. EMG examination demonstrates a myopathic pattern, but other features are especially distinctive, including myotonic discharges, trains of fibrillation and positive waves, and complex repetitive discharges. EMG discharges are very prominent in the lumbosacral paraspinal muscles. The muscle biopsy in infants typically reveals vacuoles containing glycogen and the lysosomal enzyme acid phosphatase. Electron microscopy reveals membrane-bound and free tissue glycogen. However, muscle biopsies in late-onset Pompe's disease may demonstrate only nonspecific abnormalities. Enzyme analysis of dried blood spots is a new and sensitive technique to screen for Pompe's disease. A definitive diagnosis is established by enzyme assay in muscle or cultured fibroblasts or by genetic testing.

Acid maltase deficiency is inherited as an autosomal recessive disorder caused by mutations of the α-glucosidase gene. Recently, replacement therapy with IV recombinant human α-glucosidase has been shown to be beneficial in infantile-onset Pompe disease and was approved by the U.S. Food and Drug Administration (FDA). The efficacy in later-onset cases is under study. Clinical benefits in the infantile disease include reduced heart size, improved muscle function, reduced need for ventilatory support, and longer life.

OTHER GLYCOGEN STORAGE DISEASES WITH PROGRESSIVE WEAKNESS In *debranching enzyme deficiency* (*type III glycogenosis*), a slowly progressive form of muscle weakness can develop after puberty. Rarely, myoglobinuria may be seen. Patients are usually diagnosed in infancy, however, because of hypotonia and delayed motor milestones, hepatomegaly, growth retardation, and hypoglycemia. *Branching enzyme deficiency* (*type IV glycogenosis*) is a rare and fatal glycogen storage disease characterized by failure to thrive and hepatomegaly. Hypotonia and muscle wasting may be present, but the skeletal muscle manifestations are minor compared to liver failure.

Disorders of Glycolysis Causing Exercise Intolerance Several glycolytic defects are associated with recurrent myoglobinuria: *myophosphorylase deficiency* (*type V glycogenosis*), *phosphofructokinase deficiency* (*type VII glycogenosis*), *phosphoglycerate kinase deficiency* (*type IX glycogenosis*), *phosphoglycerate mutase deficiency* (*type X glycogenosis*), *lactate dehydrogenase deficiency* (*glycogenosis type XI*), and *beta-enolase deficiency*. Myophosphorylase deficiency, also known as *McArdle's disease*, is by far the most common of the glycolytic defects associated with exercise intolerance. These glycolytic defects result in a common failure to support energy production at the initiation of exercise, although the exact site of energy failure remains controversial.

Clinical muscle manifestations in these conditions usually begin in adolescence. Symptoms are precipitated by brief bursts of high-intensity exercise, such as running or lifting heavy objects. A history of myalgia and muscle stiffness usually precedes the intensely painful muscle contractures, which may be followed by myoglobinuria. Acute renal failure accompanies significant pigmenturia.

Certain features help distinguish some enzyme defects. In McArdle's disease exercise tolerance can be enhanced by a slow induction phase (warm-up) or brief periods of rest, allowing for the start of the "second-wind" phenomenon (switching to utilization of fatty acids). Varying degrees of hemolytic anemia accompany deficiencies of both phosphofructokinase (mild) and phosphoglycerate kinase (severe). In phosphoglycerate kinase deficiency, the usual clinical presentation is a seizure disorder associated with mental retardation; exercise intolerance is an infrequent manifestation.

In all of these conditions, the serum CK levels fluctuate widely and may be elevated even during symptom-free periods. CK levels >100 times normal are expected, accompanying myoglobinuria. All patients with suspected glycolytic defects leading to exercise intolerance should undergo a forearm exercise test. An impaired rise in venous lactate is highly indicative of a glycolytic defect. In lactate dehydrogenase deficiency, venous levels of lactate do not increase, but pyruvate rises to normal. A definitive diagnosis of glycolytic disease is made by muscle biopsy and subsequent enzyme analysis or by genetic testing.

Myophosphorylase deficiency, phosphofructokinase deficiency, and phosphoglycerate mutase deficiency are inherited as autosomal recessive disorders. Phosphoglycerate kinase deficiency is X-linked recessive. Mutations can be found in the respective genes encoding the abnormal proteins in each of these disorders.

Training may enhance exercise tolerance, perhaps by increasing perfusion to muscle. Dietary intake of free glucose or fructose prior to activity may improve function but care must be taken to avoid obesity from ingesting too many calories.

LIPID AS AN ENERGY SOURCE AND ASSOCIATED DEFECTS

Lipid is an important muscle energy source during rest and during prolonged, submaximal exercise. Fatty acids are derived from circulating very low density lipoprotein (VLDL) in the blood or from triglycerides stored in muscle fibers. Oxidation of fatty acids occurs in the mitochondria. To enter the mitochondria, a fatty acid must first be converted to an "activated fatty acid," acyl-CoA. The acyl-CoA must be linked with carnitine by the enzyme carnitine palmitoyltransferase (CPT) I for transport into the mitochondria. CPT I is present on the inner side of the outer mitochondrial membrane. Carnitine is removed by CPT II, an enzyme attached to the inside of the inner mitochondrial membrane, allowing transport of acyl-CoA into the mitochondrial matrix for β-oxidation.

Carnitine Palmitoyltransferase Deficiency CPT II deficiency is the most common recognizable cause of recurrent myoglobinuria, more common than the glycolytic defects. Onset is usually in the teenage years or early twenties. Muscle pain and myoglobinuria typically occur after prolonged exercise but can also be precipitated by fasting or infections; up to 20% of patients do not exhibit myoglobinuria, however. Strength is normal between attacks. In contrast to disorders caused by defects in glycolysis, in which muscle cramps follow short, intense bursts of exercise, the muscle pain in CPT II deficiency does not occur until the limits of utilization have been exceeded and muscle breakdown has already begun. Episodes of rhabdomyolysis may produce severe weakness. In young children and newborns, CPT II deficiency can present with a very severe clinical picture including hypoketotic hypoglycemia, cardiomyopathy, liver failure, and sudden death.

Serum CK levels and EMG findings are both usually normal between episodes. A normal rise of venous lactate during forearm exercise distinguishes this condition from glycolytic defects, especially myophosphorylase deficiency. Muscle biopsy does not show lipid accumulation and is usually normal between attacks. The diagnosis requires direct measurement of muscle CPT or genetic testing.

CPT II deficiency is much more common in men than women (5:1); nevertheless, all evidence indicates autosomal recessive inheritance. A mutation in the gene for CPT II (chromosome 1p36) causes the disease in some individuals. Attempts to improve exercise tolerance with frequent meals and a low-fat, high-carbohydrate diet, or by substituting medium-chain triglycerides in the diet, have not proven to be beneficial.

Myoadenylate Deaminase Deficiency The muscle enzyme myoadenylate deaminase converts adenosine 5′-monophosphate (5′-AMP) to inosine monophosphate (IMP) with liberation of ammonia. Myoadenylate deaminase may play a role in regulating adenosine triphosphate (ATP) levels in muscles. Most individuals with myoadenylate deaminase deficiency have no symptoms. There have been a few reports of patients with this disorder who have exercise-exacerbated myalgia and myoglo-

binuria. Many questions have been raised about the clinical effects of myoadenylate deaminase deficiency, and, specifically, its relationship to exertional myalgia and fatigability, but there is no consensus.

MITOCHONDRIAL MYOPATHIES

In 1972, Olson and colleagues recognized that muscle fibers with significant numbers of abnormal mitochondria could be highlighted with the modified trichrome stain; the term *ragged red fibers* was coined. By electron microscopy, the mitochondria in ragged red fibers are enlarged and often bizarrely shaped and have crystalline inclusions. Since that seminal observation, the understanding of these disorders of muscle and other tissues has expanded (Chap. 62).

Mitochondria play a key role in energy production. Oxidation of the major nutrients derived from carbohydrate, fat, and protein leads to the generation of reducing equivalents. The latter are transported through the respiratory chain in the process known as *oxidative phosphorylation*. The energy generated by the oxidation-reduction reactions of the respiratory chain is stored in an electrochemical gradient coupled to ATP synthesis.

A novel feature of mitochondria is their genetic composition. Each mitochondrion possesses a DNA genome that is distinct from that of the nuclear DNA. Human mitochondrial DNA (mtDNA) consists of a double-strand, circular molecule comprising 16,569 base pairs. It codes for 22 transfer RNAs, 2 ribosomal RNAs, and 13 polypeptides of the respiratory chain enzymes. The genetics of mitochondrial diseases differ from the genetics of chromosomal disorders. The DNA of mitochondria is directly inherited from the cytoplasm of the gametes, mainly from the oocyte. The sperm contributes very little of its mitochondria to the offspring at the time of fertilization. Thus, mitochondrial genes are derived almost exclusively from the mother, accounting for maternal inheritance of some mitochondrial disorders.

Patients with mitochondrial disorders have clinical manifestations that fall into three groups: chronic progressive external ophthalmoplegia (CPEO), skeletal muscle–CNS syndromes, and pure myopathy simulating muscular dystrophy or metabolic myopathy.

PROGRESSIVE EXTERNAL OPHTHALMOPLEGIA SYNDROMES WITH RAGGED RED FIBERS

The single most common sign of a mitochondrial myopathy is CPEO, occurring in >50% of all mitochondrial myopathies. Varying degrees of ptosis and weakness of extraocular muscles are seen, usually in the absence of diplopia, a point of distinction from disorders with fluctuating eye weakness (e.g., myasthenia gravis).

KEARNS-SAYRE SYNDROME (KSS)

KSS is a widespread multiorgan system disorder with a defined triad of clinical findings: onset before age 20, CPEO, and pigmentary retinopathy plus one or more of the following features: complete heart block, cerebrospinal fluid (CSF) protein > 1.0 g/L (100 mg/dL), or cerebellar ataxia. Some patients with CPEO and ragged red fibers may not fulfill all of the criteria for KSS. The cardiac disease includes syncopal attacks and cardiac arrest related to the abnormalities in the cardiac conduction system: prolonged intraventricular conduction time, bundle branch block, and complete atrioventricular block. Death attributed to heart block occurs in ~20% of the patients. Varying degrees of progressive limb muscle weakness and easy fatigability affect activities of daily living. Endocrine abnormalities are common, including gonadal dysfunction in both sexes with delayed puberty, short stature, and infertility. Diabetes mellitus is a cardinal sign of mitochondrial disorders and is estimated to occur in 13% of KSS patients. Other less common endocrine disorders include thyroid disease, hyperaldosteronism, Addison's disease, and hypoparathyroidism. Both mental retardation and dementia are common accompaniments to this disorder. Serum CK levels are normal or slightly elevated. Serum lactate and pyruvate levels may be elevated. EMG is myopathic. Nerve conduction studies may be abnormal related to an associated neuropathy. Muscle biopsies reveal ragged red fibers, highlighted in oxidative enzyme stains, many showing defects in cytochrome oxidase. By electron microscopy there are increased numbers of mitochondria that often appear enlarged and contain paracrystalline inclusions.

KSS is a sporadic disorder. The disease is caused by single mtDNA deletions presumed to arise spontaneously in the ovum or zygote. The most common deletion, occurring in about one-third of patients, removes 4977 bp of contiguous mtDNA. Monitoring for cardiac conduction defects is critical. Prophylactic pacemaker implantation is indicated when ECGs demonstrate a bifascicular block. In KSS no benefit has been shown for supplementary therapies, including multivitamins or coenzyme Q10. Of all the proposed options, exercise might be the most applicable but must be approached cautiously because of defects in the cardiac conduction system.

PROGRESSIVE EXTERNAL OPHTHALMOPLEGIA (PEO)

This condition is caused by nuclear DNA mutations affecting mtDNA copy number and integrity and is thus inherited in a Mendelian fashion. Onset is usually after puberty. Fatigue, exercise intolerance, and complaints of muscle weakness are typical. Some patients notice swallowing problems. The neurologic examination confirms the ptosis and ophthalmoplegia, usually asymmetric in distribution. A sensorineural hearing loss may be encountered. Mild facial, neck flexor, and proximal weakness are typical. Rarely, respiratory muscles may be progressively affected and may be the direct cause of death. Serum CK is normal or mildly elevated. The resting lactate level is normal or slightly elevated but may rise excessively after exercise. CSF protein is normal. The EMG is myopathic, and nerve conduction studies are usually normal. Ragged red fibers are prominently displayed in the muscle biopsy. Southern blots of muscle reveal a normal mtDNA band at 16.6 kb and several additional mtDNA deletion bands with genomes varying from 0.5 to 10 kb.

This autosomal dominant form of CPEO has been linked to loci on three chromosomes: 4q35, 10q24, and 15q22-26. In the chromosome 4q–related form of disease, mutations of the gene encoding the heart and skeletal muscle–specific isoform of the adenine nucleotide translocator 1 (*ANT1*) gene are found. This highly abundant mitochondrial protein forms a homodimeric inner mitochondrial channel through which ADP enters and ATP leaves the mitochondrial matrix. In the chromosome 10q–related disorder, mutations of the gene *C10orf2* are found. Its gene product, *twinkle*, co-localizes with the mtDNA and is named for its punctate, starlike staining properties. The function of twinkle is presumed to be critical for lifetime maintenance of mitochondrial integrity. In the cases mapped to chromosome 15q, a mutation affects the gene encoding mtDNA polymerase (*POLG*), an enzyme important in mtDNA replication. Autosomal recessive PEO has also been described with mutations in the *POLG* gene. Point mutations have been identified within various mitochondrial tRNA (Leu, Ile, Asn, Trp) genes in families with maternal inheritance of PEO.

Exercise may improve function but will depend on the patients' ability to participate.

AUTOSOMAL RECESSIVE CARDIOMYOPATHY AND OPHTHALMOPLEGIA (ARCO)

ARCO is a rare mitochondrial disorder clinically important because of an associated life-threatening cardiomyopathy. CPEO is the initial manifestation, occurring between ages 8 and 10. Exercise intolerance and fatigue follow the early symptoms, accompanied by palpitations and chest pain. Examination reveals extraocular muscle weakness, ptosis, facial weakness, reduced muscle bulk, and limb weakness, greater in proximal muscles. A dilated cardiomyopathy is typical, and some patients have conduction system involvement. Death from congestive heart failure occurs as early as age 13. Serum lactate is normal at rest but increases with mild exercise. Serum CK is increased two- to fourfold. EMG is normal or myopathic. Muscle biopsy demonstrates typical ragged red fibers. Multiple mtDNA deletions are seen on Southern blots of muscle. Echocardiograms show reduced ejection fraction. Conduction block is seen on ECGs. The disease is inherited as an autosomal recessive disorder. The gene has not been identified. Heart failure may require orthotopic cardiac transplantation. Cardiac pacemakers are appropriate for patients with heart block.

TABLE 382-9 CLINICAL FEATURES OF PERIODIC PARALYSIS AND NONDYSTROPHIC MYOTONIAS

	Calcium Channel	Sodium Channel		Potassium Channel
Feature	**Hypokalemic PP**	**Hyperkalemic PP**	**Paramyotonia Congenita**	**Anderson's Syndrome[b]**
Mode of inheritance	AD	AD	AD	AD
Age of onset	Adolescence	Early childhood	Early childhood	Early childhood
Myotonia[a]	No	Yes	Yes	No
Episodic weakness	Yes	Yes	Yes	Yes
Frequency of attacks of weakness	Daily to yearly	May be 2–3/d	With cold, usually rare	Daily to yearly
Duration of attacks of weakness	2–12 h	From 1–2 h to >1 day	2–24 h	2–24 h
Serum K^+ level during attacks of weakness	Decreased	Increased or normal	Usually normal	Variable
Effect of K^+ loading	No change	Increased myotonia, then weakness	Increased myotonia	No change
Effect of muscle cooling	No change	Increased myotonia	Increased myotonia, then weakness	No change
Fixed weakness	Yes	Yes	Yes	Yes

[a]May be paradoxical in paramyotonia congenita.
[b]Dysmorphic features and cardiac arrhythmias are distinguishing features (see text).

Abbreviations: AD, autosomal dominant; PP, periodic paralysis.

mtDNA SKELETAL MUSCLE–CENTRAL NERVOUS SYSTEM SYNDROMES

Myoclonic Epilepsy with Ragged Red Fibers (MERRF) The onset of MERRF is variable, ranging from late childhood to middle adult life. Characteristic features include myoclonic epilepsy, cerebellar ataxia, and progressive muscle weakness. The seizure disorder is an integral part of the disease and may be the initial symptom. Cerebellar ataxia precedes or accompanies epilepsy. It is slowly progressive and generalized. The third major feature of the disease is muscle weakness in a limb-girdle distribution. Other more variable features include dementia, peripheral neuropathy, optic atrophy, hearing loss, and diabetes mellitus.

Serum CK levels are normal or slightly increased. The serum lactate may be elevated. EMG is myopathic, and in some patients nerve conduction studies show a neuropathy. The electroencephalogram is abnormal, corroborating clinical findings of epilepsy. Typical ragged red fibers are seen on muscle biopsy. MERRF is caused by maternally inherited point mutations of mitochondrial tRNA genes. The most common mutation found in 80% of MERRF patients is an A to G substitution at nucleotide 8344 of tRNA lysine (A8344G $tRNA^{lys}$). Other $tRNA^{lys}$ mutations include base-pair substitutions T8356C and G8363A. Only supportive treatment is possible, with special attention to epilepsy.

Mitochondrial Myopathy, Encephalopathy, Lactic Acidosis, and Stroke-Like Episodes (MELAS) MELAS is the most common mitochondrial encephalomyopathy. The term *stroke-like* is appropriate because the cerebral lesions do not conform to a strictly vascular distribution. The onset in the majority of patients is before age 20. Seizures, usually partial motor or generalized, are common and may represent the first clearly recognizable sign of disease. The cerebral insults that resemble strokes cause hemiparesis, hemianopia, and cortical blindness. A presumptive stroke occurring before age 40 should place this mitochondrial encephalomyopathy high in the differential diagnosis. Associated conditions include hearing loss, diabetes mellitus, hypothalamic pituitary dysfunction causing growth hormone deficiency, hypothyroidism, and absence of secondary sexual characteristics. In its full expression MELAS leads to dementia, a bedridden state, and a fatal outcome. Serum lactic acid is typically elevated. The CSF protein is also increased but is usually ≤1.0 g/L (100 mg/dL). Muscle biopsies show ragged red fibers. Neuroimaging demonstrates basal ganglia calcification in a high percentage of cases. Focal lesions that mimic infarction are present predominantly in the occipital and parietal lobes. Strict vascular territories are not respected, and cerebral angiography fails to demonstrate lesions of the major cerebral blood vessels.

MELAS is caused by maternally inherited point mutations of mitochondrial tRNA genes. Most of the tRNA mutations are lethal, accounting for the paucity of multigeneration families with this syndrome. The A3243G point mutation in $tRNA^{Leu(UUR)}$ is the most common, occurring in ~80% of MELAS cases. About 10% of MELAS patients have other mutations of the $tRNA^{Leu(UUR)}$ gene including 3252G, 3256T, 3271C, and 3291C. Other tRNA gene mutations have also been reported in MELAS including G583A $tRNA^{Phe}$, G1642A $tRNA^{Val}$, G4332A $tRNA^{Glu}$, and T8316C $tRNA^{Lys}$. Mutations have also been reported in mtDNA polypeptide-coding genes. Two mutations were found in the ND5 subunit of complex I of the respiratory chain. A missense mutation has been reported at mtDNA position 9957 in the gene for subunit III of cytochrome C oxidase. No specific treatment is available. Supportive treatment is essential for the stroke-like episodes, seizures, and endocrinopathies.

PURE MYOPATHY SYNDROMES

Muscle weakness and fatigue can be the predominant manifestations of mtDNA mutations. When the condition affects exclusively muscle (pure myopathy), the disorder becomes difficult to recognize. Occasionally, mitochondrial myopathies can present with recurrent myoglobinuria without fixed weakness and thus resemble a glycogen storage disorder or CPT deficiency.

Mitochondrial DNA Depletion Myopathy This disorder, clinically indistinguishable from muscular dystrophy, usually presents in the neonatal period with weakness, hypotonia, and delayed motor milestones. Some cases are rapidly fatal, with death before age 2. A milder form affects patients at a slightly later age. These patients have slowly evolving proximal muscle weakness simulating Duchenne muscular dystrophy. In some, seizures and cardiomyopathy may be present. Serum CK can reach levels of 20 to 30 times normal. Resting lactate varies from normal to mildly elevated. The EMG is myopathic, and ragged red fibers are seen on muscle biopsy. The mtDNA depletion syndrome is inherited as an autosomal recessive condition. Mutations have been identified in the *TK2* gene on chromosome 16q22 encoding thymidine kinase-2. The affected gene controls the supply of deoxyribonucleotides used for the synthesis of mtDNA. No specific treatment is available. Supportive care follows the approaches outlined for muscular dystrophy.

DISORDERS OF MUSCLE MEMBRANE EXCITABILITY

Muscle membrane excitability is affected in a group of disorders referred to as *channelopathies*. The heart may also be involved, resulting in life-threatening complications (Table 382-9).

CALCIUM CHANNEL DISORDERS OF MUSCLE

Hypokalemic Periodic Paralysis (HypoKPP) Onset occurs at adolescence. Men are more often affected because of decreased penetrance in women. Episodic weakness with onset after age 25 is almost never due to periodic paralyses with the exception of thyrotoxic periodic paralysis (see below). Attacks are often provoked by meals high in carbohydrates or sodium and may accompany rest following prolonged exercise.

Weakness usually affects proximal limb muscles more than distal. Ocular and bulbar muscles are less likely to be affected. Respiratory muscles are usually spared but when they are involved, the condition may prove fatal. Weakness may take as long as 24 h to resolve. Life-threatening cardiac arrhythmias related to hypokalemia may occur during attacks. As a late complication, patients commonly develop severe, disabling proximal lower extremity weakness.

Attacks of thyrotoxic periodic paralysis resemble those of primary HypoKPP. Despite a higher incidence of thyrotoxicosis in women, men, particularly those of Asian descent, are more likely to manifest this complication. Attacks abate with treatment of the underlying thyroid condition.

A low serum potassium level during an attack, excluding secondary causes, establishes the diagnosis. Interattack muscle biopsies show the presence of single or multiple centrally placed vacuoles or tubular aggregates. Provocative tests with glucose and insulin to establish a diagnosis are usually not necessary and are potentially hazardous.

In the midst of an attack of weakness, motor conduction studies may demonstrate reduced amplitudes, whereas EMG may show electrical silence in severely weak muscles. In between attacks, the EMG and nerve conduction studies are normal, with the exception that myopathic motor unit action potentials may be seen in patients with fixed weakness.

HypoKPP is caused by mutations in either of two genes. HypoKPP type 1, the most common form, is inherited as an autosomal dominant disorder with incomplete penetrance. These patients have mutations in the voltage-sensitive, skeletal muscle calcium channel gene, *CALCL1A3* (Fig. 382-8). Approximately 10% of cases are HypoKPP type 2, arising from mutations in the voltage-sensitive sodium channel gene (*SCN4A*).

℞ HYPOKALEMIC PERIODIC PARALYSIS

The acute paralysis improves after the administration of potassium. Muscle strength and ECG should be monitored. Oral KCl (0.2–0.4 mmol/kg) should be given every 30 min. Only rarely is IV therapy necessary (e.g., when swallowing problems or vomiting is present). Administration of potassium in a glucose solution should be avoided because it may further reduce serum potassium levels. Mannitol is the preferred vehicle for administration of IV potassium. The long-term goal of therapy is to avoid attacks. This may reduce late-onset, fixed weakness. Patients should be made aware of the importance of a low-carbohydrate, low-sodium diet and consequences of intense exercise. Prophylactic administration of acetazolamide (125–1000 mg/d in divided doses) reduces or may abolish attacks in HypoKPP type 1. Paradoxically the potassium is lowered, but this is offset by the beneficial effect of metabolic acidosis. If attacks persist on acetazolamide, oral KCl should be added. Some patients require treatment with triamterine (25–100 mg/d) or spironolactone (25–100 mg/d). However, in patients with HypoKPP type 2, attacks of weakness can be exacerbated with acetazolamide.

SODIUM CHANNEL DISORDERS OF MUSCLE

Hyperkalemic Periodic Paralysis (HyperKPP) The term *hyperkalemic* is misleading since patients are often normokalemic during attacks. The fact that attacks are precipitated by potassium administration best defines the disease. The onset is in the first decade. Attacks are brief and mild, usually lasting 30 min to 4 h. Weakness affects proximal muscles, sparing bulbar muscles. Attacks are precipitated by rest following exercise and fasting. In a variant of this disorder, the predominant symptom is myotonia without weakness (*potassium-aggravated myotonia*). The symptoms are aggravated by cold, and myotonia makes the muscles stiff and painful. This disorder can be confused with paramyotonia congenita, myotonia congenita, and proximal myotonic myopathy (DM2).

Potassium may be slightly elevated but may also be normal during an attack. As in HypoKPP, nerve conduction studies in HyperKPP muscle may demonstrate reduced motor amplitudes and the EMG may be silent in very weak muscles. In between attacks of weakness, the conduction studies are normal. The EMG will often demonstrate myotonic discharges during and between attacks.

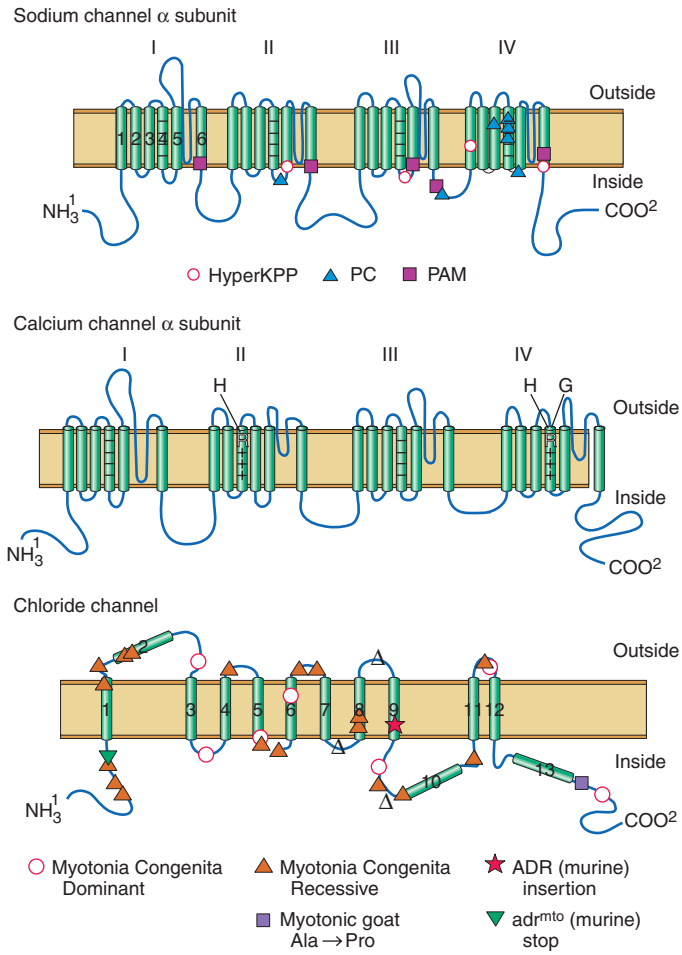

FIGURE 382-8 The sodium and calcium channels are depicted here as containing four homologous domains, each with six membrane-spanning segments. The fourth segment of each domain bears positive charges and acts as the "voltage sensor" for the channel. The association of the four domains is thought to form a pore through which ions pass. Sodium channel mutations are shown along with the phenotype that they confer. HyperKPP, hyperkalemic periodic paralysis; PC, paramyotonia congenita; PAM, potassium-aggravated myotonia. See text for details.

The chloride channel is envisioned to have ten membrane-spanning domains. The positions of mutations causing dominantly and recessively inherited myotonia congenita are indicated, along with mutations that cause this disease in mice and goats.

The muscle biopsy shows vacuoles that are smaller, less numerous, and more peripheral compared to the hypokalemic form or tubular aggregates. Provocative tests by administration of potassium can induce weakness but are usually not necessary to establish the diagnosis. HyperKPP and potassium-aggravated myotonia are inherited as autosomal dominant disorders. Mutations of the voltage-gated sodium channel *SCN4A* gene (Fig. 382-8) cause these conditions. For patients with frequent attacks, acetazolamide (125–1000 mg/d) is helpful. We have found mexiletine to be helpful in patients with significant myotonia.

Paramyotonia Congenita In paramyotonia congenita (PC) the attacks of weakness are cold-induced or occur spontaneously and are mild. Myotonia is a prominent feature but worsens with muscle activity (paradoxical myotonia). This is in contrast to classic myotonia in which exercise alleviates the condition. Attacks of weakness are seldom severe enough to require emergency room treatment. Over time patients develop interattack weakness as they do in other forms of periodic paralysis. PC is usually associated with normokalemia or hyperkalemia.

Serum CK is usually mildly elevated. Routine sensory and motor nerve conduction studies are normal. Cooling of the muscle often dra-

matically reduces the amplitude of the compound muscle action potentials. EMG reveals diffuse myotonic potentials in PC. Upon local cooling of the muscle the myotonic discharges disappear as the patient becomes unable to activate motor unit action potentials.

PC is inherited as an autosomal dominant condition; voltage-gated sodium channel mutations (Fig. 382-8) are responsible and thus this disorder is allelic with HyperKPP and potassium-aggravated myotonia. Patients with PC seldom seek treatment during attacks. Oral administration of glucose or other carbohydrates hastens recovery. Since interattack weakness may develop after repeated episodes, prophylactic treatment is usually indicated. Thiazide diuretics (e.g., chlorothiazide, 250–1000 mg/d) and mexiletine (slowly increase dose from 450 mg/d) are reported to be helpful. Patients should be advised to increase carbohydrates in their diet.

POTASSIUM CHANNEL DISORDERS

Andersen-Tawil Syndrome This rare disease is characterized by episodic weakness, cardiac arrhythmias, and dysmorphic features (short stature, scoliosis, clinodactyly, hypertelorism, small or prominent low set ears, micrognathia, and broad forehead). The cardiac arrhythmias are potentially serious and life threatening. They include long QT, ventricular ectopy, bidirectional ventricular arrhythmias, and tachycardia. For many years the classification of this disorder was uncertain because episodes of weakness are associated with elevated, normal, or reduced levels of potassium during an attack. In addition, the potassium levels differ among kindreds but are consistent within a family. Inheritance is autosomal dominant, with incomplete penetrance and variable expressivity. The disease is caused by mutations of the inwardly rectifying potassium channel (*Kir 2.1*) gene. The treatment is similar to that for other forms of periodic paralysis and must include cardiac monitoring. The episodes of weakness may differ between patients because of potassium variability. Acetazolamide decreases the attack frequency and severity.

CHLORIDE CHANNEL DISORDERS

Two forms of this disorder, autosomal dominant (*Thomsen's disease*) and autosomal recessive (*Becker's disease*) are related to the same gene abnormality. Symptoms are noted in infancy and early childhood. The severity lessens in the third to fourth decade. Myotonia is worsened by cold and improved by activity. The gait may appear slow and labored at first but improves with walking. In Thomsen's disease muscle strength is normal, but in Becker's, which is usually more severe, there may be muscle weakness. Muscle hypertrophy is usually present. Myotonic discharges are prominently displayed by EMG recordings.

Serum CK is normal or mildly elevated. The muscle biopsy shows hypertrophied fibers. The disease is inherited as dominant or recessive and is caused by mutations of the chloride channel gene (Fig. 382-8). Many patients will not require treatment and learn that the symptoms improve with activity. Medications that can be used to decrease myotonia include quinine, phenytoin, and mexiletine.

ENDOCRINE AND METABOLIC MYOPATHIES

Many endocrine disorders cause weakness. Muscle fatigue is more common than true weakness. The cause of weakness in these disorders is not well defined. It is not even clear that weakness results from disease of muscle as opposed to another part of the motor unit, since the serum CK level is often normal (except in hypothyroidism) and the muscle histology is characterized by atrophy rather than destruction of muscle fibers. Nearly all endocrine myopathies respond to treatment.

THYROID DISORDERS

(See also Chap. 335) Abnormalities of thyroid function can cause a wide array of muscle disorders. These conditions relate to the important role of thyroid hormones in regulating the metabolism of carbohydrates and lipids as well as the rate of protein synthesis and enzyme production. Thyroid hormones also stimulate calorigenesis in muscle, increase muscle demand for vitamins, and enhance muscle sensitivity to circulating catecholamines.

Hypothyroidism Patients with hypothyroidism have frequent muscle complaints, and proximal muscle weakness occurs in about one-third of them. Muscle cramps, pain, and stiffness are common. Some patients have enlarged muscles. Features of slow muscle contraction and relaxation occur in 25% of patients; the relaxation phase of muscle stretch reflexes is characteristically prolonged and best observed at the ankle or biceps brachii reflexes. The serum CK level is often elevated (up to 10 times normal), even when there is minimal clinical evidence of muscle disease. EMG is typically normal. The cause of muscle enlargement has not been determined, and muscle biopsy shows no distinctive morphologic abnormalities.

Hyperthyroidism Patients who are thyrotoxic commonly have proximal muscle weakness and atrophy on examination, but they rarely complain of myopathic symptoms. Activity of deep tendon reflexes may be enhanced. Bulbar, respiratory, and even esophageal muscles may occasionally be affected, causing dysphagia, dysphonia, and aspiration. When bulbar involvement occurs, it is usually accompanied by chronic proximal limb weakness, but occasionally it presents in the absence of generalized thyrotoxic myopathy. Fasciculations may be apparent and, when coupled with increased muscle stretch reflexes, may lead to an erroneous diagnosis of amyotrophic lateral sclerosis. Other neuromuscular disorders occur in association with hyperthyroidism, including acquired hypokalemic periodic paralysis, myasthenia gravis, and a progressive ocular myopathy associated with proptosis (*Graves' ophthalmopathy*). Serum CK levels are not elevated in thyrotoxic myopathy, the EMG is normal, and muscle histology usually shows only atrophy of muscle fibers.

PARATHYROID DISORDERS

(See also Chap. 347)

Hyperparathyroidism Muscle weakness is an integral part of primary and secondary hyperparathyroidism. Proximal muscle weakness, muscle wasting, and brisk muscle stretch reflexes are the main features of this endocrinopathy. Some patients develop neck extensor weakness (part of the dropped head syndrome). Serum CK levels are usually normal or slightly elevated. Serum parathyroid hormone levels are elevated. Serum calcium and phosphorus levels show no correlation with the clinical neuromuscular manifestations. Muscle biopsies show only varying degrees of atrophy without muscle fiber degeneration.

Hypoparathyroidism An overt myopathy due to hypocalcemia rarely occurs. Neuromuscular symptoms are usually related to localized or generalized tetany. Serum CK levels may be increased secondary to muscle damage from sustained tetany. Hyporeflexia or areflexia is usually present and contrasts with the hyperreflexia in hyperparathyroidism.

ADRENAL DISORDERS

(See also Chap. 336) Conditions associated with glucocorticoid excess cause a myopathy; in fact, steroid myopathy is the most commonly diagnosed endocrine muscle disease. Glucocorticoid excess, either endogenous or exogenous (see "Drug-Induced Myopathies," below), produces various degrees of proximal limb weakness. Muscle wasting may be striking. A cushingoid appearance usually accompanies clinical signs of myopathy. Histologic sections demonstrate muscle fiber atrophy, preferentially affecting type 2b fibers, rather than degeneration or necrosis of muscle fibers. Adrenal insufficiency commonly causes muscle fatigue. The degree of weakness may be difficult to assess but is typically mild. In primary hyperaldosteronism (*Conn's syndrome*), neuromuscular complications are due to potassium depletion. The clinical picture is one of persistent muscle weakness. Long-standing hyperaldosteronism may lead to proximal limb weakness and wasting. Serum CK levels may be elevated, and a muscle biopsy may demonstrate degenerating fibers, some with vacuoles. These changes relate to hypokalemia and are not a direct effect of aldosterone on skeletal muscle.

PITUITARY DISORDERS

(See also Chap. 333) Patients with acromegaly usually have mild proximal weakness without muscle atrophy. Muscles often appear enlarged

but exhibit decreased force generation. The duration of acromegaly, rather than the serum growth hormone levels, correlates with the degree of myopathy.

DIABETES MELLITUS

(See also Chap. 338) Neuromuscular complications of diabetes mellitus are most often related to neuropathy, with cranial and peripheral nerve palsies or distal sensorimotor polyneuropathy. *Diabetic amyotrophy* is a clumsy term since the condition represents a neuropathy affecting the proximal major nerve trunks and lumbosacral plexus. More appropriate terms for this disorder include *diabetic proximal neuropathy* and *lumbosacral radiculoplexus neuropathy*.

The only notable myopathy of diabetes mellitus is ischemic infarction of leg muscles, usually involving one of the thigh muscles but on occasion affecting the distal leg. This condition occurs in patients with poorly controlled diabetes and presents with abrupt onset of pain, tenderness, and edema of one thigh. The area of muscle infarction is hard and indurated. The muscles most often affected include the vastus lateralis, thigh adductors, and biceps femoris. CT or MRI can demonstrate focal abnormalities in the affected muscle. Diagnosis by imaging is preferable to muscle biopsy, if possible, as hemorrhage into the biopsy site can occur.

VITAMIN DEFICIENCY

Vitamin D deficiency (Chap. 71) due to either decreased intake, decreased absorption, or impaired vitamin D metabolism (as occurs in renal disease) may lead to chronic muscle weakness. Pain reflects the underlying bone disease (*osteomalacia*). Vitamin E deficiency may result from malabsorption. Clinical manifestations include ataxic neuropathy due to loss of proprioception and myopathy with proximal weakness. Progressive external ophthalmoplegia is a distinctive finding. It has not been established that deficiency of other vitamins causes a myopathy.

MYOPATHIES OF SYSTEMIC ILLNESS

Systemic illnesses such as chronic respiratory, cardiac, or hepatic failure are frequently associated with severe muscle wasting and complaints of weakness. Fatigue is usually a more significant problem than weakness, which is typically mild.

Myopathy may be a manifestation of chronic renal failure, independent of the better known uremic polyneuropathy. Abnormalities of calcium and phosphorus homeostasis and bone metabolism in chronic renal failure result from a reduction in 1,25-dihydroxyvitamin D, leading to decreased intestinal absorption of calcium. Hypocalcemia, further accentuated by hyperphosphatemia due to decreased renal phosphate clearance, leads to secondary hyperparathyroidism. Renal osteodystrophy results from the compensatory hyperparathyroidism, which leads to osteomalacia from reduced calcium availability and to osteitis fibrosa from the parathyroid hormone excess. The clinical picture of the myopathy of chronic renal failure is identical to that of primary hyperparathyroidism and osteomalacia. There is proximal limb weakness with bone pain.

Gangrenous calcification represents a separate, rare, and sometimes fatal complication of chronic renal failure. In this condition, widespread arterial calcification occurs and results in ischemia. Extensive skin necrosis may occur, along with painful myopathy and even myoglobinuria.

DRUG-INDUCED MYOPATHIES

Drug-induced myopathies are relatively uncommon in clinical practice with the exception of those caused by the cholesterol-lowering agents and glucocorticoids. Others impact practice to a lesser degree but are important to consider in specific situations. Table 382-10 provides a comprehensive list of drug-induced myopathies with their distinguishing features.

TABLE 382-10 DRUG-INDUCED MYOPATHIES

Drugs	Major Toxic Reaction
Lipid-lowering agents Fibric acid derivatives HMG-CoA reductase inhibitors Niacin (nicotinic acid)	Drugs belonging to all three of the major classes of lipid-lowering agents can produce a spectrum of toxicity: asymptomatic serum creatine kinase elevation, myalgias, exercised-induced pain, rhabdomyolysis, and myoglobinuria.
Glucocorticoids	Acute, high-dose glucocorticoid treatment can cause acute quadriplegic myopathy. These high doses of steroids are often combined with nondepolarizing neuromuscular blocking agents but the weakness can occur without their use. Chronic steroid administration produces predominantly proximal weakness.
Nondepolarizing neuromuscular blocking agents	Acute quadriplegic myopathy can occur with or without concomitant glucocorticoids.
Zidovudine	Mitochondrial myopathy with ragged red fibers.
Drugs of abuse Alcohol Amphetamines Cocaine Heroin Phencyclidine Meperidine	All drugs in this group can lead to widespread muscle breakdown, rhabdomyolysis, and myoglobinuria. Local injections cause muscle necrosis, skin induration, and limb contractures.
Autoimmune toxic myopathy D-Penicillamine	Use of this drug may cause polymyositis and myasthenia gravis.
Amphophilic cationic drugs Amiodarone Chloroquine Hydroxychloroquine	All amphophilic drugs have the potential to produce painless, proximal weakness associated with autophagic vacuoles in the muscle biopsy.
Antimicrotubular drugs Colchicine	This drug produces painless, proximal weakness especially in the setting of renal failure. Muscle biopsy shows autophagic vacuoles.

MYOPATHY FROM LIPID-LOWERING AGENTS

All classes of lipid-lowering agents have been implicated in muscle toxicity including fibrates (clofibrate, gemfibrozil), HMG-CoA reductase inhibitors (referred to as *statins*), niacin (nicotinic acid), and ezetimibe. Myalgia, malaise, and muscle tenderness are the most common manifestations. Muscle pain may be related to exercise. Patients may exhibit proximal weakness. Varying degrees of muscle necrosis are seen, and in severe reactions rhabdomyolysis and myoglobinuria occur. Concomitant use of statins with fibrates and cyclosporine is more likely to cause adverse reactions than use of one agent alone. Elevated serum CK is an important indication of toxicity. Muscle weakness is accompanied by a myopathic EMG, and muscle necrosis is observed by muscle biopsy. Severe myalgias, muscle weakness, significant elevations in serum CK (> three times baseline), and myoglobinuria are indications for stopping the drug. Patients usually improve with drug cessation, although this may take several weeks. Rare cases continue to progress after the offending agent is discontinued. It is possible that in such cases the statin may have triggered an immune-mediated necrotizing myopathy, as these individuals may respond to glucocorticoid therapy.

GLUCOCORTICOID-RELATED MYOPATHIES

Glucocorticoid myopathy occurs with chronic treatment or as "acute quadriplegic" myopathy secondary to high-dose, IV glucocorticoids. Chronic administration produces proximal weakness accompanied by cushingoid manifestations, which can be quite debilitating; the chronic use of prednisone at a daily dose of ≥30 mg/d is most often associated with toxicity. Patients taking fluorinated glucocorticoids (triamcinolone, betamethasone, dexamethasone) appear to be at especially high risk for myopathy. Patients receiving high-dose, IV glucocorticoids for status asthmaticus, chronic obstructive pulmonary disease, or other indications may develop severe generalized weakness. Involvement of the diaphragm and intercostal muscles causes respiratory failure and requires ventilatory support. In this setting, the use of glucocorticoids in combination with nondepolarizing neuromuscular blocking agents to further decrease airway resistance is particularly likely to lead to this complication. In chronic steroid myopathy the serum CK is usually normal. Serum potassium

may be low. The muscle biopsy in chronic cases shows preferential type 2 muscle fiber atrophy; this is not reflected in the EMG, which is usually normal. In acute cases with quadriplegic myopathy the muscle biopsy is abnormal, showing a distinctive loss of thick filaments (myosin) by electron microscopy. By light microscopy there is focal loss of ATPase staining in central or paracentral areas of the muscle fiber. Calpain stains show diffusely reactive atrophic fibers. Withdrawal of glucocorticoids will improve the chronic myopathy. In acute quadriplegic myopathy, recovery is slow. Patients require supportive care and rehabilitation.

MYOPATHY OF NONDEPOLARIZING NEUROMUSCULAR BLOCKING AGENTS

Patients may receive nondepolarizing neuromuscular blocking agents because of life-threatening airway resistance. Acute quadriplegic myopathy may result, with or without glucocorticoid use. The clinical features are identical to acute quadriplegic myopathy secondary to glucocorticoids.

DRUG-INDUCED MITOCHONDRIAL MYOPATHY

Zidovudine, used in the treatment of HIV infection, is a thymidine analogue that inhibits viral replication by interrupting reverse transcriptase. Myopathy is a well-established complication of this agent. Patients present with myalgias, muscle weakness, and atrophy affecting the thigh and calf muscles. The complication occurs in about 17% of patients treated with doses of 1200 mg/d for 6 months. The introduction of protease inhibitors for treatment of HIV infection has led to lower doses of zidovudine therapy and a decreased incidence of myopathy. Serum CK is elevated and EMG is myopathic. Muscle biopsy shows ragged red fibers with minimal inflammation; the lack of inflammation serves to distinguish zidovudine toxicity from HIV-related myopathy. If the myopathy is thought to be drug-related, the medication should be stopped or the dosage reduced.

DRUGS OF ABUSE AND RELATED MYOPATHIES

Myotoxicity is a potential consequence of addiction to alcohol and illicit drugs. Ethanol is one of the most commonly abused substances with potential to damage muscle. Other potential toxins include cocaine, heroin, and amphetamines. The most deleterious reactions occur from overdosing leading to coma and seizures, causing rhabdomyolysis, myoglobinuria, and renal failure. Direct toxicity can occur from cocaine, heroin, and amphetamines causing muscle breakdown and varying degrees of weakness. The effects of alcohol are more controversial. Direct muscle damage is less certain, since toxicity usually occurs in the setting of poor nutrition and possible contributing factors such as hypokalemia and hypophosphatemia. Alcoholics are also prone to neuropathy and a variety of CNS disorders (Chap. 387).

Focal myopathies from self-administration of meperidine, heroin, and pentazocine can cause pain, swelling, muscle necrosis, and hemorrhage. The cause is multifactorial; needle trauma, direct toxicity of the drug or vehicle, and infection may all play a role. When severe, there may be overlying skin induration and contractures with replacement of muscle by connective tissue. Elevated serum CK and myopathic EMG are characteristic of these reactions. The muscle biopsy shows widespread or focal areas of necrosis. In conditions leading to rhabdomyolysis, patients need adequate hydration to reduce serum myoglobin and protect renal function. In all of these conditions, counseling is essential to limit drug abuse.

DRUG-INDUCED AUTOIMMUNE MYOPATHIES

The most consistent drug-related inflammatory or antibody-mediated myopathy is caused by D-penicillamine. This drug chelates copper and is used in the treatment of Wilson's disease. It is also used to treat other disorders including scleroderma, rheumatoid arthritis, and primary biliary cirrhosis. Adverse events include drug-induced polymyositis, indistinguishable from the spontaneous disease. The incidence of this inflammatory muscle disease is about 1%. Myasthenia gravis is also induced by D-penicillamine, with a higher incidence estimated at 7%. These disorders resolve with drug withdrawal, although immunosuppressive therapy may be warranted in severe cases.

Scattered reports of other drugs causing an inflammatory myopathy are rare and include a heterogeneous group of agents: cimetidine, phenytoin, procainamide, and propylthiouracil. In most cases, a cause-and-effect relationship is uncertain. A complication of interest was related to L-tryptophan. In 1989 an epidemic of eosinophilia-myalgia syndrome (EMS) in the United States was caused by a contaminant in the product from one manufacturer. The product was withdrawn, and incidence of EMS diminished abruptly following this action.

OTHER DRUG-INDUCED MYOPATHIES

Certain drugs produce painless, largely proximal, muscle weakness. These drugs include the amphophilic cationic drugs (amiodarone, chloroquine, hydroxychloroquine) and antimicrotubular drugs (colchicine) (Table 382-10). Muscle biopsy can be useful in the identification of toxicity since autophagic vacuoles are prominent pathologic features of these toxins.

383 Polymyositis, Dermatomyositis, and Inclusion Body Myositis

Marinos C. Dalakas

The inflammatory myopathies represent the largest group of acquired and potentially treatable causes of skeletal muscle weakness. They are classified into three major groups: polymyositis (PM), dermatomyositis (DM), and inclusion body myositis (IBM).

CLINICAL FEATURES

The prevalence of the inflammatory myopathies is estimated at 1 in 100,000. PM as a stand-alone entity is a rare disease affecting adults. DM affects both children and adults and women more often than men. IBM is three times more frequent in men than in women, more common in Caucasians than blacks, and is most likely to affect persons >50 years of age.

These disorders present as progressive and symmetric muscle weakness except for IBM, which can have an asymmetric pattern. Patients usually report increasing difficulty with everyday tasks requiring the use of proximal muscles, such as getting up from a chair, climbing steps, stepping onto a curb, lifting objects, or combing hair. Fine-motor movements that depend on the strength of distal muscles, such as buttoning a shirt, sewing, knitting, or writing, are affected only late in the course of PM and DM, but fairly early in IBM. Falling is common in IBM because of early involvement of the quadriceps muscle with buckling of the knees. Ocular muscles are spared, even in advanced, untreated cases; if these muscles are affected, the diagnosis of inflammatory myopathy should be questioned. Facial muscles are unaffected in PM and DM, but mild facial muscle weakness is common in patients with IBM. In all forms of inflammatory myopathy, pharyngeal and neck-flexor muscles are often involved, causing dysphagia or difficulty in holding up the head (*head drop*). In advanced and rarely in acute cases, respiratory muscles may also be affected. Severe weakness, if untreated, is almost always associated with muscle wasting. Sensation remains normal. The tendon reflexes are preserved but may be absent in severely weakened or atrophied muscles, especially in IBM where atrophy of the quadriceps and the distal muscles is common. Myalgia and muscle tenderness may occur in a small number of patients, usually early in the disease, and particularly in DM associated with connective tissue disorders. Weakness in PM and DM progresses subacutely over a period of weeks or months and rarely acutely; by contrast, IBM progresses very slowly, over years, simulating a late-life muscular dystrophy (Chap. 382) or slowly progressive motor neuron disorder (Chap. 369).

SPECIFIC FEATURES

(Table 383-1)

Polymyositis The actual onset of PM is often not easily determined, and patients typically delay seeking medical advice for several months. This is in contrast to DM, in which the rash facilitates early recognition (see below). PM mimics many other myopathies and is a diagnosis of exclusion. It is a subacute inflammatory myopathy affecting adults, and rarely children, who *do not have* any of the following: rash, involvement of the extraocular and facial muscles, family history of a neuromuscular disease, history of exposure to myotoxic drugs or toxins, endocrinopathy, neurogenic disease, muscular dystrophy, biochemical muscle disorder (deficiency of a muscle enzyme), or IBM as excluded by muscle biopsy analysis (see below). As an isolated entity, PM is a rare (and overdiagnosed) disorder; more commonly, PM occurs in association with a systemic autoimmune or connective tissue disease, or with a known viral or bacterial infection. Drugs, especially D-penicillamine or zidovudine (AZT), may also produce an inflammatory myopathy similar to PM.

Dermatomyositis DM is a distinctive entity identified by a characteristic rash accompanying, or more often preceding, muscle weakness. The rash may consist of a blue-purple discoloration on the upper eyelids with edema (heliotrope rash; see Fig. 55-3), a flat red rash on the face and upper trunk, and erythema of the knuckles with a raised violaceous scaly eruption (*Gottron's sign*; see Fig. 55-4). The erythematous rash can also occur on other body surfaces, including the knees, elbows, malleoli, neck and anterior chest (often in a *V sign*), or back and shoulders (*shawl sign*), and may worsen after sun exposure. In some patients the rash is pruritic, especially on the scalp, chest, and back. Dilated capillary loops at the base of the fingernails are also characteristic. The cuticles may be irregular, thickened, and distorted, and the lateral and palmar areas of the fingers may become rough and cracked, with irregular, "dirty" horizontal lines, resembling *mechanic's hands*. The weakness can be mild, moderate, or severe enough to lead to quadriparesis. At times, the muscle strength appears normal, hence the term *dermatomyositis sine myositis*. When muscle biopsy is performed in such cases, however, significant perivascular and perimysial inflammation is often seen.

DM usually occurs alone but may overlap with scleroderma and mixed connective tissue disease. Fasciitis and thickening of the skin, similar to that seen in chronic cases of DM, have occurred in patients with the *eosinophilia-myalgia syndrome* associated with the ingestion of contaminated L-tryptophan.

Inclusion Body Myositis In patients ≥50 years of age, IBM is the most common of the inflammatory myopathies. It is often misdiagnosed as PM and is suspected only later when a patient with presumed PM does not respond to therapy. Weakness and atrophy of the distal muscles, especially foot extensors and deep finger flexors, occur in almost all cases of IBM and may be a clue to early diagnosis. Some patients present with falls because their knees collapse due to early quadriceps weakness. Others present with weakness in the small muscles of the

TABLE 383-1 FEATURES ASSOCIATED WITH INFLAMMATORY MYOPATHIES

Characteristic	Polymyositis	Dermatomyositis	Inclusion Body Myositis
Age at onset	>18 yr	Adulthood and childhood	>50 yr
Familial association	No	No	Yes, in some cases
Extramuscular manifestations	Yes	Yes	Yes
Associated conditions			
Connective tissue diseases	Yes[a]	Scleroderma and mixed connective tissue disease (overlap syndromes)	Yes, in up to 20% of cases[a]
Systemic autoimmune diseases[b]	Frequent	Infrequent	Infrequent
Malignancy	No	Yes, in up to 15% of cases	No
Viruses	Yes[c]	Unproven	Yes[c]
Drugs[d]	Yes	Yes, rarely	No
Parasites and bacteria[e]	Yes	No	No

[a]Systemic lupus erythematosus, rheumatoid arthritis, Sjögren's syndrome, systemic sclerosis, mixed connective tissue disease.
[b]Crohn's disease, vasculitis, sarcoidosis, primary biliary cirrhosis, adult celiac disease, chronic graft-versus-host disease, discoid lupus, ankylosing spondylitis, Behçet's syndrome, myasthenia gravis, acne fulminans, dermatitis herpetiformis, psoriasis, Hashimoto's disease, granulomatous diseases, agammaglobulinemia, monoclonal gammopathy, hypereosinophilic syndrome, Lyme disease, Kawasaki disease, autoimmune thrombocytopenia, hypergammaglobulinemic purpura, hereditary complement deficiency, IgA deficiency.
[c]HIV (human immunodeficiency virus) and HTLV-I (human T cell lymphotropic virus type I).
[d]Drugs include penicillamine (dermatomyositis and polymyositis), zidovudine (polymyositis), and contaminated tryptophan (dermatomyositis-like illness). Other myotoxic drugs may cause myopathy but not an inflammatory myopathy (see text for details).
[e]Parasites (protozoa, cestodes, nematodes), tropical and bacterial myositis (pyomyositis).

hands, especially finger flexors, and complain of inability to hold objects such as golf clubs or perform tasks such as turning keys or tying knots. On occasion, the weakness and accompanying atrophy can be asymmetric and selectively involve the quadriceps, iliopsoas, triceps, biceps, and finger flexors, resembling a lower motor neuron disease. Dysphagia is common, occurring in up to 60% of IBM patients, and may lead to episodes of choking. Sensory examination is generally normal; some patients have mildly diminished vibratory sensation at the ankles that presumably is age-related. The pattern of distal weakness, which superficially resembles motor neuron or peripheral nerve disease, results from the myopathic process affecting distal muscles selectively. Disease progression is slow but steady, and most patients require an assistive device such as cane, walker, or wheelchair within several years of onset.

In at least 20% of cases, IBM is associated with systemic autoimmune or connective tissue diseases. Familial aggregation of typical IBM may occur; such cases have been designated as *familial inflammatory IBM*. This disorder is distinct from *hereditary inclusion body myopathy* (h-IBM), which describes a heterogeneous group of recessive, and less frequently dominant, inherited syndromes; the h-IBMs are noninflammatory myopathies. A subset of h-IBM that spares the quadriceps muscles has emerged as a distinct entity. This disorder, originally described in Iranian Jews and now seen in many ethnic groups, is linked to chromosome 9p1 and results from mutations in the UDP-*N*-acetylglucosamine 2-epimerase/*N*-acetylmannosamine kinase (*GNE*) gene.

ASSOCIATED CLINICAL FINDINGS

Extramuscular Manifestations These may be present to a varying degree in patients with PM or DM, and include:

1. *Systemic symptoms*, such as fever, malaise, weight loss, arthralgia, and Raynaud's phenomenon, especially when inflammatory myopathy is associated with a connective tissue disorder.
2. *Joint contractures,* mostly in DM and especially in children.
3. *Dysphagia and gastrointestinal symptoms,* due to involvement of oropharyngeal striated muscles and upper esophagus, especially in DM and IBM.
4. *Cardiac disturbances,* including atrioventricular conduction defects, tachyarrhythmias, dilated cardiomyopathy, a low ejection fraction, and congestive heart failure, may rarely occur, either from the disease itself or from hypertension associated with long-term use of glucocorticoids.
5. *Pulmonary dysfunction,* due to weakness of the thoracic muscles, interstitial lung disease, or drug-induced pneumonitis (e.g., from methotrexate), which may cause dyspnea, nonproductive cough, and aspiration pneumonia. Interstitial lung disease may precede myopathy or occur early in the disease and develops in up to 10% of patients with PM or DM, most of whom have antibodies to t-RNA synthetases, as described below.
6. *Subcutaneous calcifications,* in DM, sometimes extruding on the skin and causing ulcerations and infections.
7. *Arthralgias,* synovitis, or deforming arthropathy with subluxation in the interphalangeal joints can occur in some patients with DM and PM who have Jo-1 antibodies (see below).

Association with Malignancies Although all the inflammatory myopathies can have a chance association with malignant lesions, especially in older age groups, the incidence of malignant conditions appears to be specifically increased only in patients with DM and not in those with PM or IBM. The most common tumors associated with DM are ovarian cancer, breast cancer, melanoma, colon cancer, and non-Hodgkin lymphoma. The extent of the search that should be conducted for an occult neoplasm in adults with DM depends on the clinical circumstances. Tumors in these patients are usually uncovered by abnormal findings in the medical history and physical examination and not through an extensive blind search. The weight of evidence argues against performing expensive, invasive, and nondirected tumor searches. A complete annual physical examination with pelvic, breast (mammogram, if indicated), and rectal examinations (with colonoscopy according to age and family history); urinalysis; complete blood count; blood chemistry tests; and a chest film should suffice in most cases. In Asians, nasopharyngeal cancer is common, and a careful examination of ears, nose, and throat is indicated.

Overlap Syndromes These describe the association of inflammatory myopathies with connective tissue diseases. A well-characterized overlap syndrome occurs in patients with DM who also have manifestations of systemic sclerosis or mixed connective tissue disease, such as sclerotic thickening of the dermis, contractures, esophageal hypomotility, microangiopathy, and calcium deposits (Table 383-1). By contrast, signs of rheumatoid arthritis, systemic lupus erythematosus, or Sjögren's syndrome are very rare in patients with DM. Patients with the overlap syndrome of DM and systemic sclerosis may have a specific antinuclear antibody, the anti-PM/Scl, directed against a nucleolar-protein complex.

PATHOGENESIS

An autoimmune etiology of the inflammatory myopathies is indirectly supported by an association with other autoimmune or connective tissue diseases; the presence of various autoantibodies; an association with specific major histocompatibility complex (MHC) genes; demonstration of T cell–mediated myocytotoxicity or complement-mediated microangiopathy; and a response to immunotherapy.

Autoantibodies and Immunogenetics Various autoantibodies against nuclear antigens (antinuclear antibodies) and cytoplasmic antigens are found in up to 20% of patients with inflammatory myopathies. The antibodies to cytoplasmic antigens are directed against ribonucleoproteins involved in protein synthesis (anti-synthetases) or translational transport (anti-signal-recognition particles). The antibody directed against the histidyl-transfer RNA synthetase, called *anti-Jo-1*, accounts for 75% of all the anti-synthetases and is clinically useful because up to 80% of patients with anti-Jo-1 antibodies have interstitial lung disease. Some patients with the anti-Jo-1 antibody also have Raynaud's phenomenon, nonerosive arthritis, and the MHC molecules DR3 and DRw52. DR3 haplotypes (molecular designation DRB1*0301, DQB1*0201) occur in up to 75% of patients with PM and IBM, whereas in juvenile DM there is an increased frequency of DQA1*0501 (Chap. 309).

Immunopathologic Mechanisms In DM, humoral immune mechanisms are implicated, resulting in a microangiopathy and muscle ischemia (Fig. 383-1). Endomysial inflammatory infiltrates are composed of B cells located in proximity to CD4 T cells, dendritic cells, and macrophages; there is a relative absence of lymphocytic invasion of nonnecrotic muscle fibers. Activation of the complement C5b-9 membranolytic attack complex is thought to be a critical early event that triggers release of proinflammatory cytokines and chemokines, induces expression of vascular cell adhesion molecule (VCAM) 1 and intracellular adhesion molecule (ICAM) 1 on endothelial cells, and facilitates migration of activated lymphoid cells to the perimysial and endomysial spaces. Necrosis of the endothelial cells, reduced numbers of endomysial capillaries, ischemia, and muscle-fiber destruction resembling microinfarcts occur. The remaining capillaries often have dilated lumens in response to the ischemic process. Larger intramuscular blood vessels may also be affected in the same pattern. Residual perifascicular atrophy reflects the endofascicular hypoperfusion that is prominent in the periphery of the muscle fascicles.

By contrast, in PM and IBM a mechanism of T cell–mediated cytotoxicity is likely. CD8 T cells, along with macrophages, initially surround and eventually invade and destroy healthy, nonnecrotic muscle fibers that aberrantly express class I MHC molecules. MHC-I expression, absent from the sarcolemma of normal muscle fibers, is probably induced by cytokines secreted by activated T cells and macrophages. The CD8/MHC-I complex is characteristic of PM and IBM; its detection can aid in confirming the histologic diagnosis of PM, as discussed below. The cytotoxic CD8 T cells contain perforin and granzyme gran-

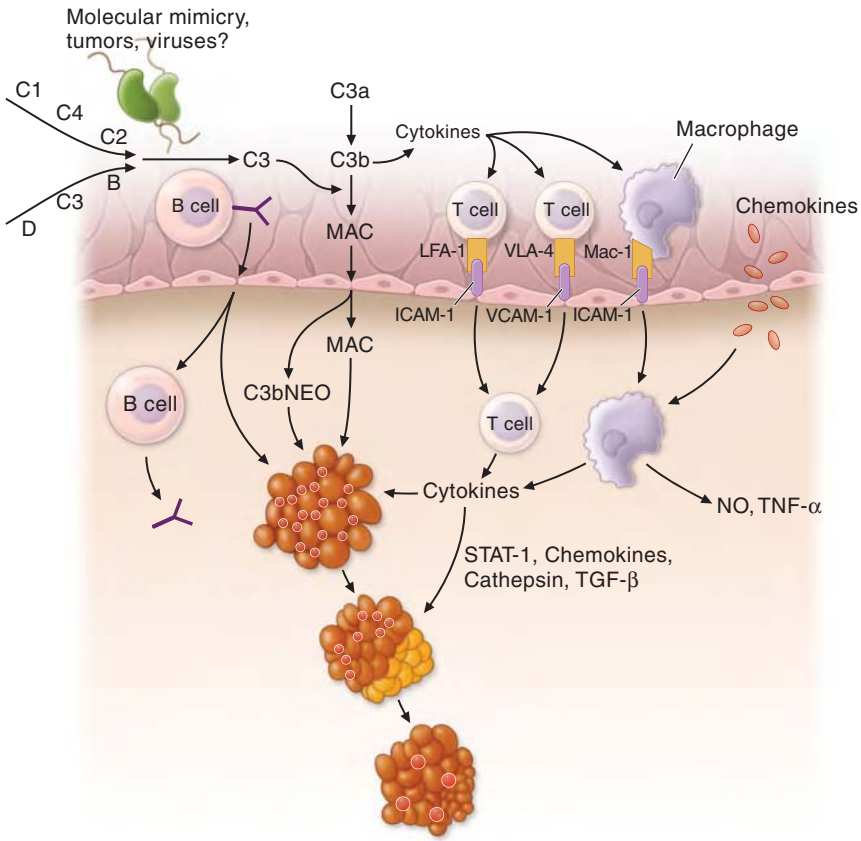

FIGURE 383-1 Immunopathogenesis of dermatomyositis. Activation of complement, possibly by autoantibodies (Y), against endothelial cells and formation of C3 via the classic or alternative pathway. Activated C3 leads to formation of C3b, C3bNEO, and membrane attack complexes (MAC), which are deposited in and around the endothelial cell wall of the endomysial capillaries. Deposition of MAC leads to destruction of capillaries, ischemia, or microinfarcts most prominent in the periphery of the fascicles, and perifascicular atrophy. B cells, CD4 T cells, and macrophages traffic from the circulation to the muscle. Endothelial expression of vascular cell adhesion molecule (VCAM) and intercellular adhesion molecule (ICAM) is induced by cytokines released by the mononuclear cells. Integrins, specifically very late activation antigen (VLA)-4 and leukocyte function-associated antigen (LFA)-1, bind VCAM and ICAM and promote T cell and macrophage infiltration of muscle through the endothelial cell wall.

ules directed towards the surface of the muscle fibers and capable of inducing myonecrosis. Analysis of T cell receptor molecules expressed by the infiltrating CD8 cells have revealed clonal expansion and conserved sequences in the antigen-binding region, both suggesting an antigen-driven T cell response. Whether the putative antigens are endogenous (e.g., muscle) or exogenous (e.g., viral) sequences is unknown. Viruses have not been identified within the muscle fibers. Co-stimulatory molecules and their counterreceptors, which are fundamental for T cell activation and antigen recognition, are strongly upregulated in PM and IBM. Key molecules involved in T cell–mediated cytotoxicity are depicted in Fig. 383-2.

The Role of Nonimmune Factors in IBM In IBM, the presence of β-amyloid deposits within vacuolated muscle fibers and abnormal mitochondria with cytochrome oxidase–negative fibers suggest that, in addition to the autoimmune component, there is also a degenerative process. Similar to Alzheimer's disease, the amyloid deposits in IBM are immunoreactive against amyloid precursor protein (APP), chymotrypsin, apolipoprotein E, and phosphorylated tau, but it is unclear whether these deposits are directly pathogenic or represent secondary phenomena. The same is true for the mitochondrial abnormalities, which may also be secondary to the effects of aging or a bystander effect of upregulated cytokines. Expression of cytokines and upregulation of MHC class I by the muscle fibers may cause an endoplasmic reticulum stress response resulting in intracellular accumulation of misfolded glycoproteins and activation of nuclear factor κB (NFκB), leading to further cytokine activation.

Association with Viral Infections and the Role of Retroviruses Several viruses, including coxsackieviruses, influenza, paramyxoviruses, mumps, cytomegalovirus, and Epstein-Barr virus, have been indirectly associated with myositis. For the coxsackieviruses, an autoimmune myositis triggered by molecular mimicry has been proposed because of structural homology between histidyl-transfer RNA synthetase that is the target of the Jo-1 antibody (see above) and genomic RNA of an animal picornavirus, the encephalomyocarditis virus. Sensitive polymerase chain reaction (PCR) studies, however, have repeatedly failed to confirm the presence of such viruses in muscle biopsies.

The best evidence of a viral connection in PM and IBM is with the retroviruses. Some individuals infected with HIV or with human T cell lymphotropic virus I (HTLV-I) develop PM or IBM; a similar disorder has been described in nonhuman primates infected with the simian immunodeficiency virus. The inflammatory myopathy may occur as the initial manifestation of a retroviral infection, or myositis may develop later in the disease course. Retroviral antigens have been detected only in occasional endomysial macrophages and not within the muscle fibers themselves, suggesting that persistent infection and viral replication within the muscle do not occur. Histologic findings are identical to retroviral-negative PM or IBM. The infiltrating T cells in the muscle are clonally driven and a number of them are retroviral-specific. This disorder should be distinguished from a toxic myopathy related to long-term therapy with AZT, characterized by fatigue, myalgia, mild muscle weakness, and mild elevation of creatine kinase (CK). AZT-induced myopathy, which generally improves when the drug is discontinued, is a mitochondrial disorder characterized histologically by "ragged-red" fibers. AZT inhibits γ-DNA polymerase, an enzyme found solely in the mitochondrial matrix.

DIFFERENTIAL DIAGNOSIS

The clinical picture of the typical skin rash and proximal or diffuse muscle weakness has few causes other than DM. However, proximal muscle weakness without skin involvement can be due to many conditions other than PM or IBM.

Subacute or Chronic Progressive Muscle Weakness This may be due to denervating conditions such as the spinal muscular atrophies or amyotrophic lateral sclerosis (Chap. 369). In addition to the muscle weakness, upper motor neuron signs in the latter and signs of denervation detected by electromyography (EMG) aid in the diagnosis. The muscular dystrophies (Chap. 382) may be additional considerations; however, these disorders usually develop over years rather than weeks or months and rarely present after the age of 30. It may be difficult, even with a muscle biopsy, to distinguish chronic PM from a rapidly advancing muscular dystrophy. This is particularly true of facioscapulohumeral muscular dystrophy, dysferlin myopathy, and the dystrophinopathies where inflammatory cell infiltration is often found early in the disease. Such doubtful cases should always be given an adequate trial of glucocorticoid therapy and undergo genetic testing to exclude muscular dystrophy. Identification of the MHC/CD8 lesion by muscle biopsy is helpful to

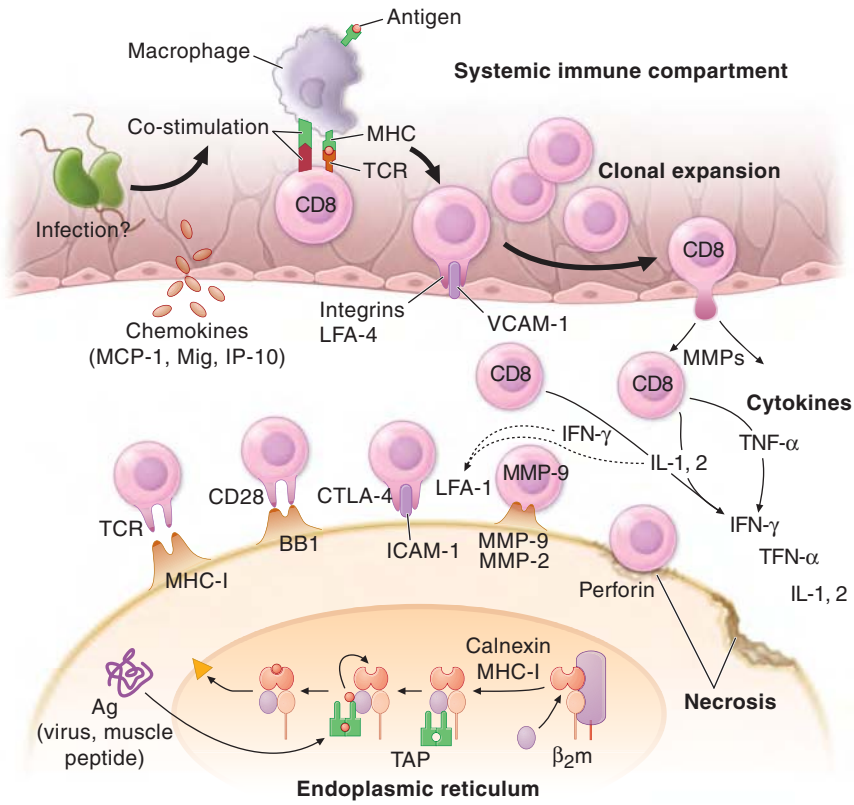

FIGURE 383-2 Cell-mediated mechanisms of muscle damage in polymyositis (PM) and inclusion body myositis (IBM). Antigen-specific CD8 cells are expanded in the periphery, cross the endothelial barrier, and bind directly to muscle fibers via T cell receptor (TCR) molecules that recognize aberrantly expressed MHC-I. Engagement of co-stimulatory molecules (BB1 and ICOSL) with their ligands (CD28, CTLA-4, and ICOS) along with ICAM-1/LFA-1, stabilize the CD8–muscle fiber interaction. Metalloproteinases (MMP) facilitate the migration of T cells and their attachment to the muscle surface. Muscle fiber necrosis occurs via perforin granules released by the autoaggressive T cells. A direct myocytotoxic effect exerted by the cytokines interferon (IFN) γ, interleukin (IL) 1, or tumor necrosis factor (TNF) α may also play a role. Death of the muscle fiber is mediated by necrosis. MHC class I molecules consist of a heavy chain and a light chain [β_2 microglobulin (β_2m)] complexed with an antigenic peptide that is transported into the endoplasmic reticulum by TAP proteins (Chap. 309).

identify cases of PM. Some metabolic myopathies, including glycogen storage disease due to myophosphorylase or acid maltase deficiency, lipid storage myopathies due to carnitine deficiency, and mitochondrial diseases produce weakness that is often associated with other characteristic clinical signs; diagnosis rests upon histochemical and biochemical studies of the muscle biopsy. The endocrine myopathies such as those due to hypercorticosteroidism, hyper- and hypothyroidism, and hyper- and hypoparathyroidism require the appropriate laboratory investigations for diagnosis. Muscle wasting in patients with an underlying neoplasm may be due to disuse, cachexia, or rarely to a paraneoplastic neuromyopathy (Chap. 97).

Diseases of the neuromuscular junction, including myasthenia gravis or the Lambert-Eaton myasthenic syndrome, cause fatiguing weakness that also affects ocular and other cranial muscles (Chap. 381). Repetitive nerve stimulation and single-fiber EMG studies aid in diagnosis.

Acute Muscle Weakness This may be caused by an acute neuropathy such as Guillain-Barré syndrome (Chap. 380), transverse myelitis (Chap. 372), a neurotoxin (Chap. 382), or a neurotropic viral infection such as poliomyelitis or West Nile virus (Chap. 376). When acute weakness is associated with painful muscle cramps, rhabdomyolysis, and myoglobinuria, it may be due to a viral infection or a metabolic disorder such as myophosphorylase deficiency or carnitine palmitoyltransferase deficiency (Chap. 382). Several animal parasites, including protozoa (*toxoplasma*, *trypanosoma*), cestodes (cysticerci), and nematodes (trichinae), may produce a focal or diffuse inflammatory myopathy known as *parasitic polymyositis*. *Staphylococcus aureus*, *Yersinia*, *Streptococcus*, or anaerobic bacteria may produce a suppurative myositis, known as *tropical polymyositis*, or *pyomyositis*. Pyomyositis, previously rare in the west, is now occasionally seen in AIDS patients. Other bacteria, such as *Borrelia burgdorferi* (Lyme disease) and *Legionella pneumophila* (Legionnaire's disease) may infrequently cause myositis.

Patients with periodic paralysis experience recurrent episodes of acute muscle weakness without pain, always beginning in childhood. Chronic alcoholics may develop painful myopathy with myoglobinuria after a bout of heavy drinking. Acute painless muscle weakness with myoglobinuria may occur with prolonged hypokalemia, or hypophosphatemia and hypomagnesemia, usually in chronic alcoholics or in patients on nasogastric suction receiving parenteral hyperalimentation.

Myofasciitis This distinctive inflammatory disorder affecting muscle and fascia presents as diffuse myalgias, skin induration, fatigue, and mild muscle weakness; mild elevations of serum CK are usually present. The most common form is eosinophilic myofasciitis characterized by peripheral blood eosinophilia and eosinophilic infiltrates in the endomysial tissue. In some patients, the eosinophilic myositis/fasciitis occurs in the context of parasitic infections, vasculitis, mixed connective tissue disease, hypereosinophilic syndrome, or toxic exposures (e.g., toxic oil syndrome, contaminated L-tryptophan) or with mutations in the calpain gene. A distinct subset of myofasciitis is characterized by pronounced infiltration of the connective tissue around the muscle by sheets of periodic acid–Schiff-positive macrophages and occasional CD8 T cells (macrophagic myofasciitis). Such histologic involvement is focal and limited to sites of previous vaccinations, which may have been administered months or years earlier. This disorder, which to date has not been observed outside of France, has been linked to an aluminum-containing substrate in vaccines. Most patients respond to glucocorticoid therapy, and the overall prognosis seems favorable.

Necrotizing Myositis This is an increasingly recognized entity that has distinct features, even though it is often labeled as PM. It presents often in the fall or winter as an acute or subacute onset of symmetric muscle weakness; CK is typically extremely high. The weakness can be severe. Coexisting interstitial lung disease and cardiomyopathy may be present. The disorder may develop after a viral infection or in association with cancer. Some patients have antibodies against signal recognition particle (SRP). The muscle biopsy demonstrates necrotic fibers infiltrated by macrophages but only rare, if any, T cell infiltrates. Muscle MHC-I expression is only slightly and focally upregulated. The capillaries may be swollen with hyalinization, thickening of the capillary wall, and deposition of complement. Some patients respond to immunotherapy, but others are resistant.

Drug-Induced Myopathies D-Penicillamine and procainamide may produce a true myositis resembling PM, and a DM-like illness had been associated with the contaminated preparations of L-tryptophan. As noted above, AZT causes a mitochondrial myopathy. Other drugs may elicit a toxic noninflammatory myopathy that is histologically different from

DM, PM, or IBM. These include cholesterol-lowering agents such as clofibrate, lovastatin, simvastatin, or provastatin, especially when combined with cyclosporine or gemfibrozil. Rhabdomyolysis and myoglobinuria have been rarely associated with amphotericin B, ε-aminocaproic acid, fenfluramine, heroin, and phencyclidine. The use of amiodarone, chloroquine, colchicine, carbimazole, emetine, etretinate, ipecac syrup, chronic laxative or licorice use resulting in hypokalemia, and glucocorticoids or growth hormone administration have also been associated with myopathic muscle weakness. Some neuromuscular blocking agents such as pancuronium, in combination with glucocorticoids, may cause an acute critical illness myopathy. A careful drug history is essential for diagnosis of these drug-induced myopathies, which do not require immunosuppressive therapy.

TABLE 383-2 CRITERIA FOR DIAGNOSIS OF INFLAMMATORY MYOPATHIES

Criterion	Polymyositis		Dermatomyositis	Inclusion Body Myositis
	Definite	Probable		
Myopathic muscle weakness[a]	Yes	Yes	Yes[b]	Yes; slow onset, early involvement of distal muscles, frequent falls
Electromyographic findings	Myopathic	Myopathic	Myopathic	Myopathic with mixed potentials
Muscle enzymes	Elevated (up to 50-fold)	Elevated (up to 50-fold)	Elevated (up to 50-fold) or normal	Elevated (up to 10-fold) or normal
Muscle biopsy findings[c]	"Primary" inflammation with the CD8/MHC-I complex and no vacuoles	Ubiquitous MCH-I expression but minimal inflammation and no vacuoles[d]	Perifascicular, perimysial, or perivascular infiltrates, perifascicular atrophy	Primary inflammation with CD8/MHC-I complex; vacuolated fibers with β-amyloid deposits; cytochrome oxygenase–negative fibers; signs of chronic myopathy[e]
Rash or calcinosis	Absent	Absent	Present[f]	Absent

[a]Myopathic muscle weakness, affecting proximal muscles more than distal ones and sparing eye and facial muscles, is characterized by a subacute onset (weeks to months) and rapid progression in patients who have no family history of neuromuscular disease, no endocrinopathy, no exposure to myotoxic drugs or toxins, and no biochemical muscle disease (excluded on the basis of muscle-biopsy findings).
[b]In some cases with the typical rash, the muscle strength is seemingly normal (dermatomyositis sine myositis); these patients often have new onset of easy fatigue and reduced endurance. Careful muscle testing may reveal mild muscle weakness.
[c]See text for details.
[d]An adequate trial of prednisone or other immunosuppressive drugs is warranted in probable cases. If, in retrospect, the disease is unresponsive to therapy, another muscle biopsy should be considered to exclude other diseases or possible evolution in inclusion body myositis.
[e]If the muscle biopsy does not contain vacuolated fibers but shows chronic myopathy with hypertrophic fibers, primary inflammation with the CD8/MHC-I complex and cytochrome oxygenase–negative fibers, the diagnosis is probable inclusion body myositis.
[f]If rash is absent but muscle biopsy findings are characteristic of dermatomyositis, the diagnosis is probable DM.

"Weakness" Due to Muscle Pain and Muscle Tenderness

A number of conditions including *polymyalgia rheumatica* (Chap. 319) and arthritic disorders of adjacent joints may enter into the differential diagnosis of inflammatory myopathy, even though they do not cause myositis. The muscle biopsy is either normal or discloses type II muscle fiber atrophy. Patients with *fibrositis* and *fibromyalgia* (Chap. 329) complain of focal or diffuse muscle tenderness, fatigue, and aching, which is sometimes poorly differentiated from joint pain. Some patients, however, have muscle tenderness, painful muscles on movement, and signs suggestive of a collagen vascular disorder, such as an increased erythrocyte sedimentation rate, C-reactive protein, antinuclear antibody, or rheumatoid factor, along with modest elevation of the serum CK and aldolase. They demonstrate a "give-way" pattern of weakness with difficulty sustaining effort but not true muscle weakness. The muscle biopsy is usually normal or nonspecific. Many such patients show some response to nonsteroidal anti-inflammatory agents or glucocorticoids, though most continue to have indolent complaints. An indolent fasciitis in the setting of an ill-defined connective tissue disorder may be present, and these patients should not be labeled as having a psychosomatic disorder. *Chronic fatigue syndrome*, which may follow a viral infection, can present with debilitating fatigue, fever, sore throat, painful lymphadenopathy, myalgia, arthralgia, sleep disorder, and headache (Chap. 384). These patients do not have muscle weakness, and the muscle biopsy is normal.

DIAGNOSIS

The clinically suspected diagnosis of PM, DM, or IBM is confirmed by examining the serum muscle enzymes, EMG findings, and muscle biopsy (Table 383-2).

The most sensitive enzyme is CK, which in active disease can be elevated as much as 50-fold. Although the CK level usually parallels disease activity, it can be normal in some patients with active IBM or DM, especially when associated with a connective tissue disease. The CK is always elevated in patients with active PM. Along with the CK, the serum glutamic-oxaloacetic and glutamate pyruvate transaminases, lactate dehydrogenase, and aldolase may be elevated.

Needle EMG shows myopathic potentials characterized by short-duration, low-amplitude polyphasic units on voluntary activation and increased spontaneous activity with fibrillations, complex repetitive discharges, and positive sharp waves. Mixed potentials (polyphasic units of short and long duration) indicating a chronic process and muscle fiber regeneration are often present in IBM. These EMG findings are not diagnostic of an inflammatory myopathy but are useful to identify the presence of active or chronic myopathy and to exclude neurogenic disorders.

MRI is not routinely used for the diagnosis of PM, DM, or IBM. However, it may guide the location of the muscle biopsy in certain clinical settings.

Muscle biopsy is the definitive test for establishing the diagnosis of inflammatory myopathy and for excluding other neuromuscular diseases. Inflammation is the histologic hallmark for these diseases; however, additional features are characteristic of each subtype (Figs. 383-3, 383-4, and 383-5).

In PM the inflammation is *primary*, a term used to indicate that T cell infiltrates, located primarily within the muscle fascicles (endomysially), surround individual, healthy muscle fibers and result in phagocytosis and necrosis (Fig. 383-3). The MHC-I molecule is ubiquitously expressed on the sarcolemma, even in fibers not invaded by CD8+ cells. The CD8/MHC-I lesion is now fundamental for confirming or establishing the diagnosis and to exclude disorders with secondary, nonspecific, inflammation. When the disease is chronic, connective tissue is increased and may react positively with alkaline phosphatase.

In DM the endomysial inflammation is predominantly perivascular or in the interfascicular septae and around, rather than within, the muscle fascicles (Fig. 383-4). The intramuscular blood vessels show endothelial hyperplasia with tubuloreticular profiles, fibrin thrombi, and obliteration of capillaries. The muscle fibers undergo necrosis, degeneration, and phagocytosis, often in groups involving a portion of a muscle fasciculus in a wedgelike shape or at the periphery of the fascicle, due to microinfarcts within the muscle. This results in perifascicular atrophy, characterized by 2–10 layers of atrophic fibers at the periphery of the fascicles. The presence of perifascicular atrophy is diagnostic of DM, *even in the absence of inflammation*.

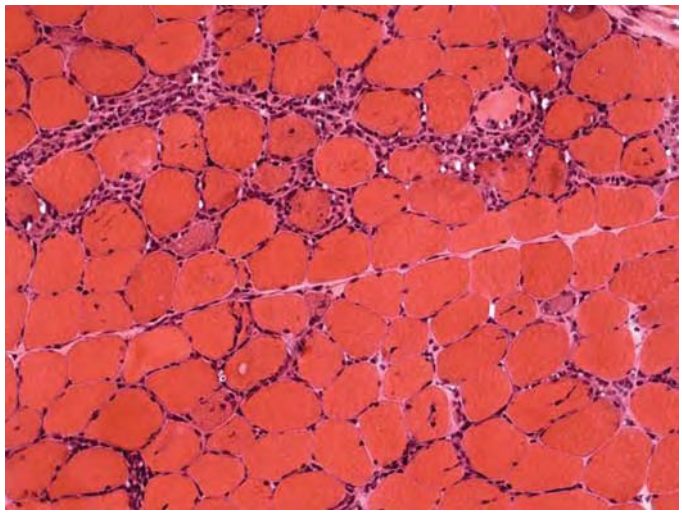

FIGURE 383-3 Cross section of a muscle biopsy from a patient with polymyositis demonstrates scattered inflammatory foci with lymphocytes invading or surrounding muscle fibers. Note lack of chronic myopathic features (increased connective tissue, atrophic or hypertrophic fibers) as seen in inclusion body myositis.

In IBM (Fig. 383-5), there is endomysial inflammation with T cells invading MHC-I-expressing nonvacuolated muscle fibers; basophilic granular deposits distributed around the edge of slitlike vacuoles (rimmed vacuoles); loss of fibers, replaced by fat and connective tissue, hypertrophic fibers, and angulated or round fibers; eosinophilic cytoplasmic inclusions; abnormal mitochondria characterized by the presence of ragged-red fibers or cytochrome oxidase–negative fibers; amyloid deposits within or next to the vacuoles; and filamentous inclusions seen by electron microscopy in the vicinity of the rimmed vacuoles.

INFLAMMATORY MYOPATHIES

The goal of therapy is to improve muscle strength, thereby improving function in activities of daily living, and ameliorate the extramuscular manifestations (rash, dysphagia, dyspnea, fever). When strength improves, the serum CK falls concurrently; however, the reverse is not always true. Unfortunately, there is a common tendency to "chase" or treat the CK level instead of the muscle weakness, a practice that has led to prolonged and unnecessary use of immunosuppressive drugs and erroneous assessment of their efficacy. It is prudent to discontinue these drugs if, after an adequate trial, there is no objective improvement in muscle strength whether or not CK levels are reduced. Agents used in the treatment of PM and DM include:

1. *Glucocorticoids*. Oral prednisone is the initial treatment of choice; the effectiveness and side effects of this therapy determine the future need for stronger immunosuppressive drugs. High-dose prednisone, at least 1 mg/kg per day, is initiated as early in the disease as possible. After 3–4 weeks, prednisone is tapered slowly over a period of 10 weeks to 1 mg/kg every other day. If there is evidence of efficacy and no serious side effects, the dosage is then further reduced by 5 or 10 mg every 3–4 weeks until the lowest possible dose that controls the disease is reached. The efficacy of prednisone is determined by an objective increase in muscle strength and activities of daily living, which almost always occurs by the third month of therapy. A feeling of increased energy or a reduction of the CK level without a concomitant increase in muscle strength is not a reliable sign of improvement. If prednisone provides no objective benefit after ~3 months of high-dose therapy, the disease is probably unresponsive to the drug and tapering should be accelerated while the next-in-line immunosuppressive drug is started. Although controlled trials have not been performed, almost all patients with true PM or DM respond to glucocorticoids to *some degree and for some period of time*; in general, DM responds better than PM.

   The long-term use of prednisone may cause increased weakness associated with a normal or unchanged CK level; this effect is referred to as *steroid myopathy*. In a patient who previously responded to high doses of prednisone, the development of new weakness may be related to steroid myopathy or to disease activity that either will respond to a higher dose of glucocorticoids or has become glucocorticoid-resistant. In uncertain cases, the prednisone dosage can be steadily increased or decreased as desired: the cause of the weakness is usually evident in 2–8 weeks.
2. *Other immunosuppressive* drugs. Approximately 75% of patients ultimately require additional treatment. This occurs when a patient fails to respond adequately to glucocorticoids after a 3-month trial, the patient becomes glucocorticoid-resistant, glucocorticoid-related side effects appear, attempts to lower the prednisone dose repeatedly result in a new relapse, or rapidly progressive disease with evolving severe weakness and respiratory failure develops.

   The following drugs are commonly used but have never been tested in controlled studies: (1) *Azathioprine* is well tolerated, has few side effects, and appears to be as effective for long-term therapy as other drugs. The dose is up to 3 mg/kg daily. (2) *Methotrexate* has a faster onset of action than azathioprine. It is given orally starting at 7.5 mg weekly for the first 3 weeks (2.5 mg every 12 h for 3 doses), with gradual dose escalation by 2.5 mg per week to a total of 25 mg weekly. A rare side effect is methotrexate pneumonitis, which can be difficult to distinguish from the interstitial lung disease of the primary myopathy associated with Jo-1 antibodies (described above). (3) *Mycophenolate mofetil* also has a faster onset of action than azathioprine. At doses up to 2.5 mg/d, it is well tolerated and appears promising for long-term use. (4) Monoclonal anti-CD20 (rituximab) has been shown in a small uncontrolled series to benefit patients with DM. (5) *Cyclosporine* has inconsistent and mild benefit. (6) *Cyclophosphamide* (0.5–1 g IV monthly for 6 months) has limited success and significant toxicity. (7) Tacrolimus (formerly known as Fk506) has been effective in some difficult cases of PM.
3. *Immunomodulation*. In a controlled trial of patients with refractory DM, intravenous immunoglobulin (IVIg) improved not only strength and rash but also the underlying immunopathology. The benefit is often short-lived (≤8 weeks); repeated infusions every 6–8 weeks are generally required to maintain improvement. A dose of 2 g/kg divided over 2–5 days per course is recommended. Uncontrolled observations suggest that IVIg may also be beneficial for patients with PM. Neither plasmapheresis nor leukapheresis appears to be effective in PM and DM.

The following sequential empirical approach to the treatment of PM and DM is suggested: *Step 1*: high-dose prednisone; *Step 2*: azathioprine, mycophenolate, or methotrexate for steroid-sparing effect; *Step 3*: IVIg; *Step 4*: a trial, with guarded optimism, of one of the following agents, chosen according to the patient's age, degree of disability, tolerance, experience with the drug, and general health: rituximab, cyclosporine, cyclophosphamide, or tacrolimus. Patients with interstitial lung disease may benefit from aggressive treatment with cyclophosphamide or tacrolimus.

A patient with presumed PM who has not responded to any form of immunotherapy most likely has IBM or another disease, usually a metabolic myopathy, a muscular dystrophy, a drug-induced myopathy, or an endo-

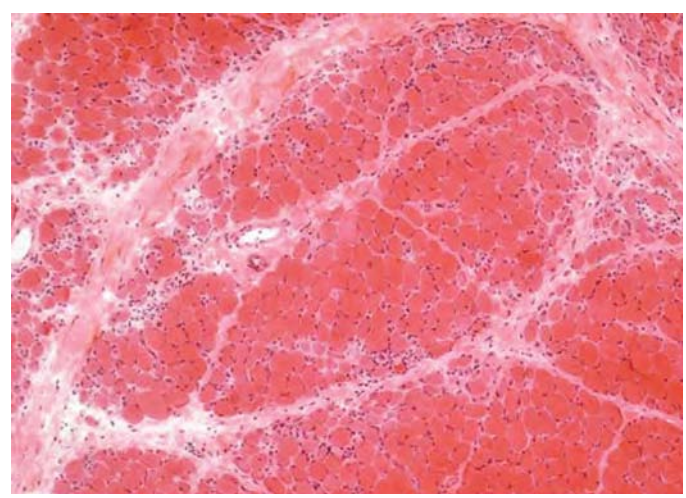

FIGURE 383-4 Cross section of a muscle biopsy from a patient with dermatomyositis demonstrates atrophy of the fibers at the periphery of the fascicle (perifascicular atrophy).

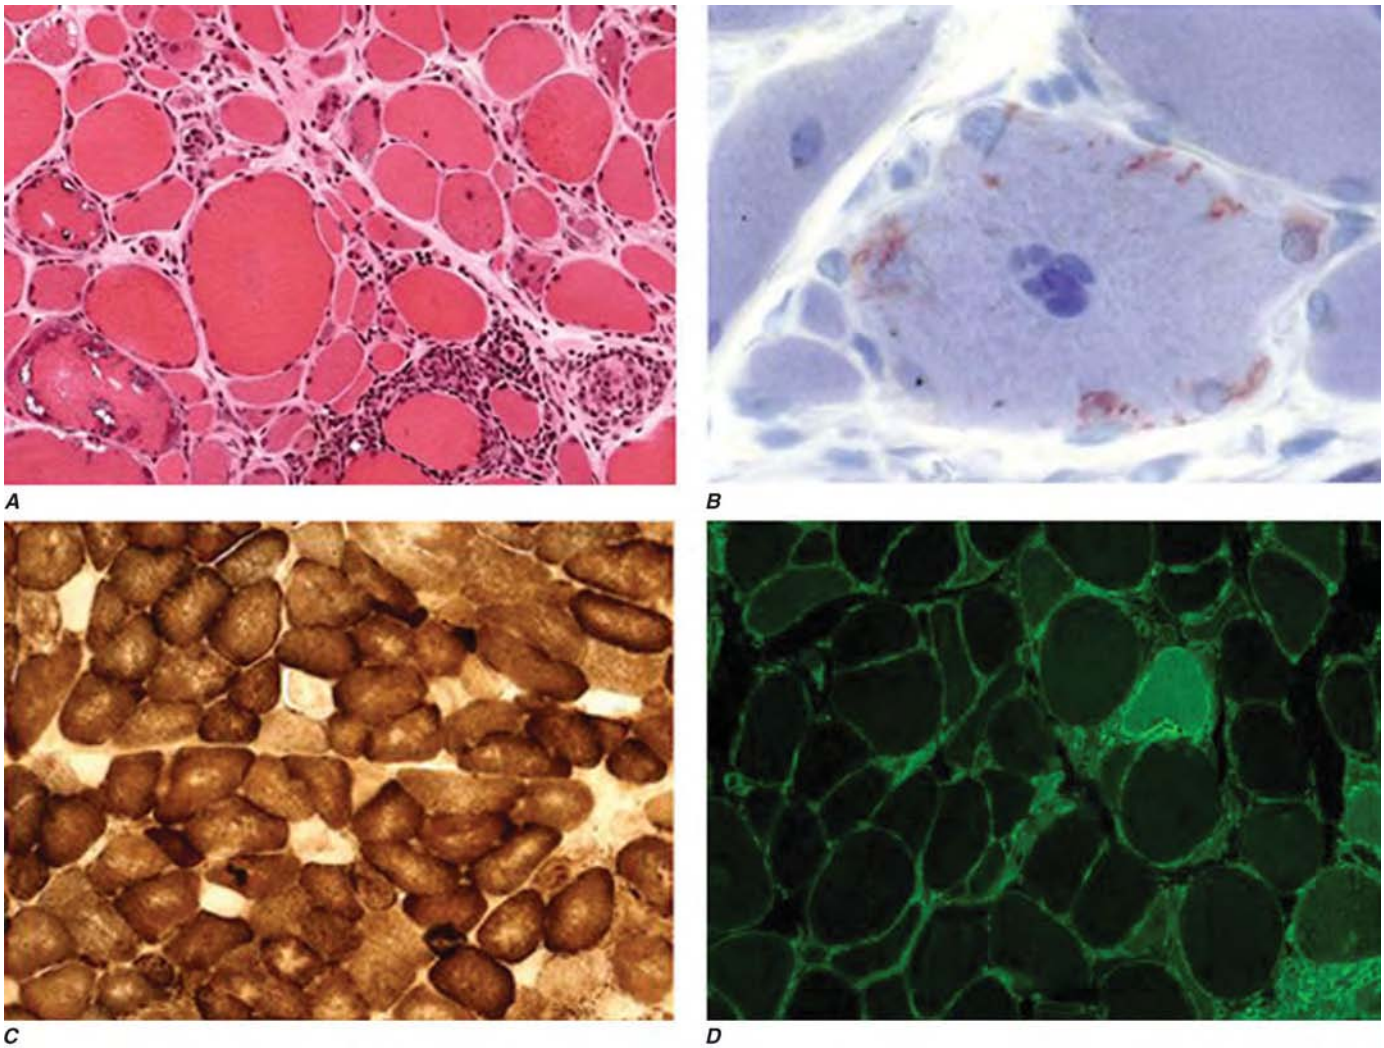

FIGURE 383-5 Cross sections of a muscle biopsy from a patient with inclusion body myositis demonstrate the typical features of vacuoles with lymphocytic infiltrates surrounding nonvacuolated or necrotic fibers (***A***), tiny endomysial deposits of amyloid visualized with crystal violet (***B***), cytochrome oxidase-negative fibers, indicative of mitochondrial dysfunction (***C***), and ubiquitous MHC-I expression at the periphery of all fibers (***D***).

crinopathy. In these cases, a repeat muscle biopsy and a renewed search for another cause of the myopathyis indicated.

Calcinosis, a manifestation of DM, is difficult to treat; however, new calcium deposits may be prevented if the primary disease responds to the available therapies. Bisphosphonates, aluminum hydroxide, probenecid, colchicine, low doses of warfarin, calcium blockers, and surgical excision have all been tried without success.

IBM is generally resistant to immunosuppressive therapies. Prednisone together with azathioprine or methotrexate is often tried for a few months in newly diagnosed patients, although results are generally disappointing. Because occasional patients may feel subjectively weaker after these drugs are discontinued, some clinicians prefer to maintain some patients on low-dose, every-other-day prednisone or weekly methotrexate in an effort to slow disease progression, even though there is no objective evidence or controlled study to support this practice. In two controlled studies of IVIg in IBM, minimal benefit in up to 30% of patients was found; the strength gains, however, were not of sufficient magnitude to justify its routine use. Another trial of IVIg combined with prednisone was ineffective. Nonetheless, many experts believe that a 2- to 3-month trial with IVIg may be reasonable for selected patients with IBM who experience rapid progression of muscle weakness or choking episodes due to worsening dysphagia.

PROGNOSIS

The 5-year survival rate for treated patients with PM and DM is ~95% and the 10-year survival 84%; death is usually due to pulmonary, cardiac, or other systemic complications. Patients severely affected at presentation or treated after long delays, those with severe dysphagia or respiratory difficulties, older patients, and those with associated cancer have a worse prognosis. DM responds more favorably to therapy than PM and thus has a better prognosis. Most patients improve with therapy, and many make a full functional recovery, which is often sustained with maintenance therapy. Up to 30% may be left with some residual muscle weakness. Relapses may occur at any time.

IBM has the least favorable prognosis of the inflammatory myopathies. Most patients will require the use of an assistive device such as a cane, walker, or wheelchair within 5–10 years of onset. In general, the older the age of onset in IBM, the more rapidly progressive is the course.

SECTION 4 CHRONIC FATIGUE SYNDROME

384 Chronic Fatigue Syndrome

Stephen E. Straus†

DEFINITION

Chronic fatigue syndrome (CFS) is the current name for a disorder characterized by debilitating fatigue and several associated physical, constitutional, and neuropsychological complaints (Table 384-1). This syndrome is not new; in the past, patients diagnosed with conditions such as the vapors, neurasthenia, effort syndrome, chronic brucellosis, epidemic neuromyasthenia, myalgic encephalomyelitis, hypoglycemia, multiple chemical sensitivity syndrome, chronic candidiasis, chronic mononucleosis, chronic Epstein-Barr virus (EBV) infection, and postviral fatigue syndrome may have had what is now called CFS. A subset of ill veterans of military campaigns suffer from CFS. The U.S. Centers for Disease Control and Prevention (CDC) has developed diagnostic criteria for CFS based upon symptoms and the exclusion of other illnesses (Table 384-2).

EPIDEMIOLOGY

Patients with CFS are twice as likely to be women as men and are generally 25–45 years old, although cases in childhood and in later life have been described.

Cases are recognized in many developed countries. Most arise sporadically, but many clusters have also been reported. Famous outbreaks of CFS occurred in Los Angeles County Hospital in 1934; in Akureyri, Iceland, in 1948; in the Royal Free Hospital, London, in 1955; and in Incline Village, Nevada, in 1985. While these clustered cases suggest a common environmental or infectious cause, none has been identified.

Estimates of the prevalence of CFS have depended on the case definition used and the method of study. Chronic fatigue itself is a common symptom, occurring in as many as 20% of patients attending general medical clinics; CFS is far less common. Community-based studies find that 100–300 individuals per 100,000 population in the United States meet the current CDC case definition.

PATHOGENESIS

The diverse names for the syndrome reflect the many and controversial hypotheses about its etiology. Several common themes underlie attempts to understand the disorder: (1) it is often postinfectious; (2) it is associated with mild immunologic disturbances and sedentary behavior during childhood; and (3) it is commonly accompanied by neuropsychological complaints, somatic preoccupation, and/or depression.

Many studies over the past quarter century sought to link CFS to acute and/or persisting infections with EBV, cytomegalovirus, human herpesvirus type 6, retroviruses, enteroviruses, *Candida albicans*, *Mycoplasma* spp., or *Coxiella burnetii*, among other microbial pathogens.

†Deceased.

TABLE 384-1 SPECIFIC SYMPTOMS REPORTED BY PATIENTS WITH CHRONIC FATIGUE SYNDROME

Symptom	Percentage
Fatigue	100
Difficulty concentrating	90
Headache	90
Sore throat	85
Tender lymph nodes	80
Muscle aches	80
Joint aches	75
Feverishness	75
Difficulty sleeping	70
Psychiatric problems	65
Allergies	55
Abdominal cramps	40
Weight loss	20
Rash	10
Rapid pulse	10
Weight gain	5
Chest pain	5
Night sweats	5

Compared to findings in age-matched control subjects, the titers of antibodies to some microorganisms are elevated in CFS patients. Reports that viral antigens and nucleic acids could be specifically identified in patients with CFS, however, have not been confirmed. One study from the United Kingdom failed to detect any association between acute infections and subsequent prolonged fatigue. Another study found that chronic fatigue did not develop after typical upper

TABLE 384-2 CDC CRITERIA FOR DIAGNOSIS OF CHRONIC FATIGUE SYNDROME

A case of chronic fatigue syndrome is defined by the presence of:
1. Clinically evaluated, unexplained, persistent or relapsing fatigue that is of new or definite onset; is not the result of ongoing exertion; is not alleviated by rest; and results in substantial reduction of previous levels of occupational, educational, social, or personal activities; and
2. Four or more of the following symptoms that persist or recur during six or more consecutive months of illness and that do not predate the fatigue:
   - Self-reported impairment in short-term memory or concentration
   - Sore throat
   - Tender cervical or axillary nodes
   - Muscle pain
   - Multijoint pain without redness or swelling
   - Headaches of a new pattern or severity
   - Unrefreshing sleep
   - Postexertional malaise lasting ≥24 h

e33 Special Issues in Inpatient Neurologic Consultation

S. Andrew Josephson, Martin A. Samuels

Inpatient neurologic consultations usually involve questions about specific disease processes or prognostication after various cerebral injuries. Common reasons for neurologic consultation include stroke (Chap. 364), seizures (Chap. 363), altered mental status (Chap. 26), headache (Chap. 15), and management of coma and other critical conditions (Chaps. 268 and 269). This chapter focuses on additional common reasons for consultation that are not addressed elsewhere in the text.

CONSULTATIONS REGARDING CENTRAL NERVOUS SYSTEM DYSFUNCTION

HYPERPERFUSION STATES

A group of neurologic disorders shares the common feature of hyperperfusion playing a key role in pathogenesis. These seemingly diverse syndromes include hypertensive encephalopathy, eclampsia, post-carotid endarterectomy syndrome, and toxicity from calcineurin-inhibitor medications. Modern imaging techniques and experimental models suggest that vasogenic edema is usually the primary process leading to neurologic dysfunction; therefore prompt recognition and management of this condition should allow for clinical recovery if superimposed hemorrhage or infarction has not occurred.

The brain's autoregulatory capability successfully maintains a fairly stable cerebral blood flow in adults despite alterations in systemic mean arterial pressure (MAP) ranging from 50–150 mmHg. In patients with chronic hypertension, this cerebral autoregulation curve is shifted, resulting in autoregulation working over a much higher range of pressures (e.g., 70–175 mmHg). In these hypertensive patients, cerebral blood flow is kept steady at higher MAP, but a rapid lowering of pressure can more easily lead to ischemia on the lower end of the autoregulatory curve. This autoregulatory phenomenon is achieved through both myogenic and neurogenic influences causing small arterioles to contract and dilate. When the systemic blood pressure exceeds the limits of this mechanism, breakthrough of autoregulation occurs, resulting in hyperperfusion via increased cerebral blood flow, capillary leakage into the interstitium, and resulting edema. The predilection of all of the hyperperfusion disorders to affect the posterior rather than anterior portions of the brain may be due to a lower threshold for autoregulatory breakthrough in the posterior circulation.

While elevated or relatively elevated blood pressure is common in many of these disorders, some hyperperfusion states such as calcineurin-inhibitor toxicity occur with no apparent pressure rise. In these cases, vasogenic edema is likely due primarily to dysfunction of the capillary endothelium itself, leading to breakdown of the blood-brain barrier. It is useful to separate disorders of hyperperfusion into those caused primarily by increased pressure and those due mostly to endothelial dysfunction from a toxic or autoimmune etiology (Table e33-1). In reality, both of these pathophysiologic processes are likely playing some role in each of these disorders.

The clinical presentation of the hyperperfusion syndromes is similar, with prominent headaches, seizures, or focal deficits. Headaches have no specific characteristics, range from mild to severe, and may be accompanied by alterations in consciousness ranging from confusion to coma. Seizures may be present, and these can be of multiple types depending on the severity and location of the edema. Nonconvulsive seizures have been described in hyperperfusion states; therefore a low threshold for obtaining an electroencephalogram (EEG) in these patients should be maintained. The typical focal deficit in hyperperfusion states is cortical visual loss, given the tendency of the process to involve the occipital lobes. However, any focal deficit can occur depending on the area affected, as evidenced by patients who, after carotid endarterectomy, exhibit neurologic dysfunction in the ipsilateral newly reperfused hemisphere. In conditions where increased cerebral blood flow plays a role, examination of the inpatient vital signs record will usually reveal a systemic blood pressure that is increased above baseline. It appears as if the rapidity of rise rather than the absolute value of pressure is the most important risk factor.

TABLE e33-1 SOME COMMON ETIOLOGIES OF HYPERPERFUSION SYNDROME

Disorders in which increased capillary pressure dominates the pathophysiology
Hypertensive encephalopathy, including secondary causes such as renovascular hypertension, pheochromocytoma, cocaine use, etc.
Post-carotid endarterectomy syndrome
Preeclampsia/eclampsia
High-altitude cerebral edema
Disorders in which endothelial dysfunction dominates the pathophysiology
Calcineurin-inhibitor toxicity
Chemotherapeutic agent toxicity (e.g., cytarabine, azathioprine, 5-fluorouracil, cisplatin, methotrexate)
Glucocorticoids
Erythropoietin
HELLP syndrome (*h*emolysis, *e*levated *l*iver enzyme levels, *l*ow *p*latelet count)
Thrombotic thrombocytopenic purpura (TTP)
Hemolytic uremic syndrome (HUS)
Systemic lupus erythematosus (SLE)
Wegener's granulomatosis

The diagnosis in all of these conditions is clinical. The symptoms of these disorders are common and nonspecific, so a long differential diagnosis should be entertained, including consideration of other causes of confusion, focal deficits, headache, and seizures. MRI has improved the ability of clinicians to diagnose hyperperfusion syndromes, although cases have been reported with normal imaging. Patients classically exhibit the high T2 signal of edema primarily in the posterior occipital lobes, not respecting any single vascular territory (Fig. e33-1). Diffusion-weighted images are typically normal, emphasizing the vasogenic rather than cytotoxic nature of this edema. Imaging with CT is less sensitive but may show a pattern of patchy hypodensity in the involved territory. Previously this classic radiographic appearance had been termed *reversible posterior leukoencephalopathy* (RPLE). However, this term has fallen out of favor because none of its elements are completely accurate: the radiographic and clinical changes are not always reversible, the territory involved is not uniquely posterior, and gray matter may be affected as well, rather than purely white matter as the word "leukoencephalopathy" intimates. Other ancillary studies such as cerebrospinal fluid (CSF) analysis often yield nonspecific results. It should be noted that many of the substances that have been implicated, such as cyclosporine, can cause this syndrome even at low doses or after years of treatment. Therefore, normal serum levels of these medications do not exclude them as inciting agents.

In cases of hyperperfusion syndromes, treatment should commence urgently once the diagnosis is considered. Hypertension plays a key role commonly, and judicious lowering of the blood pressure with IV agents such as labetolol or nicardipine is advised along with continuous cardiac and blood pressure monitoring, often through an arterial line. It is reasonable to lower mean arterial pressure by ~20% initially, as further lowering of the pressure may cause secondary ischemia as pressure drops below the lower range of the patient's autoregulatory capability. In cases where there is an identified cause of the syndrome, these etiologies should be treated promptly, including discontinuation of offending substances such as calcineurin inhibitors in toxic processes, treatment of immune-mediated disorders such as thrombotic thrombocytopenic purpura (TTP), and prompt delivery of the fetus in eclampsia. Seizures must be identified and controlled, often necessitating continuous EEG monitoring. Anticonvulsants are effective, but in the special case of eclampsia, there is good evidence to support the use of magnesium sulfate for seizure control.

POST-CARDIAC BYPASS BRAIN INJURY

Central nervous system (CNS) injuries following open heart or coronary artery bypass grafting (CABG) surgery are common and include

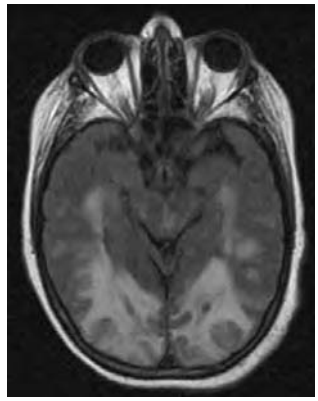

FIGURE e33-1 Axial fluid-attenuated inversion recovery (FLAIR) MRI of the brain in a patient taking cyclosporine after liver transplantation who presented with seizures, headache, and cortical blindness. Increased signal is seen bilaterally in the occipital lobes predominantly involving the white matter, consistent with a hyperperfusion state secondary to calcineurin-inhibitor exposure.

acute encephalopathy, stroke, and a chronic syndrome of cognitive impairment, which is now increasingly recognized. Hypoperfusion and embolic disease are frequently involved in the pathogenesis of these syndromes, although multiple mechanisms may be involved in these critically ill patients who are at risk for various metabolic and polypharmaceutical complications.

The frequency of hypoxic injury secondary to inadequate blood flow intraoperatively has been markedly decreased by the use of modern surgical and anesthetic techniques. Despite these advances, some patients still experience neurologic complications from cerebral hypoperfusion or may suffer focal ischemia from tight carotid or focal intracranial stenoses in the setting of regional hypoperfusion. Postoperative infarcts in the border zones between vascular territories commonly are blamed on systemic hypotension although some have suggested that these infarcts can also result from embolic disease (Fig. e33-2).

Embolic disease is likely the predominant mechanism of cerebral injury during cardiac surgery as evidenced by diffusion-weighted MRI and intraoperative transcranial Doppler studies. It should be noted that some of the emboli that are found histologically in these patients are too small to be detected by standard imaging sequences; therefore, a negative MRI after surgery does not exclude the diagnosis of embolic-related complications. Thrombus in the heart itself as well as atheromas in the aortic arch can become dislodged during cardiac surgeries, releasing a shower of particulate matter into the cerebral circulation. Cross-clamping of the aorta, manipulation of the heart, extracorporeal circulation techniques ("bypass"), arrhythmias such as atrial fibrillation, and introduction of air through suctioning have all been implicated as potential sources of emboli. Histologic studies indicate that literally millions of tiny emboli may be released, even using modern surgical techniques.

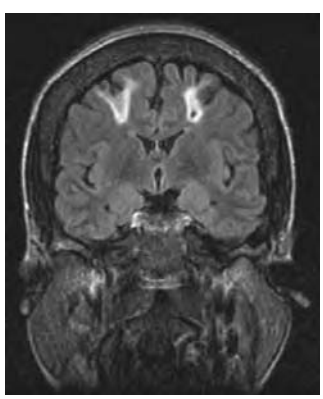

FIGURE e33-2 Coronal fluid-attenuated inversion recovery (FLAIR) MRI of the brain in a patient presenting with altered mental status after an episode of hypotension during coronary artery bypass grafting (CABG). Increased signal is seen in the border zones bilaterally between the middle cerebral artery and anterior cerebral artery territories. Diffusion-weighted MRI sequences demonstrated restricted diffusion in these same locations, suggesting acute infarction.

This shower of microemboli results in a number of clinical syndromes. Occasionally, a single large embolus leads to an isolated large-vessel stroke that presents with obvious clinical focal deficits. More commonly, the emboli released are multiple and smaller. When there is a high burden of these small emboli, an acute encephalopathy can occur postoperatively, presenting as either a hyperactive or hypoactive confusional state, the latter of which is frequently and incorrectly ascribed to depression. When the burden of microemboli is lower, no acute syndrome is recognized, but the patient may suffer a chronic cognitive deficit. Cardiac surgery can be viewed, like delirium, as a "stress test for the brain." Some patients with a low cerebral reserve due to underlying cerebrovascular disease or an early neurodegenerative process will develop a chronic, cognitive deficit, whereas others with higher reserves may remain asymptomatic despite a similar dose of microemboli. In this manner, cardiac surgery may serve to unmask the early manifestations of disorders such as vascular dementia and Alzheimer's disease.

Since modern techniques have successfully minimized hypoperfusion complications during these surgeries, much attention is now focused on reducing this inevitable shower of microemboli. Off-pump CABG surgeries have the advantages of reducing length of stay and perioperative complications; however, some recent data suggests that off-pump CABG does not preserve cognitive function compared with on-pump CABG. Filters placed in the aortic arch may have some promise in capturing these emboli, although convincing evidence is currently lacking. Development of successful endovascular operative approaches may provide a reasonable alternative to conventional CABG procedures, especially for patients at high risk of developing cognitive dysfunction after surgery due to advanced age, previous stroke, or severe atheromatous disease of the carotid arteries or aortic arch.

POST-SOLID ORGAN TRANSPLANT BRAIN INJURY

Patients who have undergone solid organ transplantation are at risk for neurologic injury in the postoperative period and for the months to years thereafter. Neurologic consultants should view these patients as a special population at risk for both unique neurologic complications as well as for the usual disorders found in any critically ill inpatient.

Immunosuppressive medications are administered in high doses to patients after solid organ transplant, and many of these compounds have well-described neurologic complications. In patients with headache, seizures, or focal neurologic deficits taking calcineurin inhibitors, the diagnosis of hyperperfusion syndrome should be considered, as discussed above. This neurotoxicity occurs mainly with cyclosporine and tacrolimus and can present even in the setting of normal serum drug levels. Treatment primarily involves lowering the drug dosage or discontinuing the drug. A related newer agent, sirolimus, has very few recorded cases of neurotoxicity and may be a reasonable alternative for some patients. Other examples of immunosuppressive medications and their neurologic complications include OKT3-associated akinetic mutism and the leukoencephalopathy seen with methotrexate, especially when it is administered intrathecally or with concurrent radiotherapy. In any solid organ transplant patient with neurologic complaints, a careful examination of the medication list is required to search for these possible drug effects.

Cerebrovascular complications of solid organ transplant are often first recognized in the immediate postoperative period. Border zone territory infarctions can occur, especially in the setting of systemic hypotension during cardiac transplant surgery. Embolic infarctions classically complicate cardiac transplantation, but all solid organ transplant procedures place patients at risk for systemic emboli. When cerebral embolization accompanies renal or liver transplantation surgery, a careful search for

Copyright © 2008 The McGraw-Hill Companies. All rights reserved.

right-to-left shunting should include evaluation of the heart with agitated saline echocardiography, as well as looking for intrapulmonary shunting. Renal and some cardiac transplant patients often have advanced atherosclerosis, providing yet another mechanism for stroke. Imaging with CT or MRI with diffusion is advised when cerebrovascular complications are suspected to confirm the diagnosis and to exclude intracerebral hemorrhage, which most often occurs in the setting of coagulopathy secondary to liver failure or after cardiac bypass procedures.

Given that patients with solid organ transplants are chronically immunosuppressed, infections are a common concern (Chap. 126). In any transplant patient with new CNS signs or symptoms such as seizure, confusion, or focal deficit, the diagnosis of a nervous system infection should be considered and evaluated through imaging (usually MRI) and possibly lumbar puncture. The most common pathogens responsible for CNS infections in these patients vary based on time since transplant. In the first month posttransplant, common pathogens include the usual bacterial organisms associated with surgical procedures and indwelling catheters. Starting in the second month posttransplant, opportunistic infections of the CNS become more common, including *Nocardia* and *Toxoplasma* species as well as fungal infections such as aspergillosis. Viral infections that can affect the brain of the immunosuppressed patient, such as herpes simplex virus, cytomegalovirus, and varicella, also become more common after the first month posttransplant. After 6 months posttransplant, immunosuppressed patients still remain at risk for these opportunistic bacterial, fungal, and viral infections but can also suffer late CNS infectious complications such as progressive multifocal leukoencephalopathy (PML) associated with JC virus and Epstein-Barr virus–driven clonal expansions of B cells resulting in CNS lymphoma.

COMMON NEUROLOGIC COMPLICATIONS OF ELECTROLYTE DISTURBANCES

A wide variety of neurologic conditions can result from abnormalities in serum electrolytes, and consideration of electrolyte disturbances should be part of any inpatient neurologic consultation. **A complete general discussion of fluid and electrolyte imbalance and homeostasis can be found in Chap. 46.**

HYPERNATREMIA AND HYPEROSMOLALITY

The normal range of serum osmolality is around 275–295 mOsm/kg, but neurologic manifestations are usually seen only at levels >325 mOsm/kg. Hyperosmolality is usually due to hypernatremia, hyperglycemia, azotemia, or the addition of extrinsic osmoles such as mannitol, which is commonly used in critically ill neurologic patients. Hyperosmolality itself can lead to a generalized encephalopathy that is nonspecific and without focal findings; however, an underlying lesion such as a mass can become symptomatic under the metabolic stress of a hyperosmolar state, producing focal signs. Some patients with hyperosmolality from severe hyperglycemia can present, for unclear reasons, with generalized seizures or unilateral movement disorders, which usually respond to lowering of the serum glucose. The treatment of all forms of hyperosmolality involves calculation of apparent water losses and slow replacement so that the serum sodium declines no faster than 2 mmol/L (2 meq/L) per hour.

Hypernatremia leads to the loss of intracellular water, leading to cell shrinkage. In the cells of the brain, solutes such as glutamine and urea are generated under these conditions in order to minimize this shrinkage. Despite this corrective mechanism, when hypernatremia is severe [serum sodium > 160 mmol/L (>160 meq/L)] or occurs rapidly, cellular metabolic processes fail and encephalopathy will result. There are many etiologies of hypernatremia including, most commonly, renal and extrarenal losses of water. Causes of neurologic relevance include central diabetes insipidus, where hyperosmolality is accompanied by submaximal urinary concentration due to inadequate release of antidiuretic hormone (ADH) from the posterior pituitary, resulting often from pituitary injury in the setting of surgery, hemorrhage, infiltrative processes, or cerebral herniation.

HYPONATREMIA

Hyponatremia is commonly defined as a serum sodium < 135 mmol/L (<135 meq/L). Neurologic symptoms occur at different levels of low sodium, depending not only on the absolute value but also on the rate of fall. In patients with hyponatremia that develops over hours, life-threatening seizures and cerebral edema may occur at values as high as 125 mmol/L. In contrast, some patients with more chronic hyponatremia that has slowly developed over months to years may be asymptomatic even with serum levels < 110 mmol/L. Correction of hyponatremia, especially when chronic, must take place slowly in order to avoid additional neurologic complications. Cells in the brain swell in hypotonic hyponatremic states but may compensate over time by excreting solute into the extracellular space, leading to restoration of cell volume when water follows the solute out of the cells. If treatment of hyponatremia results in a rapid rise in serum sodium, cells in the brain may quickly shrink, leading to osmotic demyelination, a process that previously was thought to be limited exclusively to the brainstem (central pontine myelinolysis; see Fig. 269-6), but now has been described elsewhere in the CNS.

Treatment of hyponatremia is dependent on the cause. Hypertonic hyponatremia treatment focuses on the underlying condition, such as hyperglycemia. Isovolemic hyponatremia (syndrome of inappropriate antidiuretic hormone, SIADH) is managed with water restriction or administration of ADH antagonists. The management of choice for patients with hypervolemic hypotonic hyponatremia is free-water restriction and treatment of the underlying edematous disorder, such as nephrotic syndrome or congestive heart failure. Finally, in hypovolemic hypotonic hyponatremia, volume is replaced with isotonic saline while underlying conditions of the kidneys, adrenals, and gastrointestinal tract are addressed.

One neurologic cause of hypovolemic hypotonic hyponatremia is the cerebral salt-wasting syndrome that accompanies subarachnoid hemorrhage and, less commonly, other cerebral processes such as meningitis or stroke. In these cases, the degree of renal sodium excretion can be remarkable, and large amounts of saline, hypertonic saline, or oral sodium may need to be given in a judicious fashion in order to avoid complications from cerebral edema.

HYPOKALEMIA

Hypokalemia, defined as a serum potassium level < 3.5 mmol/L (<3.5 meq/L), occurs either because of excessive potassium losses (from the kidneys or gut) or due to an abnormal potassium distribution between the intracellular and extracellular spaces. At very low levels (<1.5 mmol/L), hypokalemia may be life threatening due to the risk of cardiac arrhythmia and may present neurologically with severe muscle weakness and paralysis. Hypokalemic periodic paralysis is a rare disorder caused by excessive intracellular potassium uptake in the setting of a calcium or sodium channel mutation. Treatment of hypokalemia is dependent on the etiology but usually includes replacement of potassium through oral or IV routes as well as correcting the cause of potassium balance problems (e.g., eliminating β_2-adrenergic agonist medications).

HYPERKALEMIA

Hyperkalemia is defined as a serum potassium level > 5.5 mmol/L (>5.5 meq/L) and can neurologically present as muscle weakness with or without paresthesias. Hyperkalemia becomes life threatening when it produces electrocardiographic abnormalities such as peaked T waves or a widened QRS complex. In these cases, prompt treatment is essential and consists of strategies that protect the heart against arrhythmias (calcium gluconate administration), promote potassium redistribution into cells (with glucose, insulin, and β_2-agonist medications), and increase potassium removal (through sodium polystyrene sulfonate, loop diuretics, or hemodialysis).

CALCIUM DISTURBANCES

Hypercalcemia usually occurs in the setting of either hyperparathyroidism or systemic malignancy. Neurologic manifestations include encephalopathy as well as muscle weakness due to reduced neuromuscular excitability. Seizures can occur but are more common in states of low calcium.

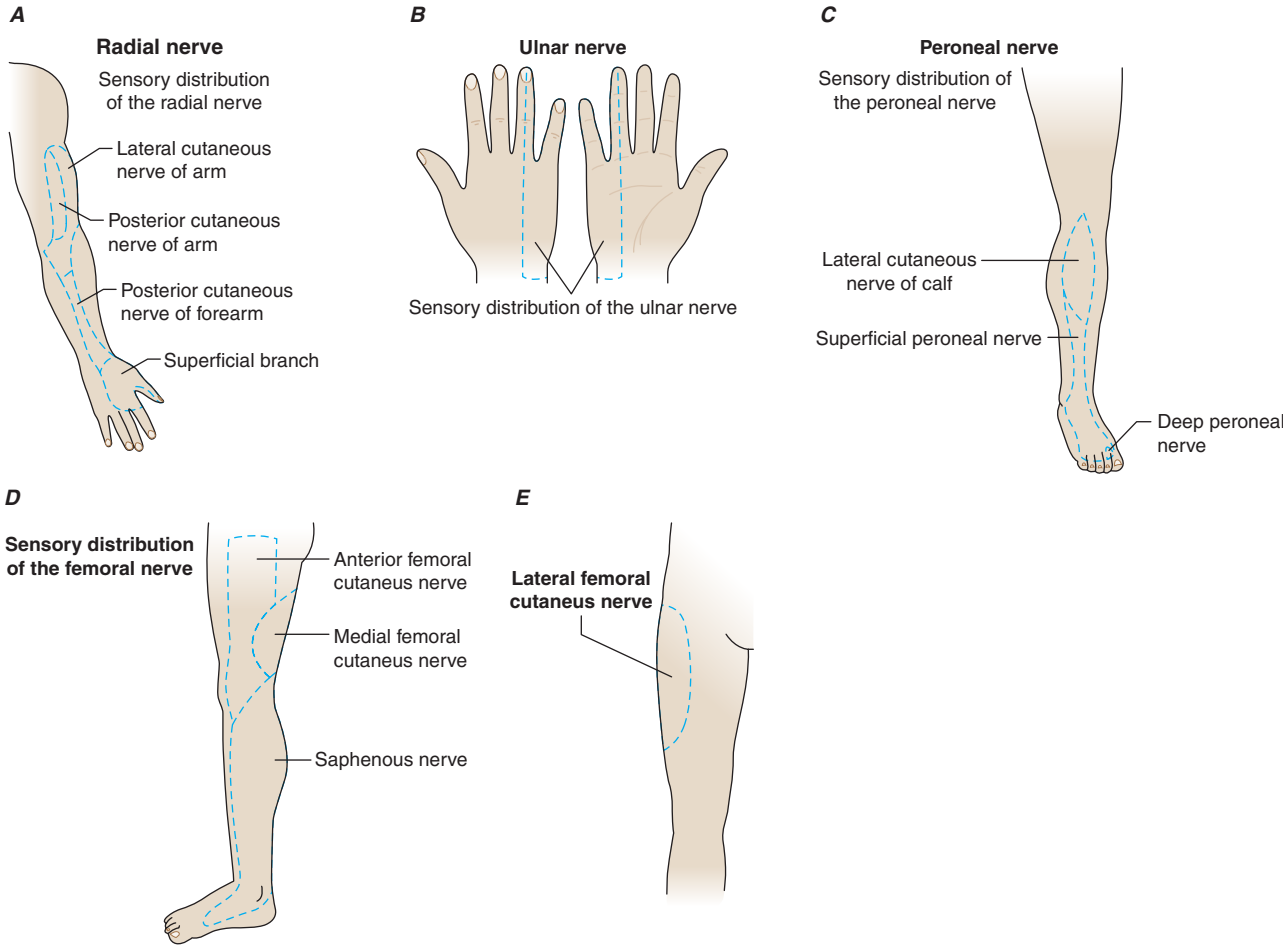

FIGURE e33-3 Sensory distribution of peripheral nerves commonly affected by entrapment neuropathies. *A.* Radial nerve. ***B.*** Ulnar nerve. ***C.*** Peroneal nerve. ***D.*** Femoral nerve. ***E.*** Lateral femoral cutaneous nerve.

Hypocalcemia in adults often follows surgical treatment of the thyroid or parathyroid. Seizures and altered mental status dominate the neurologic picture and usually resolve with calcium repletion. Tetany is due to spontaneous, repetitive action potentials in peripheral nerves and remains the classic sign of symptomatic hypocalcemia.

MAGNESIUM DISTURBANCES

Disorders of magnesium are difficult to correlate with serum levels because a very small amount of total-body magnesium is located in the extracellular space. Hypomagnesemia presents neurologically with seizures, tremor, and myoclonus. When intractable seizures occur in the setting of hypomagnesemia, only administration of magnesium will lead to resolution. High levels of magnesium, in contrast, lead to CNS depression. Hypermagnesemia usually only occurs in the setting of renal failure and can lead to confusion and muscular paralysis when severe.

CONSULTATIONS REGARDING PERIPHERAL NERVOUS SYSTEM DYSFUNCTION

ENTRAPMENT NEUROPATHIES

Polyneuropathy is a common cause of outpatient neurologic consultation (Chap. 379). In the inpatient setting, however, mononeuropathies are more frequent, especially the entrapment neuropathies that complicate many surgical procedures and medical conditions. Median neuropathy at the wrist (carpal tunnel syndrome) is the most frequent entrapment neuropathy by far, but it is rarely a cause for inpatient consultation. Mechanisms for perioperative mononeuropathy include traction, compression, and ischemia of the nerve. Imaging with MR neurography may allow these causes to be distinguished definitively. In all cases of mononeuropathy, the diagnosis can be made through the clinical examination and then confirmed with electrodiagnostic studies in the subacute period, if necessary. Treatment consists mainly of avoidance of repetitive trauma but may also include surgical approaches to relieve pressure on the nerve.

Radial Neuropathy Radial nerve injury classically presents with weakness of extension of the wrist and fingers ("wrist drop") with or without more proximal weakness of extensor muscles of the upper extremity, depending on the site of injury. Sensory loss is in the distribution of the radial nerve, which includes the dorsum of the hand (Fig. e33-3*A*). Compression at the level of the axilla, e.g., resulting from use of crutches, includes weakness of the triceps, brachioradialis, and supinator muscles in addition to wrist drop. A more common site of compression occurs in the spiral groove of the upper arm in the setting of a humerus fracture or from sleeping with the arm draped over a bench or chair ("Saturday night palsy"). Sparing of the triceps is the rule when the nerve is injured in this location. Because extensors of the upper extremity are injured preferentially in radial nerve injury, these lesions may be mistaken for the pyramidal distribution of weakness that accompanies upper motor neuron lesions from brain or spinal cord processes.

Ulnar Neuropathy Compression of the ulnar nerve is the second most common entrapment neuropathy after carpal tunnel syndrome. The most frequent site of compression is at the elbow where the nerve passes superficially in the ulnar groove. Symptoms usually begin with tingling in the ulnar distribution, including the fourth and fifth digits of the hand (Fig. e33-3*B*). Sensory symptoms may be worsened by elbow flexion due to increased pressure on the nerve, hence the tendency of patients to complain of increasing paresthesias at night when the arm is flexed at the elbow during sleep. Motor dysfunction can be dis-

Copyright © 2008 The McGraw-Hill Companies. All rights reserved.

abling and involves most of the intrinsic hand muscles, limiting dexterity and strength of grasp and pinch. Etiologies of ulnar entrapment include trauma to the nerve (hitting the "funny bone"), malpositioning during anesthesia for surgical procedures, and chronic arthritis of the elbow. When a perioperative ulnar nerve injury is considered, stretch injury or trauma to the lower trunk of the brachial plexus should be entertained as well since its symptoms can mimic those of an ulnar neuropathy. If the clinical examination is equivocal, electrodiagnostic studies can definitively distinguish between plexus and ulnar nerve lesions a few weeks after the injury. Conservative methods of treatment are often the first step, but a variety of surgical approaches may be effective, including anterior ulnar nerve transposition and release of the flexor carpi ulnaris aponeurosis.

Peroneal Neuropathy The peroneal nerve winds around the head of the fibula in the leg below the lateral aspect of the knee, and its superficial location at this site makes it vulnerable to trauma. Patients present with weakness of foot dorsiflexion ("foot drop") as well as with weakness in eversion but not inversion at the ankle. Sparing of inversion, which is a function of muscles innervated by the tibial nerve, helps to distinguish peroneal neuropathies from L5 radiculopathies. Sensory loss involves the lateral aspect of the leg as well as the dorsum of the foot (Fig. e33-3*C*). Fractures of the fibular head may be responsible for peroneal neuropathies, but in the perioperative setting poorly applied braces exerting pressure on the nerve while the patient is unconscious are more often responsible. Tight-fitting stockings or casts of the upper leg can also cause a peroneal neuropathy, and thin individuals and those with recent weight loss are at increased risk.

Proximal Femoral Neuropathy Lesions of the proximal femoral nerve are relatively uncommon but may present dramatically with weakness of hip flexion, quadriceps atrophy, weakness of knee extension (often manifesting with leg-buckling falls), and an absent patellar reflex. Adduction of the thigh is spared as these muscles are supplied by the obturator nerve, thereby distinguishing a femoral neuropathy from a more proximal lumbosacral plexus lesion. The sensory loss found is in the distribution of the femoral nerve sensory branches on the anterior part of the thigh (Fig. e33-3*D*). Compressive lesions from retroperitoneal hematomas or masses are common, and a CT of the pelvis should be obtained in all cases of femoral neuropathy to exclude these conditions. Bleeding into the pelvis resulting in hematoma can occur spontaneously, following trauma, or after intrapelvic surgeries such as renal transplantation. In intoxicated or comatose patients, stretch injuries to the femoral nerve are seen following prolonged, extreme hip flexion or extension. Rarely, attempts at femoral vein or arterial puncture can be complicated by injury to this nerve.

Lateral Femoral Cutaneous Nerve The symptoms of lateral femoral cutaneous nerve entrapment, commonly known as "meralgia paresthetica," include sensory loss, pain, and dysesthesia in part of the area supplied by the nerve (Fig. e33-3*E*). There is no motor component to the nerve, and therefore weakness is not a part of this syndrome. Symptoms often are worsened by standing or walking. Compression of the nerve occurs where it enters the leg near the inguinal ligament, usually in the setting of tight-fitting belts, pants, corsets, or recent weight gain, including that of pregnancy. The differential diagnosis of these symptoms includes hip problems such as trochanteric bursitis.

OBSTETRIC NEUROPATHIES

Pregnancy and delivery place women at special risk for a variety of nerve injuries. Radiculopathy due to a herniated lumbar disc is not common during pregnancy, but compressive injuries of the lumbosacral plexus do occur secondary to either the fetal head passing through the pelvis or the use of forceps during delivery. These plexus injuries are more frequent with cephalopelvic disproportion and often present with a painless unilateral foot drop which must be distinguished from a peroneal neuropathy caused by pressure on the nerve while in lithotomy position during delivery. Other compressive mononeuropathies of pregnancy include meralgia paresthetica, carpal tunnel syndrome, femoral neuropathy when the thigh is abducted severely in an effort to facilitate delivery of the fetal shoulder, and obturator neuropathy during lithotomy positioning. The latter presents with medial thigh pain that may be accompanied by weakness of thigh adduction. There is also a clear association between pregnancy and an increased frequency of idiopathic facial palsy (Bell's palsy).

respiratory infections but did in some individuals after infectious mononucleosis. Thus, while antecedent infections are associated with CFS, a direct microbial causality is unproven and unlikely.

Changes in numerous immune parameters of uncertain functional significance have been reported in CFS. Modest elevations in titers of antinuclear antibodies, reductions in immunoglobulin subclasses, deficiencies in mitogen-driven lymphocyte proliferation, reductions in natural killer cell activity, disturbances in cytokine production, and shifts in lymphocyte subsets have been described. None of these immune findings appears in most patients, nor do any correlate with the severity of CFS. Comparison of monozygotic twin pairs discordant for CFS showed no substantive immunologic differences between affected and unaffected individuals. In theory, symptoms of CFS could result from excessive production of a cytokine, such as interleukin 1, that induces asthenia and other flulike symptoms; however, compelling data in support of this hypothesis are lacking. A recently published population-based study from Wichita, Kansas, reported differences in gene expression patterns and in candidate gene polymorphisms between CFS patients and controls; these results are controversial and await confirmation.

In some but not the more recent studies, patients with CFS commonly manifested sensitivity to sustained upright posture or tilting, resulting in hypotension and syncope, so as to suggest a form of dysautonomia.

Disturbances in hypothalamic-pituitary-adrenal function have been identified in several controlled studies of CFS, with some evidence for normalization in patients whose fatigue abates. These neuroendocrine abnormalities could contribute to the impaired energy and depressed mood of patients.

Mild to moderate depression is present in half to two-thirds of patients. Much of this depression may be reactive, but its prevalence exceeds that seen in other chronic medical illnesses. Some propose that CFS is fundamentally a psychiatric disorder and that the various neuroendocrine and immune disturbances arise secondarily.

MANIFESTATIONS

Typically, CFS arises suddenly in a previously active individual. An otherwise unremarkable flulike illness or some other acute stress leaves unbearable exhaustion in its wake. Other symptoms, such as headache, sore throat, tender lymph nodes, muscle and joint aches, and frequent feverishness, lead to the belief that an infection persists, and medical attention is sought. Over weeks to months, despite reassurances that "nothing serious is wrong," the symptoms persist and other features of the syndrome become evident—disturbed sleep, difficulty in concentration, and depression (Table 384-1).

Depending on the dominant symptoms and the beliefs of the patient, additional consultations may be sought from allergists, rheumatologists, infectious disease specialists, psychiatrists, ecologic therapists, homeopaths, or other professionals, frequently with unsatisfactory results. Once the pattern of illness is established, the symptoms may fluctuate somewhat. Many patients report that CFS symptoms, including cognitive problems, are exacerbated by intensive physical or other stressors, yet recent prospective studies have not confirmed this impression.

Most patients remain capable of meeting family, work, or community obligations despite their symptoms; discretionary activities are abandoned first. Some feel unable to engage in any gainful employment. A minority of individuals requires help with the activities of daily living. Econometric analyses conducted by the CDC have confirmed that CFS exacts a significant toll on household and workforce productivity.

Ultimately, isolation, frustration, and pathetic resignation can mark the protracted course of illness. Patients may become angry at physicians for failing to acknowledge or resolve their plight. Fortunately, CFS does not appear to progress. On the contrary, many patients experience gradual improvement, and a minority recover fully.

DIAGNOSIS

A thorough history, physical examination, and judicious use of laboratory tests are required to exclude other causes of the patient's symptoms. Prominent abnormalities argue strongly in favor of alternative diagnoses. No laboratory test, however, can diagnose this condition or measure its severity. In most cases, elaborate, expensive workups are not helpful. Early claims that MRI or single photon emission CT can identify abnormalities in the brain of CFS patients have not withstood further study. The dilemma for patient and clinician alike is that CFS has no pathognomonic features and remains a constellation of symptoms and a diagnosis of exclusion. Often the patient presents with features that also meet criteria for other subjective disorders such as fibromyalgia and irritable bowel syndrome. Questions have been raised as to the relative merits of rendering a diagnosis of CFS. Being diagnosed can provide validation of a patient's perceived symptoms but may also perpetuate or exacerbate them. Refusal to label a patient as having CFS, however, can deny the patient the opportunity to undertake treatments that are of proven merit.

Rx CHRONIC FATIGUE SYNDROME

After other illnesses have been excluded, there are several points to address in the long-term care of a patient with chronic fatigue.

The patient should be educated about the illness and what is known of its pathogenesis; potential impact on the physical, psychological, and social dimensions of life; and prognosis. Periodic reassessment is appropriate to identify a possible underlying process that is late in declaring itself and to address intercurrent symptoms that should not be simply dismissed as additional subjective complaints.

Many symptoms of CFS respond to treatment. Nonsteroidal anti-inflammatory drugs alleviate headache, diffuse pain, and feverishness. Allergic rhinitis and sinusitis are common; when present, antihistamines or decongestants may be helpful. Although the patient may be averse to psychiatric diagnoses, depression and anxiety are often prominent and should be treated. Expert psychiatric assessment is sometimes advisable. Nonsedating antidepressants improve mood and disordered sleep and may attenuate the fatigue. Even modest improvements in symptoms can make an important difference in the patient's degree of self-sufficiency and ability to appreciate life's pleasures.

Practical advice should be given regarding life-style. Sleep disturbances are common; consumption of heavy meals, alcohol, and caffeine at night can make sleep even more elusive, compounding fatigue. Total rest leads to further deconditioning and the self-image of being an invalid, whereas overexertion may worsen exhaustion and lead to total avoidance of exercise. A carefully graded exercise regimen should be encouraged and has been proven to relieve symptoms and enhance exercise tolerance.

Controlled therapeutic trials have established that acyclovir, fludrocortisone, galantamine, modafinil, and IV immunoglobulin, among other agents, offer no significant benefit in CFS. Low doses of hydrocortisone provide modest benefit but may lead to adrenal suppression. Countless anecdotes circulate regarding other traditional and nontraditional therapies. It is important to guide patients away from those therapeutic modalities that are toxic, expensive, or unreasonable.

The physician should promote the patient's efforts to recover. Several controlled trials conducted in the United Kingdom, in Australia, and in the Netherlands showed cognitive-behavioral therapy to be helpful in adolescents and adults with CFS. This approach aims to dispel misguided beliefs and fears about CFS that can contribute to inactivity and despair. For CFS, as for many other conditions, a comprehensive approach to physical, psychological, and social aspects of well-being is in order.

385 Biology of Psychiatric Disorders

Steven E. Hyman, Eric Kandel

Psychiatric disorders are a diverse group of brain disorders with symptoms that primarily involve emotion, higher cognitive function, and the ability to control complex behaviors. A compendium of psychiatric disorders can be found in the *Diagnostic and Statistical Manual of Mental Disorders* of the American Psychiatric Association 4th edition (DSM-IV). This compendium illustrates that the boundary between psychiatric and neurologic disorders, another heterogeneous group of brain disorders, is arbitrary and shifting. In areas of overlap such as autism, Tourette's disorder, and Alzheimer's disease, the disorder is often treated by either a psychiatrist or a neurologist. The term *mental disorders*, while still widely used, fails to acknowledge the neural substrates of these disturbances and their effects on physiology and behavior.

The major psychiatric disorders are common and often run a chronic course. The chronic disorders include anxiety disorders, attention deficit hyperactivity disorder, autism, obsessive-compulsive disorder, and schizophrenia. Other psychiatric disorders such as depressive disorders recur across the life span, but even bipolar disorder, classically characterized as episodic, can run a chronic course.

The symptoms of psychiatric disorders often begin early, impairing the ability of children and adolescents to learn and compromising the functioning of adults at work and in other life roles. As a result of their high prevalence, early onset, and persistence, psychiatric disorders contribute substantially to the burden of illness in all countries in which they have been studied. In the United States they are not only a leading cause of disability but also a significant cause of premature death, because mood disorders, schizophrenia, and to some extent other psychiatric disorders constitute the most potent risk factors for suicide, a leading cause of death worldwide.

ANATOMY

Progress in understanding the pathophysiology of psychiatric disorders has been slow, despite its fundamental importance. Perhaps the most significant challenge is posed by the difficulties inherent in understanding the high-level cognitive and affective functions of the brain that are disrupted in psychiatric disorders. As a result, unlike many neurologic disorders, the common psychiatric disorders appear to involve widely distributed neural networks and lack an obvious, localized neuropathology, which, if present, would help to narrow the hunt for cellular pathology and for underlying biochemical and molecular causes. Thus, the motor disturbances in Parkinson's disease, Huntington's disease, and amyotrophic lateral sclerosis result from discrete macroscopic lesions in different parts of the motor system. By contrast, in psychiatric disorders, when candidate regions have been identified, as in schizophrenia, depression, and autism, it has proven difficult to differentiate convincingly, these abnormalities from normal variation partly because these target regions form only one component of a disorder involving a much larger neural circuit (Chap. 27).

GENETIC CONSIDERATIONS Given the challenges of identifying relatively subtle neuropathology, it has long been hoped that the identification of genetic variants conferring risk for psychiatric disorders would provide effective clues to those underlying neural abnormalities that contribute to the psychiatric disorder in question. This hope is based on the significant body of data derived from family, twin, and adoption studies demonstrating that heredity plays a significant role in the risk of major psychiatric disorders, including schizophrenia, bipolar disorder, depressive disorders, and many others. For example, the rate of schizophrenia in the general population is ~1%. However, when one member of a monozygotic twin pair is diagnosed with schizophrenia, the other twin, who is genetically identical, has nearly a 50% chance of also manifesting the disease. A first-degree relative of an affected proband (who shares on average 50% of DNA sequences) has a 9% risk of schizophrenia. Adoption-at-birth studies provide additional strong support for a genetic contribution to schizophrenia spectrum disorders; in one study from Finland, a schizophrenia-related illness was present in nearly one-quarter of adoptees whose biologic mother carried a similar diagnosis.

While there continue to be promising leads in the search for risk-conferring alleles, research over the past two decades has not succeeded in identifying with certainty risk genes for psychiatric disorders. There have been large efforts using a variety of strategies, including linkage studies and candidate gene studies, in attempts to identify genes responsible for schizophrenia, and more recently several groups have begun to undertake whole-genome association studies. The strongest candidates include: disrupted in schizophrenia (*DISC1*), a gene that was disrupted by a balanced chromosomal translocation in a Scottish family with schizophrenia-like symptoms; distrobrevin-binding protein 1 (*DTNBP1*); and neuroregulin 1 (*NRG1*), which encodes a protein involved in neuronal migration and in expression of *N*-methyl-*D*-aspartate (NMDA) glutamate receptors. Other potential candidates include *DAOA*, *RGS4*, and *AKT1*, but the evidence supporting them is weaker **(Table 385-1)**.

One problem in identifying risk genes for psychiatric diseases has been the failure to replicate convincingly the discovery of putative risk genes. The failure stems in large part from the complex nature of risk for psychiatric disorders, which appears to involve multiple genes of small effect interacting with nongenetic factors. In addition, there appear to be different risk genes in different population groups, perhaps reflecting new or recent mutations.

It is now relatively straightforward to identify genes that exert large causal effects on disease. Several less common neurologic disorders result from deleterious mutations within single genes. Thus, genes have been identified that contribute to the muscular dystrophies, triplet repeat disorders such as Huntington's disease and fragile X, and Down's syndrome. The discovery of the Huntington gene was followed by the development of powerful tools to investigate the neural basis of the disease by putting the mutated gene into worms, flies, or mice in order to study the mechanisms of pathogenesis. While such tools are only a beginning, and indeed have not yet led to development of therapies, gene identification and the study of its function have already created a strong platform for investigation. It permits, for example, the spatiotemporal characterization in the brain of the expression of disease-related genes, the generation of antibodies against the normal and altered proteins, and the production by genetic engineering of worm, fly, and mouse models that could serve as assays for testing possible therapies. Moreover, the identification of rare, Mendelian forms of Parkinson's disease, Alzheimer's disease, amyotrophic lateral sclerosis, and epilepsy has provided significant insights into the more common forms of these disorders. Thus far, however, no Mendelian form of any of the common early-onset psychiatric disorders of the brain has been identified convincingly. A small number of Mendelian disorders have symptoms that overlap with those of common psychiatric disorders. For example, Rett syndrome, which results from mutations in the methyl DNA binding protein MECP2, includes autistic-like symptoms but also many severe symptoms that are not characteristic of autism.

In psychiatric disorders such as schizophrenia, genes are not, by themselves, causative; other factors, a "second hit," must contribute. Unfortunately, these potential environmental factors, the "second hits," have been difficult to identify. One interesting finding, documented in the Netherlands following World War II and in China, is that maternal famine during gestation is correlated with an increased incidence of schizophrenia, perhaps by contributing to de novo germ-line mutations. Other potential risk factors include urban birth, migration, increasing paternal age, and intrauterine exposure to viral infection.

New genetic technologies are now available for the investigation of genetically complex disorders; these include more complete maps of human

TABLE 385-1 SCHIZOPHRENIA CANDIDATE GENES

Protein	Gene	CH Location	Evidence	Function
Disrupted in schizophrenia	*DISC1*	1q42	Initially identified through a balanced translocation in a single family with schizophrenia and affective disorder; confirmed by linkage and association in different populations.	Roles in microtubular transport and neuronal migration (via interactions with *Lis1* and *NudEL*); influences postsynaptic responses (interactions with *Citron*); activates phosphodiesterase 4B, increasing cAMP (target of antidepressant rolipram).
Dysbindin (dystrobrevin-binding protein 1)	*DTNBP1*	6p22	Linkage and association; no coding region mutations; no consistent allele or haplotype implicated in different studies; negative symptoms of schizophrenia may associate with a specific haplotype of *DTNBP1*; expression decreased in schizophrenia brain.	Wide distribution in CNS; expression in synaptic terminals of hippocampus; in vitro, reduced levels decrease glutamate in neurons.
Neuregulin 1	*NRG1*	8p12-21	Linkage and association; no coding region mutations; no consistent allele or haplotype implicated in different studies; expression increased in schizophrenia brain.	Suppresses function of NMDA receptors; role in neuronal differentiation and migration.
D-Amino oxidase activator	*DAOA*	13q32-34	Linkage and association; no consistent allele or haplotype implicated in different studies.	Activates D-amino oxidase which oxidies D-serine, an agonist at NMDA receptors; reduced D-serine levels reported in blood and CSF in schizophrenia.
Regulator of G-protein signaling 4	*RGS4*	1q21-22	Linkage and association; susceptibility allele may impair working memory and regionally reduce brain volumes	Modulates postsynaptic signal transduction, including downregulation of 5HT1a (serotonin) receptors.
V-akt murine thymoma viral oncogene homologue 1	*AKT1*	14q22-32	Inconsistent linkage, association, and brain expression studies.	Phosphorylates and inactivates glycogen synthase kinase (GSK) 3 beta.

Note: CH, chromosome; CNS, central nervous system; CSF, cerebrospinal fluid; NMDA, *N*-methyl-D-aspartate.

genetic variability, high-density whole-genome association methods, and efficient high-throughput sequencing technologies using single nucleotide polymorphism (SNP) arrays. The use of these tools has already begun to yield significant results for several common complex disorders, such as inflammatory bowel disease, age-related macular degeneration, and type 2 diabetes mellitus. Psychiatric disorders are well positioned to benefit from these new approaches. In addition, it is expected that additional emerging technologies, including cost-efficient methods for whole-genome sequencing, will soon be available, further increasing the likelihood that risk-conferring alleles for psychiatric disorders will be identified within the next few years. To take full advantage of these new methods, the psychiatric research community will need to collect very large populations for sufficiently powered genetic studies, and identify (by high-resolution imaging, gene expression patterns, or other markers) biologically meaningful phenotypes for stratification of the genetic data.

CHALLENGES WITH PHENOTYPING

Psychiatric disorders have an additional obstacle to the identification of risk genes or pathophysiologic processes that cannot be addressed simply by improving genetic technologies. There are at the moment no objective diagnostic measures for any of the common psychiatric disorders. There is not, as yet, a well-defined neuropathology for psychiatric disorders nor are there biologic markers. The diagnostic classification scheme (e.g., DSM-IV) upon which both research and clinical practice rely is derived from expert consensus based on clusters of symptoms and signs and disease course. As a result, failure to delineate well-defined disease entities and to reliably assign individuals to affected versus nonaffected status have bedeviled psychiatric research.

The lack of objective tests for phenotyping presents enormous difficulties for genetic and other forms of investigation. While type 2 diabetes mellitus and hypertension, for example, are both highly heterogeneous disorders, the measurement of glucose tolerance or of systolic and diastolic blood pressure creates a strong framework within which subtyping can occur, generally based on additional objective measures. In contrast, it is not at all certain that the boundaries currently drawn around disorders in the DSM-IV lead to an underlying and distinguishable set of neurobiologic factors. For example, there is much debate about the boundaries of schizophrenia. The DSM-IV lists three psychotic disorders as being independent—schizophrenia, schizoaffective disorder, and schizophreniform disorder (American Psychiatric Association, 2000). Yet there is little agreement on whether the latter two are sufficiently homogeneous clinical entities to warrant independent recognition.

Despite the problems with current disease classification in psychiatry, there is agreement on the core symptoms and strong cross-cultural similarity of disease manifestation. In addition, there is a strong familial nature to major psychiatric disorders and also a potent role for heredity, which can be inferred from twin and adoption studies. These findings suggest that the central criteria for diagnosing schizophrenia, bipolar disorder, autism, and other major psychiatric disorders identify, however imperfectly, distinctive, naturally occurring brain diseases.

NEUROIMAGING

In parallel with improved classification and genetic studies, attempts are being made using neuroimaging to define anatomic abnormalities as objective, measurable phenotypes of the disease. For example, new quantitative methods combined with structural MRI have suggested that, in schizophrenia, there may be disease-specific patterns of gray matter loss in frontal and temporal cerebral cortex. Longitudinal studies of individuals with childhood-onset schizophrenia have documented an accelerated loss of gray matter. More recently, attempts have been made to associate specific DISC1 haplotypes with reduced frontal gray matter. While these approaches are in their early stages, the effort to define objective brain-based phenotypes for genetic and clinical studies appears very promising.

Functional imaging of individuals with depression similarly has pinpointed abnormal activity in Brodman area 25, the subgenual prefrontal cortex, a brain region that connects to the amygdala and is thought to play a critical role in the processing of emotion-related information (Fig. 385-1). Area 25 exhibits excessive metabolic activity in major depression, which reverses with successful antidepressant treatment. This region is also activated in normal subjects in whom sadness is induced by means of emotion laden stimuli. This information serves as the basis for an experimental approach to severe depression involving the use of deep-brain stimulation of the subgenual prefrontal cortex using implanted electrodes. In an initial series, four of six patients with severe depression unresponsive to all currently proven treatments, including electroconvulsive therapy, had immediate and sustained responses; however, due to the invasiveness, risk, and cost, this approach may not become a widespread treatment. Its significance lies in the putative iden-

tification of a circuit involved in mood regulation that can be manipulated to produce therapeutic benefit.

PSYCHIATRIC DISORDERS

The high prevalence and serious consequences of psychiatric disorders make the availability of effective treatments a matter of great importance for public health. Since the middle of the twentieth century, several classes of pharmacologic treatments (antipsychotic drugs, antidepressant drugs, lithium, benzodiazepines, and anticonvulsants) and several standardized short-term psychotherapies have been developed and found to be efficacious in clinical trials. The result is an armamentarium of useful treatments for many of the common disorders; however, as is the case for many common, chronic medical disorders, there are no cures for psychiatric disorders. Residual symptoms and recurrences are common, and many pharmacologic treatments have significant side effects.

This state of affairs is typified by schizophrenia, where a large number of drugs have been developed. Initially these drugs were thought to be useful only in the treatment of schizophrenia; however, they are now commonly used to treat any psychosis, irrespective of origin. In schizophrenia, in addition to the psychotic symptoms of hallucinations and delusions, referred to as *positive symptoms*, there are also *negative symptoms* (social withdrawal, impoverished speech, lack of motivation) and *cognitive symptoms* (poor executive function). Both positive and negative symptoms are thought to be related to dopaminergic systems in the brain **(Fig. 385-2)**. The primary clinical benefit of antipsychotic drugs is the amelioration of the positive psychotic symptoms. With the exception of clozapine, often described as an atypical antipsychotic drug, which produces improvement in some patients who do not respond to other drugs, all the existing antipsychotic drugs have similar efficacy and differ primarily in their pattern of side effects. Clozapine and some other atypical drugs are thought to exert at least a modest therapeutic effect on the negative symptoms of schizophrenia. None of the drugs, however, is effective against the cognitive symptoms

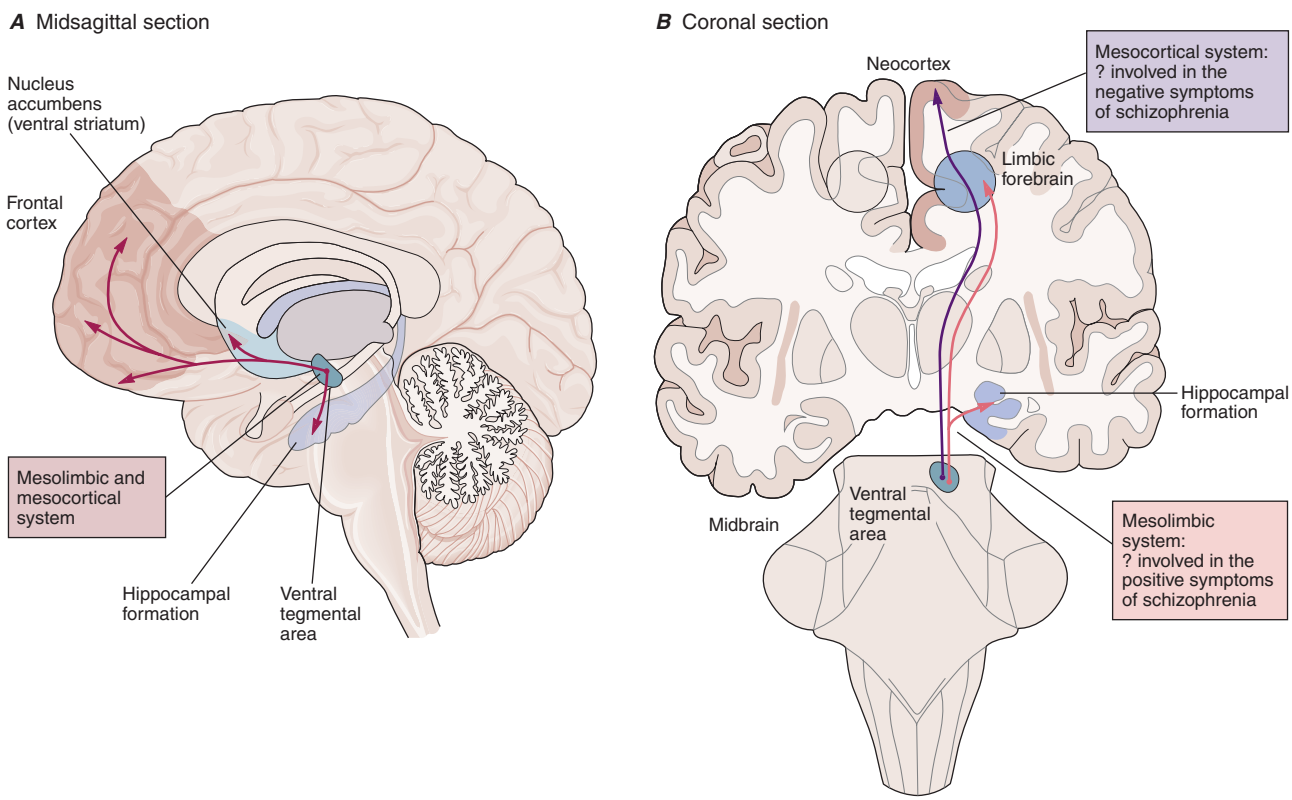

FIGURE 385-2 The major dopaminergic tracts of the brain. *(From ER Kandel et al: Principles of Neural Science, 4th ed. New York, McGraw-Hill, 2000.)*

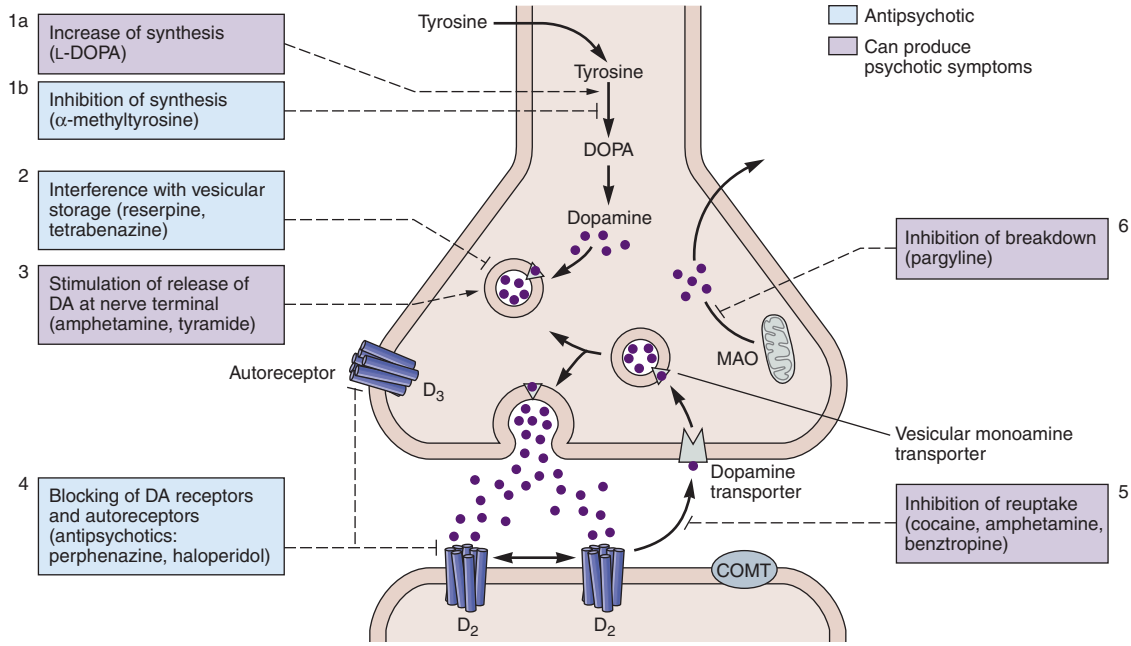

FIGURE 385-3 The key steps in the synthesis and degradation of dopamine and the sites of action of various psychoactive substances at the dopaminergic synapse. *(From ER Kandel et al: Principles of Neural Science, 4th ed. New York, McGraw-Hill, 2000.)*

are central to the illness. Furthermore, their residual presence throughout the course of the illness contributes substantially to the persistence of disability over the patient's lifetime. The search for new drugs to treat schizophrenia now focuses extensively on the ability to modify its cognitive symptoms. All antipsychotic drugs in current use block or diminish the action of dopamine at its D_2 receptors **(Fig. 385-3)**; they differ in their relative affinity at D_2 receptors and by their actions at other neurotransmitter receptors. These drugs represent important progress, but safer and more effective treatments are very much needed.

Drugs useful in depression act by increasing synaptic levels of serotonin, norepinephrine, or less commonly dopamine **(Fig. 385-4)**. The term *antidepressant* is a misnomer for this diverse class of drugs, however, because their spectrum of action is much broader than depression. These drugs are also effective in treating fear-based anxiety disorders such as panic disorder and generalized anxiety disorder. In high doses, the selective serotonin uptake inhibitors are effective for obsessive-compulsive disorder. The antidepressants are effective in the treatment of depression, but only moderately so. Many patients require sequential trials with a number of different drugs alone or in combination to achieve clinically meaningful benefit, and ~30% of patients derive no benefit at all. When pharmacologic modalities fail in depression, electroconvulsive therapy continues to be an effective treatment option. Lithium and several anticonvulsants dampen mood swings in bipolar disorder and also treat acute manic episodes; however, residual depressive symptoms, recurrences, and significant side effects are the rule. The exact mechanism of action of lithium is not known. At therapeutic levels, lithium interacts with two important signaling pathways: (1) it blocks inositol monophosphatase, thus influencing signaling via inositol phosphates, such as IP_3; and (2) it also blocks glycogen synthase kinase 3 beta (GSK3beta).

Unfortunately, there are currently very few promising drug targets that can be exploited to produce medications with truly novel mechanisms of action. Indeed, all of the major classes of drugs used to treat psychiatric disorders were identified through empirical observations of drug effects in patient populations rather than as a result of understanding pathophysiology. The molecular targets of these drugs were identified by the study of efficacious drugs and then exploited to produce improved compounds within the same class.

Cognitive-behavioral psychotherapy designed to focus on the management of specific symptoms has shown benefit in mild to moderately severe depression, fear-based anxiety disorders, and obsessive-compulsive disorder. A significant improvement in the treatment of depression in the past decade has been the standardization of psychotherapy and its evaluation in clinical trials. Instruments such as the Depression Inventory and Suicide Intent Scale are now available for measuring mental illness; these have helped to objectify research in psychopathology.

New insights into the etiology of depression have also helped to guide therapy. Depressed patients have a systematic negative bias in their cognitive styles—in the way they think about themselves and their future. These distorted patterns of thinking reflect not simply an unconscious conflict within the psyche but a disorder in cognitive style and behavior that is a key etiologic agent in maintaining the disorder.

An approach that focuses on distorted thinking, cognitive therapy has been shown in randomized trials to be an effective psychological treatment for depression. This approach is based on increasing the patients' objectivity regarding their misinterpretations of everyday situations (their cognitive distortions), their misevaluation of their internal processes (body sensations, intrusive thoughts and images), and their negative expectancies. A wide range of professionals can use the methods with highly positive results.

Cognitive therapy has also proved beneficial in individuals at risk for suicide. Validated instruments exist to classify and assess suicidal behaviors, making it possible to identify high-risk individuals prospectively. Of particular importance has been the identification of clinical and psychological variables that predict future suicide. Hopelessness and consequent suicidal ideation, which are better predictors of suicide than clinical depression per se, can be quantified and substantially reduced by cognitive interventions. Several studies with individuals who had recently attempted suicide have demonstrated that a short-term cognitive intervention can significantly reduce subsequent suicide attempts when compared to a control group.

This therapy has been extended to the treatment of other disorders including anxiety states and obsessive-compulsive disorder. With respect to obsessive-compulsive disorders, cognitive therapy has been shown to reverse a metabolic abnormality, identified by neuroimaging, in parallel with the clinical improvement **(Fig. 385-5)**.

Cognitive therapy has replaced psychoanalytically based dynamic psychotherapy as the principal psychological treatment provided by specialists in certain countries. Its success has stimulated the development of other forms of short-term psychotherapy, including Interpersonal Psychiatry and Psychoanalytic-Oriented Insight Therapy. These therapies are now also being tested in controlled clinical trials and have been found to be effective in a variety of clinical situations.

Thus, paradoxically, one of the significant advances in the era of the new brain-based biologic psychiatry has been the development of evidence-based psychotherapy, a development based on the evidence that insofar as psychotherapy and other psychiatric treatments work, they do so by altering the functioning and perhaps even the structure of the brain.

386 Mental Disorders

Victor I. Reus

Mental disorders are common in medical practice and may present either as a primary disorder or as a comorbid condition. The prevalence of mental or substance use disorders in the United States is approximately 30%. Only one-third of these individuals are currently receiving treatment. Global burden of disease statistics indicate that 4 out of the 10 most important causes of disease worldwide are psychiatric in origin.

The revised 4th edition for use by primary care physicians of the *Diagnostic and Statistical Manual* (DSM-IV-PC) provides a useful synopsis of mental disorders most likely to be seen in primary care practice. The current system of classification is multiaxial and includes the presence or absence of a major mental disorder (axis I), any underlying personality disorder (axis II), general medical condition (axis III), psychosocial and environmental problems (axis IV), and overall rating of general psychosocial functioning (axis V).

Changes in health care delivery underscore the need for primary care physicians to assume responsibility for the initial diagnosis and treatment of the most common mental disorders. Prompt diagnosis is essential to ensure that patients have access to appropriate medical services and to maximize the clinical outcome. Validated patient-based questionnaires have been developed that systematically probe for signs and symptoms associated with the most prevalent psychiatric diagnoses and guide the clinician into targeted assessment. Prime MD (and a self-report form, the PHQ) and the Symptom-Driven Diagnostic System for Primary Care (SDDS-PC) are inventories that require only 10 min to complete and link patient responses to the formal diagnostic criteria of anxiety, mood, somatoform, and eating disorders and to alcohol abuse or dependence.

A physician who refers patients to a psychiatrist should know not only when doing so is appropriate but also how to refer, since societal misconceptions and the stigma of mental illness impede the process. Primary care physicians should base referrals to a psychiatrist on the presence of signs and symptoms of a mental disorder and not simply on the absence of a physical explanation for a patient's complaint. The physician should discuss with the patient the reasons for requesting the referral or consultation and provide reassurance that he or she will continue to provide medical care and work collaboratively with the mental health professional. Consultation with a psychiatrist or transfer of care is appropriate when physicians encounter evidence of psychotic symptoms, mania, severe depression, or anxiety; symptoms of posttraumatic stress disorder (PTSD); suicidal or homicidal preoccupation; or a failure to respond to first-order treatment. **Eating disorders are discussed in Chap. 76, and the pathogenesis of psychiatric and addictive disorders in Chap. 385.**

ANXIETY DISORDERS

Anxiety disorders, the most prevalent psychiatric illnesses in the general community, are present in 15–20% of medical clinic patients. Anxiety, defined as a subjective sense of unease, dread, or foreboding, can indicate a primary psychiatric condition or can be a component of, or reaction to, a primary medical disease. The primary anxiety disorders are classified according to their duration and course and the existence and nature of precipitants.

When evaluating the anxious patient, the clinician must first determine whether the anxiety antedates or postdates a medical illness or is due to a medication side effect. Approximately one-third of patients presenting with anxiety have a medical etiology for their psychiatric symptoms, but an anxiety disorder can also present with somatic symptoms in the absence of a diagnosable medical condition.

PANIC DISORDER

Clinical Manifestations Panic disorder is defined by the presence of recurrent and unpredictable panic attacks, which are distinct episodes of intense fear and discomfort associated with a variety of physical symptoms, including palpitations, sweating, trembling, shortness of breath, chest pain, dizziness, and a fear of impending doom or death (Table 386-1). Paresthesias, gastrointestinal distress, and feelings of unreality are also common. Diagnostic criteria require at least 1 month of concern or worry about the attacks or a change in behavior related to them. The lifetime prevalence of panic disorder is 1–3%. Panic attacks have a sudden onset, developing within 10 min and usually resolving over the course of an hour, and they occur in an unexpected fashion. The frequency and severity of panic attacks vary, ranging from once a week to clusters of attacks separated by months of well-being. The first attack is usually outside the home, and onset is typically in late adolescence to early adulthood. In some individuals, anticipatory anxiety develops over time and results in a generalized fear and a progressive avoidance of places or situations in which a panic attack might recur. *Agoraphobia*, which occurs commonly in patients with panic disorder, is an acquired irrational fear of being in places where one might feel trapped or unable to escape (Table 386-2). Typically, it leads the patient into a progressive restriction in lifestyle and, in a literal sense, in geography. Frequently, patients are embarrassed that they are housebound and dependent on the company of others to go out into the world and do not volunteer this information;

TABLE 386-1 DIAGNOSTIC CRITERIA FOR PANIC ATTACK

A discrete period of intense fear or discomfort, in which four or more of the following symptoms developed abruptly and reached a peak within 10 min:

1. Palpitations, pounding heart, or accelerated heart rate
2. Sweating
3. Trembling or shaking
4. Sensations of shortness of breath or smothering
5. Feeling of choking
6. Chest pain or discomfort
7. Nausea or abdominal distress
8. Feeling dizzy, unsteady, lightheaded, or faint
9. Derealization (feelings of unreality) or depersonalization (being detached from oneself)
10. Fear of losing control or going crazy
11. Fear of dying
12. Paresthesias (numbness or tingling sensations)
13. Chills or hot flushes

Source: *Diagnostic and Statistical Manual of Mental Disorders*, 4th ed. Washington, DC, American Psychiatric Association, 2000.

TABLE 386-2 DIAGNOSTIC CRITERIA FOR AGORAPHOBIA

1. Anxiety about being in places or situations from which escape might be difficult (or embarrassing) or in which help may not be available in the event of having an unexpected or situationally predisposed panic attack or panic-like symptoms. Agoraphobic fears typically involve characteristic clusters of situations that include being outside the home alone; being in a crowd or standing in a line; being on a bridge; and traveling in a bus, train, or automobile.
2. The situations are avoided (e.g., travel is restricted) or else are endured with marked distress or with anxiety about having a panic attack or panic-like symptoms, or require the presence of a companion.
3. The anxiety or phobic avoidance is not better accounted for by another mental disorder, such as social phobia (e.g., avoidance limited to social situations because of fear of embarrassment), specific phobia (e.g., avoidance limited to a single situation like elevators), obsessive-compulsive disorder (e.g., avoidance of dirt in someone with an obsession about contamination), posttraumatic stress disorder (e.g., avoidance of stimuli associated with a severe stressor), or separation anxiety disorder (e.g., avoidance of leaving home or relatives).

Source: *Diagnostic and Statistical Manual of Mental Disorders*, 4th ed. Washington, DC, American Psychiatric Association, 2000.

thus physicians will fail to recognize the syndrome if direct questioning is not pursued.

Differential Diagnosis A diagnosis of panic disorder is made after a medical etiology for the panic attacks has been ruled out. A variety of cardiovascular, respiratory, endocrine, and neurologic conditions can present with anxiety as the chief complaint. Patients with true panic disorder will often focus on one specific feature to the exclusion of others. For example, 20% of patients who present with syncope as a primary medical complaint have a primary diagnosis of a mood, anxiety, or substance-abuse disorder, the most common being panic disorder. The differential diagnosis of panic disorder is complicated by a high rate of comorbidity with other psychiatric conditions, especially alcohol and benzodiazepine abuse, which patients initially use in an attempt at self-medication. Some 75% of panic disorder patients will also satisfy criteria for major depression at some point in their illness.

When the history is nonspecific, physical examination and focused laboratory testing must be used to rule out anxiety states resulting from medical disorders such as pheochromocytoma, thyrotoxicosis, or hypoglycemia. Electrocardiogram (ECG) and echocardiogram may detect some cardiovascular conditions associated with panic, such as paroxysmal atrial tachycardia and mitral valve prolapse. In two studies, panic disorder was the primary diagnosis in 43% of patients with chest pain who had normal coronary angiograms and was present in 9% of all outpatients referred for cardiac evaluation. Panic disorder has also been diagnosed in many patients referred for pulmonary function testing or with symptoms of irritable bowel syndrome.

Etiology and Pathophysiology The etiology of panic disorder is unknown but appears to involve a genetic predisposition, altered autonomic responsivity, and social learning. Panic disorder shows familial aggregation; the disorder is concordant in 30–45% of monozygotic twins, and genome-wide screens have identified suggestive risk loci. Acute panic attacks appear to be associated with increased noradrenergic discharges in the locus coeruleus. Intravenous infusion of sodium lactate evokes an attack in two-thirds of panic disorder patients, as do the α_2-adrenergic antagonist yohimbine, cholecystokinin tetrapeptide (CCK-4), and carbon dioxide inhalation. It is hypothesized that each of these stimuli activates a pathway involving noradrenergic neurons in the locus coeruleus and serotonergic neurons in the dorsal raphe. Agents that block serotonin reuptake can prevent attacks. Panic-disorder patients have a heightened sensitivity to somatic symptoms, which triggers increasing arousal, setting off the panic attack; accordingly, therapeutic intervention involves altering the patient's cognitive interpretation of anxiety-producing experiences as well as preventing the attack itself.

Rx PANIC DISORDER

Achievable goals of treatment are to decrease the frequency of panic attacks and to reduce their intensity. The cornerstone of drug therapy is antidepressant medication **(Tables 386-3**, **386-4**, and **386-5)**. Selective serotonin reuptake inhibitors (SSRIs) benefit the majority of panic disorder patients and do not have the adverse effects of tricyclic antidepressants (TCAs). Fluoxetine, paroxetine, and sertraline have received approval from the U.S. Food and Drug Administration (FDA) for this indication. SSRIs should be started at one-third to one-half of their usual antidepressant dose (e.g., 5–10 mg fluoxetine, 25–50 mg sertraline, 10 mg paroxetine). Monoamine oxidase inhibitors (MAOIs) are also effective and may specifically benefit patients who have comorbid features of atypical depression (i.e., hypersomnia and weight gain). Insomnia, orthostatic hypotension, and the need to maintain a low-tyramine diet (avoidance of cheese and wine) have limited their use, however. Antidepressants typically take 2–6 weeks to become effective, and doses may need to be adjusted based upon the clinical response.

Because of anticipatory anxiety and the need for immediate relief of panic symptoms, benzodiazepines are useful early in the course of treatment and sporadically thereafter **(Table 386-6)**. For example, alprazolam, starting at 0.5 mg qid and increasing to 4 mg/d in divided doses, is effective, but patients must be monitored closely, as some develop dependence and begin to escalate the dose of this medication. Clonazepam, at a final maintenance dose of 2–4 mg/d, is also helpful; its longer half-life permits twice-daily dosing, and patients appear less likely to develop dependence on this agent.

Early psychotherapeutic intervention and education aimed at symptom control enhances the effectiveness of drug treatment. Patients can be taught breathing techniques, educated about physiologic changes that occur with panic, and learn to expose themselves voluntarily to precipitating events in a treatment program spanning 12–15 sessions. Homework assignments and monitored compliance are important components of successful treatment. Once patients have achieved a satisfactory response, drug treatment should be maintained for 1–2 years to prevent relapse. Controlled trials indicate a success rate of 75–85%, although the likelihood of complete remission is somewhat lower.

GENERALIZED ANXIETY DISORDER

Clinical Manifestations Patients with generalized anxiety disorder (GAD) have persistent, excessive, and/or unrealistic worry associated with muscle tension, impaired concentration, autonomic arousal, feeling "on edge" or restless, and insomnia **(Table 386-7)**. Onset is usually before age 20, and a history of childhood fears and social inhibition may be present. The lifetime prevalence of GAD is 5–6%; the risk is higher in first-degree relatives of patients with the diagnosis. Interestingly, family studies indicate that GAD and panic disorder segregate independently. Over 80% of patients with GAD also suffer from major depression, dysthymia, or social phobia. Comorbid substance abuse is common in these patients, particularly alcohol and/or sedative/hypnotic abuse. Patients with GAD worry excessively over minor matters, with life-disrupting effects; unlike in panic disorder, complaints of shortness of breath, palpitations, and tachycardia are relatively rare.

Etiology and Pathophysiology Anxiogenic agents share in common the property of altering the binding of benzodiazepines to the γ-aminobutyric acid $(GABA)_A$ receptor/chloride ion channel complex, implicating this neurotransmitter system in the pathogenesis of anxiety and panic attacks. Benzodiazepines are thought to bind two separate $GABA_A$ receptor sites: type I, which has a broad neuroanatomic distribution, and type II, which is concentrated in the hippocampus, striatum, and neocortex. The antianxiety effects of the various benzodiazepines and side effects such as sedation and memory impairment are influenced by their relative binding to type I and type II receptor sites. Serotonin [5-hydroxytryptamine (5HT)] and 3α-reduced neuractive steroids (allosteric modulators of $GABA_A$) also appear to have a role in anxiety, and buspirone, a partial $5HT_{1A}$ receptor agonist, and certain $5HT_{2A}$ and $5HT_{2C}$ receptor antagonists (e.g., nefazodone) may have beneficial effects.

TABLE 386-3 ANTIDEPRESSANTS

Name	Usual Daily Dose, mg	Side Effects	Comments
SSRIs			
Fluoxetine (Prozac)	10–80	Headache; nausea and other GI effects; jitteriness; insomnia; sexual dysfunction; can affect plasma levels of other meds (except sertraline); akathisia rare	Once daily dosing, usually in A.M.; fluoxetine has very long half-life; must not be combined with MAOIs
Sertraline (Zoloft)	50–200		
Paroxetine (Paxil)	20–60		
Fluvoxamine (Luvox)	100–300		
Citalopram (Celexa)	20–60		
Escitalopram (Lexapro)	10–30		
TCAs			
Amitriptyline (Elavil)	150–300	Anticholinergic (dry mouth, tachycardia, constipation, urinary retention, blurred vision); sweating; tremor; postural hypotension; cardiac conduction delay; sedation; weight gain	Once daily dosing, usually qhs; blood levels of most TCAs available; can be lethal in O.D. (lethal dose = 2 g); nortriptyline best tolerated, especially by elderly
Nortriptyline (Pamelor)	50–200		
Imipramine (Tofranil)	150–300		
Desipramine (Norpramin)	150–300		
Doxepin (Sinequan)	150–300		
Clomipramine (Anafranil)	150–300		
Mixed norepinephrine/serotonin reuptake inhibitors			
Venlafaxine (Effexor)	75–375	Nausea; dizziness; dry mouth; headaches; increased blood pressure; anxiety and insomnia	Bid-tid dosing (extended release available); lower potential for drug interactions than SSRIs; contraindicated with MAOI
Duloxetine (Cymbalta)	40–60	Nausea, dizziness, headache, insomnia, constipation	May have utility in treatment of neuropathic pain and stress incontinence
Mirtazapine (Remeron)	15–45	Somnolence; weight gain; neutropenia rare	Once daily dosing
Mixed-action drugs			
Bupropion (Wellbutrin)	250–450	Jitteriness; flushing; seizures in at-risk patients; anorexia; tachycardia; psychosis	Tid dosing, but sustained release also available; fewer sexual side effects than SSRIs or TCAs; may be useful for adult ADD
Trazodone (Desyrel)	200–600	Sedation; dry mouth; ventricular irritability; postural hypotension; priapism rare	Useful in low doses for sleep because of sedating effects with no anticholinergic side effects
Nefazodone (Serzone)	300–600	Sedation; headache; dry mouth; nausea; constipation	Discontinued sale in United States and several other countries due to risk of liver failure
Amoxapine (Asendin)	200–600	Sexual dysfunction	Lethality in overdose; EPS possible
MAOIs			
Phenelzine (Nardil)	45–90	Insomnia; hypotension; anorgasmia; weight gain; hypertensive crisis; toxic reactions with SSRIs	May be more effective in patients with atypical features or treatment-refractory depression
Tranylcypromine (Parnate)	20–50		
Isocarboxazid (Marplan)	20–60		
Transdermal selegiline (Emsam)	6–12	Local skin reaction; hypertension	No dietary restrictions with 6-mg dose

Note: ADD, attention deficit disorder; MAOI, monoamine oxidase inhibitor; SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant; EPS, extrapyramidal symptoms.

Rx GENERALIZED ANXIETY DISORDER

A combination of pharmacologic and psychotherapeutic interventions is most effective in GAD, but complete symptomatic relief is rare. A short course of a benzodiazepine is usually indicated, preferably lorazepam, oxazepam, or temazepam. (The first two of these agents are metabolized via conjugation rather than oxidation and thus do not accumulate if hepatic function is altered.) Administration should be initiated at the lowest dose possible and prescribed on an as-needed basis as symptoms warrant. Benzodiazepines differ in their milligram per kilogram potency, half-life, lipid solubility, metabolic pathways, and presence of active metabolites. Agents that are absorbed rapidly and are lipid soluble, such as diazepam, have a rapid onset of action and a higher abuse potential. Benzodiazepines should generally not be prescribed for >4–6 weeks because of the development of tolerance and the risk of abuse and dependence. Withdrawal must be closely monitored as relapses can occur. It is important to warn patients that concomitant use of alcohol or other sedating drugs may be neurotoxic and impair their ability to function. An optimistic approach that encourages the patient to clarify environmental precipitants, anticipate his or her reactions, and plan effective response strategies is an essential element of therapy.

Adverse effects of benzodiazepines generally parallel their relative half-lives. Longer-acting agents, such as diazepam, chlordiazepoxide, flurazepam, and clonazepam, tend to accumulate active metabolites, with resultant sedation, impairment of cognition, and poor psychomotor performance. Shorter-acting compounds, such as alprazolam and oxazepam, can produce daytime anxiety, early morning insomnia, and, with discontinuation, rebound anxiety and insomnia. Although patients develop tolerance to the sedative effects of benzodiazepines, they are less likely to habituate to the adverse psychomotor effects. Withdrawal from the longer half-life benzodiazepines can be accomplished through gradual, stepwise dose reduction (by 10% every 1–2 weeks) over 6–12 weeks. It is usually more difficult to taper patients off shorter-acting benzodiazepines. Physicians may need to switch the patient to a benzodiazepine with a longer half-life or use an adjunctive medication, such as a beta blocker or carbamazepine, before attempting to discontinue the benzodiazepine. Withdrawal reactions vary in severity and duration; they can include depression, anxiety, lethargy, diaphoresis, autonomic arousal, and, rarely, seizures.

Buspirone is a nonbenzodiazepine anxiolytic agent. It is nonsedating, does not produce tolerance or dependence, does not interact with benzodiazepine receptors or alcohol, and has no abuse or disinhibition potential. However, it requires several weeks to take effect and requires thrice-daily dosing. Patients who were previously responsive to a benzodiazepine are unlikely to rate buspirone as equally effective, but patients with head injury or dementia who have symptoms of anxiety and/or agitation may do well with this agent. Escitalopram, paroxetine, and venlafaxine are FDA approved for the treatment of GAD, usually at doses that are comparable to their efficacy in major depression. Benzodiazepines are contraindicated during pregnancy and breast-feeding.

Anticonvulsants with GABAergic properties may also be effective against anxiety. Gabapentin, oxcarbazepine, tiagabine, pregabalin, and divalproex have all shown some degree of benefit in a variety of anxiety-related syndromes. Agents that selectively target $GABA_A$ receptor subtypes are cur-

TABLE 386-4 MANAGEMENT OF ANTIDEPRESSANT SIDE EFFECTS

Symptoms	Comments and Management Strategies
Gastrointestinal	
Nausea, loss of appetite	Usually short-lived and dose-related; consider temporary dose reduction or administration with food and antacids
Diarrhea	Famotidine, 20–40 mg/d
Constipation	Wait for tolerance; try diet change, stool softener, exercise; avoid laxatives
Sexual dysfunction	Consider dose reduction; drug holiday
Anorgasmia/ impotence; impaired ejaculation	Bethanechol, 10–20 mg, 2 h before activity, or cyproheptadine, 4–8 mg 2 h before activity, or bupropion, 100 mg bid or amantadine, 100 mg bid/tid
Orthostasis	Tolerance unlikely; increase fluid intake, use calf exercises/support hose; fludrocortisone, 0.025 mg/d
Anticholinergic	Wait for tolerance
Dry mouth, eyes	Maintain good oral hygiene; use artificial tears, sugar-free gum
Tremor/jitteriness	Antiparkinsonian drugs not effective; use dose reduction/slow increase; lorazepam, 0.5 mg bid, or propranolol, 10–20 mg bid
Insomnia	Schedule all doses for the morning; trazodone, 50–100 mg qhs
Sedation	Caffeine; schedule all dosing for bedtime; bupropion, 75–100 mg in afternoon
Headache	Evaluate diet, stress, other drugs; try dose reduction; amitriptyline, 50 mg/d
Weight gain	Decrease carbohydrates; exercise; consider fluoxetine
Loss of therapeutic benefit over time	Related to tolerance? Increase dose or drug holiday; add amantadine, 100 mg bid, buspirone, 10 mg tid, or pindolol, 2.5 mg bid

TABLE 386-5 POSSIBLE DRUG INTERACTIONS WITH SELECTIVE SEROTONIN REUPTAKE INHIBITORS

Agent	Effect
Monoamine oxidase inhibitors	Serotonin syndrome[a]—absolute contraindication
Serotonergic agonists, e.g., tryptophan, fenfluramine	Potential serotonin syndrome
Drugs that are metabolized by P450 isoenzymes: tricyclics, other SSRIs, antipsychotics, beta blockers, codeine, triazolobenzodiazepines, calcium channel blockers	Delayed metabolism resulting in increased blood levels and potential toxicity—possible fatality secondary to QT prolongation with terfenadine or astemizole
Drugs that are bound tightly to plasma proteins, e.g., warfarin	Increased bleeding secondary to displacement
Drugs that inhibit the metabolism of SSRIs by P450 isoenzymes, e.g., quinidine	Increased SSRI side effects

[a]See Rx Depressive Disorders, below.
Note: SSRI, selective serotonin reuptake inhibitor.

rently under development, and it is hoped that these will lack the sedating, memory-impairing, and addicting properties of benzodiazepines.

PHOBIC DISORDERS

Clinical Manifestations

The cardinal feature of phobic disorders is a marked and persistent fear of objects or situations, exposure to which results in an immediate anxiety reaction. The patient avoids the phobic stimulus, and this avoidance usually impairs occupational or social functioning. Panic attacks may be triggered by the phobic stimulus or may occur spontaneously. Unlike patients with other anxiety disorders, individuals with phobias usually experience anxiety only in specific situations. Common phobias include fear of closed spaces (claustrophobia), fear of blood, and fear of flying. Social phobia is distinguished by a specific fear of social or performance situations in which the individual is exposed to unfamiliar individuals or to possible examination and evaluation by others. Examples include having to converse at a party, use public restrooms, and meet strangers. In each case, the affected individual is aware that the experienced fear is excessive and unreasonable given the circumstance. The specific content of a phobia may vary across gender, ethnic, and cultural boundaries.

Phobic disorders are common, affecting ~10% of the population. Full criteria for diagnosis are usually satisfied first in early adulthood, but behavioral avoidance of unfamiliar people, situations, or objects dating from early childhood is common.

In one study of female twins, concordance rates for agoraphobia, social phobia, and animal phobia were found to be 23% for monozygotic twins and 15% for dizygotic twins. A twin study of fear conditioning, a model for the acquisition of phobias, demonstrated a heritability of 35–45%, and a genome-wide linkage scan identified a risk locus on chromosome 14 in a region previously implicated in a mouse model of fear. Animal studies of fear conditioning have indicated that processing of the fear stimulus occurs through the lateral nucleus of the amygdala, extending through the central nucleus and projecting to the periaqueductal gray region, lateral hypothalamus, and paraventricular hypothalamus.

Rx PHOBIC DISORDERS

Beta blockers (e.g., propranolol, 20–40 mg orally 2 h before the event) are particularly effective in the treatment of "performance anxiety" (but not

TABLE 386-6 ANXIOLYTICS

Name	Equivalent PO dose, mg	Onset of Action	Half-life, h	Comments
Benzodiazepines				
Diazepam (Valium)	5	Fast	20–70	Active metabolites; quite sedating
Flurazepam (Dalmane)	15	Fast	30–100	Flurazepam is a pro-drug; metabolites are active; quite sedating
Triazolam (Halcion)	0.25	Intermediate	1.5–5	No active metabolites; can induce confusion and delirium, especially in elderly
Lorazepam (Ativan)	1	Intermediate	10–20	No active metabolites; direct hepatic glucuronide conjugation; quite sedating
Alprazolam (Xanax)	0.5	Intermediate	12–15	Active metabolites; not too sedating; may have specific antidepressant and antipanic activity; tolerance and dependence develop easily
Chlordiazepoxide (Librium)	10	Intermediate	5–30	Active metabolites; moderately sedating
Oxazepam (Serax)	15	Slow	5–15	No active metabolites; direct glucuronide conjugation; not too sedating
Temazepam (Restoril)	15	Slow	9–12	No active metabolites; moderately sedating
Clonazepam (Klonopin)	0.5	Slow	18–50	No active metabolites; moderately sedating
Non-benzodiazepines				
Buspirone (BuSpar)	7.5	2 weeks	2–3	Active metabolites; tid dosing—usual daily dose 10–20 mg tid; nonsedating; no additive effects with alcohol; useful for agitation in demented or brain-injured patients

TABLE 386-7 DIAGNOSTIC CRITERIA FOR GENERALIZED ANXIETY DISORDER

A. Excessive anxiety and worry (apprehensive expectation), occurring more days than not for at least 6 months, about a number of events or activities (such as work or school performance).
B. The person finds it difficult to control the worry.
C. The anxiety and worry are associated with three (or more) of the following six symptoms (with at least some symptoms present for more days than not for the past 6 months): (1) restlessness or feeling keyed up or on edge; (2) being easily fatigued; (3) difficulty concentrating or mind going blank; (4) irritability; (5) muscle tension; (6) sleep disturbance (difficulty falling or staying asleep, or restless unsatisfying sleep).
D. The focus of the anxiety and worry is not confined to features of an Axis I disorder, e.g., the anxiety or worry is not about having a panic attack (as in panic disorder), being embarrassed in public (as in social phobia), being contaminated (as in obsessive-compulsive disorder), being away from home or close relatives (as in separation anxiety disorder), gaining weight (as in anorexia nervosa), having multiple physical complaints (as in somatization disorder), or having a serious illness (as in hypochondriasis), and the anxiety and worry do not occur exclusively during posttraumatic stress disorder.
E. The anxiety, worry, or physical symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
F. The disturbance is not due to the direct physiologic effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition (e.g., hyperthyroidism) and does not occur exclusively during a mood disorder, a psychotic disorder, or a pervasive developmental disorder.

Source: *Diagnostic and Statistical Manual of Mental Disorders*, 4th ed. Washington, DC, American Psychiatric Association, 2000.

general social phobia) and appear to work by blocking the peripheral manifestations of anxiety, such as perspiration, tachycardia, palpitations, and tremor. MAOIs alleviate social phobia independently of their antidepressant activity, and paroxetine, sertraline, and venlafaxine have received FDA approval for treatment of social anxiety. Benzodiazepines can be helpful in reducing fearful avoidance, but the chronic nature of phobic disorders limits their usefulness.

Behaviorally focused psychotherapy is an important component of treatment, as relapse rates are high when medication is used as the sole treatment. Cognitive-behavioral strategies are based upon the finding that distorted perceptions and interpretations of fear-producing stimuli play a major role in perpetuation of phobias. Individual and group therapy sessions teach the patient to identify specific negative thoughts associated with the anxiety-producing situation and help to reduce the patient's fear of loss of control. In desensitization therapy, hierarchies of feared situations are constructed and the patient is encouraged to pursue and master gradual exposure to the anxiety-producing stimuli.

Patients with social phobia, in particular, have a high rate of comorbid alcohol abuse, as well as of other psychiatric conditions (e.g., eating disorders), necessitating the need for parallel management of each disorder if anxiety reduction is to be achieved.

STRESS DISORDERS

Clinical Manifestations Patients may develop anxiety after exposure to extreme traumatic events such as the threat of personal death or injury or the death of a loved one. The reaction may occur shortly after the trauma (*acute stress disorder*) or be delayed and subject to recurrence (PTSD) (Table 386-8). In both syndromes, individuals experience associated symptoms of detachment and loss of emotional responsivity. The patient may feel depersonalized and unable to recall specific aspects of the trauma, though typically it is reexperienced through intrusions in thought, dreams, or flashbacks, particularly when cues of the original event are present. Patients often actively avoid stimuli that precipitate recollections of the trauma and demonstrate a resulting increase in vigilance, arousal, and startle response. Patients with stress disorders are at risk for the development of other disorders related to anxiety, mood, and substance abuse (especially alcohol). Between 5 and 10% of Americans will at some time in their life satisfy criteria for PTSD, with women more likely to be affected than men.

TABLE 386-8 DIAGNOSTIC CRITERIA FOR POSTTRAUMATIC STRESS DISORDER

A. The person has been exposed to a traumatic event in which both of the following were present:
   1. The person experienced, witnessed, or was confronted with an event or events that involved actual or threatened death or serious injury, or a threat to the physical integrity of self or others.
   2. The person's response involved intense fear, helplessness, or horror.
B. The traumatic event is persistently reexperienced in one (or more) of the following ways:
   1. Recurrent and intrusive distressing recollections of the event, including images, thoughts, or perceptions.
   2. Recurrent distressing dreams of the event.
   3. Acting or feeling as if the traumatic event were recurring (includes a sense of reliving the experience, illusions, hallucinations, and dissociative flashback episodes, including those that occur on awakening or when intoxicated).
   3. Intense psychological distress at exposure to internal or external cues that symbolize or resemble an aspect of the traumatic event.
   4. Physiologic reactivity on exposure to internal or external cues that symbolize or resemble an aspect of the traumatic event.
C. Persistent avoidance of stimuli associated with the trauma and numbing of general responsiveness (not present before the trauma), as indicated by three or more of the following:
   1. Efforts to avoid thoughts, feelings, or conversations associated with the trauma
   2. Efforts to avoid activities, places, or people that arouse recollections of the trauma
   3. Inability to recall an important aspect of the trauma
   4. Markedly diminished interest or participation in significant activities
   5. Feeling of detachment or estrangement from others
   6. Restricted range of affect (e.g., unable to have loving feelings)
   7. Sense of a foreshortened future (e.g., does not expect to have a career, marriage, children, or a normal life span)
D. Persistent symptoms of increased arousal (not present before the trauma), as indicated by two (or more) of the following:
   1. Difficulty falling or staying asleep
   2. Irritability or outbursts of anger
   3. Difficulty concentrating
   4. Hypervigilance
   5. Exaggerated startle response
E. Duration of the disturbance (symptoms in criteria B, C, and D) is more than 1 month.
F. The disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.

Source: *Diagnostic and Statistical Manual of Mental Disorders*, 4th ed. Washington, DC, American Psychiatric Association, 2000.

Risk factors for the development of PTSD include a past psychiatric history and personality characteristics of high neuroticism and extroversion. Twin studies show a substantial genetic influence on all symptoms associated with PTSD, with less evidence for an environmental effect.

Etiology and Pathophysiology It is hypothesized that in PTSD there is excessive release of norepinephrine from the locus coeruleus in response to stress and increased noradrenergic activity at projection sites in the hippocampus and amygdala. These changes theoretically facilitate the encoding of fear-based memories. Greater sympathetic responses to cues associated with the traumatic event occur in PTSD, although pituitary adrenal responses are blunted.

Rx STRESS DISORDERS

Acute stress reactions are usually self-limited, and treatment typically involves the short-term use of benzodiazepines and supportive/expressive psychotherapy. The chronic and recurrent nature of PTSD, however, requires a more complex approach employing drug and behavioral treatments. PTSD is highly correlated with peritraumatic dissociative symptoms and the development of an acute stress disorder at the time of the trauma. TCAs such as imipramine and amitriptyline, the MAOI phenelzine, and the SSRIs can all reduce anxiety, symptoms of intrusion, and avoidance behaviors, as can prazosin, an α_1 antagonist. Propranolol given during the acute

stress period may have beneficial effects in preventing the development of PTSD. Trazodone, a sedating antidepressant, is frequently used at night to help with insomnia (50–150 mg qhs). Carbamazepine, valproic acid, or alprazolam have also independently produced improvement in uncontrolled trials. Psychotherapeutic strategies for PTSD help the patient overcome avoidance behaviors and demoralization and master fear of recurrence of the trauma; therapies that encourage the patient to dismantle avoidance behaviors through stepwise focusing on the experience of the traumatic event are the most effective.

OBSESSIVE-COMPULSIVE DISORDER

Clinical Manifestations Obsessive-compulsive disorder (OCD) is characterized by obsessive thoughts and compulsive behaviors that impair everyday functioning. Fears of contamination and germs are common, as are handwashing, counting behaviors, and having to check and recheck such actions as whether a door is locked. The degree to which the disorder is disruptive for the individual varies, but in all cases obsessive-compulsive activities take up >1 h/d and are undertaken to relieve the anxiety triggered by the core fear. Patients often conceal their symptoms, usually because they are embarrassed by the content of their thoughts or the nature of their actions. Physicians must ask specific questions regarding recurrent thoughts and behaviors, particularly if physical clues such as chafed and reddened hands or patchy hair loss (from repetitive hair pulling, or trichotillomania) are present. Comorbid conditions are common, the most frequent being depression, other anxiety disorders, eating disorders, and tics. OCD has a lifetime prevalence of 2–3% worldwide. Onset is usually gradual, beginning in early adulthood, but childhood onset is not rare. The disorder usually has a waxing and waning course, but some cases may show a steady deterioration in psychosocial functioning.

Etiology and Pathophysiology A genetic contribution to OCD is suggested by twin studies. Family studies show an aggregation with Tourette's disorder. OCD is also more common in males and in firstborn children.

The anatomy of obsessive-compulsive behavior is thought to include the orbital frontal cortex, caudate nucleus, and globus pallidus. The caudate nucleus appears to be involved in the acquisition and maintenance of habit and skill learning, and interventions that are successful in reducing obsessive-compulsive behaviors also decrease metabolic activity measured in the caudate.

℞ OBSESSIVE-COMPULSIVE DISORDER

Clomipramine, fluoxetine, fluvoxamine, and sertraline are approved for the treatment of OCD. Clomipramine is a TCA that is often tolerated poorly owing to anticholinergic and sedative side effects at the doses required to treat the illness (25–250 mg/d). Its efficacy in OCD is unrelated to its antidepressant activity. Fluoxetine (5–60 mg/d), fluvoxamine (25–300 mg/d), and sertraline (50–150 mg/d) are as effective as clomipramine and have a more benign side-effect profile. Only 50–60% of patients with OCD show adequate improvement with pharmacotherapy alone. In treatment-resistant cases, augmentation with other serotonergic agents, such as buspirone, or with a neuroleptic or benzodiazepine may be beneficial. When a therapeutic response is achieved, long-duration maintenance therapy is usually indicated.

For many individuals, particularly those with time-consuming compulsions, behavior therapy will result in as much improvement as that afforded by medication. Effective techniques include the gradual increase in exposure to stressful situations, maintenance of a diary to clarify stressors, and homework assignments that substitute new activities for compulsive behaviors.

MOOD DISORDERS

Mood disorders are characterized by a disturbance in the regulation of mood, behavior, and affect. Mood disorders are subdivided into (1) depressive disorders, (2) bipolar disorders, and (3) depression in association with medical illness or alcohol and substance abuse (Chaps. 387, 388, and 389). Depressive disorders are differentiated from bipolar disorders by the absence of a manic or hypomanic episode. The relationship between pure depressive syndromes and bipolar disorders is not well understood; depression is more frequent in families of bipolar individuals, but the reverse is not true. In the Global Burden of Disease Study conducted by the World Health Organization, unipolar major depression ranked fourth among all diseases in terms of disability-adjusted life-years and was projected to rank second by the year 2020. In the United States, lost productivity directly related to mood disorders has been estimated at $55.1 billion per year.

DEPRESSION IN ASSOCIATION WITH MEDICAL ILLNESS

Depression occurring in the context of medical illness is difficult to evaluate. Depressive symptomatology may reflect the psychological stress of coping with the disease, may be caused by the disease process itself or by the medications used to treat it, or may simply coexist in time with the medical diagnosis.

Virtually every class of *medication* includes some agent that can induce depression. Antihypertensive drugs, anticholesterolemic agents, and antiarrhythmic agents are common triggers of depressive symptoms. Among the antihypertensive agents, β-adrenergic blockers and, to a lesser extent, calcium channel blockers are the most likely to cause depressed mood. Iatrogenic depression should also be considered in patients receiving glucocorticoids, antimicrobials, systemic analgesics, antiparkinsonian medications, and anticonvulsants. To decide whether a causal relationship exists between pharmacologic therapy and a patient's change in mood, it may sometimes be necessary to undertake an empirical trial of an alternative medication.

Between 20 and 30% of *cardiac* patients manifest a depressive disorder; an even higher percentage experience depressive symptomatology when self-reporting scales are used. Depressive symptoms following unstable angina, myocardial infarction, cardiac bypass surgery, or heart transplant impair rehabilitation and are associated with higher rates of mortality and medical morbidity. Depressed patients often show decreased variability in heart rate (an index of reduced parasympathetic nervous system activity); this has been proposed as one mechanism by which depression may predispose individuals to ventricular arrhythmia and increased morbidity. Depression also appears to increase the risk of developing coronary heart disease; increased serotonin-induced platelet aggregation has been implicated as a possible cause. TCAs are contraindicated in patients with bundle branch block, and TCA-induced tachycardia is an additional concern in patients with congestive heart failure. SSRIs appear not to induce ECG changes or adverse cardiac events and thus are reasonable first-line drugs for patients at risk for TCA-related complications. SSRIs may interfere with hepatic metabolism of anticoagulants, however, causing increased anticoagulation.

In patients with *cancer*, the mean prevalence of depression is 25%, but depression occurs in 40–50% of patients with cancers of the pancreas or oropharynx. This association is not due to the effect of cachexia alone, as the higher prevalence of depression in patients with pancreatic cancer persists when compared to those with advanced gastric cancer. Initiation of antidepressant medication in cancer patients has been shown to improve quality of life as well as mood. Psychotherapeutic approaches, particularly group therapy, may have some effect on short-term depression, anxiety, and pain symptoms.

Depression occurs frequently in patients with *neurologic disorders*, particularly cerebrovascular disorders, Parkinson's disease, dementia, multiple sclerosis, and traumatic brain injury. One in five patients with left-hemisphere stroke involving the dorsolateral frontal cortex experiences major depression. Late-onset depression in otherwise cognitively normal individuals increases the risk of a subsequent diagnosis of Alzheimer's disease. Both TCA and SSRI agents are effective against these depressions, as are stimulant compounds and, in some patients, MAOIs.

The reported prevalence of depression in patients with *diabetes mellitus* varies from 8–27%, with the severity of the mood state correlating with the level of hyperglycemia and the presence of diabetic complications. Treatment of depression may be complicated by effects of antidepressive agents on glycemic control. MAOIs can induce hypoglycemia and weight gain. TCAs can produce hyperglycemia and carbohydrate

craving. SSRIs, like MAOIs, may reduce fasting plasma glucose, but they are easier to use and may also improve dietary and medication compliance.

Hypothyroidism is frequently associated with features of depression, most commonly depressed mood and memory impairment. Hyperthyroid states may also present in a similar fashion, usually in geriatric populations. Improvement in mood usually follows normalization of thyroid function, but adjunctive antidepressant medication is sometimes required. Patients with subclinical hypothyroidism can also experience symptoms of depression and cognitive difficulty that respond to thyroid replacement.

The lifetime prevalence of depression in *HIV-positive* individuals has been estimated at 22–45%. The relationship between depression and disease progression is multifactorial and likely to involve psychological and social factors, alterations in immune function, and central nervous system disease. Chronic hepatitis C infection is also associated with depression, which may worsen with interferon-α treatment.

Some chronic disorders of uncertain etiology, such as chronic fatigue syndrome (Chap. 384) and fibromyalgia (Chap. 329), are strongly associated with depression and anxiety; patients may benefit from antidepressant treatment, usually at lower than normal dosing.

DEPRESSIVE DISORDERS

Clinical Manifestations

Major depression is defined as depressed mood on a daily basis for a minimum duration of 2 weeks (Table 386-9). An episode may be characterized by sadness, indifference, apathy, or irritability and is usually associated with: changes in sleep patterns, appetite, and weight; motor agitation or retardation; fatigue; impaired concentration and decision-making; feelings of shame or guilt; and thoughts of death or dying. Patients with depression have a profound loss of pleasure in all enjoyable activities, exhibit early morning awakening, feel that the dysphoric mood state is qualitatively different from sadness, and often notice a diurnal variation in mood (worse in morning hours).

TABLE 386-9 CRITERIA FOR MAJOR DEPRESSIVE EPISODE

A. Five (or more) of the following symptoms have been present during the same 2-week period and represent a change from previous functioning; at least one of the symptoms is either (1) depressed mood or (2) loss of interest or pleasure. **Note:** Do not include symptoms that are clearly due to a general medical condition, or mood-incongruent delusions or hallucinations.
   1. Depressed mood most of the day, nearly every day, as indicated by either subjective report (e.g., feels sad or empty) or observation made by others (e.g., appears tearful)
   2. Markedly diminished interest or pleasure in all, or almost all, activities most of the day, nearly every day (as indicated by either subjective account or observation made by others)
   3. Significant weight loss when not dieting or weight gain (e.g., a change of >5% of body weight in a month), or decrease or increase in appetite nearly every day
   4. Insomnia or hypersomnia nearly every day
   5. Psychomotor agitation or retardation nearly every day (observable by others, not merely subjective feelings of restlessness or being slowed down)
   6. Fatigue or loss of energy nearly every day
   7. Feelings of worthlessness or excessive or inappropriate guilt (which may be delusional) nearly every day (not merely self-reproach or guilt about being sick)
   8. Diminished ability to think or concentrate, or indecisiveness, nearly every day (either by subjective account or as observed by others)
   9. Recurrent thoughts of death (not just fear of dying), recurrent suicidal ideation without a specific plan, or a suicide attempt or a specific plan for committing suicide

B. The symptoms do not meet criteria for a mixed episode

C. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning

D. The symptoms are not due to the direct physiologic effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition (e.g., hypothyroidism)

E. The symptoms are not better accounted for by bereavement; i.e., after the loss of a loved one, the symptoms persist for >2 months or are characterized by marked functional impairment, morbid preoccupation with worthlessness, suicidal ideation, psychotic symptoms, or psychomotor retardation

Source: *Diagnostic and Statistical Manual of Mental Disorders,* 4th ed. Washington, DC, American Psychiatric Association, 2000.

Approximately 15% of the population experiences a major depressive episode at some point in life, and 6–8% of all outpatients in primary care settings satisfy diagnostic criteria for the disorder. Depression is often undiagnosed, and, even more frequently, it is treated inadequately. If a physician suspects the presence of a major depressive episode, the initial task is to determine whether it represents unipolar or bipolar depression or is one of the 10–15% of cases that are secondary to general medical illness or substance abuse. Physicians should also assess the risk of suicide by direct questioning, as patients are often reluctant to verbalize such thoughts without prompting. If specific plans are uncovered or if significant risk factors exist (e.g., a past history of suicide attempts, profound hopelessness, concurrent medical illness, substance abuse, or social isolation), the patient must be referred to a mental health specialist for immediate care. The physician should specifically probe each of these areas in an empathic and hopeful manner, being sensitive to denial and possible minimization of distress. The presence of anxiety, panic, or agitation significantly increases near-term suicidal risk. Approximately 4–5% of all depressed patients will commit suicide; most will have sought help from a physician within 1 month of their death.

In some depressed patients, the mood disorder does not appear to be episodic and is not clearly associated with either psychosocial dysfunction or change from the individual's usual experience in life. *Dysthymic disorder* consists of a pattern of chronic (at least 2 years), ongoing, mild depressive symptoms that are less severe and less disabling than those found in major depression; the two conditions are sometimes difficult to separate, however, and can occur together ("double depression"). Many patients who exhibit a profile of pessimism, disinterest, and low self-esteem respond to antidepressant treatment. Dysthymic disorder exists in ~5% of primary care patients. The term *minor depression* is used for individuals who experience at least two depressive symptoms for 2 weeks but who do not meet the full criteria for major depression. Despite its name, minor depression is associated with significant morbidity and disability and also responds to pharmacologic treatment.

Depression is approximately twice as common in women as in men, and the incidence increases with age in both sexes. Twin studies indicate that the liability to major depression in adult women is largely genetic in origin. Negative life events can precipitate and contribute to depression, but genetic factors influence the sensitivity of individuals to these stressful events. In most cases, both biologic and psychosocial factors are involved in the precipitation and unfolding of depressive episodes. The most potent stressors appear to involve death of a relative, assault, or severe marital or relationship problems.

Unipolar depressive disorders usually begin in early adulthood and recur episodically over the course of a lifetime. The best predictor of future risk is the number of past episodes; 50–60% of patients who have a first episode have at least one or two recurrences. Some patients experience multiple episodes that become more severe and frequent over time. The duration of an untreated episode varies greatly, ranging from a few months to ≥1 year. The pattern of recurrence and clinical progression in a developing episode are also variable. Within an individual, the nature of episodes (e.g., specific presenting symptoms, frequency and duration) may be similar over time. In a minority of patients, a severe depressive episode may progress to a psychotic state; in elderly patients, depressive symptoms may be associated with cognitive deficits mimicking dementia ("pseudodementia"). A seasonal pattern of depression, called *seasonal affective disorder*, may manifest with onset and remission of episodes at predictable times of the year. This disorder is more common in women, whose symptoms are anergy, fatigue, weight gain, hypersomnia, and episodic carbohydrate craving. The prevalence increases with distance from the equator, and improvement may occur by altering light exposure.

Etiology and Pathophysiology

Although evidence for genetic transmission of unipolar depression is not as strong as in bipolar disorder,

monozygotic twins have a higher concordance rate (46%) than dizygotic siblings (20%), with little support for any effect of a shared family environment. There is some evidence that a functional polymorphism in the serotonin transporter (*5-HTT*) gene may interact with stressful life events to markedly increase risk of depression and suicide. Positron emission tomography (PET) studies show decreased metabolic activity in the caudate nuclei and frontal lobes in depressed patients that returns to normal with recovery. Single-photon emission computed tomography (SPECT) studies show comparable changes in blood flow.

Postmortem examination of brains of suicide victims indicate altered noradrenergic activity, including increased binding to α_1-, α_2-, and β-adrenergic receptors in the cerebral cortex and decreased numbers of noradrenergic neurons in the locus coeruleus. Involvement of the serotonin system is suggested by findings of reduced plasma tryptophan levels, a decreased cerebrospinal fluid level of 5-hydroxyindolacetic acid (the principal metabolite of serotonin in brain), and decreased platelet serotonergic transporter binding. An increase in brain serotonin receptors in suicide victims and decreased expression of the cyclic AMP response element-binding (CREB) protein are also reported. Depletion of blood tryptophan, the amino acid precursor of serotonin, rapidly reverses the antidepressant benefit in depressed patients who have been successfully treated. However, a decrement in mood after tryptophan reduction is considerably less robust in untreated patients, indicating that, if presynaptic serotonergic dysfunction occurs in depression, it likely plays a contributing rather than a causal role.

Neuroendocrine abnormalities that reflect the neurovegetative signs and symptoms of depression include (1) increased cortisol and corticotropin-releasing hormone (CRH) secretion, (2) an increase in adrenal size, (3) a decreased inhibitory response of glucocorticoids to dexamethasone, and (4) a blunted response of thyroid-stimulating hormone (TSH) level to infusion of thyroid-releasing hormone (TRH). Antidepressant treatment leads to normalization of these pituitary-adrenal abnormalities. Major depression is also associated with an upregulation of proinflammatory cytokines, which normalizes with antidepressant treatment.

Diurnal variations in symptom severity and alterations in circadian rhythmicity of a number of neurochemical and neurohumoral factors suggest that biologic differences may be secondary to a primary defect in regulation of biologic rhythms. Patients with major depression show consistent findings of a decrease in rapid eye movement (REM) sleep onset (REM latency), an increase in REM density, and, in some subjects, a decrease in stage IV delta slow-wave sleep.

Although antidepressant drugs inhibit neurotransmitter uptake within hours, their therapeutic effects typically emerge over several weeks, implicating adaptive changes in second messenger systems and transcription factors as possible mechanisms of action. Antidepressant drugs have been shown to regulate neural plasticity and cell survival by increasing the expression of brain-derived neurotrophic factor (BDNF) through upregulation of the CREB protein and to alter stress responsivity through an increase in glucocorticoid receptor transcription. Secondary effects on activation of the mitogen-activated protein (MAP) kinase and phosphoinositol-3 kinase/AKT pathways and increased expression of the antiapoptotic protein, Bcl-2, are also thought to be critical to antidepressant actions.

℞ DEPRESSIVE DISORDERS

Treatment planning requires coordination of short-term strategies to induce remission combined with longer term maintenance designed to prevent recurrence. The most effective intervention for achieving remission and preventing relapse is medication, but combined treatment, incorporating psychotherapy to help the patient cope with decreased self-esteem and demoralization, improves outcome **(Fig. 386-1)**. Approximately 40% of primary care patients with depression drop out of treatment and discontinue medication if symptomatic improvement is not noted within a month, unless additional support is provided. Outcome improves with (1) increased intensity and frequency of visits during the first 4–6 weeks of treatment, (2) supplemental educational materials, and (3) psychiatric consultation as indicated. Despite the widespread use of SSRIs and other second-generation antidepressant drugs, there is no convincing evidence

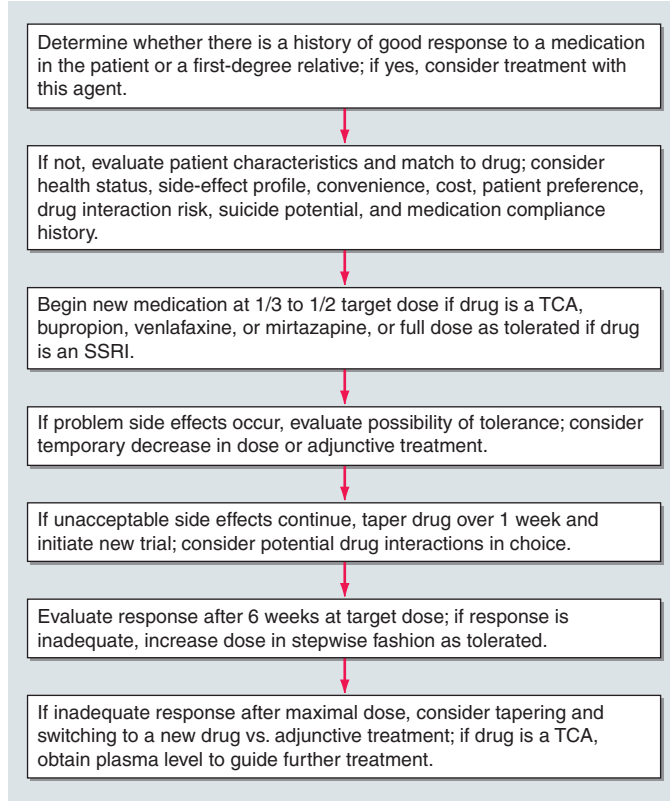

FIGURE 386-1 A guideline for the medical management of major depressive disorder. SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant.

that this class of antidepressant is more efficacious than TCAs. Between 60 and 70% of all depressed patients respond to any drug chosen, if it is given in a sufficient dose for 6–8 weeks. There is no ideal antidepressant; no current compound combines rapid onset of action, moderate half-life, a meaningful relationship between dose and blood level, a low side-effect profile, minimal interaction with other drugs, and safety in overdose.

A rational approach to selecting which antidepressant to use involves matching the patient's preference and medical history with the metabolic and side effect profile of the drug (Tables 386-4 and 386-5). A previous response, or a family history of a positive response, to a specific antidepressant often suggests that that drug be tried first. Before initiating antidepressant therapy, the physician should evaluate the possible contribution of comorbid illnesses and consider their specific treatment. In individuals with suicidal ideation, particular attention should be paid to choosing a drug with low toxicity if taken in overdose. The SSRIs and other newer antidepressant drugs are distinctly safer in this regard; nevertheless, the advantages of TCAs have not been completely superseded. The existence of generic equivalents make TCAs relatively cheap, and for several tricyclics, particularly nortriptyline, imipramine, and desipramine, well-defined relationships among dose, plasma level, and therapeutic response exist. The steady-state plasma level achieved for a given drug dose can vary more than tenfold between individuals. Plasma levels may help in interpreting apparent resistance to treatment and/or unexpected drug toxicity. The principal side effects of TCAs are antihistamine (sedation) and anticholinergic (constipation, dry mouth, urinary hesitancy, blurred vision). Cardiac toxicity due to conduction block or arrhythmias can also occur but is uncommon at therapeutic levels. TCAs are contraindicated in patients with serious cardiovascular risk factors. Overdoses of tricyclic agents can be lethal, with desipramine carrying the greatest risk. It is judicious to prescribe only a 10-day supply when suicide is a risk. Most patients require a daily dose of 150–200 mg of imipramine or amitriptyline or its equivalent to achieve a therapeutic blood level of 150–300 ng/mL and a satisfactory remission; some patients show a partial effect at lower doses. Geriatric patients may require a low starting dose and slow escalation. Ethnic differences in drug metabolism are significant; Hispanic, Asian, and African-American patients generally require lower doses than Caucasians to

achieve a comparable blood level. P450 profiling using genetic chip technology may be clinically useful in predicting individual sensitivity.

Second-generation antidepressants include amoxapine, maprotiline, trazodone, and bupropion. Amoxapine is a dibenzoxazepine derivative that blocks norepinephrine and serotonin reuptake and has a metabolite that shows a degree of dopamine blockade. Long-term use of this drug carries a risk of tardive dyskinesia. Maprotiline is a potent noradrenergic reuptake blocker that has little anticholinergic effect but may produce seizures. Bupropion is a novel antidepressant whose mechanism of action is thought to involve enhancement of noradrenergic function. It has no anticholinergic, sedating, or orthostatic side effects and has a low incidence of sexual side effects. It may, however, be associated with stimulant-like side effects, may lower seizure threshold, and has an exceptionally short half-life, requiring frequent dosing. An extended-release preparation is available.

SSRIs such as fluoxetine, sertraline, paroxetine, citalopram, and escitalopram cause a lower frequency of anticholinergic, sedating, and cardiovascular side effects but a possibly greater incidence of gastrointestinal complaints, sleep impairment, and sexual dysfunction than do TCAs. Akathisia, involving an inner sense of restlessness and anxiety in addition to increased motor activity, may also be more common, particularly during the first week of treatment. One concern is the risk of "serotonin syndrome," thought to result from hyperstimulation of brainstem $5HT_{1A}$ receptors and characterized by myoclonus, agitation, abdominal cramping, hyperpyrexia, hypertension, and potentially death. Serotonergic agonists taken in combination should be monitored closely for this reason. Considerations such as half-life, compliance, toxicity, and drug-drug interactions may guide the choice of a particular SSRI. Fluoxetine and its principal active metabolite, norfluoxetine, for example, have a combined half-life of almost 7 days, resulting in a delay of 5 weeks before steady-state levels are achieved and a similar delay for complete drug excretion once its use is discontinued. All the SSRIs may impair sexual function, resulting in diminished libido, impotence, or difficulty in achieving orgasm. Sexual dysfunction frequently results in noncompliance and should be asked about specifically. Sexual dysfunction can sometimes be ameliorated by lowering the dose, by instituting weekend drug holidays (two or three times a month), or by treatment with amantadine (100 mg tid), bethanechol (25 mg tid), buspirone (10 mg tid), or bupropion (100–150 mg/d). Paroxetine appears to be more anticholinergic than either fluoxetine or sertraline, and sertraline carries a lower risk of producing an adverse drug interaction than the other two. Rare side effects of SSRIs include angina due to vasospasm and prolongation of the prothrombin time. Escitalopram is the most specific of currently available SSRIs and appears to have no specific inhibitory effects on the P450 system.

Venlafaxine and duloxetine block the reuptake of both norepinephrine and serotonin but produce relatively little in the way of traditional tricyclic side effects. Unlike the SSRIs, venlafaxine has a relatively linear dose-response curve. Patients should be monitored for a possible increase in diastolic blood pressure, and multiple daily dosing is required because of the drug's short half-life. An extended-release form is available and has a somewhat lower incidence of gastrointestinal side effects. Mirtazapine is a tetracyclic antidepressant that has a unique spectrum of activity. It increases noradrenergic and serotonergic neurotransmission through a blockade of central α_2-adrenergic receptors and postsynaptic $5HT_2$ and $5HT_3$ receptors. It is also strongly antihistaminic and, as such, may produce sedation.

With the exception of citalopram and escitalopram, each of the SSRIs may inhibit one or more cytochrome P450 enzymes. Depending on the specific isoenzyme involved, the metabolism of a number of concomitantly administered medications can be dramatically affected. Fluoxetine and paroxetine, for example, by inhibiting 2D6, can cause dramatic increases in the blood level of type 1C antiarrhythmics, while sertraline, by acting on 3A4, may alter blood levels of carbamazepine, or digoxin.

The MAOIs are highly effective, particularly in atypical depression, but the risk of hypertensive crisis following intake of tyramine-containing food or sympathomimetic drugs makes them inappropriate as first-line agents. Transdermal selegiline may avert this risk at low dose. Common side effects include orthostatic hypotension, weight gain, insomnia, and sexual dysfunction. MAOIs should not be used concomitantly with SSRIs, because of the risk of serotonin syndrome, or with TCAs, because of possible hyperadrenergic effects.

Electroconvulsive therapy is at least as effective as medication, but its use is reserved for treatment-resistant cases and delusional depressions. Transcranial magnetic stimulation (TMS) is an investigational treatment of depression that has been shown to have efficacy in several controlled trials; it is uncertain whether the observed benefits were clinically meaningful, however. Vagus nerve stimulation (VNS) has recently been approved for treatment-resistant depression, but its degree of efficacy is controversial.

Regardless of the treatment undertaken, the response should be evaluated after ~2 months. Three-quarters of patients show improvement by this time, but if remission is inadequate the patient should be questioned about compliance and an increase in medication dose should be considered if side effects are not troublesome. If this approach is unsuccessful, referral to a mental health specialist is advised. Strategies for treatment then include selection of an alternative drug, combinations of antidepressants, and/or adjunctive treatment with other classes of drugs, including lithium, thyroid hormone, and dopamine agonists. A large randomized trial (STAR-D) was unable to show preferential efficacy. Patients whose response to an SSRI wanes over time may benefit from the addition of buspirone (10 mg tid) or pindolol (2–5 mg tid) or small amounts of a TCA such as desipramine (25 mg bid or tid). Most patients will show some degree of response but aggressive treatment should be pursued until remission is achieved, and drug treatment should be continued for at least 6–9 more months to prevent relapse. In patients who have had two or more episodes of depression, indefinite maintenance treatment should be considered.

It is essential to educate patients both about depression and the benefits and side effects of medications they are receiving. Advice about stress reduction and cautions that alcohol may exacerbate depressive symptoms and impair drug response are helpful. Patients should be given time to describe their experience, their outlook, and the impact of the depression on them and their families. Occasional empathic silence may be as helpful for the treatment alliance as verbal reassurance. Controlled trials have shown that cognitive-behavioral and interpersonal therapies are effective in improving psychological and social adjustment and that a combined treatment approach is more successful than medication alone for many patients.

BIPOLAR DISORDER

Clinical Manifestations Bipolar disorder is characterized by unpredictable swings in mood from mania (or hypomania) to depression. Some patients suffer only from recurrent attacks of *mania*, which in its pure form is associated with increased psychomotor activity; excessive social extroversion; decreased need for sleep; impulsivity and impairment in judgment; and expansive, grandiose, and sometimes irritable mood (Table 386-10). In severe mania, patients may experience delusions and paranoid thinking indistinguishable from schizophrenia. Half of patients with bipolar disorder present with a mixture of psychomotor agitation and activation with dysphoria, anxiety, and irritability. It may be difficult to distinguish *mixed mania* from *agitated depression*. In some bipolar patients (*bipolar II disorder*), the full criteria for mania are lacking, and the requisite recurrent depressions are separated by periods of mild activation and increased energy (hypomania). In *cyclothymic disorder*, there are numerous hypomanic periods, usually of relatively short duration, alternating with clusters of depressive symptoms that fail, either in severity or duration, to meet the criteria of major depression. The mood fluctuations are chronic and should be present for at least 2 years before the diagnosis is made.

Manic episodes typically emerge over a period of days to weeks, but onset within hours is possible, usually in the early morning hours. An untreated episode of either depression or mania can be as short as several weeks or last as long as 8–12 months, and rare patients have an unremitting chronic course. The term *rapid cycling* is used for patients who have four or more episodes of either depression or mania in a given year. This pattern occurs in 15% of all patients, almost all of whom are women. In some cases, rapid cycling is linked to an underlying thyroid dysfunction and, in others, it is iatrogenically triggered by prolonged antidepressant treatment. Approximately half of patients have sustained difficulties in work performance and psychosocial functioning.

Bipolar disorder is common, affecting ~1.5% of the population in the United States. Onset is typically between 20 and 30 years of age, but many individuals report premorbid symptoms in late childhood or early adolescence. The prevalence is similar for men and women; women are likely to have more depressive and men more manic episodes over a lifetime.

TABLE 386-10 CRITERIA FOR A MANIC EPISODE

A. A distinct period of abnormally and persistently elevated, expansive, or irritable mood, lasting at least 1 week (or any duration if hospitalization is necessary)
B. During the period of mood disturbance, three (or more) of the following symptoms have persisted (four if the mood is only irritable) and have been present to a significant degree:
   1. Inflated self-esteem or grandiosity
   2. Decreased need for sleep (e.g., feels rested after only 3 hours of sleep)
   3. More talkative than usual or pressure to keep talking
   4. Flight of ideas or subjective experience that thoughts are racing
   5. Distractibility (i.e., attention too easily drawn to unimportant or irrelevant external stimuli)
   6. Increase in goal-directed activity (either socially, at work or school, or sexually) or psychomotor agitation
   7. Excessive involvement in pleasurable activities that have a high potential for painful consequences (e.g., engaging in unrestrained buying sprees, sexual indiscretions, or foolish business investments)
C. The symptoms do not meet criteria for a mixed episode.
D. The mood disturbance is sufficiently severe to cause marked impairment in occupational functioning or in usual social activities or relationships with others, or to necessitate hospitalization to prevent harm to self or others, or there are psychotic features.
E. The symptoms are not due to the direct physiologic effects of a substance (e.g., a drug of abuse, a medication, or other treatment) or a general medical condition (e.g., hyperthyroidism).

Note: Manic-like episodes that are clearly caused by somatic antidepressant treatment (e.g., medication, electroconvulsive therapy, light therapy) should not count toward a diagnosis of bipolar I disorder.

TABLE 386-11 CLINICAL PHARMACOLOGY OF MOOD STABILIZERS

Agent and Dosing	Side Effects and Other Effects
Lithium Starting dose: 300 mg bid or tid Therapeutic blood level: 0.8–1.2 meq/L	*Common side effects:* Nausea/anorexia/diarrhea, fine tremor, thirst, polyuria, fatigue, weight gain, acne, folliculitis, neutrophilia, hypothyroidism Blood level is increased by thiazides, tetracyclines, and NSAIDs Blood level is decreased by bronchodilators, verapamil, and carbonic anhydrase inhibitors *Rare side effects:* Neurotoxicity, renal toxicity, hypercalcemia, ECG changes
Valproic acid Starting dose: 250 mg tid Therapeutic blood level: 50–125 μg/mL	*Common side effects:* Nausea/anorexia, weight gain, sedation, tremor, rash, alopecia Inhibits hepatic metabolism of other medications *Rare side effects:* Pancreatitis, hepatotoxicity, Stevens-Johnson syndrome
Carbamazepine/oxcarbazepine Starting dose: 200 mg bid for carbamazepine, 150 bid for oxcarbazepine Therapeutic blood level: 4–12 μg/mL for carbamazepine	*Common side effects:* Nausea/anorexia, sedation, rash, dizziness/ataxia Carbamazepine, but not oxcarbazepine, induces hepatic metabolism of other medications *Rare side effects:* Hyponatremia, agranulocytosis, Stevens-Johnson syndrome
Lamotrigine Starting dose: 25 mg/d	*Common side effects:* Rash, dizziness, headache, tremor, sedation, nausea *Rare side effect:* Stevens-Johnson syndrome

Note: NSAID, nonsteroidal anti-inflammatory drug; ECG, electrocardiogram.

Differential Diagnosis The differential diagnosis of mania includes toxic effects of stimulant or sympathomimetic drugs as well as secondary mania induced by hyperthyroidism, AIDS, or neurologic disorders, such as Huntington's or Wilson's disease, or cerebrovascular accidents. Comorbidity with alcohol and substance abuse is common, either because of poor judgment and increased impulsivity or because of an attempt to self-treat the underlying mood symptoms and sleep disturbances.

Etiology and Pathophysiology Genetic predisposition to bipolar disorder is evident from family studies; the concordance rate for monozygotic twins approaches 80%. Multiple genes are likely to be involved.

The pathophysiologic mechanisms underlying the profound and recurrent mood swings of bipolar disorder remain unknown. Neuroimaging studies have reported anatomic changes in amygdala volume as well as increases in white matter hyperintensities. Molecular studies have implicated changes in membrane Na^+- and K^+-activated ATPase and disordered signal transduction involving the phosphoinositol system and GTP-binding proteins as possible contributing mechanisms. Patients with bipolar disorder also appear to have altered circadian rhythmicity, and lithium may exert its therapeutic benefit through a resynchronization of intrinsic rhythms keyed to the light/dark cycle.

℞ BIPOLAR DISORDER

(Table 386-11) Lithium carbonate is the mainstay of treatment in bipolar disorder, although sodium valproate and olanzapine are equally effective in acute mania, as is lamotrigine in the depressed phase. The response rate to lithium carbonate is 70–80% in acute mania, with beneficial effects appearing in 1–2 weeks. Lithium also has a prophylactic effect in prevention of recurrent mania and, to a lesser extent, in the prevention of recurrent depression. A simple cation, lithium is rapidly absorbed from the gastrointestinal tract and remains unbound to plasma or tissue proteins. Some 95% of a given dose is excreted unchanged through the kidneys within 24 h.

Serious side effects from lithium are rare, but minor complaints such as gastrointestinal discomfort, nausea, diarrhea, polyuria, weight gain, skin eruptions, alopecia, and edema are common. Over time, urine-concentrating ability may be decreased, but significant nephrotoxicity does not usually occur. Lithium exerts an antithyroid effect by interfering with the synthesis and release of thyroid hormones. More serious side effects include tremor, poor concentration and memory, ataxia, dysarthria, and incoordination. There is suggestive, but not conclusive, evidence that lithium is teratogenic, inducing cardiac malformations in the first trimester.

In the treatment of acute mania, lithium is initiated at 300 mg bid or tid, and the dose is then increased by 300 mg every 2–3 days to achieve blood levels of 0.8–1.2 meq/L. Because the therapeutic effect of lithium may not appear until after 7–10 days of treatment, adjunctive usage of lorazepam (1–2 mg every 4 h) or clonazepam (0.5–1 mg every 4 h) may be beneficial to control agitation. Antipsychotics are indicated in patients with severe agitation who respond only partially to benzodiazepines. Patients using lithium should be monitored closely, since the blood levels required to achieve a therapeutic benefit are close to those associated with toxicity.

Valproic acid may be better than lithium for patients who experience rapid cycling (i.e., more than four episodes a year) or who present with a mixed or dysphoric mania. Tremor and weight gain are the most common side effects; hepatotoxicity and pancreatitis are rare toxicities.

Carbamazepine and oxcarbazepine, although not formally approved by the FDA for bipolar disorder, have clinical efficacy in the treatment of acute mania. Second-generation antipsychotic drugs (olanzapine, quetiapine, risperidone, ziprasidone, and aripiprazole) have also been shown to be effective, either alone or in combination with a mood stabilizer. An increased risk of weight gain and other metabolic abnormalities is a concern with these agents.

The recurrent nature of bipolar mood disorder necessitates maintenance treatment. A sustained blood lithium level of at least 0.8 mEq/L is important for optimal prophylaxis and has been shown to reduce risk of suicide, a finding not yet apparent for other mood stabilizers. Compliance is frequently an issue and often requires enlistment and education of concerned family members. Efforts to identify and modify psychosocial factors that may trigger episodes are important, as is an emphasis on lifestyle regularity. Antidepressant medications are sometimes required for the treatment of severe breakthrough depressions, but their use should generally be avoided during maintenance treatment because of the risk of precipitating mania or accelerating the cycle frequency. Loss of efficacy over time may be observed with any of the mood-stabilizing agents. In such situations, an alternative agent or combination therapy is usually helpful.

Consensus guidelines for the treatment of acute mania and bipolar depression are described in **Table 386-12**.

TABLE 386-12 CONSENSUS GUIDELINES FOR DRUG TREATMENT OF ACUTE MANIA AND BIPOLAR DEPRESSION

Condition	Preferred Agents
Euphoric mania	Lithium
Mixed/dysphoric mania	Valproic acid
Mania with psychosis	Valproic acid with olanzapine, conventional antipsychotic, or risperidone
Hypomania	Lithium, lamotrigine, or valproic acid alone
Severe depression with psychosis	Venlafaxine, bupropion, or paroxetine *plus* lithium *plus* olanzapine, *or* risperidone; consider ECT
Severe depression without psychosis	Bupropion, paroxetine, sertraline, venlafaxine, *or* citalopram *plus* lithium
Mild to moderate depression	Lithium *or* lamotrigine alone; add bupropion if needed

Note: ECT, electroconvulsive therapy.

SOMATOFORM DISORDERS

Clinical Manifestations Patients with multiple somatic complaints that cannot be explained by a known medical condition or by the effects of alcohol or of recreational or prescription drugs are commonly seen in primary care practice; one survey indicated a prevalence of such complaints of 5%. In *somatization disorder*, the patient presents with multiple physical complaints referable to different organ systems (Table 386-13). Onset is usually before age 30, and the disorder is persistent. Formal diagnostic criteria require the recording of at least four pain, two gastrointestinal, one sexual, and one pseudoneurologic symptom. Patients with somatization disorder often present with dramatic complaints, but the complaints are inconsistent. Symptoms of comorbid anxiety and mood disorder are common and may be the result of drug interactions due to regimens initiated independently by different physicians. Patients with somatization disorder may be impulsive and demanding and frequently qualify for a formal comorbid psychiatric diagnosis. In *conversion disorder*, the symptoms focus on deficits that involve motor or sensory function and on psychological factors that initiate or exacerbate the medical presentation. Like somatization disorder, the deficit is not intentionally produced or simulated, as is the case in factitious disorder (malingering). In *hypochondriasis*, the essential feature is a belief of serious medical illness that persists despite reassurance and appropriate medical evaluation. As with somatization disorder, patients with hypochondriasis have a history of poor relationships with physicians stemming from their sense that they have been evaluated and treated inappropriately or inadequately. Hypochondriasis can be disabling in intensity and is persistent, with waxing and waning symptomatology.

In *factitious illnesses*, the patient consciously and voluntarily produces physical symptoms of illness. The term *Munchausen's syndrome* is reserved for individuals with particularly dramatic, chronic, or severe factitious illness. In true factitious illness, the sick role itself is gratifying. A variety of signs, symptoms, and diseases have been either simulated or caused by factitious behavior, the most common including chronic diarrhea, fever of unknown origin, intestinal bleeding or hematuria, seizures, and hypoglycemia. Factitious disorder is usually not diagnosed until 5–10 years after its onset, and it can produce significant social and medical costs. In *malingering*, the fabrication derives from a desire for some external reward, such as a narcotic medication or disability reimbursement.

TABLE 386-13 DIAGNOSTIC CRITERIA FOR SOMATIZATION DISORDER

A. A history of many physical complaints beginning before age 30 that occur over a period of several years and result in treatment being sought or significant impairment in social, occupational, or other important areas of functioning.
B. Each of the following criteria must have been met, with individual symptoms occurring at any time during the course of the disturbance:
   1. *Four pain symptoms:* a history of pain related to at least four different sites or functions (e.g., head, abdomen, back, joints, extremities, chest, rectum, during menstruation, during sexual intercourse, or during urination)
   2. *Two gastrointestinal symptoms:* a history of at least two gastrointestinal symptoms other than pain (e.g., nausea, bloating, vomiting other than during pregnancy, diarrhea, or intolerance of several different foods)
   3. *One sexual symptom:* a history of at least one sexual or reproductive symptom other than pain (e.g., sexual indifference, erectile or ejaculatory dysfunction, irregular menses, excessive menstrual bleeding, vomiting throughout pregnancy)
   4. *One pseudoneurologic symptom:* a history of at least one symptom or deficit suggesting a neurologic condition not limited to pain (conversion symptoms such as impaired coordination or balance, paralysis or localized weakness, difficulty swallowing or lump in throat, aphonia, urinary retention, hallucinations, loss of touch or pain sensation, double vision, blindness, deafness, seizures; dissociative symptoms such as amnesia; or loss of consciousness other than fainting)
C. Either of the following:
   1. After appropriate investigation, each of the symptoms in criterion B cannot be fully explained by a known general medical condition or the direct effects of a substance (e.g., a drug of abuse, a medication)
   2. When there is a related general medical condition, the physical complaints or resulting social or occupational impairment are in excess of what would be expected from the history, physical examination, or laboratory findings
D. The symptoms are not intentionally produced or feigned (as in factitious disorder or malingering).

Source: *Diagnostic and Statistical Manual of Mental Disorders*, 4th ed. Washington, DC, American Psychiatric Association, 2000.

℞ SOMATOFORM DISORDERS

Patients with somatization disorders are frequently subjected to many diagnostic tests and exploratory surgeries in an attempt to find their "real" illness. Such an approach is doomed to failure and does not address the core issue. Successful treatment is best achieved through behavior modification, in which access to the physician is tightly regulated and adjusted to provide a sustained and predictable level of support that is less clearly contingent on the patient's level of presenting distress. Visits can be brief and should not be associated with a need for a diagnostic or treatment action. Although the literature is limited, some patients with somatization disorder may benefit from antidepressant treatment.

Any attempt to confront the patient usually creates a sense of humiliation and causes the patient to abandon treatment from that caregiver. A better strategy is to introduce psychological causation as one of a number of possible explanations and to include factitious illness as an option in the differential diagnoses that are discussed. Without directly linking psychotherapeutic intervention to the diagnosis, the patient can be offered a face-saving means by which the pathologic relationship with the health care system can be examined and alternative approaches to life stressors developed.

PERSONALITY DISORDERS

Clinical Manifestations Personality disorders are characteristic patterns of thinking, feeling, and interpersonal behavior that are relatively inflexible and cause significant functional impairment or subjective distress for the individual. The observed behaviors are not secondary to another mental disorder, nor are they precipitated by substance abuse or a general medical condition. This distinction is often difficult to make in clinical practice, as personality change may be the first sign of serious neurologic, endocrine, or other medical illness. Patients with frontal lobe tumors, for example, can present with changes in motivation and personality while the results of the neurologic examination remain within normal limits. Individuals with personality disorders are often regarded as "difficult patients" in clinical medical practice because they are seen as excessively demanding and/or unwilling to follow recommended treatment plans. Although DSM-IV portrays personality disorders as qualitatively distinct categories, there is an alternative perspective that personality characteristics vary as a continuum between normal functioning and formal mental disorder.

Personality disorders have been grouped into three overlapping clusters. *Cluster A* includes paranoid, schizoid, and schizotypal personality disorders. It includes individuals who are odd and eccentric

and who maintain an emotional distance from others. Individuals have a restricted emotional range and remain socially isolated. Patients with schizotypal personality disorder frequently have unusual perceptual experiences and express magical beliefs about the external world. The essential feature of paranoid personality disorder is a pervasive mistrust and suspiciousness of others to an extent that is unjustified by available evidence. *Cluster B* disorders include antisocial, borderline, histrionic, and narcissistic types and describe individuals whose behavior is impulsive, excessively emotional, and erratic. *Cluster C* incorporates avoidant, dependent, and obsessive-compulsive personality types; enduring traits are anxiety and fear. The boundaries between cluster types are to some extent artificial, and many patients who meet criteria for one personality disorder also meet criteria for aspects of another. The risk of a comorbid major mental disorder is increased in patients who qualify for a diagnosis of personality disorder.

℞ PERSONALITY DISORDERS

Dialectical behavior therapy (DBT) is a cognitive-behavioral approach that focuses on behavioral change while providing acceptance, compassion, and validation of the patient. Several randomized trials have demonstrated the efficacy of DBT in the treatment of personality disorders. Antidepressant medications and low-dose antipsychotic drugs have some efficacy in cluster A personality disorders, while anticonvulsant mood-stabilizing agents and MAOIs may be considered for patients with cluster B diagnoses who show marked mood reactivity, behavioral dyscontrol, and/or rejection hypersensitivity. Anxious or fearful cluster C patients often respond to medications used for axis I anxiety disorders (see above). It is important that the physician and the patient have reasonable expectations vis-à-vis the possible benefit of any medication used and its side effects. Improvement may be subtle and observable only over time.

SCHIZOPHRENIA

Clinical Manifestations Schizophrenia is a heterogeneous syndrome characterized by perturbations of language, perception, thinking, social activity, affect, and volition. There are no pathognomonic features. The syndrome commonly begins in late adolescence, has an insidious (and less commonly acute) onset, and, often, a poor outcome, progressing from social withdrawal and perceptual distortions to recurrent delusions and hallucinations. Patients may present with positive symptoms (such as conceptual disorganization, delusions, or hallucinations) or negative symptoms (loss of function, anhedonia, decreased emotional expression, impaired concentration, and diminished social engagement) and must have at least two of these for a 1-month period and continuous signs for at least 6 months to meet formal diagnostic criteria. As individuals age, positive psychotic symptoms tend to attenuate and some measure of social and occupational function may be regained. "Negative" symptoms predominate in one-third of the schizophrenic population and are associated with a poor long-term outcome and a poor response to drug treatment. However, marked variability in the course and individual character of symptoms is typical.

The four main subtypes of schizophrenia are catatonic, paranoid, disorganized, and residual. Many individuals have symptoms of more than one type. *Catatonic-type* describes patients whose clinical presentation is dominated by profound changes in motor activity, negativism, and echolalia or echopraxia. *Paranoid-type* describes patients who have a prominent preoccupation with a specific delusional system and who otherwise do not qualify as having *disorganized-type* disease, in which disorganized speech and behavior are accompanied by a superficial or silly affect. In *residual-type* disease, negative symptomatology exists in the absence of delusions, hallucinations, or motor disturbance. The term *schizophreniform disorder* describes patients who meet the symptom requirements but not the duration requirements for schizophrenia, and *schizoaffective disorder* is used for those who manifest symptoms of schizophrenia and independent periods of mood disturbance. Prognosis depends not on symptom severity but on the response to antipsychotic medication. A permanent remission without recurrence does occasionally occur. About 10% of schizophrenic patients commit suicide.

Schizophrenia is present in 0.85% of individuals worldwide, with a lifetime prevalence of ~1–1.5%. An estimated 300,000 episodes of acute schizophrenia occur annually in the United States, resulting in direct and indirect costs of $62.7 billion.

Differential Diagnosis The diagnosis is principally one of exclusion, requiring the absence of significant associated mood symptoms, any relevant medical condition, and substance abuse. Drug reactions that cause hallucinations, paranoia, confusion, or bizarre behavior may be dose-related or idiosyncratic; parkinsonian medications, clonidine, quinacrine, and procaine derivatives are the most common prescription medications associated with these symptoms. Drug causes should be ruled out in any case of newly emergent psychosis. The general neurologic examination in patients with schizophrenia is usually normal, but motor rigidity, tremor, and dyskinesias are noted in one-quarter of untreated patients.

Epidemiology and Pathophysiology Epidemiologic surveys identify several risk factors for schizophrenia including genetic susceptibility, early developmental insults, winter birth, and increasing parental age. Genetic factors are involved in at least a subset of individuals who develop schizophrenia. Schizophrenia is observed in ~6.6% of all first-degree relatives of an affected proband. If both parents are affected, the risk for offspring is 40%. The concordance rate for monozygotic twins is 50%, compared to 10% for dizygotic twins. Schizophrenia-prone families are also at risk for other psychiatric disorders, including schizoaffective disorder and *schizotypal* and *schizoid personality disorders*, the latter terms designating individuals who show a lifetime pattern of social and interpersonal deficits characterized by an inability to form close interpersonal relationships, eccentric behavior, and mild perceptual distortions.

Despite evidence for a genetic causation, the results of molecular genetic linkage studies in schizophrenia are inconclusive. Major gene effects appear unlikely. Possible susceptibility genes include: neuregulin-1 (chromosome 8p21); dysbindin (6p22.3); proline dehydrogenase (22q11); D-amino-acid oxidase activator (13q34); disrupted in schizophrenia 1, (DISC1), (1q42); and catechol-*O*-methyl transferase (COMT). Neuregulin-1, dysbindin, and D-amino-acid oxidase activator appear to be involved in glutamatergic function, increasing interest in *N*-methyl-D-aspartate (NMDA)–mediated glutamate signaling as a possible therapeutic target for treatment. COMT is involved in the removal of dopamine from synapses, and DISC1 is a scaffolding protein that participates in a variety of protein-protein interactions important in neuronal development. One group has reported risk variants in the α7 nicotinic acetylcholine receptor subunit gene and linked it to a specific auditory processing deficit.

Schizophrenia is also associated with gestational and perinatal complications, including Rh factor incompatibility, fetal hypoxia, prenatal exposure to influenza during the second trimester, and prenatal nutritional deficiency. Studies of monozygotic twins discordant for schizophrenia have reported neuroanatomic differences between affected and unaffected siblings, supporting a "two-strike" etiology involving both genetic susceptibility and an environmental insult. The latter might involve localized hypoxia during critical stages of brain development.

A number of structural and functional abnormalities have been identified in schizophrenia, including (1) cortical atrophy and ventricular enlargement; (2) specific volume losses in the amygdala, hippocampus, right prefrontal cortex, fusiform gyrus, and thalamus; (3) progressive reduction in cortical volume over time; (4) reduced metabolism in the thalamus and prefrontal cortex; (5) abnormalities of the planum temporale; and (6) changes in the size, orientation, and density of cells in the hippocampus and prefrontal cortex, and decreased numbers of cortical interneurons. These observations have suggested that schizophrenia may result from a disturbance in a cortical striatal–thalamic circuit resulting in abnormalities in sensory filtering and attention.

Schizophrenic individuals are highly distractible and demonstrate deficits in perceptual-motor speed, ability to shift attention, and filtering out of background stimuli. Event-related evoked potential studies of schizophrenia have defined a reduction in P300 amplitude to a novel stimulus,

TABLE 386-14 ANTIPSYCHOTIC AGENTS

Name	Usual PO Daily Dose, mg	Side Effects	Sedation	Comments
First-Generation Antipsychotics				
Low-potency				
Chlorpromazine (Thorazine)	100–1000	Anticholinergic effects; orthostasis; photosensitivity; cholestasis; QT prolongation	+ + +	EPSEs usually not prominent; can cause anticholinergic delirium in elderly patients
Thioridazine (Mellaril)	100–600			
Clozapine (Clozaril)	150–600	Agranulocytosis (1%); weight gain; seizures; drooling; hyperthermia	+ +	Requires weekly WBC for first 6 months, then biweekly if stable
Mid-potency				
Trifluoperazine (Stelazine)	2–50	Fewer anticholinergic side effects; fewer EPSEs than with higher potency agents.	+ +	Well tolerated by most patients
Perphenazine (Trilafon)	4–64		++	
Loxapine (Loxitane)	30–100	Frequent EPSEs	+ +	
Molindone (Moban)	30–100	Frequent EPSEs	0	Little weight gain
High-potency				
Haloperidol (Haldol)	.5–20	No anticholinergic side effects; EPSEs often prominent	0/+	Often prescribed in doses that are too high; long-acting injectable forms of haloperidol and fluphenazine available
Fluphenazine (Prolixin)	1–20	Frequent EPSEs	0/+	
Thiothixene (Navane)	2–50	Frequent EPSEs	0/+	
Second-Generation Antipsychotics				
Risperidone (Risperdal)	2–8	Orthostasis	+	Requires slow titration; EPSEs observed with doses >6 mg qd
Olanzapine (Zyprexa)	10–30	Weight gain	+ +	Mild prolactin elevation
Quetiapine (Seroquel)	350–800	Sedation; weight gain; anxiety	+ + +	Bid dosing
Ziprasidone (Geodon)	120–200	Orthostatic hypotension	+/++	Minimal weight gain; increases QT interval
Aripiprazole (Abilify)	10–30	Nausea, anxiety, insomnia	0/+	Mixed agonist/antagonist

Note: EPSEs, extrapyramidal side effects; WBC, white blood count.

which implicates an impairment in cognitive processing. Impaired information processing is also found in unaffected family members.

The *dopamine hypothesis* of schizophrenia is based on the discovery that agents that diminish dopaminergic activity also reduce the acute symptoms and signs of psychosis, specifically agitation, anxiety, and hallucinations. Amelioration of delusions and social withdrawal is less dramatic. Thus far, however, evidence for increased dopaminergic activity in schizophrenia is indirect, although decreased D_2 receptor occupancy by dopamine has been shown in drug-naïve patients. An increase in the activity of nigrostriatal and mesolimbic systems and a decrease in mesocortical tracts innervating the prefrontal cortex is hypothesized, although it is likely that other neurotransmitters, including serotonin, acetylcholine, glutamate, and GABA, also contribute to the pathophysiology of the illness. Possible involvement of excitatory amino acids is supported by the genetic data cited above and findings that NMDA receptor antagonists and channel blockers, such as phencyclidine (PCP) and ketamine, produce characteristic signs of schizophrenia in normal individuals; cycloserine, an NMDA receptor agonist, can decrease the negative symptoms of psychosis.

Rx SCHIZOPHRENIA

Antipsychotic agents **(Table 386-14)** are the cornerstone of acute and maintenance treatment of schizophrenia and are effective in the treatment of hallucinations, delusions and thought disorders, regardless of etiology. The mechanism of action involves, at least in part, binding to dopamine D_2/D_3 receptors in the ventral striatum; the clinical potencies of traditional antipsychotic drugs parallel their affinities for the D_2 receptor, and even the newer "atypical" agents exert some degree of D_2 receptor blockade. All neuroleptics induce expression of the immediate-early gene c-*fos* in the nucleus accumbens, a dopaminergic site connecting prefrontal and limbic cortices. The clinical efficacy of newer atypical neuroleptics, however, may involve NMDA receptor blockade, α_1- and α_2-noradrenergic activity, altering the relationship between $5HT_2$ and D_2 receptor activity, as well as faster dissociation of D_2 binding and effects on neuroplasticity.

Conventional neuroleptics differ in their potency and side-effect profile. Older agents, such as chlorpromazine and thioridazine, are more sedating and anticholinergic and more likely to cause orthostatic hypotension, while higher potency antipsychotics, such as haloperidol, perphenazine, and thiothixene, are more likely to induce extrapyramidal side effects. The model first-generation antipsychotic agent is *clozapine*, a dibenzodiazepine that has a greater potency in blocking the $5HT_2$ than the D_2 receptor and a much higher affinity for the D_4 than the D_2 receptor. Its principal disadvantage is a risk of blood dyscrasias. Unlike other antipsychotics, clozapine does not cause a rise in prolactin level. Approximately 30% of patients who do not benefit from conventional antipsychotic agents will have a better response to this drug, which also has a demonstrated superiority to other antipsychotic agents in preventing suicide; however, its side-effect profile makes it most appropriate for treatment-resistant cases. *Risperidone*, a benzisoxazole derivative, is more potent at $5HT_2$ than D_2 receptor sites, like clozapine, but it also exerts significant α_2 antagonism, a property that may contribute to its perceived ability to improve mood and increase motor activity. Risperidone is not as effective as clozapine in treatment-resistant cases but does not carry a risk of blood dyscrasias. *Olanzapine* is similar neurochemically to clozapine but has a significant risk of inducing weight gain. *Quetiapine* is distinct in having a weak D_2 effect but potent α_1 and histamine blockade. *Ziprasidone* causes minimal weight gain and is unlikely to increase prolactin but may increase QT prolongation. *Aripiprazole* also has little risk of weight gain or prolactin increase but may increase anxiety, nausea, and insomnia as a result of its partial agonist properties.

Antipsychotic agents are effective in 70% of patients presenting with a first episode. Improvement may be observed within hours or days, but full remission usually requires 6–8 weeks. The choice of agent depends principally on the side-effect profile and cost of treatment or on a past personal or family history of a favorable response to the drug in question. Atypical agents appear to be more effective in treating negative symptoms and improving cognitive function. An equivalent treatment response can usually be achieved with relatively low doses of any drug selected, i.e., 4–6 mg/d of haloperidol, 10–15 mg of olanzapine, or 4–6 mg/d of risperidone. Doses in this range result in >80% D_2 receptor blockade, and there is little evidence that higher doses increase either the rapidity or degree of response. Maintenance treatment requires careful attention to the possibility of relapse and monitoring for the development of a movement disorder. Intermittent drug treatment is less effective than regular dosing, but gradual dose reduction is likely to improve social functioning in many schizophren-

ic patients who have been maintained at high doses. If medications are completely discontinued, however, the relapse rate is 60% within 6 months. Long-acting injectable preparations (risperidone) are considered when noncompliance with oral therapy leads to relapses. In treatment-resistant patients, a transition to clozapine usually results in rapid improvement, but a prolonged delay in response in some cases necessitates a 6- to 9-month trial for maximal benefit to occur.

Antipsychotic medications can cause a broad range of side effects, including lethargy, weight gain, postural hypotension, constipation, and dry mouth. Extrapyramidal symptoms such as dystonia, akathisia, and akinesia are also frequent with first-generation agents and may contribute to poor adherence if not specifically addressed. Anticholinergic and parkinsonian symptoms respond well to trihexyphenidyl, 2 mg bid, or benztropine mesylate, 1–2 mg bid. Akathisia may respond to beta blockers. In rare cases, more serious and occasionally life-threatening side effects may emerge, including ventricular arrhythmias, gastrointestinal obstruction, retinal pigmentation, obstructive jaundice, and neuroleptic malignant syndrome (characterized by hyperthermia, autonomic dysfunction, muscular rigidity, and elevated creatine phosphokinase levels). The most serious adverse effects of clozapine are agranulocytosis, which has an incidence of 1%, and induction of seizures, which has an incidence of 10%. Weekly white blood cell counts are required, particularly during the first 3 months of treatment.

The risk of type 2 diabetes mellitus appears to be increased in schizophrenia, and second-generation agents as a group produce greater adverse effects on glucose regulation, independent of effects on obesity, than traditional agents. Clozapine, olanzapine, and quetiapine seem more likely to cause hyperglycemia, weight gain, and hypertriglyceridemia than other atypical antipsychotic drugs. Close monitoring of plasma glucose and lipid levels are indicated with the use of these agents.

A serious side effect of long-term use of first generation antipsychotic agents is *tardive dyskinesia*, characterized by repetitive, involuntary, and potentially irreversible movements of the tongue and lips (bucco-linguo-masticatory triad), and, in approximately half of cases, choreoathetosis. Tardive dyskinesia has an incidence of 2–4% per year of exposure, and a prevalence of 20% in chronically treated patients. The prevalence increases with age, total dose, and duration of drug administration. The risk associated with second-generation agents appears to be much lower. The cause may involve formation of free radicals and perhaps mitochondrial energy failure. Vitamin E may reduce abnormal involuntary movements if given early in the syndrome.

The CATIE study, a large scale investigation of the effectiveness of antipsychotic agents in "real world" patients, revealed a high rate of discontinuation of treatment over 18 months. Olanzapine showed greater effectiveness than quetiapine, risperidone, perphenazine, or ziprasidone but also a higher discontinuation rate due to weight gain and metabolic effects. Surprisingly, perphenazine, a first-generation agent, showed little evidence of inferiority to newer drugs.

Drug treatment of schizophrenia is by itself insufficient. Educational efforts directed toward families and relevant community resources have proved to be necessary to maintain stability and optimize outcome. A treatment model involving a multidisciplinary case-management team that seeks out and closely follows the patient in the community has proved particularly effective.

ASSESSMENT AND EVALUATION OF VIOLENCE

Primary care physicians may encounter situations in which family, domestic, or societal violence is discovered or suspected. Such an awareness can carry legal and moral obligations; many state laws mandate reporting of child, spousal, and elder abuse. Physicians are frequently the first point of contact for both victim and abuser. Approximately 2 million older Americans and 1.5 million U.S. children are thought to experience some form of physical maltreatment each year. Spousal abuse is thought to be even more prevalent. An interview study of 24,000 women in ten countries found a lifetime prevalence of physical or sexual violence that ranged from 15–71%; these individuals are more likely to suffer from depression, anxiety, somatization disorder, and substance abuse and to have attempted suicide. In addition, abused individuals frequently express low self-esteem, vague somatic symptomatology, social isolation, and a passive feeling of loss of control. Although it is essential to treat these elements in the victim, the first obligation is to ensure that the perpetrator has taken responsibility for preventing any further violence. Substance abuse and/or dependence and serious mental illness in the abuser may contribute to the risk of harm and require direct intervention. Depending on the situation, law enforcement agencies, community resources such as support groups and shelters, and individual and family counseling can be appropriate components of a treatment plan. A safety plan should be formulated with the victim, in addition to providing information about abuse, its likelihood of recurrence, and its tendency to increase in severity and frequency. Antianxiety and antidepressant medications may sometimes be useful in treating the acute symptoms, but only if independent evidence for an appropriate psychiatric diagnosis exists.

MENTAL HEALTH PROBLEMS IN THE HOMELESS

There is a high prevalence of mental disorders and substance abuse among homeless and impoverished individuals. Depending on the definition used, estimates of the total number of homeless individuals in the United States range from 800,000 to 2 million, one-third of whom qualify as having a serious mental disorder. Poor hygiene and nutrition, substance abuse, psychiatric illness, physical trauma, and exposure to the elements combine to make the provision of medical care challenging. Only a minority of these individuals receive formal mental health care; the main points of contact are outpatient medical clinics and emergency departments. Primary care settings represent a critical site in which housing needs, treatment of substance dependence, and evaluation and treatment of psychiatric illness can most efficiently take place. Successful intervention is dependent on breaking down traditional administrative barriers to health care and recognizing the physical constraints and emotional costs imposed by homelessness. Simplifying health care instructions and follow-up, allowing frequent visits, and dispensing medications in limited amounts that require ongoing contact are possible techniques for establishing a successful therapeutic relationship.

387 Alcohol and Alcoholism

Marc A. Schuckit

Alcohol, a drug, is consumed at some time by up to 80% of the population. At low doses alcohol can have some beneficial effects such as decreased rates of myocardial infarction, stroke, gallstones, and possibly vascular and Alzheimer's dementias. However, the consumption of more than two standard drinks per day increases the risk for health problems in many organ systems. Heavy repetitive drinking, as is seen in alcohol abuse and dependence, cuts short the life span by an estimated decade in both genders, all cultural groups, and all socioeconomic strata. Unless an individual stops drinking, a diagnosis of alcohol dependence carries a ≥80% risk for continued severe problems over the next 5 years. In addition, even relatively low doses of alcohol can adversely affect many preexisting disease states and alter the effectiveness or blood levels of most over-the-counter and prescribed medications.

PHARMACOLOGY AND NUTRITIONAL IMPACT OF ETHANOL

Ethanol is a weakly charged molecule that moves easily through cell membranes, rapidly equilibrating between blood and tissues. The level of alcohol in the blood is expressed as milligrams or grams of ethanol per deciliter (e.g., 100 mg/dL or 0.10 g/dL), with blood values of about 0.02 g/dL resulting from the ingestion of one typical drink. In round figures, 340 mL (12 oz) of beer, 115 mL (4 oz) of nonfortified wine, and 43 mL (1.5 oz) (a shot) of 80-proof beverage such as whisky, gin, or vodka each contain ~10–15 g of ethanol; 0.5 L (1 pint) of 80-proof beverage contains ~160 g (about 16 standard drinks), and 1 L of wine contains ~80 g of ethanol. These beverages also have additional components, called *congeners*, that affect the taste and effects; congeners include low-molecular-weight alcohols (e.g., methanol and butanol), aldehydes, esters, histamine, phenols, tannins, iron, lead, and cobalt. Such congeners might also contribute to the adverse health consequences associated with heavy drinking.

Ethanol is a central nervous system (CNS) depressant that decreases neuronal activity, although some behavioral stimulation is observed at low blood levels. This drug has cross-tolerance with other depressants, including benzodiazepines and barbiturates, and all produce similar behavioral alterations. Alcohol is absorbed from mucous membranes of the mouth and esophagus (in small amounts), from the stomach and large bowel (in modest amounts), and from the proximal portion of the small intestine (the major site). The rate of absorption is increased by rapid gastric emptying (as can be induced by carbonated beverages); by the absence of proteins, fats, or carbohydrates (which interfere with absorption); by the absence of congeners; and by dilution to a modest percentage of ethanol (maximum at ~20% by volume).

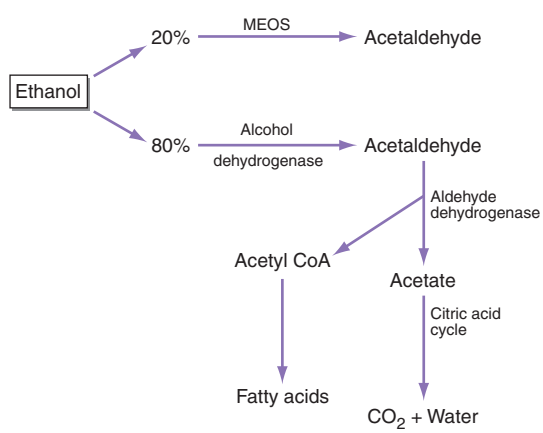

FIGURE 387-1 The metabolism of alcohol. MEOS, microsomal ethanol-oxidizing system.

Between 2% (at low blood alcohol concentrations) and 10% (at high blood alcohol concentrations) of ethanol is excreted directly through the lungs, urine, or sweat, but the greater part is metabolized to acetaldehyde, primarily in the liver. The most important pathway occurs in the cell cytosol where alcohol dehydrogenase (ADH) produces acetaldehyde, which is then rapidly destroyed by aldehyde dehydrogenase (ALDH) in the cytosol and mitochondria (Fig. 387-1). A second pathway in the microsomes of the smooth endoplasmic reticulum (the microsomal ethanol-oxidizing system, or MEOS), is responsible for ≥10% of ethanol oxidation at high blood alcohol concentrations.

While alcohol supplies calories (a drink contains ~300 kJ, or 70–100 kcal), these are devoid of nutrients such as minerals, proteins, and vitamins. Alcohol can also interfere with absorption of vitamins in the small intestine and decreases their storage in the liver with modest effects on folate (folacin or folic acid), pyridoxine (B_6), thiamine (B_1), nicotinic acid (niacin, B_3), and vitamin A.

An ethanol load in a fasting, healthy individual is likely to produce transient hypoglycemia within 6–36 h, secondary to the acute actions of ethanol on gluconeogenesis. This can temporarily result in abnormal glucose tolerance tests (with a resulting erroneous diagnosis of diabetes mellitus) until the alcoholic has abstained for 2–4 weeks. Alcohol ketoacidosis, probably reflecting a decrease in fatty acid oxidation coupled with poor diet or recurrent vomiting, can be misdiagnosed as diabetic ketosis. With the former, patients show an increase in serum ketones along with a mild increase in glucose but a large anion gap, a mild to moderate increase in serum lactate, and a β-hydroxybutyrate/lactate ratio of between 2:1 and 9:1 (with normal being 1:1).

BEHAVIORAL EFFECTS, TOLERANCE, AND DEPENDENCE

The acute effects of a drug depend on many factors. These include the dose, the rate of increase in plasma, the concomitant presence of other drugs, and the past experience with the agent. With alcohol, an additional factor is whether blood alcohol levels are rising or falling; the effects are more intense during the former period.

"Legal intoxication" in the United States requires a blood alcohol concentration of at least 0.08–0.10 g/dL, while levels of 0.04 or even lower are cited in some other countries. However, behavioral, psychomotor, and cognitive changes are seen at levels as low as 0.02–0.03 g/dL (i.e., after one to two drinks) (Table 387-1). Deep but disturbed sleep can be seen at twice the legal intoxication level, and death can occur with levels between 0.30 and 0.40 g/dL. Beverage alcohol is probably responsible for more overdose deaths than any other drug.

The intoxicating effects of alcohol reflect the actions of this drug on a wide range of neurotransmitters, receptors, and transporters. Most prominently, alcohol acutely enhances actions at γ-aminobutyric acid

TABLE 387-1 EFFECTS OF BLOOD ALCOHOL LEVELS IN THE ABSENCE OF TOLERANCE

Blood Level, g/dL	Usual Effect
0.02	Decreased inhibitions, a slight feeling of intoxication
0.08	Decrease in complex cognitive functions and motor performance
0.20	Obvious slurred speech, motor incoordination, irritability, and poor judgment
0.30	Light coma and depressed vital signs
0.40	Death

A ($GABA_A$) receptors and inhibits *N*-methyl-D-aspartate (NMDA) receptors. There are also effects on adenosine, with an inhibition of uptake of this transmitter, and a translocation of the cyclic AMP–dependent protein kinase catalytic subunit from the cytoplasm to the nucleus. Alcohol also affects opioid systems and cannabinol receptors, enhances activity of the dopamine-rich reward system, increases serotonin actions, and directly or indirectly affects most other neurochemical systems. As with most depressants, neurons adapt quickly to these actions, and tolerance to many effects develops; after repeated exposure, abrupt decreases in blood alcohol levels are likely to produce physiologic changes that are opposite to the acute effects of this drug (i.e., withdrawal). The presence of tolerance and/or withdrawal characterizes physical dependence.

Tolerance is a complex phenomenon involving at least three types of compensatory mechanisms. (1) After 1–2 weeks of daily drinking, *metabolic or pharmacokinetic tolerance* can be seen, with up to a 30% increase in the rate of hepatic ethanol metabolism. This alteration disappears almost as rapidly as it develops. (2) *Cellular or pharmacodynamic tolerance* develops through neurochemical changes that maintain relatively normal physiologic functioning despite the presence of alcohol. Subsequent decreases in blood levels contribute to symptoms of withdrawal. (3) Individuals learn to adapt their behavior so that they can function better than expected under influence of the drug (*behavioral tolerance*).

The cellular changes caused by chronic ethanol exposure may not resolve for several weeks or longer following cessation of drinking. The resulting withdrawal syndrome is most intense during the first 5 days, but some symptoms (e.g., disturbed sleep and anxiety) can take up to 4–6 months to resolve.

THE EFFECTS OF ETHANOL ON ORGAN SYSTEMS

Although one to two drinks per day in an otherwise healthy and nonpregnant individual can have some beneficial cardiovascular effects, at higher doses alcohol is toxic to most organ systems. Knowledge about the deleterious effects of alcohol helps the physician to identify alcoholic patients and provides information that can be used to help motivate patients to abstain. The information offered here generally applies to all, regardless of age or gender, although some differences apply. It is important to remember that the typical white- or blue-collar alcoholic often functions at a fairly high level for years, holding a job and maintaining ties with friends and relatives who may be unaware of the severity of the drinking problem. Not everyone develops each of the problems described below.

NERVOUS SYSTEM

Approximately 35% of drinkers (and a much higher proportion of alcoholics) experience a *blackout*, an episode of temporary anterograde amnesia, in which the person forgets all or part of what occurred during a drinking evening. Another common problem, one seen after as few as several drinks, is disturbed sleep. Although alcohol might initially help a person to fall asleep, it disrupts sleep throughout the rest of the night. The stages of sleep are also altered, and time spent in rapid eye movement (REM) and deep sleep is reduced. Patients may experience prominent and sometimes disturbing dreams. Alcohol relaxes muscles in the pharynx, which can cause snoring and exacerbate sleep apnea; symptoms of the latter occur in 75% of alcoholic men over age 60. Another common consequence of alcohol use is impaired judgment and coordination, increasing the risk of accidents and injury; 40% of drinkers in the United States have at some time driven while intoxicated. Heavy drinking can also be associated with headache, thirst, nausea, vomiting, and fatigue the following day, a hangover syndrome that is responsible for significant financial losses in most work environments.

The effect of alcohol on the nervous system is even more pronounced among alcohol-dependent individuals. Chronic high doses cause *peripheral neuropathy* in 5–15% of alcoholics: similar to diabetes, patients experience bilateral limb numbness, tingling, and paresthesias, all of which are more pronounced distally. Approximately 1% of alcoholics develop cerebellar degeneration or atrophy. This is a syndrome of progressive unsteady stance and gait often accompanied by mild nystagmus; neuroimaging studies reveal atrophy of the cerebellar vermis. Fortunately, very few alcoholics (perhaps as few as 1 in 500) develop *Wernicke's* (ophthalmoparesis, ataxia, and encephalopathy) and *Korsakoff's* (retrograde and anterograde amnesia) *syndromes.* These occur as the result of thiamine deficiency, especially in predisposed individuals, e.g., those with transketolase deficiency. Alcoholics can manifest *cognitive problems* lasting for weeks to months after an alcoholic binge. Brain atrophy, evident as ventricular enlargement and widened cortical sulci on MRI and CT scans, occurs in ~50% of chronic alcoholics; these changes are often reversible if abstinence is maintained. There is no single alcoholic dementia syndrome; rather, this label is used to describe patients who have apparently irreversible cognitive changes (possibly from diverse causes) in the context of chronic alcoholism.

As many as two-thirds of alcohol-dependent individuals meet the criteria for a psychiatric syndrome in the *Fourth Diagnostic and Statistical Manual* (DSM-IV) of the American Psychiatric Association (Chap. 386). Half of these relate to a preexisting antisocial personality manifesting as impulsivity and disinhibition. The lifetime risk is 3% in males, and ≥80% of such individuals demonstrate alcohol and/or drug dependence. Another common co-morbidity occurs with dependence on illicit substances. The remaining third of alcoholics with psychiatric syndromes have preexisting conditions such as schizophrenia or manic depressive disease and anxiety disorders such as panic disorder. The reasons for the co-morbidities of alcoholism with independent psychiatric disorders are not known, but they might represent an overlap in genetic vulnerabilities, impaired judgment resulting from the independent psychiatric condition, or an attempt to use alcohol to alleviate some of the symptoms of the disorder or side effects of medications.

Many psychiatric syndromes can be seen temporarily during heavy drinking and subsequent withdrawal. These include an intense *sadness* lasting for days to weeks in the midst of heavy drinking seen in 40% of alcoholics (alcohol-induced mood disorder); temporary severe *anxiety* in 10–30% of alcoholics, often beginning during alcohol withdrawal, and which can persist for a month or more after cessation of drinking (alcohol-induced anxiety disorder); and auditory *hallucinations* and/or paranoid delusions in a person who is alert and oriented, seen in 3–5% of alcoholics (*alcohol-induced psychotic disorder*).

Treatment of all forms of alcohol-induced psychopathology includes helping patients achieve abstinence and offering supportive care, as well as reassurance and "talk therapy" such as cognitive-behavioral approaches. However, with the exception of short-term antipsychotics for substance-induced psychosis, substance-induced psychiatric conditions only rarely require medications. Recovery is likely within several days to 4 weeks of abstinence. A history of alcohol intake is an important consideration in any patient with one of these psychiatric symptoms.

The distinction between long term, independent psychiatric conditions and temporary alcohol-induced syndromes is important because their prognoses and optimal treatments are quite different. Independent syndromes can be recognized because they often began before the alcohol dependence and/or remain after a period of a month or more of abstinence.

THE GASTROINTESTINAL SYSTEM

Esophagus and Stomach Alcohol intake can result in inflammation of the esophagus and stomach causing epigastric distress and gastrointestinal bleeding. Alcohol is one of the most common causes of hemorrhagic gastritis. Violent vomiting can produce severe bleeding through a Mallory-Weiss lesion, a longitudinal tear in the mucosa at the gastroesophageal junction.

Pancreas and Liver The incidence of acute pancreatitis (~25 per 1000 per year) is almost threefold higher in alcoholics than in the general population, accounting for an estimated 10% or more of the total cases. Alcohol impairs gluconeogenesis in the liver, resulting in a fall in the amount of glucose produced from glycogen, increased lactate pro-

duction, and decreased oxidation of fatty acids. This contributes to an increase in fat accumulation in liver cells. In healthy individuals these changes are reversible, but with repeated exposure to ethanol, more severe changes in the liver occur, including alcohol-induced hepatitis, perivenular sclerosis, and cirrhosis, with the latter observed in an estimated 15% of alcoholics (Chap. 301).

CANCER

Drinking as few as 1.5 drinks per day increases a woman's risk of breast cancer 1.4-fold. For both genders, four drinks per day increases the risk for oral and esophageal cancers approximately threefold and rectal cancers by a factor of 1.5; seven to eight or more drinks per day enhances approximately fivefold the risks for many cancers.

HEMATOPOIETIC SYSTEM

Ethanol causes an increase in red blood cell size [mean corpuscular volume, (MCV)], which reflects its effects on stem cells. If heavy drinking is accompanied by folic acid deficiency, there can also be hypersegmented neutrophils, reticulocytopenia, and a hyperplastic bone marrow; if malnutrition is present, sideroblastic changes can be observed. Chronic heavy drinking can decrease production of white blood cells, decrease granulocyte mobility and adherence, and impair delayed-hypersensitivity responses to novel antigens (with a possible false-negative tuberculin skin test). Finally, many alcoholics have mild thrombocytopenia, which usually resolves within a week of abstinence unless there is hepatic cirrhosis or congestive splenomegaly.

CARDIOVASCULAR SYSTEM

Acutely, ethanol decreases myocardial contractility and causes peripheral vasodilation, with a resulting mild decrease in blood pressure and a compensatory increase in cardiac output. Exercise-induced increases in cardiac oxygen consumption are higher after alcohol intake. These acute effects have little clinical significance for the average healthy drinker but can be problematic in men and women with persisting cardiac disease.

The consumption of three or more drinks per day results in a dose-dependent increase in blood pressure, which returns to normal within weeks of abstinence. Thus, heavy drinking is an important factor in mild to moderate hypertension. Chronic heavy drinkers have a sixfold increased risk for coronary artery disease as well as an increased risk for cardiomyopathy. Symptoms range from unexplained arrhythmias in the presence of left ventricular impairment to heart failure with dilation of all four heart chambers and hypocontractility of heart muscle. Perhaps one-third of cases of cardiomyopathy are alcohol-induced. Mural thrombi can form in the left atrium or ventricle, while heart enlargement >25% can cause mitral regurgitation. Atrial or ventricular arrhythmias, especially paroxysmal tachycardia, can also occur after a drinking binge in individuals showing no other evidence of heart disease—a syndrome known as the "holiday heart." This condition is observed transiently in the majority of alcoholics entering treatment.

Chronic intake of modest doses of alcohol can have some beneficial effects. A maximum of one to two drinks per day may decrease the risk for cardiovascular death, perhaps through an increase in high-density lipoprotein (HDL) cholesterol or changes in clotting mechanisms. In one large national study, cardiovascular mortality was reduced by 30–40% among individuals reporting one or more drinks daily compared to nondrinkers, with overall mortality lowest among those consuming approximately one drink per day. Recent data have also corroborated that regular light drinking decreases the risk for ischemic, but not hemorrhagic, stroke.

GENITOURINARY SYSTEM CHANGES, SEXUAL FUNCTIONING, AND FETAL DEVELOPMENT

Acutely, modest ethanol doses (e.g., blood alcohol concentrations of 0.06 gm/dL) can increase sexual drive but also decrease erectile capacity in men. Even in the absence of liver impairment, a significant minority of chronic alcoholic men show irreversible testicular atrophy with shrinkage of the seminiferous tubules, decreases in ejaculate volume, and a lower sperm count (Chap. 340).

The repeated ingestion of high doses of ethanol by women can result in amenorrhea, a decrease in ovarian size, absence of corpora lutea with associated infertility, and an increased risk of spontaneous abortion. Heavy drinking during pregnancy results in the rapid placental transfer of both ethanol and acetaldehyde, which may have serious consequences for fetal development. The *fetal alcohol syndrome* can include any of the following: facial changes with epicanthal eye folds; poorly formed ear concha; small teeth with faulty enamel; cardiac atrial or ventricular septal defects; an aberrant palmar crease and limitation in joint movement; and microcephaly with mental retardation. The amount of ethanol required and the time of vulnerability during pregnancy have not been defined, making it advisable for pregnant women to abstain completely.

OTHER EFFECTS OF ETHANOL

Between one-half and two-thirds of alcoholics have skeletal muscle weakness caused by acute *alcoholic myopathy*, a condition that improves but which might not fully remit with abstinence. Effects of repeated heavy drinking on the *skeletal system* include changes in calcium metabolism, lower bone density, and decreased growth in the epiphyses, leading to an increased risk for fractures and osteonecrosis of the femoral head. *Hormonal changes* include an increase in cortisol levels, which can remain elevated during heavy drinking; inhibition of vasopressin secretion at rising blood alcohol concentrations and enhanced secretion at falling blood alcohol concentrations (with the final result that most alcoholics are likely to be slightly overhydrated); a modest and reversible decrease in serum thyroxine (T_4); and a more marked decrease in serum triiodothyronine (T_3). Hormone irregularities should be reevaluated after a month of abstinence.

ALCOHOLISM (ALCOHOL ABUSE OR DEPENDENCE)

Because many drinkers occasionally imbibe to excess, temporary alcohol-related pathology is common in nonalcoholics, especially those in the late teens to the late twenties. When repeated problems in multiple life areas develop, the individual is likely to meet criteria for alcohol abuse or dependence.

DEFINITIONS AND EPIDEMIOLOGY

Alcohol dependence is defined in DSM-IV as repeated alcohol-related difficulties in at least three of seven areas of functioning that cluster together over a 12-month period. Two of these seven items, tolerance and withdrawal, may have special importance as they are associated with a more severe clinical course. Alcohol dependence is seen in all countries where alcohol is available and occurs in men and women from all socioeconomic strata and all racial backgrounds. The diagnosis of alcohol dependence predicts a course of recurrent problems with the use of alcohol and the consequent shortening of the life span by a decade on average.

Alcohol abuse is defined as repetitive problems with alcohol in any one of four life areas—social, interpersonal, legal, and occupational—or repeated use in hazardous situations such as driving while intoxicated. If an individual is not alcohol dependent, he or she still may be given a diagnosis of alcohol abuse.

The lifetime risk for alcohol dependence in most western countries is about 10–15% for men and 5–8% for women. Rates are generally similar in the United States, Canada, Germany, Australia, and England; rates tend to be lower in most Mediterranean countries, such as Italy, Greece, and Israel, and may be higher in Ireland, France, and Scandinavia. Even higher rates have been reported for several native cultures including American Indians, Eskimos, Maori groups, and aboriginal tribes of Australia. These differences reflect both cultural and genetic influences, as described below. When alcohol abuse is also considered, the rates of alcohol use disorders increase. In western countries, the typical alcoholic does not fulfill the common stereotype of a "skid-row" denizen but is more often a blue- or white-collar worker or homemaker. The lifetime risk for alcoholism among physicians is similar to that of the general population.

GENETICS OF ALCOHOLISM

Several separate and distinct characteristics appear to contribute to the risk. For example, some families carry a risk for both alcoholism and drug dependence associated with the characteristic of high levels of impulsivity, as can be seen in the antisocial personality disorder. In other families, the risk for both alcohol and drug dependence may relate to a genetic vulnerability to schizophrenia, panic disorder, or manic depressive disease. A third and different mechanism increases only the alcoholism risk (e.g., in some offspring of alcoholics and Native Americans) through a low response to alcohol and subsequent drinking higher doses to achieve the desired effects. The relatively low response to alcohol contributes to attitudes and drinking patterns that increase the risk for alcohol-related problems and alcoholism. By contrast, a decreased risk for heavy drinking can result from a more intense response to alcohol, as seen in approximately half of Asian men and women. This is due primarily to a mutation that causes the production of an inactive form of the enzyme ALDH, which results in higher levels of acetaldehyde following alcohol ingestion.

NATURAL HISTORY

Although the age of the first drink is similar in alcoholics and nonalcoholics, earlier onset of regular drinking and drunkenness is associated with a higher risk for later problems. By the early to mid-twenties, most nonalcoholic men and women moderate their drinking (perhaps learning from minor problems), whereas alcoholics are likely to escalate their patterns of drinking despite difficulties. The first major life problem from alcohol often appears in the early to mid-twenties. Once established, the course of alcoholism is likely to be one of exacerbations and remissions. As a rule, there is little difficulty in stopping alcohol use when problems develop, and this step is often followed by days to months of abstinence and then a period of carefully controlled drinking. Unless abstinence is maintained, however, these phases almost inevitably give way to escalations in alcohol intake and subsequent problems. The course is not hopeless; following treatment, between half and two-thirds of alcoholics maintain abstinence for years, and often permanently. Even without formal treatment or self-help groups there is at least a 20% chance of spontaneous remission with long-term abstinence. However, should the alcoholic continue to drink, the life span is shortened by 10–15 years on average, with the leading causes of death, in decreasing order, the result of heart disease, cancer, accidents, and suicide.

IDENTIFICATION OF THE ALCOHOLIC AND INTERVENTION

Even in affluent areas ~20% of patients have an alcohol use disorder. It is important to pay attention to the alcohol-related symptoms and signs as well as laboratory tests that are likely to be abnormal in the context of regular consumption of six to eight or more drinks per day. The two blood tests with ≥70% sensitivity and specificity for heavy alcohol consumption are γ-glutamyl transferase (GGT) (>35 U) and carbohydrate-deficient transferrin (CDT) (>20 U/L); the combination of the two is likely to be more accurate than either alone. Physicians should consider using these tests to screen all patients as indicators of possible alcoholism. These serologic markers of heavy drinking can also be useful in monitoring abstinence, as they are likely to return toward normal within several weeks of the cessation of drinking; thus, increases in values of as little as 10% are likely to indicate a resumption of heavy alcohol intake. Other blood tests that can be useful in identifying individuals consuming six or more standard drinks per day include high-normal MCVs (≥91 μm^3) and serum uric acid (>416 mol/L, or 7 mg/dL). Physical signs and symptoms that can be useful in identifying alcoholism include mild and fluctuating hypertension, repeated infections such as pneumonia, and otherwise unexplained cardiac arrhythmias. Other disorders suggestive of dependence include cancer of the head and neck, esophagus, or stomach as well as cirrhosis, unexplained hepatitis, pancreatitis, bilateral parotid gland swelling, and peripheral neuropathy.

The clinical diagnosis of alcohol abuse or dependence ultimately rests on the documentation of a pattern of repeated difficulties associated with alcohol use; the definition is not based on the quantity and frequency of alcohol consumption. Thus, in screening it is important to probe for life problems and then attempt to tie in use of alcohol or another substance. Information regarding marital or job problems, legal difficulties, histories of accidents, medical problems, evidence of tolerance, etc., are important. While all physicians should be able to take the time needed to gather such information, some standardized questionnaires can be helpful, including the 10-item Alcohol Use Disorder Screening Test (AUDIT) (Table 387-2). However, these are only screening tools, and a careful face-to-face interview is still required for a meaningful diagnosis.

TABLE 387-2 THE ALCOHOL USE DISORDERS IDENTIFICATION TEST (AUDIT)[a]

Item	5-Point Scale (Least to Most)
1. How often do you have a drink containing alcohol?	Never (0) to 4+ per week (4)
2. How many drinks containing alcohol do you have on a typical day?	1 or 2 (0) to 10+ (4)
3. How often do you have six or more drinks on one occasion?	Never (0) to daily or almost daily (4)
4. How often during the last year have you found that you were not able to stop drinking once you had started?	Never (0) to daily or almost daily (4)
5. How often during the last year have you failed to do what was normally expected from you because of drinking?	Never (0) to daily or almost daily (4)
6. How often during the last year have you needed a first drink in the morning to get yourself going after a heavy drinking session?	Never (0) to daily or almost daily (4)
7. How often during the last year have you had a feeling of guilt or remorse after drinking?	Never (0) to daily or almost daily (4)
8. How often during the last year have you been unable to remember what happened the night before because you had been drinking?	Never (0) to daily or almost daily (4)
9. Have you or someone else been injured as a result of your drinking?	No (0) to yes, during the last year (4)
10. Has a relative, friend, doctor or other health worker been concerned about your drinking or suggested that you should cut down?	No (0) to yes, during the last year (4)

[a]The AUDIT is scored by simply summing the values associated with the endorsed response.

Source: Adapted from DF Reinert, GP Allen: *Alcoholism: Clinical & Experimental Research* 26:272, 2002, and from MA Schuckit, 2006.

After alcoholism is identified, the diagnosis must be shared with the patient as part of an intervention. The presenting complaint can be used as an entrée to the alcohol problem. For instance, the patient with insomnia or hypertension can be told that these are clinically important problems which, in conjunction with other physical findings and laboratory tests, indicate that alcohol is increasing the risk for further medical and psychological problems. The physician should share information about the course of alcoholism and explore possible avenues of addressing the problem. This process can be carried out by any physician or other health care provider. Several protocols, categorized as *brief interventions* and *motivational interviewing,* are available for health care workers to follow. The technique of brief interventions has been shown to be effective in decreasing alcohol use and problems when instituted as two 15-min sessions 1 month apart, along with a telephone follow-up reminder. Motivational interviewing uses the clinician's level of concern and understanding of the need for patients to progress through their own stages of enhanced understanding of their problems to optimize their ability to alter their drinking behaviors.

The process of intervention is rarely accomplished in one session. Multiple sessions to explain the problem, the optimal treatments, and the benefits of making certain lifestyle changes are often required. For the person who refuses to stop drinking at the first intervention, a logical step is to "keep the door open," establishing future meetings so that help is available as problems escalate. In the meantime the family may benefit from counseling or referral to self-help groups such as Al-

Anon (the Alcoholics Anonymous group for family members) and Alateen (for teenage children of alcoholics).

THE ALCOHOL WITHDRAWAL SYNDROME

Once the brain has been repeatedly exposed to high doses of alcohol, any sudden decrease in intake can produce withdrawal symptoms, many of which are the opposite of those produced by intoxication. Features include tremor of the hands (shakes or jitters); agitation and anxiety; autonomic nervous system overactivity including an increase in pulse, respiratory rate, and body temperature; and insomnia, sometimes accompanied by frightening dreams. Because alcohol has a short half-life, these withdrawal symptoms generally begin within 5–10 h of decreasing ethanol intake, peak in intensity on day 2 or 3, and improve by day 4 or 5. Anxiety, insomnia, and mild levels of autonomic dysfunction may persist to some degree for 4–6 months as a protracted abstinence syndrome, which may contribute to the tendency to return to drinking.

At some point in their lives, between 2 and 5% of alcoholics experience withdrawal seizures, often within 48 h of stopping drinking. These rare events usually involve a single generalized seizure, and electroencephalographic abnormalities generally return to normal within several days.

The term *delirium tremens* (DTs) refers to an uncommon state of intense acute withdrawal that includes delirium (mental confusion, agitation, and fluctuating levels of consciousness) associated with a tremor and autonomic overactivity (e.g., marked increases in pulse, blood pressure, and respirations). Fortunately, this serious and potentially life-threatening complication of alcohol withdrawal is seen in <5% of alcohol-dependent individuals; the chance of DTs during any single withdrawal is <1%. DTs are most likely to develop in patients with concomitant severe medical disorders and can usually be avoided by identifying and treating the underlying medical conditions.

℞ ALCOHOL-RELATED CONDITIONS

ACUTE INTOXICATION The first priority is to assess vital signs and manage respiratory depression, cardiac arrhythmia, or blood pressure instability, if present. The possibility of intoxication with other drugs should be considered, and blood and urine samples are obtained to screen for opioids or other CNS depressants such as benzodiazepines or barbiturates. Other medical conditions that must be considered include hypoglycemia, hepatic failure, or diabetic ketoacidosis.

Patients who are medically stable should be placed in a quiet environment. If recumbent, patients should lie on their side to minimize the risk of aspiration. When the intoxicated person is aggressive or violent, hospital procedures should be followed, including planning for the possibility of a show of force with an intervention team. In the context of aggressiveness, patients should be reminded in a clear and nonthreatening way that the staff wants to help them to feel better and to avoid problems. If the aggressive behavior continues, relatively low doses of a short-acting benzodiazepine such as lorazepam (e.g., 1–2 mg PO or IV) may be used and can be repeated as needed, but care must be taken so that the addition of this second CNS depressant does not destabilize vital signs or worsen confusion. An alternative approach is to use an antipsychotic medication (e.g., 0.5–5 mg of haloperidol PO or IM every 48 h if needed), but this has the potential danger of lowering the seizure threshold. Two other medications useful for agitation are ziprasidone (10 mg IM every 2h as needed, up to 40 mg) and olanzapine (2.5–10 mg IM repeated at 2 h and 6 h, if needed). If aggression escalates, the patient might require a short-term admission to a locked ward, where medications can be used more safely and vital signs more closely monitored.

WITHDRAWAL The first step is to perform a thorough physical examination in all alcoholics who are considering stopping drinking, including a search for evidence of liver failure, gastrointestinal bleeding, cardiac arrhythmia, infection, and glucose or electrolyte imbalance.

The second step is to offer reassurance that the acute withdrawal is short lived and to offer adequate nutrition and rest. All patients should be given oral multiple B vitamins, including 50–100 mg of thiamine daily for a week or more. Because most alcoholics who enter withdrawal are either normally hydrated or mildly overhydrated, IV fluids should be avoided unless there is evidence of significant recent bleeding, vomiting, or diarrhea. Medications can usually be administered orally.

The third step in treatment is to recognize that most withdrawal symptoms are caused by the rapid removal of a CNS depressant, in this case, alcohol. The symptoms can be controlled by administering any drug of this class in doses that decrease the agitation, and gradually taper the dose over 3–5 days. While most CNS depressants are effective, benzodiazepines (Chap. 386) have the highest margin of safety and lowest cost and are, therefore, the preferred class of drugs. Benzodiazepines with short half-lives are especially useful for patients with serious liver impairment or evidence of preexisting encephalopathy or brain damage. However, short-acting benzodiazepines such as lorazepam can produce rapidly changing drug blood levels and must be given every 4 h to avoid abrupt fluctuations that may increase the risk for seizures. Therefore, most clinicians use drugs with longer half-lives, such as diazepam or chlordiazepoxide, administering enough drug on day 1 to alleviate most of the symptoms of withdrawal (e.g., the tremor and elevated pulse) and then gradually decreasing the dose over a period of 3–5 days. The approach is flexible; the dose is increased if signs of withdrawal escalate, and the medication is withheld if the patient is sleeping or shows signs of increasing orthostatic hypotension. The average patient requires 25–50 mg of chlordiazepoxide or 10 mg of diazepam given PO every 4–6 h on the first day.

Treatment of the patient with DTs can be challenging, and the condition is likely to run a course of 3–5 days regardless of the therapy employed. The focus of care is to identify and correct medical problems and to control behavior and prevent injuries. Many clinicians recommend the use of high doses of a benzodiazepine (as much as 800 mg/d of chlordiazepoxide has been reported), a treatment that will decrease agitation and raise the seizure threshold but probably does little to improve the confusion. Other clinicians recommend the use of antipsychotic medications, such as haloperidol, ziprasidone, or olanzapine as discussed above, although these drugs have not been directly evaluated for DTs. Antipsychotics are less likely to exacerbate confusion but may increase the risk of seizures; they have no place in the treatment of mild withdrawal symptoms.

Generalized withdrawal seizures rarely require aggressive pharmacologic intervention beyond that given to the usual patient undergoing withdrawal, i.e., adequate doses of benzodiazepines. There is little evidence that anticonvulsants such as phenytoin or gabapentin are effective in drug-withdrawal seizures, and the risk of seizures has usually passed by the time effective drug levels are reached. The rare patient with status epilepticus must be treated aggressively (Chap. 363).

While alcohol withdrawal is often treated in a hospital, efforts at reducing costs have resulted in the development of outpatient detoxification for relatively mild abstinence syndromes. This is appropriate for patients in good physical condition who demonstrate mild signs of withdrawal despite low blood alcohol concentrations and for those without prior history of DTs or withdrawal seizures. Such individuals still require a careful physical examination, appropriate blood tests, and vitamin supplementation. Benzodiazepines can be given in a 1- to 2-day supply to be administered to the patient by a spouse or other family member four times a day. Patients are asked to return daily for evaluation of vital signs and to come to the emergency room if signs and symptoms of withdrawal escalate.

REHABILITATION OF ALCOHOLICS After completing alcoholic rehabilitation, ≥60% of alcoholics, especially middle class patients, maintain abstinence for at least a year, and many achieve lifetime sobriety.

The core of treatment begins with helping patients recognize the need to change, while working with them to alter their behaviors to enhance compliance. Therapeutic maneuvers fall into several general categories, which are applied to all patients regardless of age or ethnic group. The manner in which the treatments are used should be sensitive to the practices and needs of specific populations. The first step is to help the alcoholic achieve and maintain a high level of motivation toward abstinence. This includes education about alcoholism and instructions to family and/or friends to stop protecting the patient from problems caused by alcohol. The second step is to help the patient readjust to life without alcohol and to reestablish a functional lifestyle through counseling, vocational rehabilitation, and self-help groups such as Alcoholics Anonymous (AA). The third component, called *relapse prevention*, helps the patient to identify situations in which a return to drinking is likely, formulate ways of managing these risks, and develop coping strategies that increase the chances of a return to abstinence if a slip occurs.

For many patients, especially those who are highly motivated and have supportive social systems, treatment can be on an outpatient basis. However, more intense interventions work better than less intensive measures, and some alcoholics do not respond to outpatient approaches. The decision to hospitalize or utilize residential care can be made if (1) the patient has medical problems that are difficult to treat outside a hospital; (2) depression, confusion, or psychosis interferes with outpatient care; (3) there is a severe life crisis that makes it difficult to work in an outpatient setting; (4) outpatient treatment has failed; or (5) the patient lives too far from the treatment center to participate in an outpatient program. The best predictors of continued abstinence include evidence of higher levels of life stability (e.g., supportive family and friends) and higher levels of functioning (e.g., job skills, higher levels of education, and absence of crimes unrelated to alcohol).

Whether the treatment begins in an inpatient or an outpatient setting, subsequent outpatient contact should be maintained for a minimum of 6 months and preferably a full year after abstinence is achieved. Counseling with an individual physician or through groups focuses on day-to-day living, emphasizing areas of improved functioning in the absence of alcohol (i.e., why it is a good idea to continue to abstain) and helping the patient to manage free time without alcohol, develop a nondrinking peer group, and handle stresses on the job.

The physician serves an important role in identifying the alcoholic, diagnosing and treating associated medical or psychiatric syndromes, overseeing detoxification, referring the patient to rehabilitation programs, and providing counseling. Physicians are also responsible for selecting which (if any) medication might be appropriate during alcoholism rehabilitation. Patients often complain of continuing sleep problems or anxiety when acute withdrawal treatment is over, problems that may be a component of protracted withdrawal. In general, hypnotics or antianxiety drugs should be avoided in this situation. Patients should be reassured that the trouble sleeping is normal after alcohol withdrawal and will improve over the subsequent weeks and months. Patients should follow a rigid bedtime and awakening schedule and avoid naps or the use of caffeine in the evenings. The sleep pattern will improve with time, and the patient can avoid the rebound insomnia associated with most hypnotics and the risk for developing dependence on another depressant. Anxiety can be addressed by helping the person to gain insight into the temporary nature of the symptoms and to develop strategies to achieve relaxation as well as by using forms of cognitive therapy.

While the mainstay of alcoholic rehabilitation involves counseling, education, and cognitive approaches, several medications might be useful. The optimal length of time to continue these drugs in the context of a positive response is unclear, but most clinicians would recommend 6–12 months. The first is the opioid-antagonist drug naltrexone, 50–150 mg/d, which has been reported to decrease the probability of a return to drinking and to shorten periods of relapse. Recently a once-per-month injection of this drug (380 mg) has been developed to help improve compliance. By blocking opioid receptors, naltrexone may decrease activity in the dopamine-rich ventral tegmental reward system, or decrease the feeling of pleasure or reward if alcohol is imbibed. The improved rate of functioning and abstinence with this drug is modest. The side effects are relatively few at the recommended doses and include gastrointestinal distress. A second medication, acamprosate (Campral), 2 g/d, has been widely tested in patients in the United States and Europe; results are generally similar to those reported for naltrexone. This drug inhibits the actions of NMDA receptors and has been hypothesized to act by decreasing mild symptoms of protracted withdrawal. There are few side effects, aside from mild gastrointestinal distress. Several long-term trials of combined naltrexone and acamprosate using doses similar to those noted above have reported that the combination may be superior to either drug alone, although not all studies agree.

Disulfiram, an ALDH inhibitor, has been used extensively in the past for treatment of alcoholism. In doses of 250 mg/d this drug produces an unpleasant (and potentially dangerous) reaction in the presence of alcohol, a phenomenon related to rapidly rising blood levels of the first metabolite of alcohol, acetaldehyde. Few adequate controlled trials have demonstrated a clear superiority of disulfiram over placebo. Drinking alcohol while taking disulfiram produces a reaction involving an increased pulse, changes in blood pressure, and vomiting and diarrhea. This can be dangerous, especially for patients with heart disease, stroke, diabetes mellitus, or hypertension. The drug itself has also been reported to carry potential risks of depression, psychotic symptoms, peripheral neuropathy, and liver damage. Thus, most clinicians reserve this medication for patients who have a clear history of longer-term abstinence associated with prior use of disulfiram, and for those who might take the drug under the supervision of another individual (such as a spouse), especially during discrete periods identified as representing high-risk drinking situations for them (such as the Christmas holiday). Other drugs under investigation for possible use in alcoholism rehabilitation include the serotonin antagonist ondansetron; topiramate, an anticonvulsant with possible effects on dopamine; and the cannabinol receptor antagonist ramonibant; at present, there are insufficient data to support their use in clinical settings.

Additional support for alcoholics and their relatives and friends is available through self-help programs such as AA. These groups, which typically consist of recovering alcoholics, offer an effective model of abstinence, provide a sober peer group, and make crisis intervention freely available when the urge to drink escalates. This can help patients optimize their chances for recovery, especially when incorporated into a more structured treatment milieu.

388 Opioid Drug Abuse and Dependence

Marc A. Schuckit

It is difficult to imagine modern medical practice without the use of opioid analgesics. These drugs have been part of health care since 300 B.C. Opium and codeine were isolated in the early nineteenth century, opioid-like substances produced by the body were recognized in the 1970s, and the first endogenous opioid was isolated in 1995. As important as these substances are to modern medicine, opioid drugs have many disadvantages, including overdosage and dependency; close to 1 million individuals in the United States are opioid-dependent. All opioid drugs are capable of producing a heroin-like intoxication, as well as tolerance and withdrawal.

PHARMACOLOGY

The prototypic opiates, morphine and codeine (3-methoxymorphine), are derived from the juice of the poppy *Papaver somniferum*. The semisynthetic drugs produced from morphine or thebane molecules include hydromorphone, diacetylmorphine (heroin), and oxycodone. The purely synthetic opioids and their cousins include meperidine, propoxyphene, diphenoxylate, fentanyl, buprenorphine, tramadol, methadone, and pentazocine.

The body's own endogenous opioid peptides (e.g., enkephalins, endorphins, dynorphins, and others) have distinct distributions in the central nervous system (CNS) and appear to be natural ligands for

TABLE 388-1 ACTIONS OF OPIOID RECEPTORS

Receptor Type	Actions
Mu (μ) (e.g., morphine)	Analgesia, reinforcement euphoria, cough and appetite suppression, decreased respirations, decreased GI motility, sedation, hormone changes, dopamine and acetylcholine release
Kappa (κ) (e.g., butorphanol)	Decreased dysphoria, decreased GI motility, decreased appetite, decreased respiration, psychotic symptoms, sedation, diuresis, analgesia
Delta (δ) (e.g., etorphine)	Hormone changes, appetite suppression, dopamine release

Note: GI, gastrointestinal.

opioid receptors. As summarized in Table 388-1, the receptors with which opioid peptides interact differentially produce analgesia, respiratory depression, constipation, euphoria, and other actions. Substances capable of antagonizing one or more of these actions include nalorphine, levallorphan, cyclazocine, butorphanol, buprenorphine, and pentazocine, each of which has mixed agonist and antagonist properties, as well as naloxone, nalmefene, and naltrexone, which are pure opiate antagonists.

The availability of relatively specific antagonists has helped identify at least three receptor subtypes. These include μ receptors, which influence some of the more classic opioid actions such as pain control, reinforcement, constipation, hormone levels, and respiration; κ receptors, with possible similar functions along with sedation and effects on hormones; and δ receptors, thought to relate mostly to analgesia, mood, reinforcement, and breathing. A fourth possible receptor subtype, sensitive to another endogenous peptide, is sometimes called *nociceptin* or *orphanin* and may influence pain. The major features of tolerance, dependence, and withdrawal are thought to be mediated primarily by μ receptors, and these are affected by all prescription opioids.

The most rapid and pronounced effects of opioids occur through IV administration, with only slightly less efficient absorption after smoking or inhaling the vapor ("chasing the dragon"). The slowest onset and least intense effects occur after oral consumption. Most of the metabolism of opioids occurs in the liver, primarily through conjugation with glucuronic acid, and only small amounts are excreted directly in the urine or feces. The plasma half-lives of these drugs range from 2.5–3 h for morphine to >22 h for methadone.

Street heroin is typically only 5–10% pure and is usually mixed with sugars, quinine, powdered milk, phenacetin, caffeine, antipyrine, and strychnine. Unexpected increases in the purity of street drugs can cause unintentional lethal overdoses.

ACUTE AND CHRONIC EFFECTS OF OPIOIDS

With the exception of overdose and physical dependence, most opioid effects are rapidly reversible. A major danger, however, comes through the use of contaminated needles by IV users, which increases the risk of hepatitis B and C, bacterial endocarditis, and infection with HIV (Chap. 182).

Effects on Organ Systems Euphoria and rewarding effects of opioids are due, at least in part, to stimulation of dopaminergic pathways originating in the midbrain and terminating in the nucleus accumbens. Effects on other neurotransmitter systems also occur. CNS effects of opioid drugs include nausea and vomiting (medulla), decreased pain perception (spinal cord, thalamus, and periaqueductal gray region), and sedation (reticular activating system). The adulterants added to street drugs may contribute to nervous system damage, including peripheral neuropathy, amblyopia, myelopathy, and leukoencephalopathy. Acute opioid administration inhibits release of some hormones from the hypothalamus, including corticotropin-releasing factor (CRF) and luteinizing hormone, with a subsequent reduction in some sex hormones, actions that might contribute to a decreased sex drive and problems in handling stress. Other hormonal changes include a decrease in the release of thyrotropin and increases in prolactin and possibly growth hormone (Chap. 333).

Acute changes in the respiratory system include a CNS-mediated decrease in the cough reflex (which can be useful as an antitussive) and respiratory depression, which result from a decreased response of the brainstem to carbon dioxide tension, a component of the drug overdose syndrome described below. At even low drug doses, this effect can be clinically significant for individuals with pulmonary disease. Aspiration pneumonia is an additional risk. The gastrointestinal effects of opioids can include decreased gut motility (useful in treating diarrhea), nausea, constipation, and anorexia with weight loss. Cardiovascular changes following modest doses tend to be relatively mild, with no direct opioid effect on heart rhythm or myocardial contractility, but orthostatic hypotension can occur, probably secondary to histamine release and dilation of peripheral vessels. Bacterial endocarditis with septic emboli and stroke can occur from contaminated needles.

Opioid Toxicity and Overdosage High doses of opioids can result in a potentially lethal overdose. This occurs at some point in over half of opioid-dependent persons, especially with the more potent drugs such as fentanyl (80–100 times more powerful than morphine). The typical syndrome, which occurs immediately with IV overdose, includes shallow and slow respirations, pupillary miosis (with mydriasis once brain anoxia develops), bradycardia, hypothermia, and stupor or coma (Chap. 268). If not treated rapidly, respiratory depression, cardiorespiratory arrest, and death can ensue. Postmortem examination reveals few specific changes except for diffuse cerebral edema. An "allergic-like" reaction to IV heroin, perhaps in part related to adulterants, can also occur and is characterized by decreased alertness, frothy pulmonary edema, and an elevation in the blood eosinophil count.

Rx OPIOID OVERDOSE

The first step in managing overdose is to support vital signs, using intubation if needed. Definitive treatment is the administration of a narcotic antagonist such as naloxone, 0.4–2 mg IV or IM. A response should occur in 1–2 min, but if needed, the dose can be repeated every 2–3 min up to 10 mg. With the exception of buprenorphene overdoses, a lack of response after 10 mg makes a toxic reaction due solely to opioids unlikely. It is important to titrate the dose relative to the patient's symptoms to ameliorate the respiratory depression but not provoke a severe withdrawal state; the latter cannot be aggressively treated until overdose-related vital signs are relatively stable. Because the effects of naloxone diminish within several hours, the individual must be monitored for at least 24 h after a heroin overdose and 72 h after an overdose of a longer-acting drug such as methadone. If there is little response to an opioid antagonist, the possibility of a concomitant overdose with a benzodiazepine should be considered and a challenge with IV flumazenil, 0.2 mg/min up to a maximum of 3 mg in an hour, might be used. This drug should be administered with caution as it can precipitate seizures and increase intracranial pressure.

Treatment of either the typical or the "allergic" type of opioid toxic reaction requires continued respiratory support (often with oxygen supplementation and positive-pressure breathing for the "allergic" type of overdose), IV fluids, and pressor agents when needed to support blood pressure. Activated charcoal (e.g., 1 g/kg suspended in water) should be considered if ingestion of large doses of oral opioids is suspected; alternatively, gastric lavage can be used to remove any remaining drug. Intubation is often required to prevent aspiration in the stuporous or comatose patient. Cardiac arrhythmias and/or seizures may also be part of the opioid toxic reaction, especially with codeine, propoxyphene, or meperidine.

OPIOID ABUSE AND DEPENDENCE

Definition and Epidemiology The *Fourth Diagnostic and Statistical Manual* (DSM-IV) of the American Psychiatric Association defines dependence as repeated use of a drug to the point of causing repetitive problems in multiple life areas. The definition requires evidence of three or more such problems clustered together within the same 12-month period of time, including tolerance, withdrawal, use of greater amounts of opiates than intended, and use despite consequences. Patients who do not have dependence but demonstrate repeated opioid-

related difficulties with the law, impaired ability to meet obligations, use in hazardous situations, or continued use despite problems can be labeled as having abuse.

The use of opioids for intoxication is less prevalent than the use of alcohol, marijuana, and stimulants such as cocaine or amphetamines. A national survey of adolescents and young adults published in 2005 reported that 13.5% of 12th graders (high school seniors) had tried an opioid outside of a doctor's prescription, including 1.5% who had used heroin. Figures for young adults and college students were almost 17.6% and 1.9%, respectively. In all studies, prevalence rates were only slightly higher in males than females. The prevalence of opioid dependence is estimated as a lifetime risk of about 1%.

Genetics Genetic factors appear to influence an individual's specific risk for opioid dependence as well as a more general vulnerability toward substance-related problems. The proportion of the total risk explained by genes is estimated at ~50%. Specific genes potentially include variations in the α_2 subunit of the γ-aminobutyric acid (GABA)-A receptor; this might affect the risk of abuse or dependence on a wide range of substances through effects on impulsivity and sensation-seeking. All genetic influences operate in the context of environmental factors as well.

Natural History While an opioid use disorder can develop in anyone, at least three groups are at increased risk for dependence or misuse. First, a minority of persons with chronic pain syndromes (e.g., back, joint, and muscle disorders) misuse their prescribed drugs. If physical dependence is established, any drop in opioid blood levels can intensify the pain and promote continued drug intake. Physicians can avoid contributing to physical dependence by helping the patient to accept the goal of moderation rather than disappearance of the pain, and to recognize that discomfort may not be completely eliminated (Chap. 12). Analgesic medication should be only one component of treatment and should be limited to the oral administration of the least potent analgesic that is able to "take the edge off" the pain (e.g., naproxen or ibuprofen). Behavior-modification techniques, such as muscle relaxation and meditation, and carefully selected exercises should be used as appropriate to help increase function and decrease pain. Finally, nonmedicinal approaches, including electrical transcutaneous neurostimulation for muscle and joint disease, may be useful.

The second group at high risk consists of physicians, nurses, and pharmacists, primarily because of easy access to opioids. Physicians may begin use to help with sleep or to reduce stress or physical aches and pains, and then escalate doses as tolerance develops. Because of the growing awareness of these problems, programs have been developed to identify and aid substance-impaired physicians, providing peer support and education before problems escalate to the point of licensure revocation. All physicians are advised never to prescribe opioids for themselves or family members

The third group are those who buy illicit drugs to get high. While some of these individuals have severe antisocial problems, many had a relatively high level of premorbid functioning. The typical person begins using opioids occasionally, often after experimenting with tobacco, then alcohol, then marijuana, and then brain depressants or stimulants. Occasional opioid use, or "chipping," might continue for some time, and some individuals never escalate their intake to the point of developing dependence. For others, the frequency of use and quantity needed increase, tolerance develops, excuses are made for associated problems, and a full dependence syndrome appears.

Opioid-dependent individuals are not likely to give up their intake of other drugs. Alcohol may be used to moderate withdrawal problems, to enhance the opioid high, and to serve as a substitute when the opioid is not available, including during methadone or other maintenance or antagonist treatments. Problematic drinking, including alcohol dependence, is seen in about half of opioid-dependent persons. Cocaine appears to be taken for many of the same reasons, and is often administered IV with the opioid in a mixture known as a "speedball." Another relevant class of drugs is the benzodiazepines, taken for a high or alleviation of withdrawal symptoms, especially among people in methadone maintenance.

Once persistent opioid use is established, severe problems are likely to develop. At least 25% of opioid-dependent individuals die within 10–20 years (a mortality rate 15-fold higher than the general population) from suicide, homicide, accidents, or infectious diseases such as tuberculosis, hepatitis, or AIDS. The latter has become an epidemic among injection drug users, with as many as 60% of these men and women in some locales carrying the HIV virus (Chap. 182). Although the majority of opioid-dependent persons experience frequent exacerbations and remissions, it is important to remember that even without treatment ~35% achieve long-term, often permanent, abstinence, especially after the age of 40. As is true with most drugs of abuse, a favorable prognosis is associated with a prior history of marital and employment stability and fewer prior criminal activities unrelated to drugs.

℞ OPIOID ABUSE AND DEPENDENCE

The first step in treatment is to identify the problem. It is important to discard the erroneous stereotype that opioid-dependent individuals are unemployed and homeless. Abuse or dependence is possible in any patient who demonstrates symptoms of what might be opioid withdrawal; anyone who has a chronic pain syndrome; physicians, nurses, and pharmacists or others with easy access to opioids; and patients who repeatedly seek out prescription analgesics. Before prescribing an opioid analgesic, it is important to gather a complete history that elucidates patterns of life problems and any history of opioid use. If a problem with opioids is suspected, gathering further data from a relative or close friend can be helpful. Additionally, clinicians should search for physical stigmata of misuse (e.g., needle marks) and, when appropriate, screen blood or urine for opioids.

After identifying opioid dependence, the next step is intervention as described for alcoholism in Chap. 387. Motivational interviewing techniques of empathy, careful listening, presenting options, and gauging the patient's motivational readiness to change are important, as are efforts to enlist the help of relatives and friends. Ongoing treatment even after the patient achieves abstinence is important; this includes offering help in establishing a drug-free lifestyle.

SYMPTOMS OF WITHDRAWAL Withdrawal symptoms (which are generally the opposite of the acute effects of the drug) include nausea, diarrhea, coughing, lacrimation, mydriasis, rhinorrhea, profuse sweating, twitching of muscles, and piloerection (or "goose bumps") as well as mild elevations in body temperature, respiratory rate, and blood pressure. In addition, diffuse body pain, insomnia, and yawning occur, along with intense drug craving. Withdrawal from opioids with shorter half-lives, such as morphine or heroin, usually causes symptoms within 8–16 h of the last dose; intensity peaks within 36–72 h after discontinuation of the drug; and the acute syndrome disappears within 5–8 days. A protracted abstinence phase of mild moodiness, autonomic dysfunction, and changes in pain threshold and sleep patterns may persist for ≥6 months and probably contributes to relapse. For longer-acting opioids such as methadone or continuous-release morphine, symptoms may not appear for several days, and may not peak until 7–10 days later.

TREATMENT OF THE WITHDRAWAL SYNDROME A thorough physical examination, including an assessment of neurologic function and a search for focal and systemic infections, especially abscesses, is essential. Laboratory testing includes assessment of liver function and, in IV users, HIV and hepatitis B and C status.

One treatment approach to withdrawal is to administer an opioid (e.g., 10–25 mg of methadone bid) on day 1 to decrease symptoms. After several days of a stabilized drug dose, the opioid is then decreased by 10–20% of the original day's dose each day. However, the use of opioids for detoxification is proscribed or limited in most states. Thus, pharmacologic treatments often center on relief of symptoms of diarrhea with loperamide, of "sniffles" with decongestants, and pain with nonopioid analgesics (e.g., ibuprofen). Comfort can be enhanced with administration of the α_2-adrenergic agonist clonidine in doses up to 0.3 mg given two to four times a day to decrease sympathetic nervous system overactivity. Blood pressure must be closely monitored. Some clinicians augment this regimen with low to moderate doses of benzodiazepines for 2–5 days to decrease agitation and

promote sleep. An ultra-rapid detoxification procedure using deep sedation and withdrawal precipitated by naltrexone has been proposed but has many inherent dangers and few, if any, advantages.

REHABILITATION The basic strategy, similar to that for alcoholics, includes detoxification and the establishment of realistic goals for abstinence and improvement of life functioning, along with counseling and education to increase motivation toward abstinence. A long-term commitment by the patient to maintain a lifestyle without illicit substances is essential for preventing relapse.

In most programs, patients are educated about their responsibility for improving their lives, and motivation for abstinence is increased by providing information about the medical and psychological problems that can be expected if dependence continues. Patients and families are encouraged to establish an opioid-free lifestyle by learning to cope with chronic pain and develop realistic vocational planning. The dependent person is also advised to establish a drug-free peer group and to participate in self-help groups such as Narcotics or Alcoholics Anonymous; the latter is appropriate for substance-dependent persons regardless of their usual drug of abuse. Another important treatment component is relapse prevention aimed at identifying triggers for a return to drugs and developing appropriate coping strategies.

Much of this advice and counseling can be given by the physician or by referring patients to formal drug programs, including methadone maintenance clinics, programs using narcotic antagonists, and therapeutic communities. Long-term follow-up of treated patients indicates that approximately one-third are completely drug free, and 60% no longer use opioids.

Opioid Maintenance Maintenance programs with methadone or buprenorphene should be used only in combination with education and counseling. The goal is to provide a substitute drug that is legally accessible, safer, can be taken orally, and has a relatively long half-life so that it can be taken once a day. This can help persons who have repeatedly failed in drug-free programs to improve functioning within the family and job, to decrease legal problems, and to improve health. Individuals who stay in methadone maintenance are likely to show less antisocial behavior and improvement in employment status.

Methadone is a long-acting opioid optimally dosed at 80–120 mg/d (a goal met through slow, careful increases over time). This dose is effective in blocking heroin-induced euphoria while decreasing craving, thereby helping patients to maintain abstinence from illegal opioids. Over three-quarters of patients in well-supervised methadone clinics are likely to remain heroin-free for ≥6 months. Methadone is usually administered as an oral liquid given once a day at the program, with weekend doses taken at home. After a period of maintenance (usually 6 months to ≥1 year), the clinician can work to slowly decrease the dose by ~5% per week. Some individuals however, are unable to taper off the drug and require long-term maintenance.

An alternative medication that has been used for maintenance treatment is buprenorphine, a μ opioid agonist and antagonist. A dose of 6–12 mg buprenorphine is roughly equivalent to 35–60 mg of methadone. Administered either as a sublingual liquid or tablet, doses can be gradually increased to 8–16 mg/d over the first 2 months. Doses of 16–32 mg per treatment day may be needed if the drug is given three times per week. Buprenorphine is available as monotherapy or in combination with the antagonist naltrexone (2–8 mg buprenorphine with 0.5–2 mg naltrexone), which precipitates withdrawal if the patient dissolves the pills and injects them IV. Buprenorphine has several advantages including low overdose danger, potentially easier detoxification than is seen with methadone, and a probable ceiling effect in which higher doses do not increase euphoria. It can also be given in the doctor's office by physicians who have completed a required training program. While some studies report equal effectiveness of buprenorphine and methadone, others suggest higher dropout rates or more concomitant illicit drug use with buprenorphine compared to methadone. As with all opioids, there is a danger of misuse of this drug.

In the past, the British have used heroin maintenance with goals and guidelines similar to those of current methadone programs. There is no evidence that heroin maintenance has any advantages over methadone maintenance, but the heroin approach increases the risk that the drug will be sold on the streets.

Opioid Antagonists The opioid antagonists (e.g., naltrexone) compete with heroin and other opioids at receptors, reducing the effects of the opioid agonists. Administered over long periods with the intention of blocking the opioid "high," these drugs can be useful as part of an overall treatment approach that includes counseling and support. Naltrexone doses of 50 mg/d antagonize 15 mg of heroin for 24 h, and the possibly more effective higher doses (125–150 mg) block the effects of 25 mg of IV heroin for up to 3 days. To avoid precipitating a withdrawal syndrome, patients must be free of opioids for a minimum of 5 days before beginning treatment with naltrexone and should first be challenged with 0.4 or 0.8 mg of the shorter-acting agent naloxone to be certain they can tolerate the long-acting antagonist. A test dose of 10 mg of naltrexone is then given, which can produce withdrawal symptoms in 0.5–2 h. If none appear, the patient can begin with the usual dose of 40–150 mg three times per week.

Drug-Free Programs Most opioid-dependent individuals enter treatment programs that are based primarily on the cognitive behavioral approaches of enhancing commitment to abstinence, helping individuals to rebuild their lives without substances, and preventing relapse. Whether carried out in inpatient, residential, or outpatient settings, patients usually do not receive maintenance medications.

A variation of this approach can be used for persons who are having problems maintaining a drug-free state. Here, the basic elements of treatment are incorporated into long-term (often a year or more) residence in a therapeutic community. The person begins with almost full immersion in the environment in which other individuals at various stages of recovery become the primary support group, offering advice and a drug-free atmosphere in which the opioid-dependent person progresses through ever-increasing levels of independence, including assuming a job outside the therapeutic atmosphere.

As is true for treatments of all substance-use disorders, it is likely that counseling, behavioral treatments, and relatively simple approaches to psychotherapy add significantly to a positive outcome. Most programs focus on teaching participants to cope with stress, enhancing their understanding of personality attributes, teaching better cognitive styles, and, through the process of relapse prevention, addressing issues that might contribute to increased craving, easy access to drugs, or periods of decreased motivation. A combination of these therapies with the approaches described above appears to give the best results.

Finally, it is important to discuss prevention. Except for the terminally ill, physicians should carefully monitor opioid drug use in their patients, keeping doses as low as is practical while still controlling pain, and administering opioids over as short a period as the level of pain would warrant in the average person. Physicians must be vigilant regarding their own risk for opioid abuse and dependence, never prescribing these drugs for themselves. For the nonmedical IV drug–dependent person, all possible efforts must be made to prevent AIDS, hepatitis, bacterial endocarditis, and other consequences of contaminated needles both through methadone maintenance and by considering needle-exchange programs.

389 Cocaine and Other Commonly Abused Drugs

Jack H. Mendelson, Nancy K. Mello

Initiation and perpetuation of the abuse of cocaine and other psychostimulants are determined by a complex interaction between the pharmacologic properties and relative availability of each drug, the personality and expectations of the user, and the environmental context in which the drug is used. Polydrug abuse, the concurrent use of several drugs with different pharmacologic effects, is increasingly common. Some forms of polydrug abuse, such as the combined use of heroin and cocaine intravenously, are especially dangerous and remain a major problem in hospital emergency rooms. Sometimes one drug is used to enhance the effects of another, as with the combined use of benzodiazepines and methadone, or cocaine and heroin in methadone-maintained patients.

Chronic cocaine and psychostimulant abuse may cause a number of adverse health consequences, ranging from pulmonary disease to reproductive dysfunction. Preexisting disorders such as hypertension and cardiac disease may be exacerbated by drug abuse, and the combined use of two or more drugs may accentuate medical complications associated with abuse of one of them. The adverse health consequences of drug abuse are further complicated by increased vulnerability to infections.

Drug abuse increases the risk of exposure to HIV. Cocaine and psychostimulant abuse contribute to the risk for HIV infection in part by suppression of immune function. In addition, concurrent use of cocaine and opiates (the "speedball") is frequently associated with needle-sharing by IV drug users. Intravenous drug abusers continue to represent the largest single group of persons with HIV infection in several major metropolitan areas in the United States as well as in urban areas in Scotland, Italy, Spain, Thailand, and China.

COCAINE

Cocaine is a stimulant and local anesthetic with potent vasoconstrictor properties. The leaves of the *coca* plant (*Erythroxylon coca*) contain ~0.5–1% cocaine. The drug produces physiologic and behavioral effects when administered PO, intranasally, IV, or via inhalation following pyrolysis (smoking). The reinforcing effects of cocaine appear to be related to activation of dopaminergic neurons in the mesolimbic system. Cocaine increases synaptic concentrations of the monamine neurotransmitters dopamine, norepinephrine, and serotonin by binding to transporter proteins in presynaptic neurons and blocking reuptake.

Prevalence of Cocaine Use Cocaine is widely available throughout the United States, and cocaine abuse occurs in virtually all social and economic strata of society. The prevalence of cocaine abuse in the general population has been accompanied by an increase in cocaine abuse by heroin-dependent persons, including those in methadone maintenance programs. Intravenous cocaine is often used concurrently with IV heroin. This combination purportedly attenuates the postcocaine "crash" and substitutes a cocaine "high" for the heroin "high" blocked by methadone.

Acute and Chronic Intoxication There has been an increase in both IV administration and inhalation of pyrolyzed cocaine via smoking. Following intranasal administration, changes in mood and sensation are perceived within 3–5 min, and peak effects occur at 10–20 min. The effects rarely last more than 1 h. Inhalation of pyrolyzed materials includes inhaling crack/cocaine or smoking coca paste, a product made by extracting cocaine preparations with flammable solvents, and cocaine free-base smoking. Free-base cocaine, including the free base prepared with sodium bicarbonate (crack), has become increasingly popular because of the relative high potency of the compound and its rapid onset of action (8–10 s following smoking).

Cocaine produces a brief, dose-related stimulation and enhancement of mood and an increase in cardiac rate and blood pressure. Body temperature usually increases following cocaine administration, and high doses of cocaine may induce lethal pyrexia or hypertension. Because cocaine inhibits reuptake of catecholamines at adrenergic nerve endings, the drug potentiates sympathetic nervous system activity. Cocaine has a short plasma half-life of approximately 45–60 min. Cocaine is metabolized by plasma esterases, and cocaine metabolites are excreted in urine. The very short duration of the euphorigenic effects of cocaine observed in chronic abusers is probably due to both acute and chronic tolerance. Frequent self-administration of the drug (two to three times per hour) is often reported by chronic cocaine abusers. Alcohol is used to modulate both the cocaine high and the dysphoria associated with the abrupt disappearance of cocaine's effects. A metabolite of cocaine, cocaethylene, has been detected in blood and urine of persons who concurrently abuse alcohol and cocaine. Cocaethylene induces changes in cardiovascular function similar to those of cocaine alone, and the pathophysiologic consequences of alcohol abuse plus cocaine abuse may be additive when both are used together.

The prevalent assumption that cocaine inhalation or IV administration is relatively safe is contradicted by reports of death from respiratory depression, cardiac arrhythmias, and convulsions associated with cocaine use. In addition to generalized seizures, neurologic complications may include headache, ischemic or hemorrhagic stroke, or subarachnoid hemorrhage. Disorders of cerebral blood flow and perfusion in cocaine-dependent persons have been detected with magnetic resonance spectroscopy (MRS) studies. Severe pulmonary disease may develop in individuals who inhale crack cocaine; this effect is attributed both to the direct effects of cocaine and to residual contaminants in the smoked material. Hepatic necrosis has been reported to occur following crack/cocaine use.

Although men and women who abuse cocaine may report that the drug enhances libidinal drive, chronic cocaine use causes significant loss of libido and adversely affects reproductive function. Impotence and gynecomastia have been observed in male cocaine abusers, and these abnormalities often persist for long periods following cessation of drug use. Women who abuse cocaine may experience major derangements in menstrual cycle function including galactorrhea, amenorrhea, and infertility. Chronic cocaine abuse may cause persistent hyperprolactinemia as a consequence of disordered dopaminergic inhibition of prolactin secretion by the anterior pituitary. Cocaine abuse by pregnant women, particularly the smoking of crack, has been associated with both an increased risk of congenital malformations in the fetus and perinatal cardiovascular and cerebrovascular disease in the mother. However, cocaine abuse per se is probably not the sole cause of these perinatal disorders, since many problems associated with maternal cocaine abuse, including poor nutrition and health care status as well as polydrug abuse, also contribute to the risk for perinatal disease.

Protracted cocaine abuse may cause paranoid ideation and visual and auditory hallucinations, a state that resembles alcoholic hallucinosis. Psychological dependence on cocaine, indicated by inability to abstain from frequent compulsive use, has also been reported. Although the occurrence of withdrawal syndromes involving psychomotor agitation and autonomic hyperactivity remains controversial, severe depression ("crashing") following cocaine intoxication may accompany drug withdrawal.

Rx COCAINE OVERDOSE AND CHRONIC ABUSE

Treatment of cocaine overdose is a medical emergency that is usually best managed in an intensive care unit. Cocaine toxicity produces a hyperadrenergic state characterized by hypertension, tachycardia, tonic-clonic seizures, dyspnea, and ventricular arrhythmias. Intravenous diazepam in doses up to 0.5 mg/kg administered over an 8-h period has been shown to be effective for control of seizures. Ventricular arrhythmias have been managed successfully by administration of 0.5–1.0 mg of propranolol IV. Since many instances of cocaine-related mortality have been associated with concurrent use of other illicit drugs (particularly heroin), the physician

must be prepared to institute effective emergency treatment for multiple drug toxicities.

Treatment of chronic cocaine abuse requires the combined efforts of primary care physicians, psychiatrists, and psychosocial care providers. Early abstinence from cocaine use is often complicated by symptoms of depression and guilt, insomnia, and anorexia, which may be as severe as those observed in major affective disorders. Individual and group psychotherapy, family therapy, and peer group assistance programs are often useful for inducing prolonged remission from drug use. A number of medications used for the treatment of various medical and psychiatric disorders have been administered to reduce the duration and severity of cocaine abuse and dependence. However, no available medication is both safe and highly effective for either cocaine detoxification or maintenance of abstinence. Some psychotherapeutic interventions may be effective; however, no specific form of psychotherapy or behavioral modification is uniquely beneficial.

MARIJUANA AND CANNABIS COMPOUNDS

Cannabis sativa contains >400 compounds in addition to the psychoactive substance, delta-9-tetrahydrocannabinol (THC). Marijuana cigarettes are prepared from the leaves and flowering tops of the plant, and a typical marijuana cigarette contains 0.5–1 g of plant material. Although the usual THC concentration varies between 10 and 40 mg, concentrations >100 mg per cigarette have been detected. Hashish is prepared from concentrated resin of *C. sativa* and contains a THC concentration of between 8 and 12% percent by weight. "Hash oil," a lipid-soluble plant extract, may contain a THC concentration of 25–60% and may be added to marijuana or hashish to enhance its THC concentration. Smoking is the most common mode of marijuana or hashish use. During pyrolysis, >150 compounds in addition to THC are released in the smoke. Although most of these compounds do not have psychoactive properties, they do have potential physiologic effects.

THC is quickly absorbed from the lungs into blood and is then rapidly sequestered in tissues. It is metabolized primarily in the liver, where it is converted to 11-hydroxy-THC, a psychoactive compound, and >20 other metabolites. Many THC metabolites are excreted through the feces at a rate of clearance that is relatively slow in comparison to that of most other psychoactive drugs.

Specific cannabinoid receptors (CB_1 and CB_2) have been identified in the central nervous system, including the spinal cord, and in the peripheral nervous system. High densities of these receptors have been found in the cerebral cortex, basal ganglia, and hippocampus. T and B lymphocytes also have cannabinoid receptors, and these appear to mediate anti-inflammatory and immunoregulatory properties of cannabinoids. A naturally occurring THC-like ligand has been identified in the nervous system, where it is widely distributed.

Prevalence of Use Marijuana is the most commonly used illegal drug in the United States. Use is particularly prevalent among adolescents; studies suggest that ~37% of high school students in the United States have used marijuana. Marijuana is relatively inexpensive and is often considered to be less hazardous than other controlled drugs and substances. Very potent forms of marijuana (sinsemilla) are now available in many communities, and concurrent use of marijuana with crack/cocaine and phencyclidine is increasing.

Acute and Chronic Intoxication Acute intoxication from marijuana and cannabis compounds is related to both the dose of THC and the route of administration. THC is absorbed more rapidly from marijuana smoking than from orally ingested cannabis compounds. Acute marijuana intoxication usually consists of a subjective perception of relaxation and mild euphoria resembling mild to moderate alcohol intoxication. This condition is usually accompanied by some impairment in thinking, concentration, and perceptual and psychomotor function. Higher doses of cannabis may produce behavioral effects analogous to severe alcohol intoxication. Although the effects of acute marijuana intoxication are relatively benign in normal users, the drug can precipitate severe emotional disorders in individuals who have antecedent psychotic or neurotic problems. As with other psychoactive compounds, both set (user's expectations) and setting (environmental context) are important determinants of the type and severity of behavioral intoxication.

As with abuse of cocaine, opioids, and alcohol, chronic marijuana abusers may lose interest in common socially desirable goals and steadily devote more time to drug acquisition and use. However, THC does not cause a specific and unique "amotivational syndrome." The range of symptoms sometimes attributed to marijuana use is difficult to distinguish from mild to moderate depression and the maturational dysfunctions often associated with protracted adolescence. Chronic marijuana use has also been reported to increase the risk of psychotic symptoms in individuals with a past history of schizophrenia. Persons who initiate marijuana smoking before the age of 17 may subsequently develop severe cognitive and neuropsychological disorders, and they may also be at higher risk for polydrug and alcohol abuse problems in later life.

Physical Effects Conjunctival injection and tachycardia are the most frequent immediate physical concomitants of smoking marijuana. Tolerance for marijuana-induced tachycardia develops rapidly among regular users. However, marijuana smoking may precipitate angina in persons with a history of coronary insufficiency. Exercise-induced angina may be increased after marijuana use to a greater extent than after tobacco cigarette smoking. Patients with cardiac disease should be strongly advised not to smoke marijuana or use cannabis compounds.

Significant decrements in pulmonary vital capacity have been found in regular daily marijuana smokers. Because marijuana smoking typically involves deep inhalation and prolonged retention of marijuana smoke, marijuana smokers may develop chronic bronchial irritation. Impairment of single-breath carbon monoxide diffusion capacity (D_{LCO}) is greater in persons who smoke both marijuana and tobacco than in tobacco smokers.

Although marijuana has also been associated with a number of other adverse effects, many of these studies await replication and confirmation. A reported correlation between chronic marijuana use and decreased testosterone levels in males has not been confirmed. Decreased sperm count and sperm motility and morphologic abnormalities of spermatozoa following marijuana use have been reported. Prospective studies demonstrated a correlation between impaired fetal growth and development and heavy marijuana use during pregnancy. Marijuana has also been implicated in derangements of the immune system; in chromosomal abnormalities; and in inhibition of DNA, RNA, and protein synthesis; however, these findings have not been confirmed or related to any specific physiologic effect in humans.

Tolerance and Physical Dependence Habitual marijuana users rapidly develop tolerance to the psychoactive effects of marijuana and often smoke more frequently and try to secure more potent cannabis compounds. Tolerance for the physiologic effects of marijuana develops at different rates; e.g., tolerance develops rapidly for marijuana-induced tachycardia but more slowly for marijuana-induced conjunctival injection. Tolerance for both behavioral and physiologic effects of marijuana decreases rapidly upon cessation of marijuana use.

Withdrawal signs and symptoms have been reported in chronic cannabis users, with the severity of symptoms related to dosage and duration of use. These include tremor, nystagmus, sweating, nausea, vomiting, diarrhea, irritability, anorexia, and sleep disturbances. Withdrawal signs and symptoms observed in chronic marijuana users are usually relatively mild in comparison to those observed in heavy opiate or alcohol users and rarely require medical or pharmacologic intervention. More severe and protracted abstinence syndromes may occur after sustained use of high-potency cannabis compounds.

Therapeutic Use of Marijuana Marijuana, administered as cigarettes or as a synthetic oral cannabinoid (dronabinol), has been proposed to have a number of medicinal properties that may be clinically useful in

some situations. These include antiemetic effects in chemotherapy recipients, appetite-promoting effects in AIDS patients, reduction of intraocular pressure in glaucoma, and reduction of spasticity in multiple sclerosis and other neurologic disorders. With the possible exception of AIDS-related cachexia, none of these attributes of marijuana compounds is clearly superior to other readily available therapies.

METHAMPHETAMINE

Methamphetamine is also referred to as "meth," "speed," "crank," "chalk," "ice," "glass," or "crystal." In the United States, hospital admissions for treatment of methamphetamine abuse increased substantially (from 3–8%) between 1994 and 2004. This increase occurred despite drug seizures, closures of clandestine laboratories that produce methamphetamine illegally, and an increase in methamphetamine abuse prevention programs.

Methamphetamine can be self-administered PO or by smoking, snorting, and IV injection. Individuals who abuse or become dependent upon methamphetamine report that use of this drug induces feelings of euphoria and decreases fatigue associated with difficult life situations. Adverse consequences of methamphetamine abuse include headache, difficulty concentrating, diminished appetite, abdominal pain, vomiting or diarrhea, disordered sleep, paranoid or aggressive behavior, and psychosis. Chronic methamphetamine abuse can result in severe dental caries, described as blackened, rotting, crumbling teeth. Severe, life-threatening methamphetamine toxicity may present as hypertension, cardiac arrhythmia or failure, subarachnoid hemorrhage, ischemic stroke, intracerebral hemorrhage, convulsions, or coma. Methamphetamines increase the release of monoamine neurotransmitters (dopamine, norepinephrine, and serotonin) from presynaptic neurons. It is thought that the euphoric and reinforcing effects of this class of drugs are mediated through dopamine and the mesolimbic system, whereas the cardiovascular effects are related to norepinephrine. MRS studies of the brain suggest that chronic abusers have neuronal damage in the frontal areas and basal ganglia.

Therapy of acute methamphetamine overdose is largely symptomatic. Ammonium chloride may be useful to acidify the urine and enhance clearance of the drug. Hypertension may respond to sodium nitroprusside or α-adrenergic antagonists. Sedatives may reduce agitation and other signs of central nervous system hyperactivity. Treatment of chronic methamphetamine dependence may be accomplished in either an inpatient or outpatient setting using strategies similar to those described above for cocaine abuse.

MDMA (3,4-methylenedioxymethamphetamine), or *Ecstasy*, is a derivative of methamphetamine. Ecstasy is usually taken PO but may be injected or inhaled; its effects last for 3–6 h. In addition to amphetamine-like effects, MDMA can induce hyperthermia and vivid hallucinations and other perceptual distortions.

During the past decade, an eighteenfold increase in MDMA-related emergency room incidents has been reported in the United States. Recent studies have revealed that MDMA use is associated with cognitive and memory impairment and a mild withdrawal syndrome after cessation of use. The long-term consequences of recreational use of MDMA by young persons are poorly understood.

LYSERGIC ACID DIETHYLAMIDE (LSD)

The discovery of the psychedelic effects of LSD in 1947 led to an epidemic of LSD abuse during the 1960s. Imposition of stringent constraints on the manufacture and distribution of LSD (classified as a Schedule I substance by the U.S. Food and Drug Administration), as well as public recognition that psychedelic experiences induced by LSD were a health hazard, have resulted in a reduction in LSD abuse. LSD still remains popular among adolescents and young adults, and there are indications that LSD use among young persons has been increasing in some communities in the United States.

LSD is a very potent drug; oral doses as low as 20 μg may induce profound psychological and physiologic effects. Tachycardia, hypertension, pupillary dilation, tremor, and hyperpyrexia occur within minutes following oral administration of 0.5–2 μg/kg. A variety of bizarre and often conflicting perceptual and mood changes, including visual illusions, synesthesias, and extreme lability of mood, usually occur within 30 min after LSD intake. These effects of LSD may persist for 12–18 h, even though the half-life of the drug is only 3 h.

Tolerance develops rapidly for LSD-induced changes in psychological function when the drug is used one or more times per day for >4 days. Abrupt abstinence following continued use does not produce withdrawal signs or symptoms. There have been no clinical reports of death caused by the direct effects of LSD.

The most frequent acute medical emergency associated with LSD use is a panic episode (the "bad trip"), which may persist up to 24 h. Management of this problem is best accomplished by supportive reassurance ("talking down") and, if necessary, administration of small doses of anxiolytic drugs. Adverse consequences of chronic LSD use include enhanced risk for schizophreniform psychosis and derangements in memory function, problem solving, and abstract thinking. Treatment of these disorders is best carried out in specialized psychiatric facilities.

PHENCYCLIDINE

Phencyclidine (PCP), a cyclohexylamine derivative, is widely used in veterinary medicine to briefly immobilize large animals and is sometimes described as a dissociative anesthetic. PCP binds to ionotropic *n*-methyl-*d*-aspartate (NMDA) receptors in the nervous system, blocking ion current through these channels. PCP is easily synthesized; its abusers are primarily young people and polydrug users. It is used PO, by smoking, or by IV injection. It is also used as an adulterant in THC, LSD, amphetamine, or cocaine. The most common street preparation, *angel dust*, is a white granular powder that contains 50–100% percent of the drug. Low doses (5 mg) produce agitation, excitement, impaired motor coordination, dysarthria, and analgesia. Users may have horizontal or vertical nystagmus, flushing, diaphoresis, and hyperacusis. Behavioral changes include distortions of body image, disorganization of thinking, and feelings of estrangement. Higher doses of PCP (5–10 mg) may produce profuse salivation, vomiting, myoclonus, fever, stupor, or coma. PCP doses of ≥10 mg cause convulsions, opisthotonus, and decerebrate posturing, which may be followed by prolonged coma.

The diagnosis of PCP overdose is difficult because the patient's initial symptoms may suggest an acute schizophrenic reaction. Confirmation of PCP use is possible by determination of PCP levels in serum or urine. PCP assays are available at most toxicologic centers. PCP remains in urine for 1–5 days following high-dose intake.

PCP overdose requires life-support measures, including treatment of coma, convulsions, and respiratory depression in an intensive care unit. There is no specific antidote or antagonist for PCP. PCP excretion from the body can be enhanced by gastric lavage and acidification of urine. Death from PCP overdose may occur as a consequence of some combination of pharyngeal hypersecretion, hyperthermia, respiratory depression, severe hypertension, seizures, hypertensive encephalopathy, and intracerebral hemorrhage.

Acute psychosis associated with PCP use should be considered a psychiatric emergency since patients may be at high risk for suicide or extreme violence toward others. Phenothiazines should not be used for treatment because these drugs potentiate PCP's anticholinergic effects. Haloperidol (5 mg IM) has been administered on an hourly basis to induce suppression of psychotic behavior. PCP, like LSD and mescaline, produces vasospasm of cerebral arteries at relatively low doses. Chronic PCP use has been shown to induce insomnia, anorexia, severe social and behavioral changes, and, in some cases, chronic schizophrenia.

POLYDRUG ABUSE

Although drug abusers often report a preference for a particular drug, such as alcohol or opiates, the concurrent use of other drugs is common. Polydrug abuse often involves substances that may have different pharmacologic effects from the preferred drug. For example, concurrent use

of such dissimilar compounds as stimulants and opiates or stimulants and alcohol is not unusual. The diversity of reported drug use combinations suggests that achieving some perceptible change in state, rather than any particular direction of change (stimulation or sedation), may be the primary reinforcer in polydrug use and abuse. There is also evidence that intoxication with alcohol or opiates is associated with increased tobacco smoking. There is relatively little systematic information available about multiple drug abuse interactions. However, the combined use of cocaine, heroin, and alcohol increases the risk for toxic effects and adverse medical consequences over risks associated with use of a single drug. One determinant of polydrug use patterns is the relative availability and cost of the drugs. There are many examples of situationally determined drug use patterns. For example, alcohol abuse, with its attendant medical complications, is one of the most serious problems encountered in former heroin addicts participating in methadone maintenance programs.

The physician must recognize that perpetuation of polydrug abuse and drug dependence is not necessarily a symptom of an underlying emotional disorder. Neither alleviation of anxiety nor reduction of depression accounts for initiation and perpetuation of polydrug abuse. Severe depression and anxiety are as frequently the consequences of polydrug abuse as they are the antecedents. There is also evidence that some of the most adverse consequences of drug use may be reinforcing and contribute to the continuation of polydrug abuse.

℞ POLYDRUG ABUSE

Adequate treatment of polydrug abuse, as well as other forms of drug abuse, requires innovative programs of intervention. The first step in successful treatment is detoxification, a process that may be difficult because of the abuse of several drugs with different pharmacologic actions (e.g., alcohol, opiates, and cocaine). Since patients may not recall or may deny simultaneous multiple drug use, diagnostic evaluation should always include urinalysis for qualitative detection of psychoactive substances and their metabolites. Treatment of polydrug abuse often requires hospitalization or inpatient residential care during detoxification and the initial phase of drug abstinence. When possible, specialized facilities for the care and treatment of chemically dependent persons should be used. Outpatient detoxification of polydrug abuse patients is likely to be ineffective and may be dangerous.

Drug abuse disorders often respond to effective treatment, but episodes of relapse may occur unpredictably. The physician should continue to assist patients during relapse and recognize that occasional recurrent drug use is not unusual in this complex behavioral disorder.

390 Nicotine Addiction

David M. Burns

The use of tobacco leaf to create and satisfy nicotine addiction was introduced to Columbus by Native Americans and spread rapidly to Europe. The use of tobacco as cigarettes, however, became popular in the twentieth century and so is a modern phenomenon, as is the epidemic of disease caused by this form of tobacco.

Nicotine is the principal constituent of tobacco responsible for its addictive character. Addicted smokers regulate their nicotine intake and blood levels by adjusting the frequency and intensity of their tobacco use both to obtain the desired psychoactive effects and avoid withdrawal.

Unburned cured tobacco contains nicotine, carcinogens, and other toxins capable of causing gum disease, oral cancer, and possibly a slight increase in the risk of heart disease. When tobacco is burned, the resultant smoke contains, in addition to nicotine, 4000 other compounds that result from volatilization, pyrolysis, and pyrosynthesis of tobacco and various chemical additives used in making different tobacco products. The smoke is composed of a fine aerosol and a vapor phase; aerosolized particles are of a size range that results in deposition in the airways and alveolar surfaces of the lungs. The bulk of the toxicity and carcinogenicity of the smoke resides in the aerosolized particulate phase, which contains a large number of toxic constituents and carcinogenic compounds. The aggregate of particulate matter, after subtracting nicotine and moisture, is referred to as tar. The vapor phase contains carbon monoxide, respiratory irritants, and ciliotoxins as well as many of the volatile compounds responsible for the distinctive smell of cigarette smoke.

The alkaline pH of smoke from blends of tobacco utilized for pipes and cigars allows sufficient absorption of nicotine across the oral mucosa to satisfy the smoker's need for this drug. Therefore, smokers of pipes and cigars tend not to inhale the smoke into the lung, confining the toxic and carcinogenic exposure (and the increased rates of disease) largely to the upper airway for most users of these products. The acidic pH of smoke generated by the tobacco used in cigarettes dramatically reduces absorption of nicotine in the mouth, necessitating inhalation of the smoke into the larger surface of the lungs in order to absorb quantities of nicotine sufficient to satisfy the smoker's addiction. The shift to using tobacco as cigarettes, with resultant increased deposition of smoke in the lung, has created the epidemic of heart disease, lung disease, and lung cancer that dominates the current disease manifestations of tobacco use.

Several genes have been associated with nicotine addiction. Some reduce the clearance of nicotine, and others have been associated with an increased likelihood of becoming dependent on tobacco and other drugs as well as a higher incidence of depression. It is unlikely that genetic factors are the principal determinants of addiction. Rates of smoking cessation have increased, and rates of nicotine addiction have decreased dramatically, since the mid-1950s, suggesting that factors other than genetics are important. It is more likely that genetic susceptibility can influence the probability that adolescent experimentation with tobacco will lead to addiction as an adult.

Adult cigarette smoking prevalence has declined to about 20% in the United States, with similar declines in Canada and most European countries. Male smoking prevalence is falling but remains high in most Asian countries, with increasing smoking prevalence among women in those countries. The highest rates of smoking and least cessation are observed in the former Soviet block countries. Of particular concern is the rapidly rising smoking rate observed in the developing world; it is hoped that the recently ratified World Health Organization Framework Convention on Tobacco Control will encourage effective tobacco control approaches in these countries in order to prevent a future epidemic of tobacco-related illness.

DISEASE MANIFESTATIONS OF CIGARETTE SMOKING

Over 400,000 individuals die prematurely each year in the United States from cigarette use; this represents approximately one out of every five deaths in the United States. Approximately 40% of cigarette smokers will die prematurely due to cigarette smoking unless they are able to quit.

TABLE 390-1 RELATIVE RISKS FOR CURRENT SMOKERS OF CIGARETTES

Disease or Condition	Current Smokers	
	Males	Females
Coronary heart disease		
Age 35–64	2.8	3.1
Age ≥65	1.5	1.6
Cerebrovascular disease		
Age 35–64	3.3	4
Age ≥65	1.6	1.5
Aortic aneurysm	6.2	7.1
Chronic airway obstruction	10.6	13.1
Cancer		
Lung	23.3	12.7
Larynx	14.6	13
Lip, oral cavity, pharynx	10.9	5.1
Esophagus	6.8	7.8
Bladder, other urinary organs	3.3	2.2
Kidney	2.7	1.3
Pancreas	2.3	2.3
Stomach	2	1.4
Cervix		1.6
Acute myeloid leukemia	1.4	1.4
Sudden infant death syndrome		2.3
Infant respiratory distress syndrome		1.3
Low birth weight at delivery		1.8

The major diseases caused by cigarette smoking are listed in Table 390-1. The ratio of smoking-related disease rates in smokers compared to never smokers (relative risk) is greater at younger ages, particularly for coronary artery disease and stroke. At older ages, the background rate of disease in nonsmokers increases, diminishing the fractional contribution of smoking and the relative risk; however, absolute excess rates of disease mortality found in smokers compared to nonsmokers increase with increasing age. The organ damage caused by smoking and the number of smokers who die from smoking are both greater among the elderly, as one would expect from a process of cumulative injury.

CARDIOVASCULAR DISEASES

Cigarette smokers are more likely than nonsmokers to develop large-vessel atherosclerosis as well as small-vessel disease. Approximately 90% of peripheral vascular disease in the nondiabetic population can be attributed to cigarette smoking, as can ~50% of aortic aneurysms. In contrast, 20–30% of coronary artery disease and ~10% of occlusive cerebrovascular disease are caused by cigarette smoking. There is a multiplicative interaction between cigarette smoking and other cardiac risk factors such that the increment in risk produced by smoking among individuals with hypertension or elevated serum lipids is substantially greater than the increment in risk produced by smoking for individuals without these risk factors.

In addition to its role in promoting atherosclerosis, cigarette smoking also increases the likelihood of myocardial infarction and sudden cardiac death by promoting platelet aggregation and vascular occlusion. Reversal of these effects may explain the rapid benefit of smoking cessation for a new coronary event demonstrable among those who have survived a first myocardial infarction. This effect may also explain the substantially higher rates of graft occlusion among continuing smokers following vascular bypass surgery for cardiac or peripheral vascular disease.

Cessation of cigarette smoking reduces the risk of a second coronary event within 6–12 months; rates of first myocardial infarction or death from coronary heart disease also decline within the first few years following cessation. After 15 years of cessation, the risk of a new myocardial infarction or death from coronary heart disease in former smokers is similar to that for those who have never smoked.

CANCER

Tobacco smoking causes cancer of the lung, oral cavity, naso-, oro-, and hypopharynx, nasal cavity and paranasal sinuses, larynx, esophagus, stomach, pancreas, liver, kidney (body and pelvis), ureter, urinary bladder, and uterine cervix and also causes myeloid leukemia. There is evidence suggesting that cigarette smoking may play a role in increasing the risk of colorectal and possibly premenopausal breast cancer, but there is no association with postmenopausal breast cancer. There does not appear to be a causal link between cigarette smoking and cancer of the endometrium, and there is a lower risk of uterine cancer among postmenopausal women who smoke. The risks of cancer increase with the increasing number of cigarettes smoked per day and with increasing duration of smoking. Additionally, there are synergistic interactions between cigarette smoking and alcohol use for cancer of the oral cavity, esophagus, and possibly lung. Several occupational exposures also synergistically increase lung cancer risk among cigarette smokers, most notably occupational asbestos and radon exposure.

Cessation of cigarette smoking reduces the risk of developing cancer relative to continuing smoking, but even 20 years after cessation there is a modest persistent increased risk of developing lung cancer.

RESPIRATORY DISEASE

Cigarette smoking is responsible for 90% of chronic obstructive pulmonary disease. Within 1–2 years of beginning to smoke regularly, many young smokers will develop inflammatory changes in their small airways, although lung function measures of these changes do not predict development of chronic airflow obstruction. After 20 years of smoking, pathophysiologic changes in the lungs develop and progress proportional to smoking intensity and duration. Chronic mucous hyperplasia of the larger airways results in a chronic productive cough in as many as 80% of smokers >60 years. Chronic inflammation and narrowing of the small airways and/or enzymatic digestion of alveolar walls resulting in pulmonary emphysema can result in reduced expiratory airflow sufficient to produce clinical symptoms of respiratory limitation in ~15% of smokers.

Changes in the small airways of young smokers will reverse after 1–2 years of cessation. There may also be a small increase in measures of expiratory airflow among individuals who have developed chronic airflow obstruction, but the major change following cessation is a slowing of the rate of decline in lung function with advancing age rather than a return of lung function toward normal.

PREGNANCY

Cigarette smoking is associated with several maternal complications of pregnancy: premature rupture of membranes, abruptio placentae, and placenta previa; there is also a small increase in the risk of spontaneous abortion among smokers. Infants of smoking mothers are more likely to experience preterm delivery, have a higher perinatal mortality, be small for their gestational age, and have higher rates of infant respiratory distress syndrome; they are more likely to die of sudden infant death syndrome, and appear to have a developmental lag for at least the first several years of life.

OTHER CONDITIONS

Smoking delays healing of peptic ulcers; increases the risk of osteoporosis, senile cataracts, and macular degeneration; and results in premature menopause, wrinkling of the skin, gallstones and cholecystitis in women, and male impotence.

ENVIRONMENTAL TOBACCO SMOKE

Long-term exposure to environmental tobacco smoke increases the risk of lung cancer and coronary artery disease among nonsmokers. It also increases the incidence of respiratory infections, chronic otitis media, and asthma in children as well as causing exacerbation of asthma in children.

PHARMACOLOGIC INTERACTIONS

Cigarette smoking may interact with a variety of other drugs (Table 390-2). Cigarette smoking induces the cytochrome P450 system, which may alter the metabolic clearance of drugs such as theophylline. This may result in inadequate serum levels in smokers as outpatients when the dosage is established in the hospital under nonsmoking conditions.

TABLE 390-2 INTERACTIONS OF SMOKING AND PRESCRIPTION DRUGS

Drug	Interaction
Benzodiazepines	Less sedation
Beta-blockers	Reduced lowering of heart rate and blood pressure
Caffeine	Faster metabolic clearance
Chlorpromazine	Decreased serum concentrations[a]
Clomipramine	Decreased serum concentrations[a]
Clozapine	Decreased serum concentrations[a]
Dextropropoxyphene	Less analgesia
Oral estrogens	Increased hepatic clearance
Flecainide	Increased first-pass clearance
Fluphenazine	Decreased serum concentrations[a]
Fluvoxamine	Decreased serum concentrations[a]
Haloperidol	Decreased serum concentrations[a]
Heparin	Faster clearance
Imipramine	Decreased serum concentrations[a]
Insulin	Delayed absorption due to skin vasoconstriction
Lidocaine	Increased first-pass clearance
Mexiletine	Increased first-pass clearance
Olanzapine	Faster clearance
Pentazocine	Less analgesia, possible increased clearance
Propanolol	Increased first-pass clearance
Tacrine	Faster metabolic clearance
Theophylline	Faster metabolic clearance
Thiothixene	Faster metabolic clearance
Trazodone	Decreased serum concentrations[a]

[a]Clinical implications uncertain.

Correspondingly, serum levels may rise when smokers are hospitalized and not allowed to smoke. Smokers may also have higher first-pass clearance for drugs such as lidocaine, and the stimulant effects of nicotine may reduce the effect of benzodiazepines or beta blockers.

OTHER FORMS OF TOBACCO USE

Other major forms of tobacco use are moist snuff deposited between the cheek and gum, chewing tobacco, pipes and cigars, and recently bidi (tobacco wrapped in tendu or temburni leaf; commonly used in India), clove cigarettes, and water pipes. Oral tobacco use leads to gum disease and can result in oral cancer. All forms of burned tobacco generate toxic and carcinogenic smoke similar to that of cigarette smoke. The differences in disease consequences of use relate to frequency of use and depth of inhalation. The risk of upper airway cancers is similar among cigarette and cigar smokers, while those who have smoked only cigars have a much lower risk of lung cancer, heart disease, and chronic obstructive pulmonary disease. However, cigarette smokers who switch to pipes or cigars do tend to inhale the smoke, increasing their risk; and it is likely that comparable inhalation and frequency of exposure to tobacco smoke from any of these forms of tobacco use will lead to comparable disease outcomes.

A resurgence of cigar, bidi, and water pipe use among adolescents of both genders has raised concerns that these older forms of tobacco use are once again causing a public health problem.

LOWER TAR AND NICOTINE CIGARETTES

Filtered cigarettes with lower machine-measured yields of tar and nicotine have been recommended as offering lower disease risks. However, these cigarettes commonly use ventilation holes in the filters and other engineering designs to artificially lower the machine measurements. Smokers, however, can compensate and preserve their intake of nicotine (and tar) by changing the manner in which they puff on the cigarette or the number of cigarettes smoked per day. There is no meaningful disease-reduction benefit for smokers who switch to lower-yield cigarettes, and smokers should be discouraged from thinking of low-yield cigarettes as an alternative to cessation.

CESSATION

The process of stopping smoking is often a cyclical one, with the smoker sometimes making multiple attempts to quit and failing before finally being successful. Approximately 70–80% of smokers would like to quit smoking, approximately one-third of current smokers attempt to quit each year, and 90% of these unassisted attempts fail. Clinician-based smoking interventions should encourage smokers to try to quit and to use different forms of cessation assistance with each new cessation attempt rather than focusing exclusively on immediate cessation at the time of the first visit.

Advice from a physician to quit smoking, particularly around an acute illness, is a powerful trigger for cessation attempts, with up to half of patients who are advised to quit making a cessation effort. Other triggers include the cost of cigarettes, media campaigns, and changes in rules to restrict smoking in the workplace.

PHYSICIAN INTERVENTION (Table 390-3)

All patients should be asked whether they smoke, their past experience with quitting, and whether they are currently interested in quitting. Those who are not interested in quitting should be encouraged and motivated to quit; provided a clear, strong, and personalized physician message that smoking is an important health concern; and offered assistance if they become interested in quitting in the future. There is a relationship between the amount of assistance a patient is willing to accept and the success of the cessation attempt. A quit date should be negotiated, usually not the day of the visit but within the next few weeks, and a follow-up contact by office staff around the time of the quit date should be provided.

There are a variety of nicotine-replacement products, including over-the-counter nicotine patches, gum, and lozenges, as well as nicotine nasal and oral inhalers available by prescription. These products can be used for up to 3–6 months, and some products are formulated to allow a gradual step-down in dosage with increasing duration of abstinence. Antidepressants such as bupropion (300 mg in divided doses for up to 6 months) have also been shown to be effective, as has varenicline, a partial agonist for the nicotinic acetylcholine receptor (initial dose 0.5 mg daily increasing to 1 mg twice daily at day 8; treatment duration up to 6 months). Some evidence supports the combined use of nicotine-replacement therapy and antidepressants as well as the use of gum or lozenges for acute cravings in patients using patches. Nicotine-replacement therapy is provided in different dosages with higher doses being recommended for more intense smokers. Clonidine or nortriptyline may be useful for patients who have failed on first-line pharmacologic treat-

TABLE 390-3 CLINICAL PRACTICE GUIDELINES

Physician actions
- Ask: Systematically identify all tobacco users at every visit
- Advise: Strongly urge all smokers to quit
- Identify smokers willing to quit
- Assist the patient in quitting
- Arrange follow-up contact

Effective pharmacologic interventions[a]
- First-line therapies
  - Nicotine gum (1.5)
  - Nicotine patch (1.9)
  - Nicotine nasal inhaler (2.7)
  - Nicotine oral inhaler (2.5)
  - Nicotine lozenge (2.0)
  - Bupropion (2.1)
  - Varenicline (2.7)
- Second-line therapies
  - Clonidine (2.1)
  - Nortriptyline (3.2)

Other Effective Interventions[a]
- Physician or other medical personnel counseling (10 min) (1.3)
- Intensive smoking cessation programs (at least 4–7 sessions of 20–30 min duration lasting at least 2 and preferably 8 weeks) (2.3)
- Clinic-based smoking status identification system (3.1)
- Counseling by nonclinicians and social support by family and friends
- Telephone counseling (1.2)

[a]Numerical value following the intervention is the multiple for cessation success compared to no intervention.

ment or who are unable to use other therapies. Antidepressants are more effective in those with a history of depression symptoms.

Current recommendations are to offer pharmacologic treatment, usually with nicotine replacement therapy (NRT) and bupropion, to all who will accept it and to provide counseling and other support as a part of the cessation attempt. Currently, indications approved by the U.S. Food and Drug Administration for NRT products limit their use to short-term use in conjunction with a cessation attempt. Nevertheless, it is not uncommon for individual smokers to use these products, particularly the products available over the counter, for longer durations and sometimes with no intent to stop. There are some data to suggest that longer-term use of NRT may enable cessation in some smokers who are unable to quit with shorter duration use and that some individuals are able to achieve abstinence from tobacco through use of NRT chronically. It is useful for the practicing physician to recognize that these patterns of use exist among smokers trying to quit and that they may contribute to successful abstinence in some smokers. Cessation advice alone by a physician or his or her staff is likely to increase success compared with no intervention; a more comprehensive approach with advice, pharmacologic assistance, and counseling can increase cessation success by almost threefold.

Incorporation of cessation assistance into a practice requires a change of the care delivery infrastructure. Simple changes include: (1) adding questions about smoking and interest in cessation on patient-intake questionnaires, (2) asking patients whether they smoke as part of the initial vital sign measurements made by office staff, (3) listing smoking as a problem in the medical record, and (4) automating follow-up contact with the patient on the quit date. These changes are essential to institutionalizing smoking intervention within the practice setting; without this institutionalization, the best intentions of physicians to intervene with their patients who smoke are often lost in the time crush of a busy practice.

PREVENTION

Approximately 90% of individuals who will become cigarette smokers initiate the behavior during adolescence. Factors that promote adolescent initiation are parental or older generation cigarette smoking, tobacco advertising and promotional activities, the availability of cigarettes, and the social acceptability of smoking. The need for an enhanced self-image and to imitate adult behavior is greatest for those adolescents who have the least external validation of their self-worth, which may explain in part the enormous differences in adolescent smoking prevalence by socioeconomic and school performance strata.

Prevention of smoking initiation must begin early, preferably in the elementary school years. Physicians who treat adolescents should be sensitive to the prevalence of this problem. Physicians should ask all adolescents whether they have experimented with tobacco or currently use tobacco, reinforce the facts that most adolescents and adults do not smoke, and explain that all forms of tobacco are both addictive and harmful.

e34 Heavy Metal Poisoning

Howard Hu

Metals pose a significant threat to health through occupational as well as environmental exposures. One indication of their importance relative to other potential hazards is their ranking by the U.S. Agency for Toxic Substances and Disease Registry, which lists all hazards present in toxic waste sites according to their prevalence and the severity of their toxicity. The first, second, third, and sixth hazards on the list are heavy metals: lead, mercury, arsenic, and cadmium, respectively. Specific information pertaining to each of these metals, including sources and metabolism, toxic effects produced, diagnosis, and the appropriate treatment for poisoning, is summarized in Table e34-1.

Metals are inhaled primarily as dusts and fumes (the latter defined as tiny particles generated by combustion). Metal poisoning can also result from exposure to vapors (e.g., mercury vapor in creating dental amalgams). When metals are ingested in contaminated food or drink or by hand-to-mouth activity (implicated especially in children), their gastrointestinal absorption varies greatly with the specific chemical form of the metal and the nutritional status of the host. Once a metal is absorbed, blood is the main medium for its transport, with the precise kinetics dependent on diffusibility, protein binding, rates of biotransformation, availability of intracellular ligands, and other factors. Some organs (e.g., bone, liver, and kidney) sequester metals in relatively high concentrations for years. Most metals are excreted through renal clearance and gastrointestinal excretion; some proportion is also excreted through salivation, perspiration, exhalation, lactation, skin exfoliation, and loss of hair and nails. The intrinsic stability of metals facilitates tracing and measurement in biologic material, although the clinical significance of the levels measured is not always clear.

Some metals, such as copper and selenium, are essential to normal metabolic function as trace elements (Chap. 71) but are toxic at high levels of exposure. Others, such as lead and mercury, are xenobiotic and theoretically are capable of exerting toxic effects at any level of exposure. Indeed, much research is currently focused on the contribution of low-level xenobiotic metal exposure to chronic diseases and to subtle changes in health that may have significant public health consequences. Genetic factors also may modify the impact of metals on health and thereby account, at least in part, for individual susceptibility to metal effects.

The most important component of treatment for metal toxicity is the termination of exposure. *Chelating agents* are used to bind metals into stable cyclic compounds with relatively low toxicity and to enhance their excretion. The principal chelating agents are dimercaprol (British Anti-Lewisite, BAL), edetate (EDTA), succimer (DMSA, dimercaptosuccinic acid), and penicillamine; their specific use depends on the metal involved and the clinical circumstances. Activated charcoal does not bind metals and thus is of limited usefulness in cases of acute metal ingestion.

In addition to the information provided in Table e34-1, several other aspects of exposure, toxicity, or management are worthy of discussion with respect to the four most hazardous toxicants (arsenic, cadmium, lead, and mercury).

Arsenic exposure from natural contamination of shallow tube wells inserted for drinking water is a huge environmental problem for millions of residents in parts of Bangladesh and Western India. Contamination was formerly considered only a problem with deep wells; however, the geology of this region allows most residents only a few alternatives for potable drinking water.

Serious *cadmium* poisoning from the contamination of food and water by mining effluents in Japan contributed to the 1946 outbreak of "itai-itai" ("ouch-ouch") disease, so named because of cadmium-induced bone toxicity that led to painful bone fractures. Modest exposures from environmental contamination near a smelter in Belgium were recently associated with a lower bone density, a higher incidence of fractures, and a faster decline in height in both men and women, ef-

TABLE e34-1 HEAVY METALS

Main Sources	Metabolism	Toxicity	Diagnosis	Treatment
		Arsenic		
Smelting and microelectronics industries; wood preservatives, pesticides, herbicides, fungicides; contaminant of deep-water wells; folk remedies; and coal; incineration of these products	Organic arsenic (arsenobentaine, arsenocholine) is ingested in seafood and fish, but is nontoxic; inorganic arsenic is readily absorbed (lung and GI); sequesters in liver, spleen, kidneys, lungs, and GI tract; residues persist in skin, hair, and nails; biomethylation results in detoxification, but this process saturates.	Acute arsenic poisoning results in necrosis of intestinal mucosa with hemorrhagic gastroenteritis, fluid loss, hypotension, delayed cardiomyopathy, acute tubular necrosis, and hemolysis. Chronic arsenic exposure causes diabetes, vasospasm, peripheral vascular insufficiency and gangrene, peripheral neuropathy, and cancer of skin, lung, liver (angiosarcoma), bladder, kidney. Lethal dose: 120–200 mg (adults); 2 mg/kg (children).	Nausea, vomiting, diarrhea, abdominal pain, delirium, coma, seizures; garlicky odor on breath; hyperkeratosis, hyperpigmentation, exfoliative dermatitis, and Mees' lines (transverse white striae of the fingernails); sensory and motor polyneuritis, distal weakness. Radiopaque sign on abdominal x-ray; ECG–QRS broadening, QT prolongation, ST depression, T-wave flattening; 24-h urinary arsenic >67 μmol/d or 50 μg/d; (no seafood × 24 h); if recent exposure, serum arsenic >0.9 μmol/L (7 μg/dL). High arsenic in hair or nails.	If acute ingestion, ipecac to induce vomiting, gastric lavage, activated charcoal with a cathartic. Supportive care in ICU. Dimercaprol 3–5 mg/kg IM q4h × 2 days; q6h × 1 day, then q12h × 10 days; alternative: oral succimer.
		Cadmium		
Metal-plating, pigment, smelting, battery, and plastics industries; tobacco; incineration of these products; ingestion of food that concentrates cadmium (grains, cereals).	Absorbed through ingestion or inhalation; bound by metallothionein, filtered at the glomerulus, but reabsorbed by proximal tubules (thus, poorly excreted). Biologic 1/2 life: 10–30 y. Binds cellular sulfhydryl groups, competes with zinc, calcium for binding sites. Concentrates in liver and kidneys.	Acute cadmium inhalation causes pneumonitis after 4–24 h; acute ingestion causes gastroenteritis. Chronic exposure causes anosmia, yellowing of teeth, emphysema, minor LFT elevations, microcytic hypochromic anemia unresponsive to iron therapy, proteinuria, increased urinary β_2- microglobulin, calciuria, leading to chronic renal failure, osteomalacia, and fractures.	With inhalation: pleuritic chest pain, dyspnea, cyanosis, fever, tachycardia, nausea, noncardiogenic pulmonary edema. With ingestion: nausea, vomiting, cramps, diarrhea. Bone pain, fractures with osteomalacia. If recent exposure, serum cadmium >500 nmol/L (5 μg/dL). Urinary cadmium >100 nmol/L (10 μg/g creatinine) and/or urinary β_2-microglobulin >750 μg/g creatinine (but urinary β_2-microglobulin also increased in other renal diseases such as pyelonephritis).	There is no effective treatment for cadmium poisoning (chelation not useful; dimercaprol can exacerbate nephrotoxicity). Avoidance of further exposure, supportive therapy, vitamin D for osteomalacia.

TABLE e34-1 HEAVY METALS (CONTINUED)

Main Sources	Metabolism	Toxicity	Diagnosis	Treatment
		Lead		
Manufacturing of auto batteries, lead crystal, ceramics, fishing weights, etc.; demolition or sanding of lead-painted houses, bridges; stained glass making, plumbing, soldering; environmental exposure to paint chips, house dust (in home built <1975), firing ranges (from bullet dust), food or water from improperly glazed ceramics, lead pipes; contaminated herbal remedies, candies; exposure to the combustion of leaded fuels.	Absorbed through ingestion or inhalation; organic lead (e.g., tetraethyl lead) absorbed dermally. In blood, 95–99% sequestered in RBCs—thus, must measure lead in whole blood (not serum). Distributed widely in soft tissue, with $^1/_2$ life ~30 days; 15% of dose sequestered in bone with $^1/_2$ life of >20 years. Excreted mostly in urine, but also appears in other fluids including breast milk. Interferes with mitochondrial oxidative phosphorylation, ATPases, calcium-dependent messengers; enhances oxidation and cell apoptosis.	Acute exposure with blood lead levels (BPb) of > 60–80 μg/dL can cause impaired neurotransmission and neuronal cell death (with central and peripheral nervous system effects); impaired hematopoiesis and renal tubular dysfunction. At higher levels of exposure (e.g., BPb > 80–120 μg/dL), acute encephalopathy with convulsions, coma, and death may occur. Subclinical exposures in children (BPb 25–60 μg/dL) are associated with anemia; mental retardation; and deficits in language, motor function, balance, hearing, behavior, and school performance. Impairment of IQ appears to occur at even lower levels of exposure with no measurable threshold above the limit of detection in most assays of 1 μg/dL. In adults, chronic subclinical exposures (BPb > 40 μg/dL) are associated with an increased risk of anemia, demyelinating peripheral neuropathy (mainly motor), impairments of reaction time, hypertension, ECG conduction delays, interstitial nephritis and chronic renal failure, diminished sperm counts, spontaneous abortions.	Abdominal pain, irritability, lethargy, anorexia, anemia, Fanconi's syndrome, pyuria, azotemia in children with blood lead level (BPb) >80 μg/dL; may also see epiphyseal plate "lead lines" on long bone x-rays. Convulsions, coma at BPb > 120 μg/dL. Noticeable neurodevelopmental delays at BPb of 40–80 μg/dL; may also see symptoms associated with higher BPb levels. In the U.S., screening of all children when they begin to crawl (~6 months) is recommended by the CDC; source identification and intervention is begun if the BPb > 10 μg/dL. In adults, acute exposure causes similar symptoms as in children as well as headaches, arthralgias, myalgias, depression, impaired short-term memory, loss of libido. Physical exam may reveal a "lead line" at the gingiva-tooth border, pallor, wrist drop, and cognitive dysfunction (e.g., declines on the mini-mental status exam); lab tests may reveal a normocytic, normochromic anemia, basophilic stippling, an elevated blood protoporphyrin level (free erythrocyte or zinc), and motor delays on nerve conduction. In the U.S., OSHA requires regular testing of lead-exposed workers with removal if BPb > 40 μg/dL.	Identification and correction of exposure sources is critical. In some U.S. states, screening and reporting to local health boards of children with BPb > 10 μg/dL and workers with BPb > 40 μg/dL is required. In the highly exposed individual with symptoms, chelation is recommended with oral DMSA (succimer); if acutely toxic, hospitalization and IV or IM chelation with edentate calcium disodium (CaEDTA) may be required, with the addition of dimercaprol to prevent worsening of encephalopathy. It is uncertain whether children with asymptomatic lead exposure (e.g., BPb 20–40 μg/dL) benefit from chelation. Correction of dietary deficiencies in iron, calcium, magnesium, and zinc will lower lead absorption and may also improve toxicity. Vitamin C is a weak but natural chelating agent.
		Mercury		
Metallic, mercurous, and mercuric mercury (Hg^0, Hg^+, Hg^{2+}) exposures occur in some chemical, metal-processing, electrical-equipment, automotive industries; they are also in thermometers, dental amalgams, batteries. Mercury is dispersed by waste incineration. Environmental bacteria convert inorganic to organic mercury, which then bioconcentrates up the aquatic food chain to contaminate tuna, swordfish, and other pelagic fish.	Elemental mercury (Hg^0) is not well absorbed; however, it will volatilize into highly absorbable vapor. Inorganic mercury is absorbed through the gut and skin. Organic mercury is well absorbed through inhalation and ingestion. Elemental and organic mercury cross the blood-brain barrier and placenta. Mercury is excreted in urine and feces and has a $^1/_2$ life in blood of ~60 days; however, deposits will remain in the kidney and brain for years. Exposure to mercury stimulates the kidney to produce metallothionein, which provides some detoxification benefit. Mercury binds sulfhydryl groups and interferes with a wide variety of critical enzymatic processes.	Acute inhalation of Hg^0 vapor causes pneumonitis and noncardiogenic pulmonary edema leading to death, CNS symptoms, and polyneuropathy. Chronic high exposure causes CNS toxicity (mercurial *erethism*; see diagnosis); lower exposures impair renal function, motor speed, memory, coordination. Acute ingestion of inorganic mercury causes gastroenteritis, the nephritic syndrome, or acute renal failure, hypertension, tachycardia, and cardiovascular collapse, with death at a dose of 10–42 mg/kg. Ingestion of organic mercury causes gastroenteritis, arrhythmias, and lesions in the basal ganglia, gray matter, and cerebellum at doses >1.7 mg/kg. High exposure during pregnancy causes derangement of fetal neuronal migration resulting in severe mental retardation. Mild exposures during pregnancy (from fish consumption) are associated with declines in neurobehavioral performance in offspring. Dimethylmercury, a compound only found in research labs, is "superoxic"—a few drops of exposure via skin absorption or inhaled vapor can cause severe cerebellar degeneration and death.	Chronic exposure to metallic mercury vapor produces a characteristic intention tremor and mercurial *erethism*: excitability, memory loss, insomnia, timidity, and delirium ("mad as a hatter"). On neurobehavioral tests: decreased motor speed, visual scanning, verbal and visual memory, visuomotor coordination. Children exposed to mercury in any form may develop *acrodynia* ("pink disease"): flushing, itching, swelling, tachycardia, hypertension, excessive salivation or perspiration, irritability, weakness, morbilliform rashes, desquamation of palms and soles. Toxicity from elemental or inorganic mercury exposure begins when blood levels >180 nmol/L (3.6 μg/dL) and urine levels >0.7 μmol/L (15 μg/dL). Exposures that ended years ago may result in a >20-μg increase in 24-h urine after a 2-g dose of succimer. Organic mercury exposure is best measured by levels in blood (if recent) or hair (if chronic); CNS toxicity in children may derive from fetal exposures associated with maternal hair Hg > 30 nmol/g (6 μg/g).	Treat acute ingestion of mercuric salts with induced emesis or gastric lavage and polythiol resins (to bind mercury in the GI tract). Chelate with dimercaprol (up to 24 mg/kg per day IM in divided doses), DMSA (succimer), or penicillamine, with 5-day courses separated by several days of rest. If renal failure occurs, treat with peritoneal dialysis, hemodialysis, or extracorporeal regional complexing hemodialysis and succimer. Chronic inorganic mercury poisoning is best treated with *N*-acetyl penicillamine.

Note: GI, gastrointestinal; ECG, electrocardiogram; ICU, intensive care unit; LFT, liver function tests; RBC, red blood cell; IQ, intelligence quotient; CDC, Centers for Disease Control and Prevention; OSHA, Occupational Safety and Health Administration; CNS, central nervous system.

fects that may be related to cadmium's calciuric effect on the kidney. Such research is creating concern that cadmium exposure may be contributing significantly to morbidity and mortality from osteoporosis in the general population.

Advances in our understanding of *lead* toxicity have recently benefited by the development of K-x-ray fluorescence (KXRF) instruments for making safe in vivo measurements of lead levels in bone (which, in turn, reflect cumulative exposure over many years, as opposed to blood lead levels, which mostly reflect recent exposure). High bone lead levels measured by KXRF have been linked to increased risk of hypertension in both men and women from an urban population. In addition, high maternal bone lead levels were found to predict lower birth weight, head circumference, birth length, and neurodevelopmental performance in offspring by age 2.

The toxicity of low-level organic *mercury* exposure (as manifested by neurobehavioral performance) is of increasing concern based on studies of the offspring of mothers who ingested mercury-contaminated fish. However, current evidence has not supported the recent contention that ethyl mercury, used as a preservative in multiuse vaccines administered in early childhood, has played a significant role in causing neurodevelopmental problems such as autism.

A few additional metals deserve brief mention but are not covered in Table e34-1 because of the relative rarity of their being clinically encountered, or the uncertainty regarding their potential toxicities. *Aluminum* contributes to the encephalopathy in patients with severe renal disease who are undergoing dialysis (Chap. 347). High levels of aluminum are found in the neurofibrillary tangles in the cerebral cortex and hippocampus of patients with Alzheimer's disease, as well as in the drinking water and soil of areas with an unusually high incidence of Alzheimer's. The experimental and epidemiologic evidence for the aluminum–Alzheimer's disease link is so far relatively weak, however, and it cannot be concluded that aluminum is a causal agent or a contributing factor in neurodegenerative disease. Hexavalent chromium is corrosive and sensitizing. Workers in the chromate and chrome pigment production industries have consistently had a greater risk of lung cancer. The introduction of *cobalt* chloride as a fortifier in beer led to outbreaks of fatal cardiomyopathy among heavy consumers. Occupational exposure (e.g., of miners, dry-battery manufacturers, and arc welders) to manganese can cause a Parkinsonian syndrome within 1–2 years, including gait disorders; postural instability; a masked, expressionless face; tremor; and psychiatric symptoms. With the introduction of methylcyclopentadienyl manganese tricarbonyl (MMT) as a gasoline additive, there is concern for the toxic potential of environmental manganese exposure. *Nickel* exposure induces an allergic response, and inhalation of nickel compounds with low aqueous solubility (e.g., nickel subsulfide and nickel oxide) in occupational settings is associated with an increased risk of lung cancer. Overexposure to selenium may cause local irritation of the respiratory system and eyes, gastrointestinal irritation, liver inflammation, loss of hair, depigmentation, and peripheral nerve damage. Workers exposed to certain organic forms of *tin* (particularly trimethyl and triethyl derivatives) have developed psychomotor disturbances, including tremor, convulsions, hallucinations, and psychotic behavior.

Thallium, which is a component of some insecticides, metal alloys, and fireworks, is absorbed through the skin as well as by ingestion and inhalation. Severe poisoning follows a single ingested dose of >1 g or >8 mg/kg. Nausea and vomiting, abdominal pain, and hematemesis precede confusion, psychosis, organic brain syndrome, and coma. Thallium is radiopaque. Induced emesis or gastric lavage is indicated within 4–6 h of acute ingestion; Prussian blue prevents absorption and is given orally at 250 mg/kg in divided doses. Unlike other types of metal poisoning, thallium poisoning may be less severe when activated charcoal is used to interrupt its enterohepatic circulation. Other measures include forced diuresis, treatment with potassium chloride (which promotes renal excretion of thallium), and peritoneal dialysis.

e35 Poisoning and Drug Overdosage

Christopher H. Linden, Michael J. Burns, Mark B. Mycyk

Poisoning refers to the development of dose-related adverse effects following exposure to chemicals, drugs, or other xenobiotics. To paraphrase Paracelsus, the dose makes the poison. In excessive amounts, substances that are usually innocuous, such as oxygen and water, can cause poisoning. Conversely, in small doses, substances commonly regarded as poisons, such as arsenic and cyanide, can be consumed without ill effect. There is, however, substantial individual variability in the response to, and disposition of, a given dose. Some of this variability is genetic, and some is acquired on the basis of enzyme induction or inhibition, or because of tolerance. Poisoning may be local (e.g., skin, eyes, or lungs) or systemic depending on the chemical and physical properties of the poison, its mechanism of action, and the route of exposure. The severity and reversibility of poisoning also depend on the functional reserve of the individual or target organ, which is influenced by age and preexisting disease.

EPIDEMIOLOGY

About 5 million poison exposures occur in the United States each year. Most are acute, accidental (unintentional), involve a single agent, occur in the home, result in minor or no toxicity, and involve children under 6 years of age. Pharmaceuticals are involved in 47% of exposures and 84% of serious or fatal poisonings. Unintentional exposures can result from the improper use of chemicals at work or play; product mislabeling; label misreading; mistaken identification of unlabeled chemicals; uninformed self-medication; and dosing errors by nurses, parents, pharmacists, physicians, and the elderly. Excluding the recreational use of ethanol, attempted suicide (deliberate self-harm) is the most common reason for intentional exposure. Unintended poisonings may result from the recreational use of prescribed and over-the-counter drugs for psychotropic or euphoric effects (abuse) or excessive self-dosing (misuse).

About 25% of exposures require health professional evaluation, and 5% of all exposures require hospitalization. Poisonings account for 5–10% of all ambulance transports, emergency department visits, and intensive care unit admissions. Up to 30% of psychiatric admissions are prompted by attempted suicide via overdosage. Overall, the mortality rate is low: 0.4% of all exposures. It is much higher (1–2%) in hospitalized patients with intentional (suicidal) overdose, who account for the majority of serious poisonings. Acetaminophen is the pharmaceutical agent most often implicated in fatal poisoning. Overall, carbon monoxide is the leading cause of death from poisoning, but this is not reflected in hospital or poison center statistics because patients with such poisoning are typically dead when discovered and are referred directly to medical examiners.

DIAGNOSIS

Although poisoning can mimic other illnesses, the correct diagnosis can usually be established by the history, physical examination, routine and toxicologic laboratory evaluations, and characteristic clinical course. The *history* should include the time, route, duration, and circumstances (location, surrounding events, and intent) of exposure; the name and amount of each drug, chemical, or ingredient involved; the time of onset, nature, and severity of symptoms; the time and type of first aid measures provided; and the medical and psychiatric history.

In many cases the victim is confused, comatose, unaware of an exposure, or unable or unwilling to admit to one. Suspicious circumstances include unexplained illness in a previously healthy person; a history of psychiatric problems (particularly depression); recent changes in health, economic status, or social relationships; and onset of illness while working with chemicals or after ingesting food, drink (especially ethanol), or medications. Patients who become ill soon after arriving from a foreign country or being arrested for criminal activity should be suspected of "body packing" or "body stuffing" (ingesting or concealing illicit drugs in a body cavity). Relevant history may be available from family, friends, paramedics, police, pharmacists, physicians, and employers, who should be questioned regarding the patient's habits, hobbies, behavior changes, available medications, and antecedent events. A search of clothes, belongings, and place of discovery may reveal a suicide note or a container of drugs or chemicals. The imprint code on pills and the label on chemical products may be used to identify the ingredients and potential toxicity of a suspected poison by consulting a reference text, a computerized database, the manufacturer, or a regional poison information center. Occupational exposures require review of available MSDS (Material Safety Data Sheets) from the worksite.

The *physical examination* should focus initially on the vital signs, cardiopulmonary system, and neurologic status. The neurologic examination should include documentation of neuromuscular abnormalities such as dyskinesia, dystonia, fasciculations, myoclonus, rigidity, tremors. The patient should also be examined for evidence of trauma and underlying illnesses. Focal neurologic findings are uncommon in poisoning, and their presence should prompt evaluation for a structural central nervous system (CNS) lesion. Examination of the eyes (for nystagmus, pupil size and reactivity), abdomen (for bowel activity and bladder size), and skin (for burns, bullae, color, warmth, moisture, pressure sores, and puncture marks) may reveal findings of diagnostic value. When the history is unclear, all orifices should be examined for the presence of chemical burns and drug packets. The odor of breath or vomitus and the color of nails, skin, or urine may provide diagnostic clues.

The diagnosis of poisoning in cases of unknown etiology primarily relies on pattern recognition. The first step is to assess the pulse, blood pressure, respiratory rate, temperature, and neurologic status and characterize the overall physiologic state as stimulated, depressed, discordant, or normal (Table e35-1). Obtaining a complete set of vital signs and reassessing them frequently are critical. Measuring core temperature is especially important, even in difficult or combative patients, since temperature elevation is the most reliable prognosticator of poor outcome in poisoning. The next step is to consider the underlying causes of the observed physiologic state and attempt to identify a pathophysiologic pattern or toxic syndrome (*toxidrome*) based on further analysis of the vital signs, neurologic status, and other physical findings. Assessing the severity of physiologic derangements (Table e35-2) is useful in this regard and also for assessing the clinical course and response to treatment. The final step is to attempt to identify the particular agent involved by looking for unique or relatively poison-specific physical or ancillary test abnormalities. This approach is summarized below.

Increased pulse, blood pressure, respiratory rate, temperature, and neuromuscular activity characterize the stimulant toxidromes: sympathetic, antimuscarinic (anticholinergic), hallucinogen poisoning and drug withdrawal (Table e35-1). Other features are noted in Table e35-2. Mydriasis, a characteristic feature of all stimulant toxidromes, is most marked in antimuscarinic (anticholinergic) poisoning since pupillary reactivity relies on muscarinic control; in sympathetic poisoning (e.g., cocaine), pupils are also enlarged but some reactivity to light is observed. The anticholinergic (antimuscarinic) toxidrome is also distinguished by the presence of hot, dry, flushed skin; decreased bowel sounds; and urinary retention (Table e35-1). Other stimulant toxidromes increase sympathetic activity and cause diaphoresis, pallor, and increased bowel activity with varying degrees of nausea, vomiting, abnormal distress, and occasionally diarrhea. The absolute and relative degree of vital sign changes and neuromuscular hyperactivity can help distinguish among stimulant toxidromes. Since sympathetics stimulate the peripheral nervous system more directly than do hallucinogens or drug withdrawal, markedly increased vital signs and organ ischemia suggest sympathetic poisoning. Findings helpful in suggesting the particular drug or class causing physiologic stimulation include reflex

TABLE e35-1 DIFFERENTIAL DIAGNOSIS OF POISONING BASED ON PHYSIOLOGIC STATE

Stimulated	Depressed	Discordant	Normal
Sympathetics	Sympatholytics	Asphyxiants	Nontoxic exposure
Sympathomimetics	α_1-Adrenergic antagonists	Cytochrome oxidase inhibitors	Psychogenic illness
Ergot alkaloids	α_2-Adrenergic agonists	Inert gases	Toxic time-bombs
Methylxanthines	ACE inhibitors	Irritant gases	Slow absorption
Monoamine oxidase inhibitors	Angiotensin receptor blockers	Methemoglobin inducers	Anticholinergics
Thyroid hormones	Antipsychotics	Oxidative phosphorylation inhibitors	Carbamazepine
Anticholinergics	β-adrenergic blockers	AGMA inducers	Concretion formers
Antihistamines	Calcium channel blockers	Alcohol (ketoacidosis)	Dilantin Kapseals
Antiparkinsonian agents	Cardiac glycosides	Ethylene glycol	Drug packets
Antipsychotics	Cyclic antidepressants	Iron	Enteric-coated pills
Antispasmodics	Cholinergics	Methanol	Lomotil
Belladonna alkaloids	Acetylcholinesterase inhibitors	Salicylate	Opioids
Cyclic antidepressants	Muscarinic agonists	Toluene	Salicylates
Muscle relaxants	Nicotinic agonists	CNS syndromes	Sustained-release pills
Mushrooms and plants	Opioids	Extrapyramidal reactions	Slow distribution
Hallucinogens	Analgesics	Hydrocarbon inhalation	Cardiac glycosides
Cannabinoids (marijuana)	GI antispasmodics	Isoniazid	Lithium
LSD and analogues	Heroin	Lithium	Metals
Mescaline and analogues	Sedative-hypnotics	Neuroleptic malignant syndrome	Salicylate
Mushrooms	Alcohols	Serotonin syndrome	Toxic metabolite
Phencyclidine and analogues	Anticonvulsants	Strychnine	Acetaminophen
Withdrawal syndromes	Barbiturates	Membrane-active agents	Carbon tetrachloride
Barbiturates	Benzodiazepines	Amantidine	Cyanogenic glycosides
Benzodiazepines	GABA precursors	Antiarrhythmics	Ethylene glycol
Ethanol	Muscle relaxants	Antihistamines	Methanol
Opioids	Other agents	Antipsychotics	Methemoglobin inducers
Sedative-hypnotics	GHB Products	Carbamazepine	Mushroom toxins
Sympatholytics		Cyclic antidepressants	Organophosphate insecticides
		Local anesthetics	Paraquat
		Opioids (some)	Metabolism disruptors
		Orphenadrine	Antineoplastic agents
		Quinoline antimalarials	Antiviral agents
			Colchicine
			Hypoglycemic agents
			Immunosuppressive agents
			MAO inhibitors
			Metals
			Salicylate
			Warfarins

Note: ACE, angiotensin-converting enzyme; AGMA, anion-gap metabolic alkalosis; GHB, γ-hydroxybutyric; GI, gastrointestinal; CNS, central nervous system; LSD, lysergic acid diethylamide; GABA, γ-aminobutyric acid; MAO; monoamine oxidase; GHB, γ-hydroxybutyric.

bradycardia from selective α-adrenergic stimulants (e.g., decongestants), hypotension from selective β-adrenergic stimulants (e.g., asthma therapeutics), limb ischemia from ergot alkaloids, nystagmus from phencyclidine and ketamine (the only physiologic stimulants that cause this finding), and delayed cardiac conduction from high doses of cocaine and some anticholinergic agents (e.g., antihistamines, cyclic antidepressants, and antipsychotics). Seizures suggest a sympathetic etiology, an anticholinergic agent with membrane-active properties (e.g., cyclic antidepressants, orphenadrine, phenothiazines), or a withdrawal syndrome. Other manifestations of grade 4 physiologic stimulation (Table e35-2) are likely only in sympathetic poisoning. Close attention to core temperature is critical in these patients.

Decreased pulse, blood pressure, respiratory rate, temperature, and neuromuscular activity are indicative of physiologic depression caused by "functional" sympatholytics (agents that decrease cardiac function and vascular tone as well as symthathetic activity), cholinergic (muscarinic and nicotinic) agents, opioids, and sedative-hypnotic γ-aminobutyric acid (GABA)-ergic] agents (Tables e35-1 and e35-2). Miosis is also common and most pronounced in opioid and cholinergic poisoning. The latter is distinguished from other depressant toxidromes by the presence of muscarinic and nicotinic signs and symptoms (Table e35-1). Pronounced cardiovascular depression in the absence of significant CNS depression suggests a direct or peripherally acting sympatholytic. In contrast, in opioid and sedative-hypnotic poisoning, vital sign changes are secondary to depression of CNS cardiovascular and respiratory centers (or consequent hypoxemia) and significant abnormalities in these parameters do not occur until there is a marked decrease in the level of consciousness (grade 3 or 4 physiologic depression, Table e35-2). Other clues that suggest the cause of physiologic depression include cardiac arrhythmias and conduction disturbances (due to antiarrhythmics, β-adrenergic antagonists, calcium-channel blockers, digitalis glycosides, propoxyphene, and cyclic antidepressants), mydriasis [due to tricyclic antidepressants, some antiarrhythmics, meperidine, and diphenoxylate-atropine (Lomotil)], nystagmus (due to sedative-hypnotics), and seizures (due to cholinergic agents, propoxyphene, cyclic antidepressants).

Discordant or mixed vital sign and neuromuscular abnormalities are characteristic of poisoning by asphyxiants, CNS syndromes, membrane-active agents, and anion-gap metabolic acidosis (AGMA) inducers (Table e35-1). In these conditions, manifestations of physiologic stimulation and physiologic depression occur together or at different times during the clinical course. For example, membrane-active agents can cause simultaneous coma, seizures, hypotension, and tachyarrhythmias. Alternatively, vital signs may be normal but the patient has altered mental status or is obviously sick or clearly symptomatic. Early, pronounced vital sign and mental status changes suggest asphyxiant or membrane-active agent poisoning; the lack of such abnormalities suggests an AGMA inducer, and marked neuromuscular dysfunction without significant vital sign abnormalities suggests a CNS syndrome. As noted below, AGMA inducer poisoning can be distinguished from other causes of AGMA by the serum lactate concentration.

A normal physiologic status and physical examination may be due to a nontoxic exposure, psychogenic illness, or poisoning by "toxic time-bombs," agents that are slowly absorbed, slowly distributed to

TABLE e35-2 SEVERITY OF PHYSIOLOGIC STIMULATION AND DEPRESSION IN POISONING AND DRUG WITHDRAWAL

Physiologic Stimulation	
Grade 1	Anxious, irritable, tremulous; vital signs normal; diaphoresis, flushing or pallor, mydriasis, and hyperreflexia may be present
Grade 2	Agitated; may have confusion or hallucinations but is able to converse and follow commands; vital signs mildly to moderately increased
Grade 3	Delirious; unintelligible speech, uncontrollable motor hyperactivity; moderately to markedly increased vital signs; tachyarrhythmias possible
Grade 4	Coma, seizures, cardiovascular collapse
Physiologic Depression	
Grade 1	Awake, lethargic, or sleeping but arousable by voice or tactile stimulation; able to converse and follow commands; may be confused
Grade 2	Responds to pain but not voice; can vocalize but not converse; spontaneous motor activity present; brainstem reflexes intact
Grade 3	Unresponsive to pain; spontaneous motor activity absent; brainstem reflexes depressed; motor tone, respirations, and temperature decreased
Grade 4	Unresponsive to pain; flaccid paralysis; brainstem reflexes and respirations absent; cardiovascular vital signs decreased

their sites of action, require metabolic activation, or disrupt metabolic processes (Table e35-1). Because so many medications are now reformulated in a once-a-day form for patient convenience and adherance, "toxic time-bombs" are increasingly common. Diagnosing a nontoxic exposure requires that the identity of the exposure agent be known or that a toxic time-bomb exposure has been excluded and that the time since exposure exceeds the longest known or predicted interval between exposure and peak toxicity. Psychogenic illness (fear of being poisoned, mass hysteria) may also occur after a nontoxic exposure and should be considered when symptoms are inconsistent with the exposure history. Anxiety reactions resulting from a nontoxic exposure can cause mild physiologic stimulation (Table e35-2) and be indistinguishable from toxicologic causes (Table e35-1) without ancillary testing or a suitable period of observation.

Laboratory assessment may be helpful in the differential diagnosis (Fig. e35-1). An increased AGMA is characteristic of advanced methanol, ethylene glycol, and salicylate intoxication but can occur with other agents (Table e35-1) and in any poisoning that results in hepatic, renal, or respiratory failure; seizures; or shock. The serum lactate concentration is low (less than the anion gap) in the former and high (nearly equal to the anion gap) in the latter. An abnormally low anion gap can be due to elevated blood levels of bromide, calcium, iodine, lithium, magnesium, or nitrate. An increased osmolal gap—a difference between the serum osmolality (measured by freezing point depression) and that calculated from the serum sodium, glucose, and blood urea nitrogen of >10 mmol/L—suggests the presence of a low-molecular-weight solute such as acetone, an alcohol (benzyl, ethanol, isopropanol, methanol), a glycol (diethylene, ethylene, propylene), ether (ethyl, glycol), or an "unmeasured" cation (calcium, magnesium) or sugar (glycerol, mannitol, sorbitol). Ketosis suggests acetone, isopropyl alcohol, or salicylate poisoning. Hypoglycemia may be due to poisoning with β-adrenergic blockers, ethanol, insulin, oral hypoglycemic agents, quinine, and salicylates, whereas hyperglycemia can occur in poisoning with acetone, β-adrenergic agonists, caffeine, calcium channel blockers, iron, theophylline, or N-3-pyridylmethyl-N′-p-nitrophenylurea (PNU, Vacor). Hypokalemia can be caused by barium, β-adrenergic agonists, caffeine, diuretics, theophylline, or toluene; hyperkalemia suggests poisoning with an α-adrenergic agonist, a β-adrenergic blocker, cardiac glycosides, or fluoride. Hypocalcemia may be seen in ethylene glycol, fluoride, and oxalate poisoning.

The *electrocardiogram* (ECG) can sometimes be useful for rapid diagnostic purposes. Bradycardia and atrioventricular block may occur in patients poisoned by α-adrenergic agonists, antiarrhythmic agents, beta blockers, calcium channel blockers, cholinergic agents (carbamate and organophosphate insecticides), cardiac glycosides, lithium, magnesium, or tricyclic antidepressants. QRS- and QT-interval prolongation may be caused by hyperkalemia and by membrane-active drugs (Table e35-1). Ventricular tachyarrhythmias may be seen in poisoning with cardiac glycosides, fluorides, membrane-active drugs, methylxanthines, sympathomimetics, and agents that cause hyperkalemia or potentiate the effects of endogenous catecholamines (e.g., chloral hydrate, aliphatic and halogenated hydrocarbons).

Radiologic studies may also be useful. Pulmonary edema (adult respiratory distress syndrome, or ARDS) can be caused by poisoning with carbon monoxide, cyanide, an opioid, paraquat, phencyclidine, a sedative-hypnotic, or salicylate; by inhalation of irritant gases, fumes, or vapors (acids and alkali, ammonia, aldehydes, chlorine, hydrogen sulfide, isocyanates, metal oxides, mercury, phosgene, polymers); or by prolonged anoxia, hyperthermia, or shock. Aspiration pneumonia is common in patients with coma, seizures, and petroleum distillate ingestion. The presence of radiopaque densities on abdominal x-rays suggests the ingestion of calcium salts, chloral hydrate, chlorinated hydrocarbons, heavy metals, illicit drug packets, iodinated compounds, potassium salts, psychotherapeutic agents, lithium, phenothiazines, enteric-coated tablets, or salicylates.

Toxicologic analysis of urine and blood (and occasionally of gastric contents and chemical samples) can sometimes confirm or rule out suspected poisoning. Interpretation of laboratory data requires knowledge of the tests used for screening and confirmation (thin-layer, gas-liquid, or high-performance liquid chromatography; colorimetric and fluorometric assays; enzyme-multiplied, fluorescence polarization, and radio-

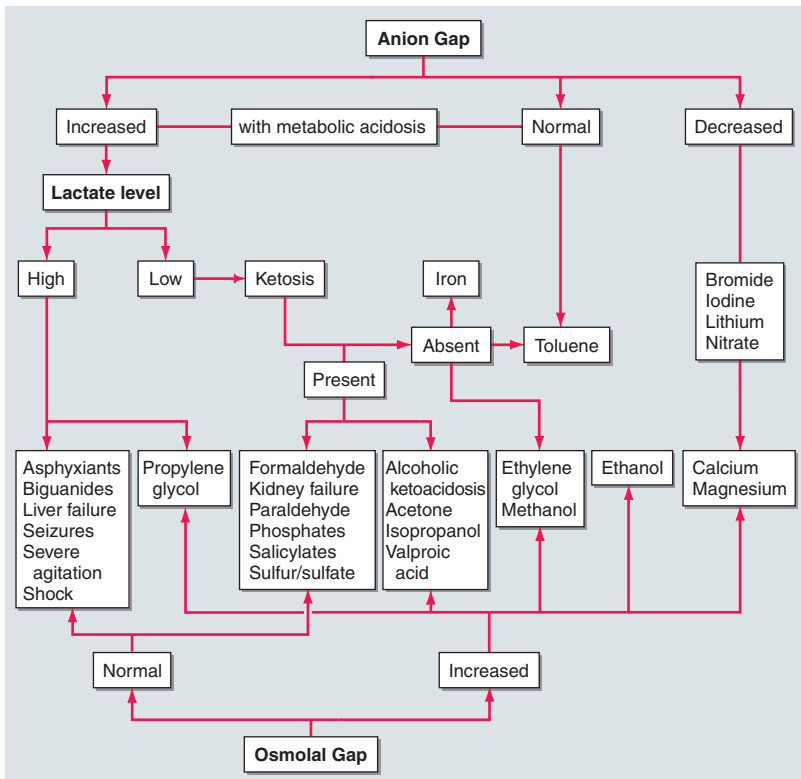

FIGURE e35-1 Differential diagnosis of poisoning based on the results of routine laboratory tests.

Copyright © 2008 The McGraw-Hill Companies. All rights reserved.

immunoassays; gas chromatography; mass spectrometry), their sensitivity (limit of detection) and specificity, the preferred biologic specimen for analysis, and the optimal time of specimen sampling. Personal communication with the laboratory is essential. A negative result may mean the substance is not detectable by the test used or that its concentration is too low for detection at the time of sampling. In the latter case, repeating the test at a later time may yield a positive result.

Although rapid qualitative screening tests for a limited number of drugs of abuse are available, comprehensive screening tests require 2–6 h for completion. Thus, immediate management must often be based on the history, physical examination, and routine bedside ancillary tests (e.g., ECG). In addition, when the patient is asymptomatic, or when the clinical picture is consistent with the reported history, qualitative screening is neither clinically useful nor cost-effective. It is of greatest value in patients with severe or unexplained toxicity such as coma, seizures, cardiovascular instability, metabolic or respiratory acidosis, and non-sinus cardiac rhythms. Quantitative analysis is useful for poisoning with acetaminophen (Chap. 299), acetone, alcohols (including ethylene glycol and methanol), antiarrhythmics, anticonvulsants, barbiturates, digoxin, heavy metals, lithium, salicylate, and theophylline, as well as for carboxyhemoglobin and methemoglobin. Results can often be available within an hour.

The *response to antidotes* may be useful for diagnostic purposes. Resolution of altered mental status and abnormal vital signs within minutes of IV administration of dextrose, naloxone, or flumazenil is virtually diagnostic of hypoglycemia, narcotic poisoning, and benzodiazepine intoxication, respectively. The prompt reversal of dystonic (extrapyramidal) signs and symptoms following an IV dose of benztropine or diphenhydramine confirms a drug etiology. Although complete reversal of both central and peripheral manifestations of anticholinergic poisoning by physostigmine is diagnostic of this condition, physostigmine may cause some arousal in patients with CNS depression of any etiology.

POISONING AND DRUG OVERDOSE

GENERAL PRINCIPLES Treatment goals include support of vital signs, prevention of further poison absorption, enhancement of poison elimination, administration of specific antidotes, and prevention of reexposure **(Table e35-3)**. Specific treatment depends on the identity of the poison, the route and amount of exposure, the time of presentation relative to the time of exposure, and the severity of poisoning. Knowledge of the offending agents' pharmacokinetics and pharmacodynamics is essential.

During the *pretoxic phase*, prior to the onset of poisoning, decontamination is the highest priority, and treatment is based solely on the history. The maximum potential toxicity based on the greatest possible exposure should be assumed. Since decontamination is more effective when accomplished soon after exposure, the initial history and physical examination should be focused and brief. It is also advisable to establish IV access and initiate cardiac monitoring, particularly in patients with potentially serious ingestions or unclear histories.

When an accurate history is not obtainable and a poison causing delayed toxicity or irreversible damage is suspected, blood and urine should be sent for toxicologic screening and, if indicated, for quantitative analysis. During absorption and distribution, blood levels may be greater than those in tissue and may not correlate with toxicity. However, high blood levels of agents whose metabolites are more toxic than the parent compound (acetaminophen, ethylene glycol, or methanol) may indicate the need for additional interventions (antidotes, dialysis).

Most patients who remain or become asymptomatic 4–6 h after ingestion will not develop subsequent toxicity and can be discharged safely. Longer observation will likely be necessary for patients who have ingested toxic time-bombs, agents that are slowly absorbed, slowly distributed to their sites of action, require metabolic activation, or disrupt metabolic processes (Table e35-1). During the *toxic phase*, the time between the onset of poisoning and the peak effects, management is based primarily on clinical and laboratory findings. *Effects after an overdose usually begin sooner, peak later, and last longer than they do after a therapeutic dose.* A drug's published pharmacokinetic profile in standard references like the Physician's Desk Reference (PDR) is usually different from its toxicokinetic profile in overdose. Resuscitation and stabilization are the first priority. Symptomatic patients should have an IV line, oxygen saturation determination, cardiac monitoring, and continuous observation. Baseline laboratory, ECG, and x-ray evaluation may also be appropriate. Intravenous glucose (unless the serum level is documented to be normal), naloxone, and thiamine should be considered in patients with altered mental status, particularly those with coma or seizures. Decontamination should also be considered, but it is less likely to be effective during this phase than during the pretoxic one.

TABLE e35-3 FUNDAMENTALS OF POISONING MANAGEMENT

Supportive Care	
Airway protection	Treatment of seizures
Oxygenation/ventilation	Correction of temperature abnormalities
Treatment of arrhythmias	Correction of metabolic derangements
Hemodynamic support	Prevention of secondary complications
Prevention of Further Poison Absorption	
Gastrointestinal decontamination	Decontamination of other sites
Syrup of ipecac–induced emesis	Eye decontamination
Gastric lavage	Skin decontamination
Activated charcoal	Body cavity evacuation
Whole-bowel irrigation	
Catharsis	
Dilution	
Endoscopic/surgical removal	
Enhancement of Poison Elimination	
Multiple-dose activated charcoal	Extracorporeal removal
Diuresis	Peritoneal dialysis
Alteration of urinary pH	Hemodialysis
Chelation	Hemoperfusion
	Hemofiltration
	Plasmapheresis
	Exchange transfusion
	Hyperbaric oxygenation
Administration of Antidotes	
Neutralization by antibodies	Metabolic antagonism
Neutralization by chemical binding	Physiologic antagonism
Prevention of Reexposure	
Adult education	Notification of regulatory agencies
Child-proofing	Psychiatric referral

Measures that enhance poison elimination may shorten the duration of toxicity and lessen its severity. However, they are not without risk, which must be weighed against the potential benefit. Diagnostic certainty (usually via laboratory confirmation) is generally a prerequisite. Intestinal (or "gut") dialysis with repetitive doses of activated charcoal is usually safe and can enhance the elimination of selected poisons. Urinary alkalinization and chelation therapy enhance the elimination of a relatively small number of poisons, and their use is associated with potential complications. Extracorporeal elimination methods are effective for many poisons, but their expense and risk make their use reasonable only in patients who would otherwise have an unfavorable outcome.

During the *resolution phase* of poisoning, supportive care and monitoring should continue until clinical, laboratory, and ECG abnormalities have resolved. Since chemicals are eliminated sooner from the blood than from tissues, blood levels are usually lower than tissue levels during this phase and again may not correlate with toxicity. This is particularly true when extracorporeal elimination procedures are used. Redistribution from tissues may cause a rebound increase in the blood level after termination of these procedures. When a metabolite is responsible for toxic effects, continued treatment might be necessary in the absence of clinical toxicity or abnormal laboratory studies.

SUPPORTIVE CARE The goal of supportive therapy is to maintain physiologic homeostasis until detoxification is accomplished and to prevent and treat secondary complications such as aspiration, bedsores, cerebral and pulmonary edema, pneumonia, rhabdomyolysis, renal failure, sepsis, thromboembolic disease, coagulopathy, and generalized organ dysfunction due to hypoxia or shock.

Copyright © 2008 The McGraw-Hill Companies. All rights reserved.

Admission to an intensive care unit is indicated for the following: patients with severe poisoning (coma, respiratory depression, hypotension, cardiac conduction abnormalities, cardiac arrhythmias, hypothermia or hyperthermia, seizures); those needing close monitoring, antidotes, or enhanced elimination therapy; those showing progressive clinical deterioration; and those with significant underlying medical problems. Patients with mild to moderate toxicity can be managed on a general medical service, intermediate care unit, or emergency department observation area, depending on the anticipated duration and level of monitoring needed (intermittent clinical observation versus continuous clinical, cardiac, and respiratory monitoring). Patients who have attempted suicide require continuous observation and measures to prevent self-injury until they are no longer suicidal.

Respiratory Care Endotracheal intubation for protection against the aspiration of gastrointestinal contents is of paramount importance in patients with CNS depression or seizures as this complication can increase morbidity and mortality. Mechanical ventilation may be necessary for patients with respiratory depression or hypoxia and to facilitate therapeutic sedation or paralysis in order to prevent or treat hyperthermia, acidosis, and rhabdomyolysis associated with neuromuscular hyperactivity. Since clinical assessment of respiratory function can be inaccurate, the need for oxygenation and ventilation is best determined by continuous pulse oximetry or arterial blood-gas analysis. The gag reflex is not a reliable indicator of the need for intubation. A patient with CNS depression may maintain airway patency while being stimulated but not if left alone. Those who cannot respond to voice or who are unable to sit and drink fluids without assistance are best managed by prophylactic intubation.

Drug-induced pulmonary edema is usually noncardiac rather than cardiac in origin, although profound CNS depression and cardiac conduction abnormalities suggest the latter. Measurement of pulmonary artery pressure may be necessary to establish the cause and direct appropriate therapy. Extracorporeal measures (membrane oxygenation, venoarterial perfusion, cardiopulmonary bypass) and partial liquid (perfluorocarbon) ventilation may be appropriate for severe but reversible respiratory failure.

Cardiovascular Therapy Maintenance of normal tissue perfusion is critical for complete recovery to occur once the offending agent has been eliminated. If hypotension is unresponsive to volume expansion, treatment with norepinephrine, epinephrine, or high-dose dopamine may be necessary. Intraaortic balloon pump counterpulsation and venoarterial or cardiopulmonary perfusion techniques should be considered for severe but reversible cardiac failure. Bradyarrhythmias associated with hypotension generally should be treated as described in Chap. 225. Glucagon, calcium, and high-dose insulin with dextrose may be effective in both beta blocker and calcium channel blocker poisoning. Antibody therapy may be indicated for cardiac glycoside poisoning.

Supraventricular tachycardia associated with hypertension and CNS excitation is almost always due to agents that cause generalized physiologic excitation (Table e35-1). Most cases are mild or moderate in severity and require only observation or nonspecific sedation with a benzodiazepine. In severe cases or those associated with hemodynamic instability, chest pain, or ECG evidence of ischemia, specific therapy is indicated. When the etiology is sympathetic hyperactivity, treatment with a benzodiazepine should be prioritized. Further treatment with a combined alpha and beta blocker (labetalol), a calcium channel blocker (verapamil or diltiazem), or a combination of a beta blocker and a vasodilator (esmolol and nitroprusside) may be considered for cases refractory to high doses of benzodiazepines. Treatment with an α-adrenergic antagonist (phentolamine) alone may sometimes be appropriate. If the cause is anticholinergic poisoning, physostigmine is the treatment of choice. Supraventricular tachycardia without hypertension is generally secondary to vasodilation or hypovolemia and responds to fluid administration.

For ventricular tachyarrhythmias due to tricyclic antidepressants and probably other membrane-active agents (Table e35-1), sodium bicarbonate is indicated, whereas class IA, IC, and III antiarrhythmic agents are contraindicated because of similar electrophysiologic effects. Although lidocaine and phenytoin are historically safe for ventricular tachyarrhythmias of any etiology, sodium bicarbonate should be considered first for any ventricular arrhythmia suspected to have a toxicologic etiology. Beta blockers can be hazardous if the arrhythmia is due to sympathetic hyperactivity. Magnesium sulfate and overdrive pacing (by isoproterenol or a pacemaker) may be useful in patients with torsades des pointes and prolonged QT intervals. Magnesium and anti-digoxin antibodies should be considered in patients with severe cardiac glycoside poisoning. Invasive (esophageal or intracardiac) ECG recording may be necessary to determine the origin (ventricular or supraventricular) of wide-complex tachycardias (Chap. 226). If the patient is hemodynamically stable, however, it is reasonable to simply observe them rather than to administer another potentially proarrhythmic agent. Arrhythmias may be resistant to drug therapy until underlying acid-base, electrolyte, oxygenation, and temperature derangements are corrected.

Central Nervous System Therapies Neuromuscular hyperactivity and seizures can lead to hyperthermia, lactic acidosis, and rhabdomyolysis, with their attendant complications, and should be treated aggressively. Seizures caused by excessive stimulation of catecholamine receptors (sympathomimetic or hallucinogen poisoning and drug withdrawal) or decreased activity of GABA (isoniazid poisoning) or glycine (strychnine poisoning) receptors are best treated with agents that enhance GABA activity, such as benzodiazepine or barbiturates. Since benzodiazepines and barbiturates act by slightly different mechanisms (the former increases the frequency and the latter increases the duration of chloride channel opening in response to GABA), therapy with both may be effective when neither is effective alone. Seizures caused by isoniazid, which inhibits the synthesis of GABA at several steps by interfering with the cofactor pyridoxine (vitamin B_6), may require high doses of supplemental pyridoxine. Seizures resulting from membrane destabilization (beta blocker or cyclic antidepressant poisoning) require GABA enhancers (benzodiazepines first, barbiturates second). Phenytoin is contraindicated in toxicologic seizures: animal and human data demonstrate worse outcomes after phenytoin loading, especially in theophylline overdose. For poisons with central dopaminergic effects (phencyclidine) manifested by psychotic behavior, a dopamine receptor antagonist, such as haloperidol, may be useful. In anticholinergic and cyanide poisoning, specific antidotal therapy may be necessary. The treatment of seizures secondary to cerebral ischemia or edema or to metabolic abnormalities should include correction of the underlying cause. Neuromuscular paralysis is indicated in refractory cases. Electroencephalographic monitoring and continuing treatment of seizures are necessary to prevent permanent neurologic damage. Serotonergic receptor overstimulation in serotonin syndrome may be treated with cyproheptadine.

Other Measures Temperature extremes, metabolic abnormalities, hepatic and renal dysfunction, and secondary complications should be treated by standard therapies.

PREVENTION OF POISON ABSORPTION

Gastrointestinal Decontamination Whether or not to perform gastrointestinal decontamination, and which procedure to use, depends on the time since ingestion; the existing and predicted toxicity of the ingestant; the availability, efficacy, and contraindications of the procedure; and the nature, severity, and risk of complications. The efficacy of activated charcoal, gastric lavage, and syrup of ipecac decreases with time, and there are insufficient data to support or exclude a beneficial effect when they are used >1 h after ingestion. The average time from ingestion to presentation for treatment is >1 h for children and >3 h for adults. Most patients will recover from poisoning uneventfully with good supportive care alone, but complications of gastrointestinal decontamination, particularly aspiration, can prolong this process. Hence, gastrointestinal decontamination should be performed selectively, not routinely, in the management of overdose patients. It is clearly unnecessary when predicted toxicity is minimal or the time of expected maximal toxicity has passed without significant effect.

Activated charcoal has comparable or greater efficacy, fewer contraindications and complications, and is less aversive and invasive than ipecac or gastric lavage; thus it is the preferred method of gastrointestinal decontamination in most situations. Activated charcoal suspension (in water) is given orally via a cup, straw, or small-bore nasogastric tube. The recommended dose is 1 g/kg body weight. Palatability may be increased by adding a sweetener (sorbitol) or a flavoring agent (cherry, chocolate, or cola syrup) to the suspension. Charcoal adsorbs ingested poisons within the gut lumen, allowing the charcoal-toxin complex to be evacuated with stool. In vitro, charcoal adsorbs ≥90% of most substances when given in an amount equal to 10 times the weight of the substance. Charged (ionized) chemicals such as mineral acids, alkalis, and highly dissociated salts of cyanide, fluoride, iron, lithium, and other inorganic compounds are not well

Copyright © 2008 The McGraw-Hill Companies. All rights reserved.

adsorbed by charcoal. In animal and human volunteer studies, charcoal decreases the absorption of ingestants by an average of 73% when given within 5 min of ingestant administration, 51% when given at 30 min, and 36% at 60 min. Side effects of charcoal include nausea, vomiting, and diarrhea or constipation. Charcoal may also prevent the absorption of orally administered therapeutic agents. Complications include mechanical obstruction of the airway, aspiration, vomiting, and bowel obstruction and infarction caused by inspissated charcoal. Charcoal is not recommended for patients who have ingested corrosives because it obscures endoscopy.

Gastric lavage is performed by sequentially administering and aspirating ~5 mL fluid per kilogram of body weight through a no. 40 French orogastric tube (no. 28 French tube for children). Except for infants, where normal saline is recommended, tap water is acceptable. The patient should be placed in Trendelenburg and left lateral decubitus positions to prevent aspiration (even if an endotracheal tube is in place). Lavage decreases ingestant absorption by an average of 52% if performed within 5 min of ingestion administration, 26% if performed at 30 min, and 16% if performed at 60 min. Its efficacy is similar to that of ipecac. Significant amounts of ingested drug are recovered in ~10% of patients. Aspiration is a common complication (occurring in up to 10% of patients), especially when lavage is perfomed improperly. Serious complications (esophageal and gastric perforation, tube misplacement in the trachea) occur in ~1% of patients. For this reason, the physician should personally insert the lavage tube and confirm its placement, and the patient must be cooperative or adequately restrained (with pharmacologic sedation if necessary) during the procedure. Gastric lavage is contraindicated in corrosive or petroleum distillate ingestions because of the respective risks of gastroesophageal perforation and aspiration pneumonitis. It is also contraindicated in those with a compromised unprotected airway and those at risk for hemorrhage or perforation due to esophageal or gastric pathology or recent surgery. Finally, gastric lavage is absolutely contraindicated in combative patients or those who refuse, as most published complications involve patient resistance to the procedure.

Syrup of ipecac, once the most commonly used decontamination procedure, has no role in the hospital setting. Even the American Academy of Pediatrics (AAP), traditionally the strongest proponent of ipecac, issued a policy statement in 2003 recommending that ipecac should no longer be used in poisoning treatment. Some argue it can still be considered for the home management of patients with unintentional ingestions, reliable histories, and mild predicted toxicity when transport to a hospital site is prolonged. Ipecac irritates the stomach and stimulates the central chemoreceptor trigger zone. Vomiting usually occurs about 20 min after administration. Nausea and vomiting from ipecac may prevent use of other, more effective decontamination procedures. Chronic ipecac use (by patients with anorexia nervosa or bulimia) may cause electrolyte and fluid abnormalities, cardiac toxicity, and myopathy. Except for aspiration, serious complications (e.g., gastric or esophageal tears and perforations) are rare. Ipecac is contraindicated in patients with recent gastrointestinal surgery, CNS depression, or seizures, and in those who have ingested corrosives or rapidly acting CNS poisons (camphor, cyanide, tricyclic antidepressants, propoxyphene, strychnine).

Whole-bowel irrigation is performed by administering a bowel-cleansing solution containing electrolytes and polyethylene glycol (Golytely, Colyte) orally or by gastric tube at a rate of 2.0 L/h (0.5 L/h in children) until rectal effluent is clear. The patient must be in a sitting position. Although data are limited, whole-bowel irrigation appears to be as effective as other decontamination procedures. It is most appropriate for those who have ingested foreign bodies, packets of illicit drugs, slow-release or enteric-coated medications, and agents that are poorly adsorbed by charcoal (e.g., heavy metals). It is contraindicated in patients with bowel obstruction, ileus, hemodynamic instability, and compromised unprotected airways.

Cathartics are salts (disodium phosphate, magnesium citrate and sulfate, sodium sulfate) or saccharides (mannitol, sorbitol) that promote the rectal evacuation of gastrointestinal contents. The most effective cathartic is sorbitol in a dose of 1–2 g/kg of body weight. Alone, cathartics do not prevent ingestant absorption and should not be used as a method of gut decontamination. Their primary use is to prevent constipation following a single dose of charcoal. Abdominal cramps, nausea, and occasional vomiting are side effects. Complications of repeated dosing include hypermagnesemia (from magnesium salts) and excessive diarrhea. Cathartics are contraindicated in patients who have ingested corrosives and in those with preexisting diarrhea. Magnesium-containing cathartics should not be used in patients with renal failure.

Dilution (i.e., drinking 5 mL/kg of body weight of water or another clear liquid) is recommended only after the ingestion of corrosives (acids, alkali). It may increase the dissolution rate (and hence absorption) of capsules, tablets, and other solid ingestants and should *not* be used in these circumstances.

Endoscopic or surgical removal of poisons may be useful in rare situations, such as ingestion of a potentially toxic foreign body that fails to transit the gastrointestinal tract, a potentially lethal amount of a heavy metal (arsenic, iron, mercury, thallium), or agents that have coalesced into gastric concretions or bezoars (barbiturates, glutethimide, heavy metals, lithium, meprobamate, salicylates, sustained-release preparations). Patients who become toxic from cocaine due to its leakage from ingested drug packets require immediate surgical intervention.

Decontamination of Other Sites Immediate, copious flushing with water, saline, or another available clear, drinkable liquid is the initial treatment for topical exposures (exceptions include alkali metals, calcium oxide, phosphorus). Saline is preferred for eye irrigation. A triple wash (water, soap, water) may be best for dermal decontamination. Inhalational exposures should be treated initially with fresh air or oxygen. The removal of liquids from body cavities such as the vagina or rectum is best accomplished by irrigation. Solids (drug packets, pills) should be removed manually, preferably under direct visualization.

ENHANCEMENT OF POISON ELIMINATION Although the elimination of most poisons can be accelerated by therapeutic interventions, the pharmacokinetic efficacy (removal of drug at a rate greater than that accomplished by intrinsic elimination) and clinical benefit (shortened duration of toxicity or improved outcome) of such interventions are often more theoretical than proven. Hence, the decision to use such measures should be based on the actual or predicted toxicity and the potential efficacy, cost, and risks of therapy.

Multiple-Dose Activated Charcoal Repetitive oral dosing with charcoal can enhance the elimination of previously absorbed substances by binding them within the gut as they are excreted in the bile, secreted by gastrointestinal cells, or passively diffuse into the gut lumen (reverse absorption or enterocapillary exsorption). Doses of 0.5–1 g/kg body weight every 2–4 h, adjusted downward to avoid regurgitation in patients with decreased gastrointestinal motility, are generally recommended. Pharmacokinetic efficacy approaches that of hemodialysis for some agents (e.g., phenobarbital, theophylline). Multiple-dose therapy should be considered only for selected agents (theophylline, phenobarbital, carbamazepine, dapsone, quinine) and is not effective in accelerating elimination of chlorpropamide, tobramycin, or agents that adsorb poorly to charcoal. Complications include intestinal obstruction, pseudoobstruction, and nonocclusive intestinal infarction in patients with decreased gut motility. Sorbitol and other cathartics are absolutely contraindicated when administering multiple doses of activated charcoal because of electrolyte and fluid shifts.

Urinary Alkalinization Ion trapping via alteration of urine pH may prevent the renal reabsorption of poisons that undergo excretion by glomerular filtration and active tubular secretion. Since membranes are more permeable to nonionized molecules than to their ionized counterparts, acidic (low-pK_a) poisons are ionized and trapped in alkaline urine, whereas basic ones become ionized and trapped in acid urine. Urinary alkalinization (producing a urine pH ≥7.5 and a urine output of 3–6 mL/kg body weight per hour by adding sodium bicarbonate to an IV solution) enhances the excretion of chlorphenoxyacetic acid herbicides, chlorpropamide, diflunisal, fluoride, methotrexate, phenobarbital, sulfonamides, and salicylates. Contraindications include congestive heart failure, renal failure, and cerebral edema. Acid-base, fluid, and electrolyte parameters should be monitored carefully. While making theoretical sense for some overdoses (amphetamines), acid diuresis is never indicated and is potentially harmful.

Extracorporeal Removal Peritoneal dialysis, hemodialysis, charcoal or resin hemoperfusion, hemofiltration, plasmapheresis, and exchange transfusion are capable of removing any toxin from the bloodstream. Agents most amenable to enhanced elimination by dialysis have low molecular mass (<500 Da), high water solubility, low protein binding, small volumes of distribution (<1 L/kg body weight), prolonged elimination (long half-life), and high dialysis clearance relative to total-body clearance. Molecular weight, water solubility, or protein binding do not limit the efficacy of the other forms of extracorporeal removal.

Copyright © 2008 The McGraw-Hill Companies. All rights reserved.

Dialysis should be considered in cases of severe poisoning due to acetone, barbiturates, bromide, carbamazepine, chloral hydrate, ethanol, ethylene glycol, isopropyl alcohol, lithium, methanol, procainamide, theophylline, salicylates, and valproate. Although hemoperfusion may be more effective in removing some of these poisons, it does not correct associated acid-base and electrolyte abnormalities, and most hospitals no longer have hemoperfusion cartridges readily available. Fortunately, recent advances in hemodialysis technology make it useful for removing poisons such as caffeine, carbamazepine, carbon tetrachloride, chloramphenicol, dapsone, disopyramide, hypnotic-sedatives (barbiturates, ethchlorvynol, glutethimide, meprobamate, methaqualone), methotrexate, mushrooms (amatoxin-containing), paraquat, phenytoin, procainamide, theophylline, and valproate. Both techniques require central venous access and systemic anticoagulation and often result in transient hypotension. Hemoperfusion may also cause hemolysis, hypocalcemia, and thrombocytopenia. Peritoneal dialysis and exchange transfusion are less effective but may be used when other procedures are either not available, contraindicated, or technically difficult (e.g., in infants). Exchange transfusion may be indicated in the treatment of severe arsine- or sodium chlorate–induced hemolysis, methemoglobinemia, and sulfhemogloginemia. Although hemofiltration can enhance elimination of aminoglycosides, vancomycin, and metal-chelate complexes, the roles of hemofiltration and plasmapheresis in the treatment of poisoning are not yet defined.

Candidates for extracorporeal removal therapies include patients with severe toxicity who deteriorate despite aggressive supportive therapy; those with potentially prolonged, irreversible, or fatal toxicity; those with dangerous blood levels of toxins; those who lack the capacity for self-detoxification because of liver or renal failure; and those with a serious underlying illness or complication that will adversely affect recovery.

Other Techniques The elimination of heavy metals can be enhanced by chelation, and the removal of carbon monoxide can be increased by hyperbaric oxygenation.

ADMINISTRATION OF ANTIDOTES Antidotes counteract the effects of poisons by neutralizing them (e.g., antibody-antigen reactions, chelation, chemical binding) or by antagonizing their physiologic effects (e.g., activation of opposing nervous system activity, provision of competitive metabolic or receptor substrate). Poisons or conditions with specific antidotes include acetaminophen, anticholinergic agents, anticoagulants, benzodiazepines, beta blockers, calcium channel blockers, carbon monoxide, cardiac glycosides, cholinergic agents, cyanide, drug-induced dystonic reactions, ethylene glycol, fluoride, heavy metals, hydrogen sulfide, hypoglycemic agents, isoniazid, membrane-active agents, methemoglobinemia, opioids, sympathomimetics, and a variety of envenomations. Antidotes can significantly reduce morbidity and mortality but are potentially toxic if used for inappropriate reasons. Since their safe use requires correct identification of a specific poisoning or syndrome, details of antidotal therapy are discussed with the conditions for which they are indicated **(Table e35-4)**.

TABLE e35-4 PATHOPHYSIOLOGIC FEATURES AND TREATMENT OF SPECIFIC TOXIC SYNDROMES AND POISONINGS

Physiologic Condition, Causes	Examples	Mechanism of Action	Clinical Features	Specific Treatments
Stimulated				
Sympathetics (see also Chap. 389)				
Sympathomimetics	α_1-Adrenergic agonists (decongestants): phenylephrine, phenylpropanolamine β_2-Adrenergic agonists (bronchodilators): albuterol, terbutaline Nonspecific adrenergic agonists: amphetamines, cocaine, ephedrine	Stimulation of central and peripheral sympathetic receptors directly or indirectly (by promoting the release or inhibiting the reuptake of norepinephrine and sometimes dopamine)	Physiologic stimulation (Table e35-2); reflex bradycardia can occur with selective α_1 agonists; β agonists can cause hypotension and hypokalemia.	Phentolamine, a nonselective α_1-adrenergic receptor antagonist, for severe hypertension due to α_1-adrenergic agonists; propranolol, a nonselective β blocker, for hypotension and tachycardia due to β_2 agonists; labetalol, a β blocker with α-blocking activity, or phentolamine with esmolol, metoprolol, or other cardioselective β blocker for hypertension with tachycardia due to nonselective agents (β blockers, if used alone, can exacerbate hypertension and vasospasm due to unopposed α stimulation); benzodiazepines; propofol.
Ergot alkaloids	Ergotamine, methysergide, bromocriptine, pergolide	Stimulation and inhibition of serotonergic and α-adrenergic receptors; stimulation of dopamine receptors	Physiologic stimulation (Table e35-2); formication; vasospasm with limb (isolated or generalized), myocardial, and cerebral ischemia progressing to gangrene or infarction; hypotension, bradycardia, and involuntary movements can also occur.	Nitroprusside or nitroglycerine for severe vasospasm; prazocin (an α_1 blocker), captopril, nifedipine, and cyproheptidene (a serotonin receptor antagonist) for mild to moderate limb ischemia; dopamine receptor antagonists (antipsychotics) for hallucinations and movement disorders
Methylxanthines	Caffeine, theophylline	Inhibition of adenosine synthesis and adenosine receptor antagonism; stimulation of epinephrine and norepinephrine release; inhibition of phosphodiesterase resulting in increased intracellular cyclic adenosine and quanosine monophosphate	Physiologic stimulation (Table e35-2); pronounced gastrointestinal symptoms and β agonist effects (see above). Toxicity occurs at lower drug levels in chronic poisoning than in acute poisoning.	Propranolol, a nonselective β blocker, for tachycardia with hypotension; any β blocker for supraventricular or ventricular tachycardia without hypotension; elimination enhanced by multiple-dose charcoal, hemoperfusion, and hemodialysis; indications for hemoperfusion or hemodialysis include unstable vital signs, seizures, and a theophylline level of 80–100 μg/mL after acute overdose and 40–60 μg/mL with chronic exposure.

TABLE e35-4 PATHOPHYSIOLOGIC FEATURES AND TREATMENT OF SPECIFIC TOXIC SYNDROMES AND POISONINGS (CONTINUED)

Physiologic Condition, Causes	Examples	Mechanism of Action	Clinical Features	Specific Treatments
Monoamine oxidase inhibitors	Phenelzine, tranylcypromine, selegiline	Inhibition of monoamine oxidase resulting in impaired metabolism of endogenous catecholamines and exogenous sympathomimetic agents	Delayed or slowly progressive physiologic stimulation (Table e35-2); terminal hypotension and bradycardia in severe cases.	Short-acting agents (e.g., nitroprusside, esmolol) for severe hypertension and tachycardia; direct-acting sympathomimetics (e.g., norepinephrine, epinephrine) for hypotension and bradycardia
Anticholinergics				
Antihistamines	Diphenhydramine, doxylamine, pyrilamine	Inhibition of central and postganglionic parasympathetic muscarinic cholinergic receptors. At high doses, amantidine, diphenhydramine, orphenadrine, phenothiazines, and tricyclic antidepressants have additional nonanticholinergic activity (see below).	Physiologic stimulation (Table e35-2); dry skin and mucous membranes, decreased bowel sounds, flushing, and urinary retention; myoclonus and picking activity. Central effects may occur without significant autonomic dysfunction.	Physostigmine, an acetylcholinesterase inhibitor (see below) for delirium, hallucinations, and neuromuscular hyperactivity. Contraindications include nonanticholinergic cardiovascular toxicity (e.g., cardiac conduction abnormalities, hypotension, and ventricular arrhythmias).
Antiparkinsonian agents	Amantidine, trihexiphenydyl			
Antipsychotics	Chlorpromazine, olanzapine, quetiapine, thioridazine			
Antispasmotics	Clinidium, dicyclomine			
Belladonna alkaloids	Atropine, hyoscyamine, scopolamine			
Cyclic antidepressants	Amitriptyline, doxepin, imipramine			
Muscle relaxants	Cyclobenzaprine, orphenadrine			
Mushrooms and plants	*Amanita muscaria* and *A. pantherina*, henbane, jimson weed, nightshade			
Depressed				
Sympatholytics				
α_2-Adrenergic agonists	Clonidine, guanabenz, tetrahydrozoline and other imidazoline decongestants, tizanidine and other imidazoline muscle relaxants	Stimulation of α_2-adrenergic receptors leading to inhibition of CNS sympathetic outflow; activity at nonadrenergic imidazoline binding sites also contributes to CNS effects.	Physiologic depression (Table e35-2), miosis. Transient initial hypertension may be seen.	Dopamine and norepinephrine for hypotension. Atropine for symptomatic bradycardia. Naloxone for CNS depression (inconsistently effective).
Antipsychotics	Chlorpromazine, clozapine, haloperidol, risperidone, thioridazine	Inhibition of α-adrenergic, dopaminergic, histaminergic, muscarinic, and serotonergic receptors. Some agents also inhibit sodium, potassium, and calcium channels.	Physiologic depression (Table e35-2), miosis, anticholinergic effects (see above), extrapyramidal reactions (see below), tachycardia. Cardiac conduction delays (increased PR, QRS, JT, and QT intervals) with ventricular tachydysrhythmias, including torsades des pointes, can sometimes develop.	Sodium bicarbonate and lidocaine for ventricular tachydysrhythmias associated with QRS prolongation. Magnesium, isoproterenol, and overdrive pacing for torsades de pointes. Avoid class IA, IC, and III antiarrhythmics.
β-Adrenergic blockers	Cardioselective (β_1) blockers: atenolol, esmolol, metoprolol Nonselective (β_1 and β_2) blockers: nadolol, propranolol, timolol Partial β agonists: acebutolol, pindolol α_1 Antagonists: carvedilol, labetalol Membrane-active agents: acebutolol, propranolol, sotalol	Inhibition of β-adrenergic receptors (class II antiarrhythmic effect). Some agents have activity at additional receptors or have membrane effects (see below).	Physiologic depression (Table e35-2), atrioventricular block, hypoglycemia, hyperkalemia, seizures. Partial agonists can cause hypertension and tachycardia. Sotalol can cause increased QT interval and ventricular tachydysrhythmias. Onset may be delayed after sotalol and sustained-release formulation overdose.	Glucagon and calcium for hypotension and symptomatic bradycardia. Atropine, isoproterenol, amrinone, dopamine, dobutamine, epinephrine, and norepinephrine may sometimes be effective. High-dose insulin (with glucose and potassium to maintain euglycemia and normokalemia), electrical pacing, and mechanical cardiovascular support for refractory cases.
Calcium channel blockers	Diltiazem, nifedipine and other dihydropyridine derivatives, verapamil	Inhibition of slow (type L) cardiovascular calcium channels (class IV antiarrhythmic effect).	Physiologic depression (Table e35-2), atrioventricular block, organ ischemia and infarction, hyperglycemia, seizures. Hypotension is usually due to decreased vascular resistance rather than to decreased cardiac output. Onset may be delayed for ≥12 h after overdose of sustained-release formulations.	Calcium and glucagon for hypotension and symptomatic bradycardia. Dopamine, epinephrine, norepinephrine, atropine, and isoproterenol are less often effective but can be used adjunctively. Amrinone, high-dose insulin (with glucose and potassium to maintain euglycemia and normokalemia), electrical pacing, and mechanical cardiovascular support for refractory cases.

TABLE e35-4 PATHOPHYSIOLOGIC FEATURES AND TREATMENT OF SPECIFIC TOXIC SYNDROMES AND POISONINGS (CONTINUED)

Physiologic Condition, Causes	Examples	Mechanism of Action	Clinical Features	Specific Treatments
Cardiac glycosides	Digoxin, endogenous cardioactive steroids, foxglove and other plants, toad skin secretions (*Bufonidae* sp.)	Inhibition of cardiac Na^+, K^+-ATPase membrane pump.	Physiologic depression (Table e35-2); gastrointestinal, psychiatric, and visual symptoms; atrioventricular block with or without concomitant supraventricular tachyarrhythmia; ventricular tachyarrhythmias. Hyperkalemia in acute poisoning. Toxicity occurs at lower drug levels in chronic poisoning than in acute poisoning.	Digoxin-specific antibody fragments for hemodyamically compromising dysrhythmias, Mobitz II or third-degree atrioventricular block, hyperkalemia (>5.5 meq/L; in acute poisoning only). Temporizing measures include atropine, dopamine, epinephrine, phenytoin, and external cardiac pacing for bradydysrhythmias and magnesium, lidocaine, phenytoin, and bretylium for ventricular tachydysrhythmias. Internal cardiac pacing and cardioversion can increase ventricular irritability and should be reserved for refractory cases.
Cyclic antidepressants	Amitriptyline, doxepin, imipramine	Inhibition of α-adrenergic dopaminergic, GABA-ergic, histaminergic, muscarinic, and serotonergic receptors; inhibition of sodium channels (see membrane-active agents); inhibition of norepinephrine and serotonin reuptake.	Physiologic depression (Table e35-2), seizures, tachycardia, cardiac conduction delays (increased PR, QRS, JT, and QT intervals; terminal QRS right axis deviation) with aberrancy and ventricular tachydysrhythmias. Anticholinergic toxidrome (see above).	Hypertonic sodium bicarbonate (or hypertonic saline) and lidocaine for ventricular tachydysrhythmias associated with QRS prolongation. Use of phenytoin is controversial. Avoid class IA, IC, and III antiarrhythmics.
Cholinergics				
Acetylcholinesterase inhibitors	Carbamate insecticides (aldicarb, carbaryl, propoxur) and medicinals (neostigmine, physostigmine, tacrine); nerve gases (sarin, soman, tabun, VX) organophosphate insecticides (diazinon, chlopyriphos, malathion)	Inhibition of acetylcholinesterase leading to increased synaptic acetylcholine at muscarinic and nicotinic cholinergic receptor sites	Physiologic depression (Table e35-2). Muscarinic signs and symptoms: seizures, excessive secretions (lacrimation, salivation, bronchorrhea and wheezing, diaphoresis), and increased bowel and bladder activity with nausea, vomiting, diarrhea, abdominal cramps, and incontinence of feces and urine. Nicotinic signs and symptoms: hypertension, tachycardia, muscle cramps, fasciculations, weakness, and paralysis. Death is usually due to respiratory failure. Cholinesterase activity in plasma and red cells <50% of normal in acetylcholinesterase inhibitor poisoning.	Atropine for muscarinic signs and symptoms. Pralidoxime (2-PAM), a cholinesterase reactivator, for nicotinic signs and symptoms due to organophosphates, nerve gases, or an unknown anticholinesterase.
Muscarinic agonists	Bethanecol, mushrooms (*Boletus*, *Clitocybe*, *Inocybe* sp.), pilocarpine	Stimulation of CNS and postganglionic parasympathetic cholinergic (muscarinic) receptors		
Nicotinic agonists	Lobeline, nicotine (tobacco)	Stimulation of preganglionic sympathetic and parasympathetic and striated muscle (neuromuscular junction) cholinergic (nicotine) receptors		
Sedative-hypnotics (see also Chap. 388)				
Anticonvulsants	Carbamazepine, ethosuximide, felbamate, gabapentin, lamotrigine, levetiracetam, oxcarbazepine, phenytoin, tiagabine, topiramate, valproate, zonisamide	Potentiation of the inhibitory effects of GABA by binding to the neuronal GABA-A chloride channel receptor complex and increasing the frequency or duration of chloride channel opening in response to GABA stimulation. Baclofen and, to some extent, GHB act at the GABA-B rector complex; meprobamate, its metabolite carisoprodol, felbamate, and orphenidrine antagonize *N*-methyl-D-aspartate (NDMA) excitatory receptors; ethosuximide, valproate, and zonisamide decrease conduction through T-type calcium channels; valproate	Physiologic depression (Table e35-2), nystagmus. Delayed absorption can occur with carbamazepine, phenytoin, and valproate. Myoclonus, seizures, hypertension, and tachyarrhythmias can occur with baclofen, carbamazepine, and orphenadrine. Tachyarrhythias can also occur with chloral hydrate. AGMA, hypernatremia, hyperosmolality, hyperammonemia, chemical hepatitis, and hypoglycemia can be seen in valproate poisoning. Carbamazepine and oxcarbazepine may produce hyponatremia from SIADH.	Flumazenil for benzodiazepine and zolpidem poisoning. Benzodiazepines and barbiturates for seizures. Elimination of phenobarbital and possibly other long-acting agents enhanced by multiple-dose charcoal. He modialysis and hemoperfusion may be indicated for severe poisoning by some agents (see Extracorporeal Removal, in text). See above and below for treatment of anticholinergic and sodium channel (membrane) blocking effects.
Barbiturates	Short-acting: butabarbital, pentobarbital, secobarbital Long-acting: phenobarbital, primadone			
Benzodiazepines	Ultrashort-acting: estazolam, midazolam, temazapam, triazolam Short-acting: alprazolam, flunitrazepam, lorazepam, oxazepam Long-acting: chlordiazepoxide, clonazepam, diazepam, flurazepam Pharmacologically related agents: zaleplon, zolpidem

TABLE e35-4 PATHOPHYSIOLOGIC FEATURES AND TREATMENT OF SPECIFIC TOXIC SYNDROMES AND POISONINGS (CONTINUED)

Physiologic Condition, Causes	Examples	Mechanism of Action	Clinical Features	Specific Treatments
GABA precursors	γ-Hydroxybutyrate (sodium oxybate; GHB), γ-butyrolactone (GBL), 1,4-butanediol.	decreases GABA degradation, and tiagabine blocks GABA reuptake; carbamazepine, lamotrigine, oxcarbazepine, phenytoin, topiramate, valproate, and zonisamide slow the rate of recovery of inactivated sodium channels. Some agents also have α_2 agonist, anticholinergic, and sodium channel blocking activity (see above and below).	Some agents can cause anticholinergic and sodium channel (membrane) blocking effects (see above and below).	
Muscle relaxants	Baclofen, carisoprodol, cyclobenzaprine, etomidate, metaxalone, methocarbamol, orphenadrine, propafol, tizanidine and other imidazoline muscle relaxants.			
Other agents	Chloral hydrate, ethclorvynol, glutethimide, meprobamate, methaqualone, methyprylon			
Discordant				
Asphyxiants				
Cytochrome oxidase inhibitors	Carbon monoxide, cyanide, hydrogen sulfide	Inhibition of mitochrondrial cytochrome oxidase, thereby blocking electron transport and oxidative metabolism. Carbon monoxide also binds to hemoglobin and myoglobin and prevents oxygen binding, transport, and tissue uptake (binding to hemoglobin shifts the oxygen dissociation curve to the left).	Signs and symptoms of hypoxia with initial physiologic stimulation and subsequent depression (Table e35-2); lactic acidosis; normal P_{O_2} and calculated oxygen saturation but decreased oxygen saturation by co-oximetry (that measured by pulse oximetry is falsely elevated but is less than normal and less than the calculated value). Headache and nausea are common with carbon monoxide. Sudden collapse may occur with cyanide and hydrogen sulfide exposure. A bitter almond breath odor may be noted with cyanide ingestion, and hydrogen sulfide smells like rotten eggs.	High-dose oxygen. Inhaled amyl nitrite and IV sodium nitrite and sodium thiosulfate (Lilly cyanide antidote kit) for coma, metabolic acidosis, and cardiovascular dysfunction in cyanide poisoning. Amyl and sodium nitrite (without thiosulfate) for similar toxicity in hydrogen sulfide poisoning. Hyperbaric oxygen for moderate to severe carbon monoxide poisoning and for cyanide or hydrogen sulfide poisoning unresponsive to other measures.
Methemoglobin inducers	Aniline derivatives, dapsone, local anesthetics, nitrates, nitrites, nitrogen oxides, nitro- and nitrosohydrocarbons, phenazopyridine, primaquine-type antimalarials, sulfonamides.	Oxidation of hemoglobin iron from ferrous (Fe^{2+}) to ferric (Fe^{3+}) state prevents oxygen binding, transport, and tissue uptake (methemoglobinemia shifts oxygen dissociation curve to the left). Oxidation of hemoglobin protein causes hemoglobin precipitation and hemolytic anemia (manifest as Heinz bodies and "bite cells" on peripheral blood smear).	Signs and symptoms of hypoxia with initial physiologic stimulation and subsequent depression (Table e35-2), gray-brown cyanosis unresponsive to oxygen at methemoglobin fractions > 15–20%, headache, lactic acidosis (at methemoglobin fractions > 45%), normal P_{O_2} and calculated oxygen saturation but decreased oxygen saturation and increased methehemoglobin fraction by co-oximetry (oxygen saturation by pulse oximetry may be falsely increased or decreased but is less than normal and less than the calculated value).	High-dose oxygen. Intravenous methylene blue for methemoglobin fraction > 30%, symptomatic hypoxia, or ischemia (contraindicated in G6PD deficiency). Exchange transfusion and hyperbaric oxygen for severe or refractory cases.
AGMA inducers	Ethylene glycol	Ethylene glycol causes CNS depression and increased serum osmolality. Metabolites (primarily glycolic acid) cause AGMA, CNS depression, and renal failure. Precipitation of oxalic acid metabolite as calcium salt in tissues and urine results in hypocalcemia, tissue edema, and crystalluria.	Initial ethanol-like intoxication, nausea, vomiting, increased osmolar gap, calcium oxylate crystalluria. Delayed AGMA, back pain, renal failure. Coma, seizures, hypotension, ARDS in severe cases.	Gastric aspiration for recent ingestions. Sodium bicarbonate to correct acidemia. Thiamine, folinic acid, magnesium, and high-dose pyridoxine to facilitate metabolism. Ethanol or fomepizole for AGMA, crystalluria or renal dysfunction, ethylene glycol level > 3 mmol/L (20 mg/dL), and for ethanol-like intoxication or increased osmolal gap if level not readily obtainable. Hemodialysis for persistent AGMA, lack of clinical improvement, and renal dysfunction. Hemodialysis also useful for enhancing ethylene glycol elimination and shortening duration of treatment when ethylene glycol level > 8 mmol/L (50 mg/dL).

TABLE e35-4 PATHOPHYSIOLOGIC FEATURES AND TREATMENT OF SPECIFIC TOXIC SYNDROMES AND POISONINGS (CONTINUED)

Physiologic Condition, Causes	Examples	Mechanism of Action	Clinical Features	Specific Treatments
AGMA inducers	Iron	Hydration of ferric (Fe^{3+}) ion generates H^+. Non-transferrin-bound iron catalyzes formation of free radicals that cause mitochondrial injury, lipid peroxidation, increased capillary permeability, vasodilation, and organ toxicity.	Initial nausea, vomiting, abdominal pain, diarrhea. AGMA, cardiovascular and CNS depression, hepatitis, coagulopathy, and seizures in severe cases. Radiopaque iron tablets may be seen on abdominal x-ray.	Whole-bowel irrigation for large ingestions. Endoscopy and gastrostomy if clinical toxicity and large number of tablets still visible on x-ray. IV hydration. Sodium bicarbonate for acidemia. IV deferoxamine for systemic toxicity, iron level > 90 μmol/L (500 μg/dL).
	Methanol	Methanol causes ethanol-like CNS depression and increased serum osmolality. Formic acid metabolite causes AGMA and retinal toxicity.	Initial ethanol-like intoxication, nausea, vomiting, increased osmolar gap. Delayed AGMA, visual (clouding, spots, blindness) and retinal (edema, hyperemia) abnormalities. Coma, seizures, cardiovascular depression in severe cases. Possible pancreatitis.	Gastric aspiration for recent ingestions. Sodium bicarbonate to correct acidemia. High-dose folinic acid or folate to facilitate metabolism. Ethanol or fomepizole for AGMA, visual symptoms, methanol level > 6 mmol/L (20 mg/dL), and for ethanol-like intoxication or increased osmolal gap if level not readily obtainable. Hemodialysis for persistent AGMA, lack of clinical improvement, and renal dysfunction. Hemodialysis also useful for enhancing methanol elimination and shortening duration of treatment when methanol level > 15 mmol/L (50 mg/dL).
	Salicylate	Increased sensitivity of CNS respiratory center to changes in P_{O_2} and P_{CO_2} stimulates respiration. Uncoupling of oxidative phosphorylation, inhibition of Kreb's cycle enzymes, and stimulation of carbohydrate and lipid metabolism generate unmeasured endogenous anions and cause AGMA.	Initial nausea, vomiting, hyperventilation, alkalemia, alkaluria. Subsequent alkalemia with both respiratory alkalosis and AGMA, and paradoxical aciduria. Late acidemia with CNS and respiratory depression. Cerebral and pulmonary edema in severe cases. Hypoglycemia, hypocalcemia, hypokalemia, and seizures can occur.	IV hydration and supplemental glucose. Sodium bicarbonate to correct acidemia. Alkaline diuresis for systemic toxicity. Hemodialysis for coma, cerebral edema, seizures, pulmonary edema, renal failure, progressive acid-base disturbances or clinical toxicity, salicylate level > 7 mmol/L (100 mg/dL) following acute overdose.
CNS syndromes				
Extrapyramidal reactions	Antipsychotics (see above), some cyclic antidepressants and antihistamines.	Decreased CNS dopaminergic activity with relative excess of cholinergic activity.	Akathisia, dystonia, parkinsonism	Oral or parenteral anticholinergic agent such as benztropine or diphenhydramine.
Isoniazid		Interference with activation and supply of pyridoxal-5-phosphate, a cofactor for glutamic acid decarboxylase, which converts glutamic acid to GABA, results in decreased levels of this inhibitory CNS neurotransmitter; complexation with and depletion of pyridoxine itself; inhibition of nicotine-adenine dinucleotide dependent lactate and hydroxybutyrate dehydrogenases resulting in substrate accumulation.	Nausea, vomiting, agitation, confusion; coma, respiratory depression, seizures, lactic and ketoacidosis in severe cases.	High-dose intravenous pyridoxine (vitamin B_6) for agitation, confusion, coma, and seizures. Diazepam or barbiturates for seizures.

TABLE e35-4 PATHOPHYSIOLOGIC FEATURES AND TREATMENT OF SPECIFIC TOXIC SYNDROMES AND POISONINGS (CONTINUED)

Physiologic Condition, Causes	Examples	Mechanism of Action	Clinical Features	Specific Treatments
Lithium		Interference with cell membrane ion transport, adenylate cyclase and Na^+, K^+-ATPase activity, and neurotransmitter release.	Nausea, vomiting, diarrhea, ataxia, choreoathetosis, encephalopathy, hyperreflexia, myoclonus, nystagmus, nephrogenic diabetes insipidus, falsely elevated serum chloride with low anion gap, tachycardia. Coma, seizures, arrhythmias, hyperthermia, and prolonged or permanent encephalopathy and movement disorders in severe cases. Delayed onset after acute overdose, particularly with delayed-release formations. Toxicity occurs at lower drug levels in chronic poisoning than in acute poisoning.	Whole-bowel irrigation for large ingestions. Consider endoscopic removal if high and rising drug level with progressive clinical toxicity. IV hydration. Hemodialysis for coma, seizures, severe, progressive, or persistent encephalopathy or neuromuscular dysfunction, peak lithium level > 8 meq/L (mmol/L) following acute overdose.
Serotonin syndrome	Amphetamines, cocaine, dextromethorphan, meperidine, MAO inhibitors, selective serotonin (5HT) reuptake inhibitors, tricyclic antidepressants, tramadol, triptans, tryptophan.	Promotion of serotonin release, inhibition of serotonin reuptake, or direct stimulation of CNS and peripheral serotonin receptors (primarily 5HT-1a and 5HT-2), alone or in combination.	Altered mental status (agitation, confusion, mutism, coma, seizures), neuromuscular hyperactivity (hyperreflexia, myoclonus, rigidity, tremors), and autonomic dysfunction (abdominal pain, diarrhea, diaphoresis, fever, flushing, labile hypertension, mydriasis, tearing, salivation, tachycardia). Complications include hyperthermia, lactic acidosis, rhabdomyolysis, and multisystem organ failure.	Serotonin receptor antagonist such as cyproheptadine or chlorpromazine.
Membrane-active agents	Amantidine, antiarrhythmics (class I and III agents; some β blockers), antipsychotics (see above), antihistamines (particularly diphenhydramine), carbamazepine, local anesthetics (including cocaine), opioids (meperidine, propoxyphene), orphenadrine, quinoline antimalarials (chloroquine, hydroxychloroquine, quinine), cyclic antidepressants (see above).	Blockade of fast sodium membrane channels prolongs phase 0 (depolarization) of the cardiac action potential, which prolongs the QRS duration and promotes reentrant (monomorphic) ventricular tachycardia. Class Ia, Ic, and III antiarrhythmics also block potassium channels during phases 2 and 3 (repolarization) of the action potential, prolonging the JT interval and promoting early afterdepolarizations and polymorphic (torsades des pointes) ventricular tachycardia. Similar effects on neuronal membrane channels cause CNS dysfunction. Some agents also block α-adrenergic and cholinergic receptors or have opioid effects (see above and Chap. 388).	QRS and JT prolongation (or both) with hypotension, ventricular tachyarrhythmias, CNS depression, seizures. Anticholinergic effects with amantidine, antihistamines, carbamazepine, disopyramide, antipsychotics, and cyclic antidepressants (see above). Opioid effects with meperidine and propoxyphene (see Chap. 388). Cinchonism (hearing loss, tinnitus, nausea, vomiting, vertigo, ataxia, headache, flushing, diaphoresis) and blindness with quinoline antimalarials.	Hypertonic sodium bicarbonate (or hypertonic saline) for cardiac conduction delays and monomorphic ventricular tachycardia. Lidocaine for monomorphic ventricular tachycardia (except when due to class Ib antiarrhythmics). Magnesium, isoproterenol, and overdrive pacing for polymorphic ventricular tachycardia. Physostigmine for anticholinergic effects (see above). Naloxone for opioid effects (see Chap. 388). Extracorporeal removal for some agents (see text).

Note: AGMA, anion-gap metabolic acidosis; ARDS, adult respiratory distress syndrome; CNS, central nervous system; GABA, γ-aminobutyric acid; G6PD, glucose-6-phosphate dehydrogenase; MAO, monoamine oxidase; SIADH, syndrome of inappropriate antidiuretic hormone.

PREVENTION OF REEXPOSURE Poisoning is a preventable illness. Unfortunately, some adults and children are poison-prone, and recurrences are common. Unintentional polypharmacy poisoning has become especially common among adults with developmental delays and among the growing population of geriatric patients who are prescribed a large number of medications. Adults with unintentional exposures should be instructed regarding the safe use of medications and chemicals (according to labeling instructions). Confused patients may need assistance with the administration of their medications. Errors in dosing by health care providers may require educational efforts. Patients should be advised to avoid circumstances that result

Copyright © 2008 The McGraw-Hill Companies. All rights reserved.

in chemical exposure or poisoning. Appropriate agencies and health departments should be notified in cases of environmental or workplace exposure. The best approach with young children and patients with intentional overdose (deliberate self-harm or suicide) is to limit their access to poisons. In households where children live or visit, alcoholic beverages, medications, household products (automotive, cleaning, fuel, pet-care, toiletry products), nonedible plants, and vitamins should be kept out of reach or in locked or child-proof cabinets. Depressed or psychotic patients should receive psychiatric assessment, disposition, and follow-up. They should be given prescriptions for a limited supply of drugs and with a limited number of refills and be monitored for compliance and response to therapy.

SPECIFIC TOXIC SYNDROMES AND POISONINGS

Table e35-4 summarizes the pathophysiology, clinical features, and treatment of toxidromes and poisonings that are common, produce life-threatening toxicity, or require unique therapeutic interventions. In all cases, treatment should include attending to the general principles discussed above, particularly supportive care. Details regarding specific therapies can be found in the references cited here and at *harrisonsonline.com*. Poisonings not covered in this chapter are discussed in the referenced texts. **Alcohol, cocaine, hallucinogen, and opioid poisoning and alcohol and opioid withdrawal are discussed in Chaps. 387 to 390; acetaminophen poisoning is discussed in Chap. 299; the neuroleptic malignant syndrome is discussed in Chap. 366; and heavy metal poisoning is discussed in Chap. e34.**

391 Disorders Caused by Reptile Bites and Marine Animal Exposures

Paul S. Auerbach, Robert L. Norris

This chapter outlines general principles for evaluation and management of victims of envenomation by venomous snakes and marine creatures. Because the incidence of serious bites and stings is relatively low in developed nations, there remains a paucity of relevant clinical research, and therapeutic decision-making is often based on anecdotal information.

VENOMOUS SNAKEBITE

EPIDEMIOLOGY

Venomous snakes of the world belong to the families Viperidae (subfamily Viperinae: Old World vipers; subfamily Crotalinae: New World and Asian pit vipers), Elapidae (including cobras, kraits, coral snakes, and all Australian venomous snakes), Hydrophiidae (sea snakes), Atractaspididae (burrowing asps), and Colubridae (a large family, of which most species are nonvenomous and only a few are dangerously toxic to humans). Bite rates are highest in temperate and tropical regions where the population subsists by manual agriculture. Estimates indicate >5 million bites annually by venomous snakes worldwide, with >125,000 deaths.

SNAKE ANATOMY/IDENTIFICATION

The typical snake-venom apparatus consists of bilateral venom glands located below and behind the eye and connected by ducts to hollow, anterior maxillary teeth. In viperids (vipers and pit vipers), these teeth are long mobile fangs that retract against the roof of the mouth when the animal is at rest. In elapids and sea snakes, the fangs are smaller and are relatively fixed in an erect position. In ~20% of pit viper bites and higher percentages of other snakebites (e.g., up to 75% for sea snakes), no venom is released ("dry" bites). Significant envenomation probably occurs in ~50% of all venomous snakebites.

Differentiation of venomous from nonvenomous snake species can be difficult. Viperids are characterized by somewhat triangular heads (a feature shared with many harmless snakes); elliptical pupils (also seen in some nonvenomous snakes, such as boas and pythons); enlarged maxillary fangs; and, in pit vipers, paired heat-sensing pits (foveal organs) on each side of the head. The New World rattlesnakes generally have a series of interlocking keratin plates (the rattle) on the tip of the tail; the rattle is used to warn potentially threatening intruders. Color pattern is notoriously misleading in identifying most venomous snakes. Many harmless snakes have color patterns that closely mimic venomous snakes found in the same region.

VENOMS AND CLINICAL MANIFESTATIONS

Snake venoms are complex mixtures of enzymes, low-molecular-weight polypeptides, glycoproteins, and metal ions. Among the deleterious components are hemorrhagins that promote vascular leakage and cause both local and systemic bleeding. Proteolytic enzymes cause local tissue necrosis, affect the coagulation pathway at various steps, and impair organ function. Myocardial depressant factors reduce cardiac output, and neurotoxins act either pre- or postsynaptically to inhibit peripheral nerve impulses. Most snake venoms have multisystem effects in their victims.

Envenomations by most viperids and some elapids with necrotizing venoms typically cause progressive local swelling, pain, ecchymosis (Fig. 391-1), and (over a period of hours or days) hemorrhagic bullae and serum-filled vesicles. In serious bites, tissue loss can be significant (Fig. 391-2). Systemic findings can include changes in taste, mouth numbness, muscle fasciculations, tachycardia or bradycardia, hypotension, pulmonary edema, hemorrhage (from essentially any anatomic site), and renal dysfunction. Envenomations by neurotoxic elapids such as kraits (*Bungarus* spp.), many Australian elapids [e.g., death adders (*Atractaspis* spp.) and tiger snakes (*Notechis* spp.)], some cobras (*Naja* spp.), and some viperids [e.g., the South American rattlesnake (*Crotalus durissus*) and some Indian Russell's vipers (*Daboia russelii*)] cause neurologic dysfunction. Early findings may consist of cranial nerve weakness (e.g., manifested by ptosis) and altered mental status. Severe poisoning may result in paralysis, including the muscles of respiration, and lead to death due to respiratory failure and aspiration. After elapid bites, the time of onset of venom intoxication varies from minutes to hours depending on the species involved, the anatomic location of the bite, and the amount of venom injected. Sea snake envenomation usually causes local pain (variable), myalgias, rhabdomyolysis, and neurotoxicity; these manifestations are occasionally delayed for hours.

Rx VENOMOUS SNAKEBITE

Field Management The most important aspect of prehospital care of a victim bitten by a venomous snake is rapid delivery to a medical facility equipped to provide supportive care (airway, breathing, and circulation) and antivenom administration. Most first aid recommendations made in

FIGURE 391-1 Northern Pacific rattlesnake (*Crotalus oreganus oreganus*) envenomations. ***Left:*** Moderately severe envenomation. Note edema and early ecchymosis 2 h after a bite to the finger. ***Right:*** Severe envenomation. Note extensive ecchymosis 5 days after a bite to the ankle.

FIGURE 391-2 Early stages of severe, full-thickness necrosis 5 days after a **Russell's viper (*Daboia russelii*) bite** in southwestern India.

the past are of little benefit, and some can actually worsen outcome. It is reasonable to apply a splint to the bitten extremity in order to lessen bleeding and discomfort and, if possible, to keep the extremity at approximately heart level. In developing regions, indigenous people should be encouraged to seek care quickly at health care facilities equipped with antivenoms as opposed to consulting traditional healers.

Although mechanical suction has been recommended in the field management of venomous snakebite for many years, there is now evidence that this intervention is of no benefit and can actually be deleterious in terms of local tissue damage.

Techniques or devices used for centuries in an effort to limit venom spread remain controversial. Lympho-occlusive bandages or tourniquets may limit spread only at the cost of greater local tissue damage, particularly with necrotic venoms. Because tourniquets lead to higher rates of amputation and loss of function, they absolutely should not be used. Elapid venoms that are primarily neurotoxic and have no significant local tissue effects may be localized by pressure-immobilization, in which the entire limb is immediately wrapped with a bandage (e.g., crepe or elastic) and then splinted. The wrap pressure must reach ~40–70 mmHg to be effective. Furthermore, if more than a few minutes from medical care, the victim must be carried out from the scene of the bite. Otherwise, muscular pumping will promote venom dispersal, even in bites to the upper extremities. In short, pressure-immobilization should be used only in cases where the offending snake is reliably identified and has a primarily neurotoxic venom, the rescuer is skilled in pressure-wrap application, and the victim can be carried to medical care—an uncommon combination of conditions. Besides tourniquets, other forbidden measures include incising or cooling the bite site, giving the victim alcoholic beverages, and applying electric shocks. The best first aid advice, as coined by Dr. Ian Simpson of the World Health Organization's Snakebite Treatment Group, is to "do it 'RIGHT'": *r*eassure the victim, *i*mmobilize the extremity, *g*et to the *h*ospital, and inform the physician of *t*elltale symptoms and signs.

Hospital Management In the hospital, the victim should be closely monitored (vital signs, cardiac rhythm, oxygen saturation, urine output) while a history is quickly obtained and a rapid, thorough physical examination is performed. Victims of neurotoxic envenomation should be watched carefully for evidence of difficulty swallowing or respiratory insufficiency, which should prompt definitive securing of the airway by endotracheal intubation. To provide objective evidence of the progression of envenomation, the level of swelling in a bitten extremity should be marked and limb circumferences measured in several locations every 15 min until swelling has stabilized. Large-bore IV access in unaffected extremities should be established. Early hypotension is due to pooling of blood in the pulmonary and splanchnic vascular beds. Later, hemolysis and loss of intravascular volume into soft tissues may play important roles. Fluid resuscitation with isotonic saline should be initiated for clinical shock. If the blood pressure response to administration of crystalloid (20–40 mL/kg) is inadequate, a trial of 5% albumin (10–20 mL/kg) is prudent. If tissue perfusion fails to respond to volume resuscitation and antivenom infusion (see below), vasopressors (e.g., dopamine) can be added. Invasive hemodynamic monitoring (central venous and/or pulmonary arterial pressures) can be helpful in such cases, although obtaining access is risky if coagulopathy has developed.

Blood should be drawn for typing and cross-matching and for laboratory evaluation as soon as possible. Important studies include a complete blood count (to evaluate degree of hemorrhage or hemolysis and effects on platelet count), studies of renal and hepatic function, coagulation studies (to identify consumptive coagulopathy), and testing of urine for blood or myoglobin. In developing regions, the 20-min whole-blood clotting test (WBCT) can be used to diagnose coagulopathy reliably. A few milliliters of fresh blood are placed in a new, plain glass receptacle (e.g., test tube) and left undisturbed for 20 min. The tube is then tipped once to 45° to determine whether a clot has formed. If not, coagulopathy is diagnosed. In severe envenomations or with significant comorbidity, arterial blood gas studies, electrocardiography, and chest radiography may be helpful. Any arterial puncture in the setting of coagulopathy, however, requires great caution and must be performed at an anatomic site amenable to direct-pressure tamponade. After antivenom therapy (see below), laboratory values should be rechecked every 6 h until clinical stability is achieved.

The key to management of venomous snakebite is the administration of specific antivenom. Circulating venom components bind quickly with heterologous antibodies produced in animals immunized with the venom in question (or a very closely related venom). Antivenoms may be monospecific (for a particular snake species) or polyspecific (covering several medically important species in the region) but rarely offer cross-protection against snake species other than those used in their production unless the species are known to have homologous venoms. In the United States, assistance in finding antivenom can be obtained 24 h a day from regional poison control centers.

Indications for antivenom administration in victims of viperid bites include any evidence of systemic envenomation (systemic symptoms or signs; laboratory abnormalities) and (possibly) significant, progressive local findings (e.g., soft tissue swelling crossing a joint or involving more than half the bitten limb in the absence of a tourniquet). Care must be used in determining the significance of isolated soft-tissue swelling as, in many countries, the saliva of some relatively harmless snakes causes mild edema at the bite site. In such bites, antivenoms are unhelpful and unnecessary.

In the developing world (e.g., much of Asia and Africa), elapid bites are generally treated similarly to viperid bites. Systemic symptoms such as ptosis, other manifestations of cranial nerve impairment, or respiratory compromise constitute grounds for antivenom administration. Decisions about antivenom administration to victims with isolated local signs or symptoms are based on the criteria listed above for viperid bites.

Production of the only antivenom currently available in the United States for coral snake bites has been discontinued, and remaining stocks will be exhausted or will expire shortly. Until a suitable substitute is produced or imported, physicians caring for victims of *Micrurus* bites may have to rely on sound supportive care, especially airway management and respiratory support.

The package insert for the selected antivenom can be consulted regarding species covered, method of administration, starting dose, and need (if any) for re-dosing. The information in antivenom package inserts, however, is not always accurate and reliable. Whenever possible, it is advisable for treating physicians to seek advice from experts in snakebite management regarding indications for and dosing of antivenom. For viperid bites, antivenom administration should generally be continued as needed until the victim shows definite improvement (e.g., stabilized vital signs, reduced pain, restored coagulation). Neurotoxicity from elapid bites may be harder to reverse with antivenom. Once neurotoxicity is established and endotracheal intubation is required, further doses of antivenom are unlikely to be beneficial. In such cases, the victim must be maintained on mechanical ventilation until recovery occurs, which may take days to weeks.

TABLE 391-1 COMPARISON OF ANTIVENOMS RECENTLY AVAILABLE FOR TREATMENT OF PIT VIPER BITES IN THE UNITED STATES

	Antivenin (Crotalidae) Polyvalent[a]	CroFab[b]
Available since	1954	2000
Origin	Equine	Ovine
Snakes used in manufacture	*Crotalus adamanteus* *C. atrox* *C. durissus terrificus* *Bothrops atrox*	*C. adamanteus* *C. atrox* *C. scutulatus* *Agkistrodon piscivorus*
Snakes covered	All North, Central, and South American and some Asian pit vipers	All North American pit vipers (and possibly other Latin American pit vipers)
Contains	IgG, equine albumin	Fab fragments
Skin testing recommended by manufacturer	Yes	No
Pretreatment with antihistamines recommended	Yes	No
Dosing (for North American pit viper bites only)[c]		
Dry bite	None	None
Mild	0 or 5 vials	4 vials
Moderate	10 vials	4–6 vials
Severe	15–20 vials	6 vials
Repeat dosing	As needed	Repeat starting dose if patient fails to stabilize. After stabilization, give 2 vials q6h for 3 more doses. (Alternatively, re-dose on an as-needed basis with close observation for recurrence of abnormalities.)
Volume of diluent	1000 mL[d]	250 mL
Administer over	2 h	1 h
Incidence of anaphylactic/-oid reaction	23–56%[e]	14%[f]
Incidence of delayed serum sickness	18–86%[g]	3%

[a]Wyeth-Ayerst Laboratories, Philadelphia, PA.
[b]Fougera, Melville, NY.
[c]Degrees of envenomation: mild = progressive local findings (no systemic findings and normal laboratory tests); moderate = local findings plus either mild systemic findings or mild laboratory abnormalities; and severe = local findings plus either severe systemic findings or severe laboratory abnormalities.
[d]Reduce for children and for patients with congestive heart failure.
[e]Some reactions have been severe, and some have been fatal.
[f]To date, all reactions have been relatively mild.
[g]Incidence is higher with larger doses.

The newest available antivenom in the United States (CroFab; Fougera, Melville, NY) is an ovine, Fab fragment antivenom that covers systemic venom effects of all North American pit viper species and carries a low risk of allergic sequelae. **Table 391-1** compares the two antivenoms recently available for the treatment of pit viper bites in the United States. The manufacturer of Antivenin (Crotalidae) Polyvalent has recently discontinued its production, leaving CroFab as the current drug of choice for the management of indigenous pit viper envenomations in the United States. Use of any heterologous serum product carries a risk of anaphylactoid reactions and delayed-hypersensitivity reactions (serum sickness). Skin testing for potential allergy is insensitive and nonspecific and should be omitted. Worldwide, the quality and availability of antivenoms are highly variable. In many developing countries, antivenom resources are scarce, contributing to high morbidity and mortality rates in these regions. The rates of acute anaphylactoid reactions to some of these products exceed 50%. If the risk of allergic reaction is significant, pretreatment with appropriate loading doses of IV antihistamines (e.g., diphenhydramine, 1 mg/kg to a maximum of 100 mg; and cimetidine, 5–10 mg/kg to a maximum of 300 mg) may be considered. In some regions, a prophylactic SC or IM dose of epinephrine is given in an effort to reduce the risk of reaction. Further research is necessary to determine whether any pretreatment measures are truly beneficial. Modest expansion of the patient's intravascular volume with crystalloids could blunt an acute adverse reaction.

Pretreatment is not recommended by the manufacturer of CroFab. Epinephrine should, however, always be immediately available, and the antivenom dose to be administered should be diluted in an appropriate volume of crystalloid according to the package insert. Antivenom should be given only by the IV route, and the infusion should be started slowly, with the physician at the bedside during the initial period to intervene immediately at the first signs of any acute reaction. The rate of infusion can be increased gradually in the absence of a reaction until the full starting dose has been administered (over a total period of ~1 h). Further antivenom may be necessary if the patient's clinical condition fails to stabilize or worsens. After stabilization, additional doses of CroFab are often recommended as the small-molecular-weight Fab fragments are rapidly cleared from the circulation. Larger, whole IgG or $F(ab)_2$ antivenoms have longer half-lives that eliminate the need for re-dosing after initial stabilization unless definitive symptoms of envenomation reappear.

If the patient develops an acute reaction to antivenom, the infusion should be temporarily stopped and the reaction immediately treated with IM epinephrine and IV antihistamine and steroids (Chap. 311). If the severity of envenomation warrants additional antivenom, the dose should be further diluted in isotonic saline and restarted as soon as possible. Rarely, in recalcitrant cases, a concomitant IV infusion of epinephrine may be required to hold allergic sequelae at bay while further antivenom is administered. The patient must be very closely monitored, preferably in an intensive care setting, during such therapy.

Blood products are rarely necessary in the management of the envenomated patient. The venoms of many snake species can cause a drop in platelet count or hematocrit and depletion of coagulation factors. Nevertheless, these components usually rebound within hours after administration of adequate antivenom. If the need for blood products is thought to be great (e.g., for a dangerously low platelet count in a hemorrhaging patient), these products still should be given only after adequate antivenom administration to avoid adding fuel to ongoing consumptive coagulopathy.

Rhabdomyolysis and hemolysis should be managed in standard fashion. Victims who develop acute renal failure should be evaluated by a nephrologist and referred for dialysis (peritoneal or hemodialysis) as needed. Such renal failure, usually due to acute tubular necrosis, is frequently reversible. If bilateral cortical necrosis occurs, however, the prognosis for renal recovery is more grim, and long-term dialysis with possible renal transplantation may be necessary.

Acetylcholinesterase inhibitors (e.g., edrophonium and neostigmine) may promote neurologic improvement in patients bitten by snakes with postsynaptic neurotoxins. Victims with objective evidence of neurologic dysfunction after snakebite should receive a trial of acetylcholinesterase inhibitors as outlined in **Table 391-2**. If they respond, additional doses of long-acting neostigmine can be continued as needed. Special vigilance is required to prevent aspiration if repetitive dosing of neostigmine is used in an attempt to obviate endotracheal intubation.

Care of the bite wound includes application of a dry sterile dressing and splinting of the extremity with padding between the digits. Once the administration of an indicated antivenom has been initiated, the extremity should be elevated above heart level to relieve edema. Tetanus immunization should be updated as appropriate. Prophylactic antibiotics are generally unnecessary after bites by North American snakes, as the incidence of secondary infection is low. Antibiotics can be considered, however, if misguided first-aid efforts have included incisions or mouth suction. In some regions of the world, secondary bacterial infection is more common and the consequences are dire. In these regions, prophylactic antibiotics (e.g., cephalosporins) are commonly used.

Most snake envenomations involve subcutaneous deposition of venom. On occasion, however, venom can be injected more deeply into muscle

TABLE 391-2 USE OF ACETYLCHOLINESTERASE INHIBITORS IN NEUROTOXIC SNAKE ENVENOMATION

1. Patients with clear, objective evidence of neurotoxicity after snakebite (e.g., ptosis or inability to maintain upward gaze) should receive a trial of edrophonium (if available) or neostigmine.
   a. Pretreat with atropine: 0.6 mg IV (children, 0.02 mg/kg; minimum of 0.1 mg)
   b. Follow with:
   Edrophonium: 10 mg IV (children, 0.25 mg/kg)
   or
   Neostigmine: 1.5–2.0 mg IM (children, 0.025–0.08 mg/kg)
2. If objective improvement is evident at 5 min, continue neostigmine at a dose of 0.5 mg (children, 0.01 mg/kg) every 30 min as needed, with continued administration of atropine by continuous infusion of 0.6 mg over 8 h (children, 0.02 mg/kg over 8 h).
3. Maintain vigilance regarding aspiration risk, and secure the airway with endotracheal intubation as needed.

compartments. If swelling in the bitten extremity raises concern that subfascial muscle edema may be impeding tissue perfusion (muscle-compartment syndrome), intracompartmental pressures (ICPs) should be checked by any minimally invasive technique—e.g., wick catheter or ICP monitor (Stryker Instruments, Kalamazoo, MI). If any ICP is high (>30–40 mmHg), the extremity should be kept elevated while further antivenom is given. A dose of IV mannitol (1 g/kg) can be given in an effort to reduce muscle edema if the patient's hemodynamic status is stable. If, after 1 h of such therapy, the ICP remains elevated, a surgical consultation for possible fasciotomy should be obtained. While evidence from studies of animals suggests that fasciotomy may actually worsen myonecrosis, compartmental decompression is still required to preserve nerve function. Fortunately, the incidence of muscle-compartment syndrome is very low following snakebite.

Wound care in the days after the bite may require careful aseptic debridement of clearly necrotic tissue once coagulation has been restored. Intact serum-filled vesicles or hemorrhagic blebs should be left undisturbed. If ruptured, they should be debrided with sterile technique.

Physical therapy should be started when pain allows in order to return the victim to a functional state. The incidence of long-term loss of function (e.g., reduced range of motion, impaired sensory function) is unclear but is probably quite high (>30%), particularly after viperid bites.

Any patient with signs of venom poisoning should be observed in the hospital for at least 24 h. In North America, a patient with an apparently "dry" viperid bite should be watched for at least 8 h before discharge, as significant toxicity occasionally develops after a delay of several hours. The onset of systemic symptoms is commonly delayed for a number of hours after bites by several of the elapids (including coral snakes), some non–North American viperids [e.g., the hump-nosed pit viper (*Hypnale hypnale*)], and sea snakes. Patients bitten by these reptiles should be observed in the hospital for at least 24 h. Unstable patients should be admitted to a monitored setting.

At discharge, victims of venomous snakebite should be warned about signs and symptoms of wound infection and serum sickness as well as other potential long-term sequelae, such as pituitary insufficiency in Russell's viper (*D. russelii*) bites. If the victim had evidence of coagulopathy early on, this abnormality can recur during the first 2–3 weeks after the bite. Such victims should be warned to avoid elective surgery or activities posing a high risk of trauma during this period. Outpatient analgesic treatment and physical therapy should be continued.

In the event of serum sickness (fever, chills, urticaria, myalgias, arthralgias, and possibly renal or neurologic dysfunction developing 1–2 weeks after antivenom administration), the victim should be treated with systemic glucocorticoids (e.g., oral prednisone, 1–2 mg/kg daily) until all findings resolve, at which point the dose is tapered over 1–2 weeks. Oral antihistamines (e.g., diphenhydramine in standard doses) provide additional relief of symptoms.

MORBIDITY AND MORTALITY

The overall mortality rates for venomous snakebite are low in areas with rapid access to medical care and appropriate antivenoms. In the United States, for example, the mortality rate is <1% for victims who receive antivenom. Eastern and western diamondback rattlesnakes (*Crotalus adamanteus* and *C. atrox*, respectively) are responsible for the few snakebite deaths occurring in the United States. Snakes responsible for large numbers of deaths in other regions include cobras (*Naja* spp.), carpet and saw-scaled vipers (*Echis* spp.), Russell's vipers (*D. russelii*), large African vipers (*Bitis* spp.), lancehead pit vipers (*Bothrops* spp.), and tropical rattlesnakes (*C. durissus*).

The incidence of morbidity—defined as permanent functional loss in a bitten extremity—is difficult to estimate but is substantial. Morbidity may be due to muscle, nerve, or vascular injury or to scar contracture. In the United States, such loss tends to be more common and severe after rattlesnake bites than after bites by copperheads (*Agkistrodon contortrix*) or water moccasins (*A. piscivorus*).

MARINE ENVENOMATIONS

Management of venom poisoning by marine creatures is similar to that of venomous snakebite in that much of the treatment administered is supportive in nature. A specific marine antivenom can be used when appropriate.

INVERTEBRATES

Hydroids, fire coral, jellyfish, Portuguese man-of-war, and *sea anemones* possess specialized living stinging cells called *cnidocytes*, which encapsulate intracytoplasmic stinging organelles called *cnidae* (including nematocysts). The venoms from these organisms are mixtures of proteins, carbohydrates, and other components. Victims usually report immediate prickling or burning, pruritus, paresthesias, and painful throbbing with radiation. The skin becomes reddened, darkened, edematous, and/or blistered. A legion of neurologic, cardiovascular, respiratory, rheumatologic, gastrointestinal, renal, and ocular symptoms have been described. Anaphylaxis sometimes develops. During stabilization, the skin should immediately be decontaminated with a generous application of vinegar (5% acetic acid), which is the all-purpose agent most useful in inactivating the nematocysts. Rubbing alcohol (40–70% isopropyl alcohol), baking soda (sodium bicarbonate), papain (unseasoned meat tenderizer), fresh lemon or lime juice, household ammonia, olive oil, or sugar may be effective, depending on the species of stinging creature. For the sting of the venomous box-jellyfish (*Chironex fleckeri*), vinegar should be used. Perfume, aftershave lotion, and high-proof ethanol are not efficacious and may be detrimental; formalin, ether, gasoline, and other organic solvents should not be used. Shaving the skin helps remove remaining nematocysts. Freshwater irrigation and rubbing lead to further stinging by adherent nematocysts and should be avoided. Commercial (chemical) cold packs or real ice packs applied over a thin dry cloth or plastic membrane have been shown to be effective in alleviating mild or moderate *Physalia utriculus* (bluebottle jellyfish) stings. Recent observations suggest that local application of heat [up to 45°C (113°F)] may be as effective as or more effective than application of cold. After decontamination, application of anesthetic ointment (lidocaine, benzocaine), antihistamine (diphenhydramine), or steroid (hydrocortisone) topical preparations may be helpful. Persistent severe pain after decontamination may be treated with morphine, meperidine, fentanyl, or another narcotic analgesic. Muscle spasms may respond to 10% calcium gluconate (5–10 mL) or diazepam (2–5 mg, titrated upward as necessary) given IV. An ovine-derived antivenom is available from Commonwealth Serum Laboratories (see section on antivenom sources, below) for stings from the box-jellyfish found in Australian and Indo-Pacific waters. As of this writing, this antivenom has not yet been used to treat envenomation by the box-shaped jellyfish (possibly of the genus *Chiropsalmus*) that has been found in Florida waters. The pressure-immobilization technique is no longer recommended for venom containment in the setting of a jellyfish sting. Safe Sea, a "jellyfish-safe" sunblock (*www.nidaria.com*) applied to the skin before an individual enters the water, inactivates the recognition and discharge mechanisms of nematocysts, has been tested successfully against a number of marine stingers, and may prevent or diminish the effects of coelenterate stings.

Touching a *sea sponge* may result in dermatitis. The afflicted skin should be gently dried and adhesive tape used to remove embedded

spicules. Vinegar should be applied immediately and then for 10–30 min three or four times a day. Rubbing alcohol may be used if vinegar is unavailable. After spicule removal and skin decontamination, steroid or antihistamine cream may be applied to the skin. Severe vesiculation should be treated with a 2-week course of systemic glucocorticoids.

Annelid worms (bristleworms) possess rows of soft, cactus-like spines capable of inflicting painful stings. Contact results in symptoms similar to those of nematocyst envenomation. Without treatment, pain usually subsides over several hours, but inflammation may persist for up to a week. Victims should resist the urge to scratch, since scratching may fracture retrievable spines. Visible bristles should be removed with forceps and adhesive tape or a commercial facial peel; alternatively, a thin layer of rubber cement can be used to entrap the spines. Use of vinegar, rubbing alcohol, or dilute ammonia or a brief application of unseasoned meat tenderizer (papain) may provide additional relief. Local inflammation should be treated with topical or systemic glucocorticoids.

Sea urchins possess either hollow, venom-filled, calcified spines or triple-jawed, globiferous pedicellariae with venom glands. The venom contains toxic components, including steroid glycosides, hemolysins, proteases, serotonin, and cholinergic substances. Contact with either venom apparatus produces immediate and intensely painful stings. The affected part should be immersed immediately in hot water (see below). Accessible embedded spines should be removed but may break off and remain lodged in the victim. Residual dye from the surface of a spine remaining after the spine's removal may mimic a retained spine but is otherwise of no consequence. Soft tissue radiography or MRI can confirm the presence of retained spines, which may warrant referral for attempted surgical removal if the spines are located near vital structures (e.g., joints, neurovascular bundles). Retained spines may cause the formation of granulomas that are amenable to excision or to intralesional injection with triamcinolone hexacetonide (5 mg/mL). Local and diffuse neuropathies have been observed after penetration by multiple spines of the black sea urchin (*Diadema* spp.). The pathophysiology of this phenomenon has not yet been determined.

Serious envenomations and deaths have followed bites of the *Australian blue-ringed octopuses* (*Octopus maculosus* and *O. lunulata*). Although these animals rarely exceed 20 cm in length, their venom contains a potent neurotoxin (maculotoxin) that inhibits peripheral nerve transmission by blocking sodium conductance. Oral and facial numbness develop within several minutes of a serious envenomation and rapidly progress to total flaccid paralysis, including failure of respiratory muscles. Immediately after envenomation, a circumferential pressure-immobilization dressing 15 cm wide should be applied over a gauze pad (~7 × 7 × 2 cm) that has been placed directly over the sting. The dressing should be applied at venous-lymphatic pressure, with the preservation of distal arterial pulses. Once the victim has been transported to the nearest medical facility, the bandage can be released. Since there is no antidote, treatment is supportive. If respirations are assisted, the victim may remain awake although completely paralyzed. Even with serious envenomations, significant recovery often takes place within 4–10 h. Sequelae are uncommon unless related to hypoxia.

VERTEBRATES

A *stingray* injury is both an envenomation and a traumatic wound. The venom, which contains serotonin, 5′-nucleotidase, and phosphodiesterase, causes immediate, intense pain that may last up to 48 h. The wound often becomes ischemic in appearance and heals poorly, with adjacent soft tissue swelling and prolonged disability. Systemic effects include weakness, diaphoresis, nausea, vomiting, diarrhea, dysrhythmias, syncope, hypotension, muscle cramps, fasciculations, paralysis, and (in rare cases) death.

The designation *scorpionfish* encompasses members of the family Scorpaenidae and includes not only scorpionfish but also lionfish and stonefish. A complex venom with neuromuscular toxicity is delivered through 12 or 13 dorsal, 2 pelvic, and 3 anal spines. In general, the sting of a stonefish is regarded as the most serious (severe to life-threatening); that of the scorpionfish is of intermediate seriousness; and that of the lionfish is the least serious. Like that of a stingray, the sting of a scorpionfish is immediately and intensely painful. Pain from a stonefish envenomation may last for days. Systemic manifestations of scorpionfish stings are similar to those of stingray envenomations but may be more pronounced, particularly in the case of a stonefish sting. The rare deaths following stonefish envenomation usually occur within 6–8 h.

Two species of marine catfish—*Plotosus lineatus* (the oriental catfish) and *Galeichthys felis* (the common sea catfish)—as well as several species of freshwater catfish are capable of stinging humans. Venom is delivered through a single dorsal spine and two pectoral spines. Clinically, a catfish sting is comparable to that of a stingray, although marine catfish envenomations are generally more severe than those of their freshwater counterparts. Surgeonfish (doctorfish, tang), weeverfish, ratfish, and horned venomous sharks have also envenomated humans.

℞ MARINE VERTEBRATE STINGS

The stings of all marine vertebrates are treated in a similar fashion. Except for stonefish and serious scorpionfish envenomations (see below), no antivenom is available. The affected part should be immersed immediately in nonscalding hot water (45°C/113°F) for 30–90 min or until there is significant relief of pain. Recurrent pain may respond to repeated hot-water treatment. Cryotherapy is contraindicated. Opiates will help alleviate the pain, as will local wound infiltration or regional nerve block with 1% lidocaine, 0.5% bupivacaine, and sodium bicarbonate mixed in a 5:5:1 ratio. After soaking and anesthetic administration, the wound must be explored and debrided. Radiography (in particular, MRI) may be helpful in identification of foreign bodies. After exploration and debridement, the wound should be vigorously irrigated with warm sterile water, saline, or 1% povidone-iodine in solution. Bleeding can usually be controlled by sustained local pressure for 10–15 min. In general, wounds should be left open to heal by secondary intention or treated by delayed primary closure. Tetanus immunization should be updated. Antibiotic treatment should be considered for serious wounds and for envenomation in immunocompromised hosts. The initial antibiotics should cover *Staphylococcus* and *Streptococcus* spp. If the victim is immunocompromised, if a wound is primarily repaired and is more than minor, or if an infection develops, antibiotic coverage should be broadened to include *Vibrio* spp.

APPROACH TO THE PATIENT: Marine Envenomations

It is useful to be familiar with the local marine fauna and to recognize patterns of injury.

A large puncture wound or jagged laceration (particularly on the lower extremity) that is more painful than one would expect from the size and configuration of the wound is likely to be a stingray envenomation. Smaller punctures, as described above, represent the activity of a sea urchin or starfish. Stony corals cause rough abrasions and, in rare instances, lacerations or puncture wounds.

Coelenterate (marine invertebrate) stings sometimes create diagnostic skin patterns. A diffuse urticarial rash on exposed skin is often indicative of exposure to fragmented hydroids or larval anemones. A linear, whiplike print pattern appears where a jellyfish tentacle has contacted the skin. In the case of the dreaded box-jellyfish (Fig. 391-3), a cross-hatched, sometimes frosted appearance, followed by development of dark purple coloration within a few hours of the sting, heralds skin necrosis. The frosted appearance may be augmented by aluminum salt–based remedies applied to the wound. An encounter with fire coral causes immediate pain and swollen red skin irritation in the pattern of contact, similar to but more severe than the imprint left by exposure to an intact feather hydroid. Seabather's eruption, caused by thimble jellyfishes and larval anemones, may produce a diffuse rash that consists of clusters of erythematous macules or raised papules, accompanied by intense itching (Fig. 391-4). Toxic sponges create a burning and painful red rash on exposed skin, which may blister and later desquamate. Virtually all marine stingers invoke the sequelae of inflammation, so that local erythema, swelling, and adenopathy are fairly nonspecific.

SOURCES OF ANTIVENOMS AND OTHER ASSISTANCE

The best way to locate a specific antivenom in the United States is to call a regional poison control center and ask for assistance. Divers Alert Network, a nonprofit organization designed to assist in the care of injured divers, may also help with the treatment of marine injuries. The network can be reached on the Internet at www.diversalertnetwork.org or by telephone 24 hours a day at (919) 684-8111. An antivenom for stonefish (and severe scorpionfish) envenomation is made in Australia by the Commonwealth Serum Laboratories (CSL; 45 Poplar Road, Parkville, Victoria, Australia 3052; *www.csl.com.au*; 61-3-389-1911). Polyvalent sea snake antivenom is also available from CSL. It is no longer recommended that tiger snake antivenom be used if sea snake antivenom is unavailable.

MARINE POISONINGS

CIGUATERA

Ciguatera poisoning is the most common nonbacterial food poisoning associated with fish in the United States; most U.S. cases occur in Florida and Hawaii. The poisoning almost exclusively involves tropical and semitropical marine coral reef fish common in the Indian Ocean, the South Pacific, and the Caribbean Sea. Of reported cases, 75% (except in Hawaii) involve the barracuda, snapper, jack, or grouper. The ciguatera syndrome is associated with at least five polyether sodium channel activator toxins that originate in photosynthetic dinoflagellates (such as *Gambierdiscus toxicus*) and accumulate in the food chain. Three major ciguatoxins are found in the flesh and viscera of ciguateric fishes: CTX-1, -2, and -3. Most, if not all, ciguatoxins are unaffected by freeze-drying, heat, cold, and gastric acid. None of the toxins affects the odor, color, or taste of fish. Cooking methods may alter the relative concentrations of the various toxins.

FIGURE 391-4 Erythematous, papular rash typical of seabather's eruption caused by thimble jellyfish and larval anemones.

The onset of symptoms may come within 15–30 min of ingestion and typically takes place within 2–6 h. Symptoms increase in severity over the ensuing 4–6 h. Most victims develop symptoms within 12 h of ingestion, and virtually all are afflicted within 24 h. The >150 symptoms reported include abdominal pain, nausea, vomiting, diarrhea, chills, paresthesias, pruritus, tongue and throat numbness or burning, sensation of "carbonation" during swallowing, odontalgia or dental dysesthesias, dysphagia, dysuria, dyspnea, weakness, fatigue, tremor, fasciculations, athetosis, meningismus, aphonia, ataxia, vertigo, pain and weakness in the lower extremities, visual blurring, transient blindness, hyporeflexia, seizures, nasal congestion and dryness, conjunctivitis, maculopapular rash, skin vesiculations, dermatographism, sialorrhea, diaphoresis, headache, arthralgias, myalgias, insomnia, bradycardia, hypotension, central respiratory failure, and coma. Death is rare.

Diarrhea, vomiting, and abdominal pain usually develop 3–6 h after ingestion of a ciguatoxic fish. Symptoms may persist for 48 h and then generally resolve (even without treatment). A pathognomonic symptom is the reversal of hot and cold tactile perception, which develops in some persons after 3–5 days and may last for months. Tachycardia and hypertension have been described, in some cases after potentially severe transient bradycardia and hypotension. More severe reactions tend to occur in persons previously stricken with the disease. Persons who have ingested parrotfish (scaritoxin) may develop classic ciguatera poisoning as well as a "second-phase" syndrome (after 5–10 days' delay) of disequilibrium with locomotor ataxia, dysmetria, and resting or kinetic tremor. This syndrome may persist for 2–6 weeks.

The differential diagnosis of ciguatera includes paralytic shellfish poisoning, eosinophilic meningitis, type E botulism, organophosphate insecticide poisoning, tetrodotoxin poisoning, and psychogenic hyperventilation. At present, the diagnosis of ciguatera poisoning is made on clinical grounds because no routinely used laboratory test detects ciguatoxin in human blood. High-performance liquid chromatography (HPLC) is available for ciguatoxins and okadaic acid but is of limited clinical value because most health care institutions do not have the equipment needed to perform the test. A ciguatoxin enzyme immunoassay or radioimmunoassay may be used to test small portions of the suspected fish, but even these tests may not detect the very small amount of toxin (0.1 ppb) necessary to render fish flesh toxic.

Rx CIGUATERA POISONING

Therapy is supportive and based on symptoms. Nausea and vomiting may be controlled with an antiemetic, such as prochlorperazine (2.5–5 mg IV). Hypotension may require the administration of IV crystalloid and, in rare cases, a pressor drug. Bradyarrhythmias that lead to cardiac insufficiency and hypotension generally respond well to atropine (0.5 mg IV, up to 2 mg). Cool showers or the administration of hydroxyzine (25 mg PO every 6–8 h) may relieve pruritus. Amitriptyline (25 mg PO twice a day) reportedly ameliorates pruritus and dysesthesias. In three cases unresponsive to amitriptyline, tocainide appeared to be efficacious. Nifedipine has been used to treat headache. IV infusion of mannitol may be beneficial in moderate or severe cases, particularly for the relief of distressing neurologic or cardiovascular symptoms, although the efficacy of this therapy has been challenged and has not been definitively proven. The infusion is rendered initially as 1 g/kg per day over 45–60 min during the acute phase (days 1–5). If symptoms improve, a second dose may be given within 3–4 h and repeated on the following day. Care must be taken to avoid dehydration in the treated patient. The mechanism of the benefit against ciguatera intoxication is perhaps hyperosmotic water-drawing action, which reverses ciguatoxin-induced Schwann cell edema. Mannitol may also act in some fashion as a "hydroxyl scavenger" or may competitively inhibit ciguatoxin at the cell membrane.

During recovery from ciguatera poisoning, the victim should exclude the following from the diet: fish (fresh or preserved), fish sauces, shellfish, shell-

fish sauces, alcoholic beverages, nuts, and nut oils. Consumption of fish in ciguatera-endemic regions should be avoided. All oversized fish of any predacious reef species should be suspected of harboring ciguatoxin. Neither moray eels nor the viscera of tropical marine fish should ever be eaten.

PARALYTIC SHELLFISH POISONING

Paralytic shellfish poisoning is induced by ingestion of any of a variety of feral or aquacultured filter-feeding organisms, including clams, oysters, scallops, mussels, chitons, limpets, starfish, and sand crabs. The origin of their toxicity is the chemical toxin they accumulate and concentrate by feeding on various planktonic dinoflagellates (e.g., *Protogonyaulax*, *Ptychodiscus,* and *Gymnodinium*) and protozoan organisms. The unicellular phytoplanktonic organisms form the foundation of the food chain, and in warm summer months these organisms "bloom" in nutrient-rich coastal temperate and semitropical waters. These planktonic species can release massive amounts of toxic metabolites into the water and cause mortality in bird and marine populations. The paralytic shellfish toxins are water-soluble as well as heat- and acid-stable; they cannot be destroyed by ordinary cooking. The best-characterized and most frequently identified paralytic shellfish toxin is saxitoxin, which takes its name from the Alaska butter clam *Saxidomus giganteus*. A toxin concentration of >75 μg/100 g of foodstuff is considered hazardous to humans. In the 1972 New England "red tide," the concentration of saxitoxin in blue mussels exceeded 9000 μg/100 g of foodstuff. Saxitoxin appears to block sodium conductance, inhibiting neuromuscular transmission at the axonal and muscle membrane levels.

The onset of intraoral and perioral paresthesias (notably of the lips, tongue, and gums) comes within minutes to a few hours after ingestion of contaminated shellfish, and these paresthesias progress rapidly to involve the neck and distal extremities. The tingling or burning sensation later changes to numbness. Other symptoms rapidly develop and include lightheadedness, disequilibrium, incoordination, weakness, hyperreflexia, incoherence, dysarthria, sialorrhea, dysphagia, thirst, diarrhea, abdominal pain, nausea, vomiting, nystagmus, dysmetria, headache, diaphoresis, loss of vision, chest pain, and tachycardia. Flaccid paralysis and respiratory insufficiency may follow 2–12 h after ingestion. In the absence of hypoxia, the victim often remains alert but paralyzed.

℞ PARALYTIC SHELLFISH POISONING

Treatment is supportive and based on symptoms. If the victim comes to medical attention within the first few hours after poison ingestion, the stomach should be emptied by gastric lavage and then irrigated with 2 L (in 200-mL aliquots) of a solution of 2% sodium bicarbonate; this intervention has not been proved to be of benefit but is based on the notion that gastric acidity may enhance the potency of saxitoxin. Because breathing difficulty can be rapid in onset, induction of emesis is not advised. The administration of activated charcoal (50–100 g) and a cathartic (sorbitol, 20–50 g) makes empirical sense since these shellfish toxins are believed to bind well to charcoal. Some authors advise against administration of magnesium-based solutions (e.g., certain cathartics), cautioning that hypermagnesemia may contribute to suppression of nerve conduction.

The most serious problem is respiratory paralysis. The victim should be closely observed in a hospital for at least 24 h for respiratory distress. With prompt recognition of ventilatory failure, endotracheal intubation and assisted ventilation prevent anoxic myocardial and brain injury.

A direct human serum assay to identify the toxin responsible for paralytic shellfish poisoning is not yet clinically available; the mouse bioassay in widespread use may be replaced by an automated tissue culture bioassay. Polyclonal enzyme-linked immunosorbent assay (ELISA) to measure specific toxins is under development, as is fluorimetric HPLC.

DOMOIC ACID INTOXICATION (AMNESTIC SHELLFISH POISONING)

In late 1987 in eastern Canada, an outbreak of gastrointestinal and neurologic symptoms (amnestic shellfish poisoning) was documented in persons who had consumed mussels found to be contaminated with domoic acid. In this outbreak, the source of the toxin was *Nitzschia pungens*, a diatom ingested by the mussels. In 1991, an epidemic of domoic acid poisoning in the state of Washington was attributed to the consumption of razor clams. A heat-stable neuroexcitatory amino acid whose biochemical analogues are kainic acid and glutamic acid, domoic acid binds to the kainate type of glutamate receptor with three times the affinity of kainic acid and is 20 times as powerful a toxin. Shellfish can be tested for domoic acid by mouse bioassay and HPLC. The regulatory limit for domoic acid in shellfish is 20 parts per million.

The abnormalities noted within 24 h of ingesting contaminated mussels (*Mytilus edulis*) include arousal, confusion, disorientation, and memory loss. The median time of onset is 5.5 h. Other prominent symptoms include severe headache, nausea, vomiting, diarrhea, abdominal cramps, hiccoughs, arrhythmias, hypotension, seizures, ophthalmoplegia, pupillary dilation, piloerection, hemiparesis, mutism, grimacing, agitation, emotional lability, coma, copious bronchial secretions, and pulmonary edema. Histologic study of brain tissue taken at autopsy has shown neuronal necrosis or cell loss and astrocytosis, most prominently in the hippocampus and the amygdaloid nucleus—findings similar to those in animals poisoned with kainic acid. Several months after the primary intoxication, victims still display chronic residual memory deficits and motor neuronopathy or axonopathy. Non-neurologic illness does not persist.

℞ DOMOIC ACID INTOXICATION

Therapy is supportive and based on symptoms. Since kainic acid neuropathology seems to be nearly entirely seizure-mediated, an emphasis should be placed on anticonvulsive therapy, for which diazepam appears to be as effective as any other drug.

SCOMBROID POISONING

Scombroid (mackerel-like) fish include the albacore, bluefin, and yellowfin tuna; mackerel; saury; needlefish; wahoo; skipjack; and bonito. Nonscombroid fish that produce scombroid poisoning include the dolphinfish (Hawaiian mahimahi, *Coryphaena hippurus*), kahawai, sardine, black marlin, pilchard, anchovy, herring, amberjack, and Australian ocean salmon. In the northeastern and mid-Atlantic United States, bluefish (*Pomatomus saltatrix*) has been linked to scombroid poisoning. Because greater numbers of nonscombroid fish are being recognized as scombrotoxic, the syndrome may more appropriately be called *pseudoallergic fish poisoning*.

Under conditions of inadequate preservation or refrigeration, the musculature of these dark- or red-fleshed fish undergoes bacterial decomposition, which includes decarboxylation of the amino acid L-histidine to histamine, histamine phosphate, and histamine hydrochloride. Histamine levels of 20–50 mg/100 g are noted in toxic fish, with levels >400 mg/100 g on occasion. However, it is possible that some other compound may be responsible for this intoxication, since large doses of oral histamine do not reproduce the affliction. Whatever toxin(s) are involved are heat-stable and are not destroyed by domestic or commercial cooking. Affected fish typically have a sharply metallic or peppery taste; however, they may be normal in appearance, color, and flavor. Not all persons who eat a contaminated fish necessarily become ill, perhaps because of uneven distribution of decay within the fish.

Symptoms develop within 15–90 min of ingestion and include flushing (sharply demarcated; exacerbated by ultraviolet exposure; particularly pronounced on the face, neck, and upper trunk), a sensation of warmth without elevated core temperature, conjunctival hyperemia, pruritus, urticaria, angioneurotic edema, bronchospasm, nausea, vomiting, diarrhea, epigastric pain, abdominal cramps, dysphagia, headache, thirst, pharyngitis, gingival burning, palpitations, tachycardia, dizziness, and hypotension. Without treatment, the symptoms generally resolve within 8–12 h. Because of blockade of gastrointestinal tract histaminase, the reaction may be more severe in a person who is concurrently ingesting isoniazid.

℞ SCOMBROID POISONING

Therapy is directed at reversing the histamine effect with antihistamines, either H-1 or H-2. If bronchospasm is severe, an inhaled bronchodilator—or in rare, extremely severe circumstances, injected epinephrine—may be used. Glucocorticoids are of no proven benefit. Protracted nausea and vomiting, which may empty the stomach of toxin, may be controlled with a specific antiemetic, such as prochlorperazine. The persistent headache of scombroid poisoning may respond to cimetidine or a similar antihistamine if standard analgesics are not effective.

392 Ectoparasite Infestations and Arthropod Bites and Stings

Richard J. Pollack, James H. Maguire

Ectoparasites are arthropods or helminths that infest the skin or hair of other animals, from which they derive sustenance and shelter. They may penetrate beneath the surface of the host or attach superficially by their mouthparts. These organisms damage their hosts by inflicting direct injury, by eliciting a hypersensitivity reaction, or by inoculating toxins or pathogens. The main medically important ectoparasites are arachnids (including mites and ticks), insects (including lice, fleas, bedbugs, and flies), pentastomes (tongue worms), and leeches. Arthropods may also harm humans through brief encounters during which they take a blood meal or attempt to defend themselves by biting, stinging, or exuding venoms. Various arachnids (spiders, scorpions), insects (bees, hornets, wasps, ants, flies, bugs, caterpillars, and beetles), millipedes, and centipedes produce ill effects in this manner, as do certain ectoparasites of animals, including ticks, biting mites, and fleas. In the United States, more people die each year as a consequence of arthropod stings than from the bites of poisonous snakes.

SCABIES

The human itch mite, *Sarcoptes scabiei*, is a common cause of itching dermatosis infesting ~300 million persons worldwide. Gravid female mites, measuring ~0.3 mm in length, burrow superficially beneath the stratum corneum, depositing three or fewer eggs per day. Nymphs mature in ~2 weeks and then emerge as adults to the surface of the skin, where they mate and (re)invade the skin of the same or another host. Transfer of newly fertilized female mites from person to person occurs mainly by intimate contact and is facilitated by crowding, poor hygiene, and multiple sexual partners. Generally, these mites die within a day or so in the absence of host contact. Transmission via sharing of contaminated bedding or clothing is therefore infrequent. In the United States, scabies may account for up to 5% of visits to dermatologists. Outbreaks occur in nursing homes, mental institutions, and hospitals.

The itching and rash associated with scabies derive from a sensitization reaction directed against the excreta that the mite deposits in its burrow. An initial infestation remains asymptomatic for up to 6 weeks, and a reinfestation produces a hypersensitivity reaction without delay. Burrows become surrounded by infiltrates of eosinophils, lymphocytes, and histiocytes, and a generalized hypersensitivity rash later develops in remote sites. Immunity and associated scratching limit most infestations to <15 mites per person. Hyperinfestation with thousands of mites, a condition known as *crusted scabies* or *Norwegian scabies*, may result from glucocorticoid use, immunodeficiency, and neurologic and psychiatric illnesses that limit itching and scratching.

Intense itching worsens at night and after a hot shower. Typical burrows may be difficult to find because they are few in number and may be obscured by excoriations. Burrows appear as dark wavy lines in the epidermis and measure up to 15 mm. Lesions occur most frequently on the volar wrists, between the fingers, on the elbows, and on the penis. Small papules and vesicles, often accompanied by eczematous plaques, pustules, or nodules, are symmetrically distributed in these sites and in skin folds under the breasts and around the navel, axillae, belt line, buttocks, upper thighs, and scrotum. Except in infants, the face, scalp, neck, palms, and soles are spared. Crusted scabies resembles psoriasis in its typical widespread erythema, thick keratotic crusts, scaling, and dystrophic nails. Characteristic burrows are not seen in crusted scabies, and patients usually do not itch, although their infestations are highly contagious and have been responsible for outbreaks of classic scabies in hospitals.

Scabies should be considered in patients with pruritus and symmetric polymorphic skin lesions in characteristic locations, particularly if there is a history of household contact with a case. Burrows should be sought and unroofed with a sterile needle or scalpel blade, and the scrapings should be examined microscopically for the mite, its eggs, and its fecal pellets. Biopsies, scrapings of papulovesicular lesions, and microscopic inspection of clear adhesive tape lifted from lesions may also be diagnostic. In the absence of identifiable mites or mite products, the diagnosis is based on clinical presentation and history. Diverse kinds of dermatitis due to other causes are frequently misdiagnosed as scabies.

℞ SCABIES

Permethrin cream (5%) is less toxic than 1% lindane preparations and is effective against lindane-tolerant infestations. Scabicides are applied thinly but thoroughly behind the ears and from the neck down after bathing and are removed 8 h later with soap and water. Successful treatment of crusted scabies requires pre-application of a keratolytic agent such as 6% salicylic acid and then of scabicides to the scalp, face, and ears. Repeated treatments or the sequential use of several agents may be necessary. Although ivermectin has not yet been approved by the U.S. Food and Drug Administration (FDA) for use against any form of scabies, a single oral dose (200 μg/kg) effectively treats scabies in otherwise-healthy persons; patients with crusted scabies may require two doses separated by an interval of 1–2 weeks.

Although effectively treated scabies infestations become noninfectious within a day, itching and rash due to hypersensitivity to the dead mites and

their excreted and secreted products frequently persist for weeks or months. Unnecessary re-treatment with topical agents may provoke contact dermatitis. Antihistamines, salicylates, and calamine lotion relieve itching during treatment, and topical glucocorticoids are useful for pruritus that lingers after effective treatment. To prevent reinfestations, bedding and clothing should be washed and/or dried on high heat or heat-pressed, and close contacts, even if asymptomatic, should be treated simultaneously.

CHIGGERS AND OTHER BITING MITES

Chiggers are the larvae of trombiculid (harvest) mites that normally feed on mice in grassy or brush-covered sites in the tropics and subtropics and less frequently in temperate areas during warm months. They wait for hosts on low vegetation and attach themselves to passing animals or to humans. The larva pierces the skin of its host and produces a secreted tube-like structure (*stylostome*) in the dermis through which it imbibes tissue fluids. The stylostome is highly antigenic and causes an exceptionally pruritic papular, papulovesicular, or papulourticarial lesion (≤2 cm in diameter) that develops within hours of attachment in persons previously sensitized to mite antigen. Feeding mites appear as tiny red vesicles adjacent to hair follicles. Scratching invariably destroys the body of a mite. Generally, lesions vesiculate and develop a hemorrhagic base. Itching and burning persist for weeks. The rash is common on the ankles and where clothing obstructs the further wanderings of the mites. Repellents are useful for preventing chigger bites.

Diverse mites associated with birds and rodents can be particularly bothersome when they invade homes and bite human inhabitants. In North America, the northern fowl mite, the chicken mite, the tropical rat mite, and the house mouse mite normally feed on poultry, various songbirds, or small mammals and are abundant in and near their hosts' nests. These mites invade homes after their natural hosts die or leave their nests. Although the mites often are not seen because of their small size, their bites can be painful and pruritic. Painful bite-like sensations associated only with certain rooms of a home may be due to biting mites. Rodent- and bird-associated mites are best eliminated by excluding hosts, removing nests, and cleaning and treating the nesting area with appropriate acaricides. *Pyemotes* and other mites that infest grain, straw, cheese, or other animal products occasionally produce similar episodes of rash and discomfort.

Diagnosis of mite-induced dermatitides (including those caused by chiggers) relies on a history of exposure to the source of the mite. Antihistamines or topical steroids effectively reduce mite-induced pruritus.

TICK BITES AND TICK PARALYSIS

Ticks attach and feed painlessly; blood is their only food. Their secretions produce local reactions, a febrile illness, or paralysis and transmit diverse pathogens. Generally, soft ticks attach for <1 h and may produce erythematous macular lesions ≤3 cm in diameter. Some species in Africa, the western United States, and Mexico produce painful hemorrhagic lesions. In contrast, hard ticks attach and feed for several days or sometimes for >1 week. At the site of hard-tick bites, small areas of induration with surrounding erythema and occasionally necrotic ulcers develop. Chronic nodules (tick granulomas) reach several centimeters in diameter and may require surgical excision. Tick-induced fever, associated with headache, nausea, and malaise, usually resolves ≤36 h after the tick is removed.

Tick paralysis, an ascending flaccid paralysis, is believed to be caused by a toxin in tick saliva that produces neuromuscular block and decreases nerve conduction. Throughout the world, this rare complication has followed the bites of >40 kinds of ticks; in the United States, dog and wood ticks are most commonly involved. Weakness begins in the lower extremities ≤6 days after the tick's attachment and ascends symmetrically over several days to result in complete paralysis of the extremities and cranial nerves. Deep tendon reflexes are diminished or lacking altogether, but sensory examination and findings on lumbar puncture are typically normal. Removal of the tick generally results in improvement within a few hours and complete recovery after several days. Failure to remove the tick may lead to dysarthria, dysphagia, and ultimately death from aspiration or respiratory paralysis. Diagnosis depends on finding the tick, which is often hidden beneath hair. An antiserum to the saliva of *Ixodes holocyclus*, the usual cause of tick paralysis in Australia, effectively reverses paralysis caused by these ticks.

FIGURE 392-1 Deer ticks (*Ixodes scapularis*, black-legged ticks) on a U.S. penny: larva (*below ear*), nymph (*right*), adult male (*above*), and adult female (*left*).

Ticks should be removed by firm traction with a forceps placed near the point of attachment. Use of occlusive dressings, heat, or other substances merely delays tick removal. The site of attachment should be disinfected. Tick mouthparts remaining in the skin generally are shed within days without excision. Removal of ticks during the first 48 h of attachment nearly always prevents transmission of the agents of Lyme disease, babesiosis, anaplasmosis, and ehrlichiosis. Gentle handling (to avoid rupture of ticks) and use of gloves may avert accidental contamination with tick fluids containing pathogens. Rather than awaiting results of tick testing or seroconversion to Lyme disease, patients with bites thought to be associated with deer ticks (Fig. 392-1) may be treated presumptively with a short course of oral doxycycline.

PEDICULIASIS (LOUSE INFESTATION)

Nymphs and adults of all three kinds of human lice feed at least once a day, ingesting human blood exclusively. Head lice (*Pediculus capitis*) infest mainly the hair of the scalp, body lice (*Pediculus humanus*) the clothing, and crab or pubic lice (*Phthirus pubis*) mainly the hair of the pubis. The saliva of lice produces an intensely irritating maculopapular or urticarial rash in sensitized persons. Female head and pubic lice cement their eggs firmly to hair and female body lice to clothing. A nymph hatches after ~10 days of development. The empty egg (nit) may remain affixed for months thereafter.

In North America, head lice infest ~1% of elementary school–aged children. Head lice are transmitted mainly by direct head-to-head contact rather than by fomites (shared headgear, grooming implements, bedding). Infestations by head lice tend to be asymptomatic. Pruritus, due mainly to hypersensitivity to the louse's saliva, generally is transient and mild. Head lice removed from a person succumb to desiccation and starvation within ~1 day. Head lice are unimportant as vectors of pathogenic agents.

Body lice remain on clothing except when feeding and generally succumb in ≤2 days if separated from their host. These lice mainly infest disaster victims or indigent people who are in close contact with other infested individuals. Body lice are acquired by direct contact or by sharing of clothing and bedding. These lice are vectors for the agents of louse-borne typhus (Chap. 167), louse-borne relapsing fever (Chap. 165), and trench fever (Chap. 153). Pruritic lesions are particularly common around the neckline. Chronic infestations result in a postinflammatory hyperpigmentation and thickening of skin known as *vagabonds' disease*.

The crab or pubic louse is transmitted mainly by sexual contact. These lice occur mainly on pubic hair and less frequently on hair of the axillae and the face, including the eyelashes. Children and adults may acquire pubic lice by sexual or close nonsexual contact. Intensely

FIGURE 392-2 Adult female human head louse (*Pediculus capitis*) on a nit (louse-egg) comb.

pruritic lesions and blue macules ~3 mm in diameter (*maculae ceruleae*) develop at the site of bites. Blepharitis commonly accompanies infestations of the eyelashes.

Pediculiasis may be suspected upon the detection of nits on hairs or in clothing, but confirmation should be based upon discovery of a live louse.

Rx PEDICULIASIS

Generally, treatment is warranted only if live lice are discovered. The presence of nits alone is evidence of former—but not current—infestation. Mechanical removal of lice and their eggs by means of a fine-toothed louse or nit comb **(Fig. 392-2)** often fails to eliminate infestations. Treatment of newly identified active infestations generally relies upon a 10-min application of ~1% permethrin or pyrethrins, with a second application 10 days later. Lice persisting after this treatment may be resistant to pyrethroids (see below). Chronic infestations may be treated for ≤12 h with 0.5% malathion. Lindane is applied for just 4 min but seems less effective and may pose a greater risk of adverse reaction, particularly when misused. Resistance of head lice to permethrin, malathion, and lindane has been reported. Ivermectin may be useful in cases of resistance to malathion and permethrin but has not been approved for this purpose by the FDA. Although children infested by head lice are frequently isolated or excluded from school, this practice is increasingly seen as unjustified.

Body lice are usually eliminated by bathing and by changing to laundered clothes. Application of topical pediculicides from head to foot may be necessary for hirsute patients. Clothes and bedding are effectively deloused by heating in a clothes dryer at ≥55°C for 30 min or by heat-pressing. Emergency mass delousing of persons and clothing may be warranted during periods of civil strife and after natural disasters to reduce the risk of pathogen transmission by body lice.

Pubic lice infestations are treated with topical pediculicides except for eyelid infestations (*phthiriasis palpebrum*), which generally respond to a coating of petrolatum applied for 3–4 days.

MYIASIS (FLY INFESTATION)

Myiasis refers to infestations by fly larvae (maggots) that invade living or necrotic tissue or body cavities and produce different clinical syndromes, depending on the species of fly.

In forested parts of Central and South America, larvae of the human botfly *Dermatobia hominis* produce boil-like subcutaneous nodules ≤3 cm in diameter. The adult female captures a mosquito or another bloodsucking insect and deposits her eggs on its abdomen. When the carrier insect attacks a human or bovine host several days later, the warmth and moisture of the host's surface stimulate the larvae to hatch. The larvae promptly penetrate intact skin. After 6–12 weeks of development, mature larvae emerge from the skin and drop to the ground. The African tumbu fly *Cordylobia anthropophaga* deposits its eggs on sand or drying laundry contaminated with urine or sweat. Larvae hatch on contact with the body, penetrate the skin, and produce boils from which they emerge ~9 days later. Furuncular myiasis is suggested by uncomfortable lesions with a central breathing pore that emits bubbles when submerged in water. A sensation of movement under the patient's skin may lead to severe emotional distress. Botfly larvae may be induced to emerge if the air pore is coated with petrolatum or another occlusive substance. Removal may be facilitated by injection of a local anesthetic into the surrounding tissue, but surgical excision is often necessary because upward-pointing spines of some species hold the larva firmly in place.

Larvae of the horse botfly *Gasterophilus intestinalis* do not mature after penetrating human skin but migrate for weeks in the epidermis. The resulting pruritic and serpiginous eruption resembles cutaneous larva migrans caused by hookworms (Chap. 209). Horseback riders become infested when eggs deposited on the flank of the horse hatch against their bare legs. Larvae are removed with a needle. The larvae of the cattle botfly invade more deeply and produce boil-like swellings.

Certain flies are attracted to blood and pus, and their newly hatched larvae enter wounds or diseased skin. Larvae of the green bottle fly usually remain superficial and confined to necrotic tissue. Larvae of screwworm flies and the flesh fly invade viable tissue more deeply and produce large suppurating lesions. Larvae that infest wounds may also infest body cavities such as the mouth, nose, ears, sinuses, anus, vagina, and lower urinary tract, particularly in unconscious or otherwise debilitated patients. The consequences range from harmless colonization to destruction of the nose, meningitis, and deafness. Treatment involves removal of maggots and debridement of tissue.

The maggots responsible for furuncular and wound myiasis may also cause ophthalmomyiasis. Sequelae include nodules in the eyelid, retinal detachment, and destruction of the globe. Most instances in which maggots are found in human feces are the result of larviposition by flesh flies on recently passed stools.

PENTASTOMIASIS

Pentastomids (tongue worms) inhabit the respiratory passages of reptiles and carnivorous mammals. Human infestation by *Linguatula serrata* is common in the Middle East and results from the ingestion of encysted larval stages in raw liver or lymph nodes of sheep and goats—the intermediate hosts. Larvae migrate to the nasopharynx and produce an acute self-limiting syndrome known as *Halzoun* or *Marrara*, which is characterized by pain and itching of the throat and ears, coughing, hoarseness, dysphagia, and dyspnea. Severe edema may cause obstruction that necessitates tracheostomy; ocular invasion has been described. Diagnostic larvae measuring ≤10 mm in length appear in copious nasal discharge or vomitus. Individuals become infected with *Armillifer armillatus* by ingesting eggs in contaminated food or drink or after handling the definitive host, the African python. Larvae encyst in various organs but rarely cause symptoms. Cysts occasionally require surgical removal as they enlarge during molting, but they are usually encountered as an incidental finding at autopsy. Cutaneous larva migrans syndromes due to other pentastomes have been reported from Southeast Asia and Central America.

LEECH INFESTATIONS

Medically important leeches are annelid worms that attach to their hosts with chitinous cutting jaws and draw blood through muscular suckers. The medicinal leech *Hirudo medicinalis* is still used occasionally to reduce venous congestion in surgical flaps or replanted body parts. This practice has been complicated by wound infections, myonecrosis, and sepsis due to *Aeromonas hydrophila*, which colonizes the gullets of commercially available leeches.

Ubiquitous aquatic leeches that parasitize fish, frogs, and turtles readily attach to the skin of humans and avidly suck blood. More notorious are the land leeches that live among moist vegetation of tropical rain forests. Attachment is usually painless. Hirudinin, a powerful anticoagulant secreted by the leech, causes continued bleeding after the leech has detached. Healing of the wound is slow, and bacterial infections are not uncommon. Several kinds of aquatic leeches in Africa, Asia, and southern Europe can enter through the mouth, nose, and genitourinary tract and attach to mucosal surfaces at sites as deep as the esophagus and trachea. Externally attached leeches generally drop off after they have engorged, but removal is hastened by gentle scraping aside of the anterior and posterior suckers and traction or by application of alcohol, salt, vinegar, insect repellent, or a flame or heated instrument to the leech. Internally

attached leeches may detach on exposure to gargled saline or may be removed by forceps.

SPIDER BITES

Of the >30,000 recognized species of spiders, only ~100 defend themselves aggressively and have fangs sufficiently long to penetrate human skin. The venom that spiders use to immobilize and digest their prey can cause necrosis of skin and systemic toxicity. Whereas the bites of most spiders are painful but not harmful, envenomations of the brown or fiddle spiders (*Loxosceles* species) and widow spiders (*Latrodectus* species) may be life-threatening. Identification of the offending spider should be attempted, both because specific treatments exist for bites of widow and brown recluse spiders and because injuries attributed to spiders are frequently due to other causes. Except in cases where the patient actually observes a spider immediately associated with the bite or fleeing from the site, lesions reported to be due to spider bites are most often due to other injuries or bacterial infections.

Recluse Spider Bites and Necrotic Arachnidism Severe necrosis of skin and subcutaneous tissue follows envenomation by the brown recluse spider, which is found mainly in the southern and midwestern United States, and by its close relatives in the Americas, Africa, and the Middle East. Necrotic ulcerations also result from bites of the hobo spider in the Pacific Northwest and sac spiders throughout the United States and abroad. These spiders are not aggressive toward human beings and bite only if threatened or pressed against the skin. They hide under rocks and logs or in caves and animal burrows. They invade homes and seek dark and undisturbed hiding spots in closets, in folds of clothing, or under furniture and rubbish in storage rooms, garages, and attics. Despite their impressive abundance in some homes, these spiders only infrequently bite humans. Bites tend to occur while the victim is dressing and are sustained primarily on the arms, neck, and lower abdomen.

The venoms of these spiders contain an esterase, alkaline phosphatase, proteases, and other enzymes that produce tissue necrosis and hemolysis. Sphingomyelinase B, the most important dermonecrotic factor, binds cell membranes and promotes chemotaxis of neutrophils, leading to vascular thrombosis and an Arthus-like reaction. Initially, the bite is painless or produces a stinging sensation. Within the next few hours, the site becomes painful and pruritic, with central induration surrounded by a pale zone of ischemia and a zone of erythema. In most cases, the lesion resolves without treatment in just a few days. In severe cases, the erythema spreads, and the center of the lesion becomes hemorrhagic and necrotic with an overlying bulla. A black eschar forms and sloughs several weeks later, leaving an ulcer that may eventually result in a depressed scar. Healing usually takes place in ≤6 months but may take as long as 3 years if adipose tissue is involved. Local complications include injury to nerves and secondary infection. Fever, chills, weakness, headache, nausea, vomiting, myalgia, arthralgia, maculopapular rash, and leukocytosis may develop ≤72 h after the bite. In rare instances, acute complications such as hemolytic anemia, hemoglobinuria, and renal failure are fatal.

Rx RECLUSE SPIDER BITES

Initial management includes local cleansing, application of sterile dressings and cold compresses, and elevation and loose immobilization of the affected limb. Analgesics, antihistamines, antibiotics, and tetanus prophylaxis should be administered if indicated. Within the first 48–72 h, the oral administration of dapsone (50–100 mg twice daily after glucose-6-phosphate dehydrogenase deficiency has been ruled out) may halt the progression of necrosis. Debridement and later skin grafting may be necessary after signs of acute inflammation have subsided, but immediate surgical excision of the wound is detrimental. Patients should be monitored closely for signs of hemolysis, renal failure, and other systemic complications.

Widow Spider Bites The bites of the female widow spiders are notorious for their potent neurotoxins. The black widow, which is best known and most abundant in the southeastern United States, measures ≤1 cm in body length and 5 cm in leg span and is shiny black with a red hourglass marking on the ventral abdomen. Other dangerous *Latrodectus* species occur elsewhere in temperate and subtropical parts of the world.

Widow spiders spin their webs under stones, logs, plants, or rock piles or in dark spaces in barns, garages, and outhouses. Bites are most common in the summer and early autumn and occur when the web is disturbed or when the spider is trapped or provoked. The initial bite goes unnoticed or is perceived as a sharp pinprick. Two small red marks, mild erythema, and edema develop at the fang entrance site. The venom that is injected does not produce local necrosis, and some persons experience no other symptoms. α-Latrotoxin, the most active component of the venom, binds irreversibly to nerves and causes release and eventual depletion of acetylcholine, norepinephrine, and other neurotransmitters from presynaptic terminals. Painful cramps may spread within 60 min from the bite site to large muscles of the extremities and trunk. Extreme rigidity of the abdominal muscles and excruciating pain may suggest peritonitis, but the abdomen is not tender on palpation. The pain begins to subside during the first 12 h but may recur during several days or weeks before resolving spontaneously. Other features include salivation, diaphoresis, vomiting, hypertension, tachycardia, labored breathing, anxiety, headache, weakness, fasciculations, paresthesia, hyperreflexia, urinary retention, uterine contractions, and premature labor. Rhabdomyolysis and renal failure have been reported, and respiratory arrest, cerebral hemorrhage, or cardiac failure may end fatally, especially in very young, elderly, or debilitated persons.

Rx WIDOW SPIDER BITES

Treatment consists of local cleansing, application of ice packs, and tetanus prophylaxis. Hypertension that does not respond to analgesics and antispasmodics (e.g., benzodiazepines or methocarbamol) requires specific antihypertensive medication. IV administration of a widely available equine antivenom rapidly relieves pain and can be life-saving. Because of the risk of anaphylaxis and serum sickness, antivenom should be reserved for severe cases involving respiratory arrest, uncontrollable hypertension, seizures, or pregnancy.

Tarantulas and Other Spiders Tarantulas are hairy spiders of which 30 species are found in the United States, mainly in the Southwest. The tarantulas that have become popular household pets are usually imported species. Tarantulas bite only when threatened and cause no more harm than a bee sting, but the venom occasionally provokes deep pain and swelling. Tarantulas of several species are covered with urticating hairs that are brushed off in the thousands when a threatened spider rubs its hind legs across its dorsal abdomen. These hairs penetrate human skin and produce pruritic papules that may persist for weeks. Failure to wear gloves or to wash the hands after handling the Chilean Rose tarantula, a popular pet spider, has resulted in transfer of hairs to the eye and devastating ocular inflammation. Treatment of bites includes local washing and elevation of the bitten area, tetanus prophylaxis, and analgesic administration. Antihistamines and topical or systemic glucocorticoids are given for exposure to urticating hairs.

Atrax robustus, a funnel-web spider of Australia, and *Phoneutria* species, the South American banana spiders, are among the most dangerous spiders in the world because of their aggressive behavior and potent neurotoxins. Envenomation by *A. robustus* causes a rapidly progressive neuromotor syndrome that can be fatal within 2 h. The bite of a banana spider causes severe local pain followed by profound systemic symptoms and respiratory paralysis that can lead to death within 2–6 h. Specific antivenoms for envenomation by each of these spiders are available.

SCORPION STINGS

Scorpions are arachnids that feed on ground-dwelling arthropods and small lizards, which they paralyze by injecting venom from a stinger

on the tip of the tail. Painful but relatively harmless scorpion stings need to be distinguished from the potentially lethal envenomations that are produced by ~30 of the ~1000 known species and that cause >5000 deaths worldwide each year. Scorpions feed at night and remain hidden during the day in crevices or burrows or under wood, loose bark, or rocks on the ground. They seek cool spots under buildings and often enter houses, where they hide in shoes, clothing, or bedding or enter bathtubs and sinks in search of water. Scorpions sting human beings only when disturbed.

Of the 40 or so scorpion species in the United States, only the bark scorpion (*Centruroides sculpturatus* or *C. exilicauda*) produces venom that can be lethal. Its venom contains neurotoxins that cause sodium channels to remain open and neurons to fire repetitively. Such envenomations are usually associated with little swelling, but prominent pain, paresthesia, and hyperesthesia can be accentuated by tapping on the affected area (the tap test). These symptoms soon spread to other locations; dysfunction of cranial nerves and hyperexcitability of skeletal muscles develop within hours. Patients present with restlessness, blurred vision, abnormal eye movements, profuse salivation, lacrimation, rhinorrhea, slurred speech, difficulty in handling secretions, diaphoresis, nausea, and vomiting. Muscle twitching, jerking, and shaking may be mistaken for a seizure. Complications include tachycardia, arrhythmias, hypertension, hyperthermia, rhabdomyolysis, and acidosis. Symptoms progress to maximal severity in ~5 h and subside within a day or two, although pain and paresthesia can last for weeks. Fatal respiratory arrest is most common among young children and the elderly.

Envenomations by *Leiurus quinquestriatus* in the Middle East and North Africa, by *Mesobuthus tamulus* in India, by *Androctonus* species along the Mediterranean littoral and in North Africa and the Middle East, and by *Tityus serrulatus* in Brazil cause massive release of endogenous catecholamines with hypertensive crises, arrhythmias, pulmonary edema, and myocardial damage. Acute pancreatitis occurs with stings of *Tityus trinitatis* in Trinidad, and central nervous toxicity complicates stings of *Parabuthus* and *Buthotus* scorpions of South Africa. Tissue necrosis and hemolysis may follow stings of the Iranian *Hemiscorpius lepturus*.

Stings of most other species cause immediate sharp local pain followed by edema, ecchymosis, and a burning sensation. Symptoms typically resolve within a few hours, and skin does not slough. Allergic reactions to the venom sometimes develop.

℞ SCORPION STINGS

Identification of the offending scorpion aids in planning therapy. Stings of nonlethal species require at most ice packs, analgesics, or antihistamines. Because most victims experience only local discomfort, they can be managed at home with instructions to return to the emergency department if signs of cranial-nerve or neuromuscular dysfunction develop. Aggressive supportive care and judicious use of antivenom can reduce or eliminate deaths from more severe envenomations. Keeping the patient calm and applying pressure dressings and cold packs to the sting site are measures that decrease the absorption of venom. A continuous IV infusion of midazolam controls the agitation, flailing, and involuntary muscle movements produced by scorpion stings. Close monitoring during treatment with this drug and other sedatives or narcotics is necessary for persons with neuromuscular symptoms because of the risk of respiratory arrest. Hypertension and pulmonary edema respond to nifedipine, nitroprusside, hydralazine, or prazosin, and bradyarrhythmias can be controlled with atropine.

Commercially prepared antivenoms are available in several countries for some of the most dangerous species. A *C. sculpturatus* antivenom (not yet approved by the FDA) is available as an investigational drug only in Arizona. IV administration of antivenom rapidly reverses cranial-nerve dysfunction and muscular symptoms but does not affect pain and paresthesia. The benefit of scorpion antivenom has not been established in controlled trials.

HYMENOPTERA STINGS

Insects that sting to defend their colonies or subdue their prey belong to the order Hymenoptera, which includes apids (bees and bumblebees), vespids (wasps, hornets, and yellow jackets), and formicids (ants). Their venoms contain a wide array of amines, peptides, and enzymes that cause local and systemic reactions. Although the toxic effect of multiple stings can be fatal, nearly all of the ≥100 deaths due to hymenopteran stings in the United States each year are the result of allergic reactions.

Bee and Wasp Stings Honeybees often lose their stinging apparatus and the attached venom sac in the act of stinging and subsequently die, while other bees, ants, and vespids can sting numerous times in succession. The familiar honeybees (*Apis mellifera*) and bumblebees (*Bombus* and other genera) generally attack only when a colony is disturbed. Africanized honeybees, however, respond to minimal intrusions more aggressively. Since their introduction into Brazil in 1957, these "killer bees" have spread through South and Central America to the southern and western United States.

In bees and wasps, venom is produced in glands at the posterior end of the abdomen and is expelled rapidly by contraction of muscles of the venom sac, which has a capacity of up to 0.1 mL. The venoms of different species of hymenopterans are biochemically and immunologically distinct. Direct toxic effects are mediated by mixtures of low-molecular-weight compounds such as serotonin, histamine, and acetylcholine and several kinins. Polypeptide toxins in honeybee venom include mellitin, which damages cell membranes; mast cell–degranulating protein, which causes histamine release; apamin, a neurotoxin; and adolapin, which has anti-inflammatory activity. Enzymes in venom include hyaluronidase, which allows the spread of other venom components, and phospholipases, which may be among the major venom allergens. There appears to be little cross-sensitization between honeybee and wasp venoms.

Uncomplicated stings cause immediate pain, a wheal-and-flare reaction, and local edema and swelling that subside in a few hours. Stings from accidentally swallowed insects may induce life-threatening edema of the upper airways. Multiple stings can lead to vomiting, diarrhea, generalized edema, dyspnea, hypotension, and collapse. Rhabdomyolysis and intravascular hemolysis may cause renal failure. Death from the direct effects of venom has followed 300–500 honeybee stings.

Large local reactions that spread ≥10 cm around the sting site over 24–48 h are not uncommon. These reactions may resemble cellulitis but are caused by hypersensitivity rather than secondary infection. Such reactions tend to recur on subsequent exposure but are seldom accompanied by anaphylaxis and are not prevented by venom immunotherapy.

An estimated 0.4–4.0% of the U.S. population exhibits clinical immediate-type hypersensitivity to insect stings, and 15% may have asymptomatic sensitization manifested by positive skin tests. Persons who experience severe allergic reactions are likely to have similar reactions after subsequent stings; occasionally, adults who have had mild reactions later experience serious reactions. Mild anaphylactic reactions from insect stings, as from other causes, consist of nausea, abdominal cramping, generalized urticaria, flushing, and angioedema. Serious reactions, including upper airway edema, bronchospasm, hypotension, and shock, may be rapidly fatal. Severe reactions usually begin within 10 min of the sting and only rarely develop after 5 h.

℞ BEE AND WASP STINGS

Stingers from honeybees embedded in the skin should be removed as promptly as possible, using any method available, to limit the quantity of venom delivered. The previously suggested approach of scraping or brushing off the stinger with a blade or a fingernail but not removing it with forceps simply delays removal and exacerbates the consequences. The site should be cleansed and disinfected and ice packs applied to slow the spread of venom. Elevation of the affected site and administration of analgesics, oral antihistamines, and topical calamine lotion relieve symptoms. Large local reactions may require a short course of oral therapy with glucocorticoids. Patients with numerous stings should be monitored for 24 h for evidence of renal failure or coagulopathy.

Anaphylaxis is treated with SC injection of 0.3–0.5 mL of epinephrine hydrochloride in a 1:1000 dilution; treatment is repeated every 20–30 min

as necessary. IV epinephrine (2–5 mL of a 1:10,000 solution administered by slow push) is indicated for profound shock. A tourniquet may slow the spread of venom. Parenteral antihistamines, fluid resuscitation, bronchodilators, oxygen, intubation, and vasopressors may be required. Patients should be observed for 24 h for recurrent anaphylaxis.

Persons with a history of allergy to insect stings should carry a sting kit with a preloaded syringe containing epinephrine for self-administration. These patients should seek medical attention immediately after using the kit.

Repeated injections of purified venom produce a blocking IgG antibody response to venom and reduce the incidence of recurrent anaphylaxis. Honeybee, wasp, yellow jacket, and mixed vespid venoms are commercially available for desensitization and for skin testing. Results of skin tests and venom-specific radioallergosorbent tests aid in the selection of patients for immunotherapy and guide the design of such treatment.

Stinging Ants Stinging fire ants are an important medical problem in the United States. Imported fire ants infest southern states from Texas to North Carolina, with colonies in California, New Mexico, Arizona, and Virginia. Slight disturbances of their mound nests have provoked massive outpourings of ants and as many as 10,000 stings on a single person. Elderly and immobile persons are at high risk for attacks when fire ants invade dwellings.

Fire ants attach to skin with powerful mandibles and rotate their bodies while repeatedly injecting venom with posteriorly situated stingers. The alkaloid venom consists of cytotoxic and hemolytic piperidines and several proteins with enzymatic activity. The initial wheal-and-flare reaction, burning, and itching resolve in ~30 min, and a sterile pustule develops within 24 h. The pustule ulcerates over the next 48 h and then heals in ≥1 week. Large areas of erythema and edema lasting several days are not uncommon and in extreme cases may compress nerves and blood vessels. Anaphylaxis occurs in ≤2% of persons, and seizures and mononeuritis have been reported. Stings are treated with ice packs, topical glucocorticoids, and oral antihistamines. Covering pustules with bandages and antibiotic ointment may prevent bacterial infection. Epinephrine and supportive measures are indicated for anaphylactic reactions. Whole-body extracts are available for skin testing and immunotherapy, which appears to lower the rate of anaphylactic reactions.

The western United States is home to harvester ants. The painful local reaction following harvester ant stings often extends to lymph nodes and may be accompanied by anaphylaxis.

Dipteran (Fly and Mosquito) Bites In the process of feeding on vertebrate blood, adults of certain fly species inflict painful bites, produce local allergic reactions, or transmit pathogenic agents. Bites of mosquitoes, tiny "no-see-um" midges, and phlebotomine sand flies typically produce a wheal and a pruritic papule. Nodular lesions at the site of midge bites may last for months. Bites of small humpbacked black flies or simuliids leave a bleeding laceration and a painful and pruritic sore that are slow to heal; regional lymphadenopathy, fever, or anaphylaxis occasionally ensues. The widely distributed deer and horse flies as well as the tsetse flies of Africa are stout flies measuring ≤25 mm in length that attack during the day and produce large and painful bleeding punctures.

℞ FLY AND MOSQUITO BITES

Treatment of fly bites is symptom-based. Topical application of antipruritic agents, glucocorticoids, or antiseptic lotions may relieve itching and pain. Allergic reactions may require oral antihistamines. Antibiotics may be necessary for the treatment of large bite wounds that become secondarily infected.

Flea Bites Common human-biting fleas include the dog and cat fleas (*Ctenocephalides* species) and the rat flea (*Xenopsylla cheopis*), which inhabit the nests and resting sites of their hosts. Sensitized persons develop erythematous pruritic papules, urticaria, and occasionally vesicles and bacterial superinfection at the site of the bite. Treatment consists of antihistamines and antipruritics.

Flea infestations are eliminated by frequent cleaning of nesting sites and of the host's bedding and by application of contact insecticides. Flea infestations in the home may abate if pets are treated with veterinary antiparasitic agents and insect growth regulators.

Tunga penetrans, like other fleas, is a wingless, laterally flattened insect that feeds on blood. Also known as the chigoe flea, sand flea, or jigger, it occurs in tropical regions of Africa and the Americas. Adults live in sandy soil and burrow under the skin between toes, under nails, or on the soles of bare feet. Chigoes engorge on blood and grow from pinpoint to pea size during a 2-week period. The lesions they produce resemble a white pustule with a central black depression and may be pruritic or painful. Occasional complications include tetanus, bacterial infections, and autoamputation of toes. Tungiasis is treated by removal of the intact flea with a sterile needle or scalpel, tetanus vaccination, and topical application of antibiotics.

Hemipteran (True Bug) Bites Several true bugs of the family Reduviidae inflict bites that produce allergic reactions and are sometimes painful. The cone-nose bugs, so called because of their elongated heads, include the assassin and wheel bugs, which feed on other insects and bite vertebrates only in self-defense, and the kissing bugs, which routinely feed on vertebrate blood. The bites of the nocturnally feeding kissing bugs are painless. Reactions to such bites depend on prior sensitization and include tender and pruritic papules, vesicular or bullous lesions, giant urticaria, fever, lymphadenopathy, and anaphylaxis. Bug bites are treated with topical antipruritics or oral antihistamines. Persons with anaphylactic reactions to reduviid bites should keep an epinephrine kit available. The cosmopolitan bedbugs (*Cimex* species) hide in crevices of mattresses, bed frames and other furniture, walls, and picture frames and under loose wallpaper. Bedbugs have become resurgent, recently attaining populations and spreading to an extent not encountered since the mid-twentieth century. These bugs are now a fairly common nuisance in homes, dormitories, and hotels and on cruise ships. The bugs hide during the day and take their blood meal at night. Their bite is painless, but sensitized persons develop erythema, itching, and wheals around a central hemorrhagic punctum. Bedbugs are not known to transmit pathogens.

Centipede Bites and Millipede Dermatitis The fangs of centipedes of the genus *Scolopendra* can penetrate human skin and deliver a venom that produces intense burning pain, swelling, erythema, and lymphangitis. Dizziness, nausea, and anxiety are occasionally described, and rhabdomyolysis and renal failure have been reported. Treatment includes washing of the site, application of cold dressings, oral analgesic administration or local lidocaine infiltration, and tetanus prophylaxis.

Millipedes, unlike centipedes, do not bite, but some secrete defensive fluids that burn and discolor human skin. Affected skin turns brown overnight and may blister and exfoliate. Secretions in the eye cause intense pain and inflammation that may lead to corneal ulceration and blindness. Management includes irrigation with copious amounts of water or saline, use of analgesics, and local care of denuded skin.

Caterpillar Stings and Dermatitis The surface of caterpillars of several moth species is covered with hairs or spines that produce mechanical irritation and may contain or be coated with venom. Contact with these caterpillars causes an immediate burning sensation followed by local swelling and erythema and occasionally by regional lymphadenopathy, nausea, vomiting, and headache; shock, seizures, and coagulopathy are rare complications. In the United States, dermatitis is most often associated with io, puss, saddleback, and brown-tail moths. Contact with even detached hairs of other caterpillars, such as gypsy moth larvae, can later produce a pruritic urticarial or papular rash. Spines may be deposited on tree trunks and drying laundry or may be airborne and cause irritation of the eyes and upper airways. Treatment of caterpillar stings consists of repeated application of adhesive or cellophane tape to remove the hairs, which can then be identified micro-

 scopically. Local ice packs, topical steroids, and oral antihistamines relieve symptoms.

Beetle Vesication When disturbed, blister beetles extrude cantharidin, a low-molecular-weight toxin that produces thin-walled blisters measuring ≤5 cm in diameter 2–5 h after contact. The blisters are not painful or pruritic unless broken and resolve without treatment in ≤10 days. Nephritis may follow unusually heavy cantharidin exposure. Contact occurs when individuals sit on the ground, work in the garden, or deliberately handle the beetles. The hemolymph of certain rove beetles contains paederin, a potent vesicant. When these beetles are crushed or brushed against the skin, the released fluid may provoke erythematous and bullous lesions. These beetles occur worldwide but are most numerous and problematic in parts of Africa and Asia. Ocular lesions are common from impacts with the flying beetles at night or transfer of the vesicant on the fingers. Treatment is rarely necessary, although ruptured blisters should be kept clean and bandaged.

DELUSIONAL INFESTATIONS

The groundless conviction that one is infested with arthropods or other parasites is an extremely difficult disorder to treat and unfortunately is not rare. Patients report infestations of their skin, clothing, or homes and describe sensations of something moving in or on their skin. Excoriations often accompany reports of pruritus or insect bites. Frequently, patients submit as evidence of infestation specimens that consist of plant-feeding and nonbiting peridomestic arthropods, pieces of skin, vegetable matter, or inanimate objects. It is imperative to rule out true infestations and bites by arthropods, endocrinopathies, neuropathies, drug use, environmental irritants (e.g., fragments or threads of glass insulation), and other causes of tingling or prickling sensations. Frequently, such patients repeatedly seek medical consultations, resist alternative explanations for their symptoms, and exacerbate their discomfort by self-treatment. Pharmacotherapy with pimozide has been more helpful than psychotherapy in treating this disorder.

e36 Pulmonary Biomarkers in COPD

Peter J. Barnes

INTRODUCTION

There has been increasing interest in using pulmonary biomarkers to understand and monitor the inflammation in the respiratory tracts of patients with chronic obstructive pulmonary disease (COPD). COPD involves a specific pattern of inflammation in the respiratory tract and lung parenchyma, with increased production of multiple inflammatory mediators.[1]

A *biomarker* refers to the measurement of any molecule or material (cells, tissue) that reflects the disease process. In COPD, several types of biomarker have been measured that are related to disease pathobiology and the inflammatory and destructive process in the lung. Here, biomarkers in bronchial biopsies, sputum, bronchoalveolar lavage (BAL), and exhaled breath are considered. Unfortunately, few of these biomarkers have been validated, and there is little information about their reproducibility and the relationship to disease severity or progression.[2] A meta-analysis of biomarker measurements in 150,000 patients with COPD revealed the poor sensitivity of current biomarkers to define clinical status and quantify the effect of treatment. Only sputum neutrophils, interleukin (IL) 8, serum tumor necrosis factor (TNF) α, and C-reactive protein (CRP) showed any trend towards separating different stages of COPD.[3] More research in this area is now needed with repeated measurements in carefully phenotyped patients. With the development of many new drugs that target inflammation in COPD, there is a pressing need to identify reliable biomarkers that may indicate whether an anti-inflammatory therapy is likely to have clinical benefit. A major barrier is the lack of any "gold standard" anti-inflammatory therapy that is effective in COPD, as are inhaled glucocorticoids in asthma, as a yardstick to compare potential therapies.

Many inflammatory cells, mediators, and enzymes are involved in the complex pathobiology of COPD, and, as a result, there are many possible biomarkers to study with a high degree of redundancy.[1] Pulmonary inflammation in COPD appears to increase with disease progression and increases during exacerbations. It is likely that some biomarkers will prove to be much more useful than others in terms of reproducibility of measurement, ease of assay, relationship to disease severity, and predictability for assessing therapeutic efficacy. Some biomarkers are more easily measurable and reliable than others and are more easily applied in clinical studies, especially in multicenter studies involving large numbers of patients. New assays may have greater sensitivity and assay reproducibility; in addition, many novel biomarkers may be identified by genomic and proteomic analyses of COPD samples in the future.

BRONCHIAL BIOPSIES

Although the inflammation in COPD involves predominantly lung parenchyma and small airways, bronchial biopsies appear to reflect at least some of the cellular abnormalities described in peripheral lung tissue. Bronchial biopsies are useful for documenting the structural changes, cellular patterns, and expression of inflammatory proteins in patients with COPD.[4] In stable COPD, there is increased infiltration of macrophages and activated T lymphocytes, particularly of CD8+ T lymphocytes, which express interferon (IFN) γ, CXCL10 (IP-10), and IL-9, and the pattern of inflammation differs substantially from that described in asthma (Table e36-1). Moreover, these lymphocytes express chemokine receptors associated with a type 1 response, such as CXCR3, in contrast to lymphocytes in asthma, which express chemokine receptors typical of a type 2 response (chemokine receptor CCR4). There is also a reduction in T cells expressing CCR5 in COPD. While a prominent neutrophilia is present in the airway lumen of stable patients with COPD, it is not observed at the tissue level, except in patients with severe airflow limitation. During exacerbations of the disease, an increased recruitment of eosinophils and neutrophils has been described, which is associated with upregulation of specific chemoattractants, such as CCL5 (RANTES) and CXCL5 (ENA-78).

TABLE e36-1 MORPHOLOGIC CHANGES IN BRONCHIAL BIOPSIES OF PATIENTS WITH COPD AND ASTHMA

	COPD	Asthma
Reticular basement membrane thickness	Within normal range	Increased
Inflammatory cell infiltrate	Macrophages CD8+ T lymphocytes Eosinophils and neutrophils during exacerbations Neutrophils in severe disease	Eosinophils, mast cells CD4+ T lymphocytes Eosinophils and neutrophils during exacerbations Neutrophils in severe disease
Cytokines, chemokines, and receptors	IFN-γ, CXCL10, IL-9, CXCR3	IL-4, IL-5, IL-9, IL-13, CCR4

Abbreviations: IFN, interferon; IL, interleukin; CXCL, CXC chemokine ligand; CCR, CC chemokine receptor.

Bronchial biopsies may give some insights into disease pathogenesis. For example, there is increased activation of the transcription factor nuclear factor-κB (NF-κB) in bronchial epithelial cells of COPD patients, which increases with disease severity.[5] There is also a reduction in histone deacetylase (HDAC) activity and HDAC2 expression in bronchial biopsies of COPD patients compared to normal smokers and nonsmokers, and this change is correlated with a reduction in NF-κB activity and increased expression of inflammatory genes.[6] These changes in bronchial biopsies reflect the changes in NF-κB and HDAC found in lung parenchyma.

Several studies have assessed the potential anti-inflammatory effects of treatments in bronchial biopsies of patients with COPD. These studies usually involve either a baseline biopsy and then a second biopsy after a defined period of treatment, or a single biopsy at the end of active treatment with a biopsy in a parallel group of patients taking placebo therapy. Overall, inhaled glucocorticoids seem to have little effect on the airway inflammation typical of COPD, although they are able to reduce mast cells, an effect associated with a reduction in the frequency of exacerbations. Greater anti-inflammatory effects have been obtained after treatment with either a phosphodiesterase (PDE) 4 inhibitor or with the combination of a glucocorticoid and a long-acting β_2-agonist, but these changes have not been related to functional or clinical improvements. However, further studies are required to establish whether the airway inflammation in COPD can be successfully suppressed (as with glucocorticoids in asthma) and whether this would result in significant clinical improvement.

The main advantage of endobronchial biopsies is that they directly sample airway tissue, maintaining the spatial relationships of structural components that may be important for functional changes. Unlike sputum and BAL, bronchial biopsies provide an assessment of structural components of the airway wall, such as epithelium, basement membrane, vessels, connective tissue, and, on occasion, smooth muscle and submucosal glands. This means that biomarkers of structural modification, apoptosis or uncontrolled proliferation, can be measured. Moreover, the different inflammatory cell subtypes can be identified by immunohistochemistry in their microenvironment, thus allowing investigation of interactions between inflammatory and resident cells. Finally, individual structural components can be dissected from the biopsies and studied in isolation using techniques recently developed, such as laser microdissection.

Problems There are, however, several limitations to analysis of bronchial biopsies to assess outcome in COPD. Since this is an invasive procedure, it may be difficult to recruit patients, especially in studies investigating treatment effects that require two biopsies (pre- and posttreatment). The biopsy of proximal airways may not closely reflect all the pathologic changes present in peripheral airways and lung parenchyma, the primary sites responsible for airflow limitation in COPD. Moreover, it may not be possible to apply this procedure to pa-

tients with more severe disease, complicated by cardiac comorbid conditions and often associated with significant oxygen desaturation and hypercapnia. There is also a relatively high variability in baseline measurements of inflammatory cells, which necessitates multiple biopsies. Finally, since studies evaluating the effect of treatment should be designed to provide a power of at least 80%, a large number of patients for each treatment group is usually required.

BRONCHOALVEOLAR LAVAGE

BAL has the advantage, unlike bronchial biopsies, of sampling inflammation in the lung periphery. BAL can generally be safely performed, provided careful assessment is performed and guidelines are followed. In general, fluid recovery is greater in patients with less extensive emphysema as assessed by diffusion capacity.[7] BAL may be performed in the same patients as bronchial biopsy, thus providing additional and complementary information.

Cellular Composition The cellular composition in individuals with COPD is predominantly (>80%) alveolar macrophages, with some neutrophils and T lymphocytes, and some patients having increased numbers of eosinophils. The percentages of macrophages and neutrophils are usually higher than in healthy nonsmokers and healthy smokers. Studies investigating individuals with COPD, healthy smokers, and ex-smokers show that smoking is generally associated with increased numbers of neutrophils. Numbers of lymphocytes are generally higher in ex-smokers than in smokers, with or without COPD. Moreover, some studies have shown that patients with COPD have higher eosinophil percentages than healthy smokers. Alveolar macrophages, which may be separated by adhesion and cultured in vitro for functional studies, from COPD patients behave abnormally in tissue culture, with increased expression of inflammatory proteins, such as TNF-α, IL-8, and matrix metalloproteinase (MMP) 9. Alveolar macrophages also show a reduction in expression and activity of HDAC2, which modulates the expression of inflammatory genes, with progressive reduction with disease severity. The reduction in HDAC2 is associated with increased activation of the NF-κB. It may be possible in the future to study the effects of treatment in patients on cellular behavior in vitro.

Mediators and Proteases Several inflammatory mediators can be measured in BAL fluid. Levels of eosinophil cationic protein (ECP), myeloperoxidase (MPO), and IL-8 are increased in COPD patients and in healthy smokers, compared to healthy nonsmokers, suggesting that smoking induces the changes, rather than COPD itself. Studies investigating other mediators have not been replicated and are not discussed here. Proteases and antiproteases are also detectable in BAL fluid: there is an increase in total elastase activity and a decrease in antielastase activity in COPD patients compared to normal smokers, confirming the imbalance between proteases and antiproteases.

Effect of Smoking and Disease Severity In one study, ex-smokers with COPD had lower mast cell numbers in BAL than ex-smokers without COPD. No other studies have compared smokers and ex-smokers with COPD. Only one study has investigated the association between the severity of COPD and BAL inflammation, and showed that healthy smoking men with a near normal FEV_1 show signs of inflammation in the lower airways that are related to a decrease in lung diffusion (DL_{CO}) and to emphysematous lesions on high-resolution CT. This inflammation seems to be the result of macrophage and neutrophil activation, as assessed by mediators measured in BAL. In contrast, in a healthy population, the number of inflammatory cells did not correlate with lung function decline over a 4-year follow-up; however, higher levels of neutrophil elastase-α_1 protease inhibitor complexes in BAL fluid have been significantly associated with accelerated decline in FEV_1. This also suggests that the number or percentage of cells is not a prerequisite for development or progression of emphysema, but that the activation state of these cells with accompanying mediator release may be important.

Effects of Therapy There are few published studies of the effects of treatments on cellular and mediator components of BAL. Three studies, one open label and two double-blind, assessed the effect of different types of inhaled glucocorticoids, for various periods of treatment on inflammatory cell counts and mediators in BAL.[2] Although the numbers of patients involved were small, precluding firm conclusions, these studies suggest that there may be a reduction in percentages of neutrophils and lymphocytes with inhaled glucocorticoid treatment; however, long-term studies in larger populations are needed. Some studies have investigated the effects of smoking cessation on BAL composition, showing inconsistent decreases in cell numbers, particularly macrophages.

Problems BAL is an invasive procedure and may cause more discomfort to the patients than bronchial biopsy; it may also cause transient fever. The recovery of fluid is often reduced in COPD patients, resulting in samples that are inadequate for analysis. Quantification of biomarkers in supernatant is a problem as there is no satisfactory marker to account for the dilutional effect of the saline lavage. This is one of the factors that may contribute to the variability in measurements and the necessity for relatively large numbers of patients.

SPUTUM

Many COPD patients produce suitable sputum spontaneously, but spontaneously produced sputum may contain a high proportion of dead cells, which potentially give misleading cell counts and mediator measurements. For this reason, induced sputum has usually been the procedure of choice.[8] It should be recognized that "sputum" obtained after inhaling nebulized hypertonic saline may have a different composition than mucus and may be more similar to proximal airway washings. The procedure is tolerated by patients with FEV_1 >30% predicted; however, airflow obstruction is often observed and cannot be prevented by premedication with β_2-agonists.

Cells There is an abnormal pattern of inflammatory cells in COPD patients, with an increase in the number of total inflammatory cells and in the percentage of neutrophils, and, in some patients, eosinophils (the latter predicting a greater likelihood of response to glucocorticoids). CD8+ T cells are increased in the induced sputum of COPD patients. An increased number of eosinophils may indicate concomitant asthma and appears to predict the patients who show a larger bronchodilator response and improvement with glucocorticoids. There is little information about the reproducibility of differential cell counts in induced sputum of COPD patients, but there appears to be a reasonably good reproducibility of cells and mediators in long-term repeatability studies.[9] Neutrophils have been studied most extensively and are increased in number in COPD patients compared to those in matched smokers with normal lung function. Several studies have reported the effects of drugs on sputum neutrophils. Most studies have shown no change in inflammatory cells with inhaled or oral glucocorticoids. A significant reduction in neutrophils with low-dose oral theophylline has been reported.

Mediators Many mediators have been reported to be increased in the sputum supernatant of COPD patients, and most show a greater increase in COPD than in smokers without COPD, with a further increase during exacerbations; few have been related to disease severity or progression.[2] Sputum IL-8 has been studied most extensively, is increased in COPD patients compared to smokers, is related to disease severity (FEV_1 % predicted), and may be further increased with exacerbations. Sputum concentrations are unaffected by glucocorticoids but are reduced by theophylline. Increased concentrations of TNF-α and soluble TNF receptors are found in sputum of COPD patients compared to that in normal smokers. Higher concentrations of inflammatory cytokines, including TNF-α, IL-8, and IL-6, are reported in patients with more severe compared to less severe COPD. Leptin is detectable in the induced sputum of COPD patients and is correlated with other inflammatory markers, including TNF-α and CRP.

Increased concentrations of proteases have been reported in the sputum of patients with COPD, including neutrophil elastase, MMP-8, MMP-9, and MMP-12. MMP-9 is increased more in COPD patients with CT evidence of emphysema than in patients of similar respiratory functional severity without evidence of emphysema.[10] Sputum markers of structural changes in the airways have been difficult to identify. Hyaluronan, a component of extracellular matrix, is found in higher concentration in the sputum of COPD patients than in the sputum of smokers without COPD and nonsmokers, especially in patients with the lowest FEV_1 values; this suggests increased degradation of extracellular matrix in COPD. No differences in the concentrations of the tachykinins substance P and neurokinin A were found in COPD patients compared with smokers without COPD and nonsmokers, although there was a reduction in tachykinins noted during exacerbations of COPD in one study.

Problems Although induced sputum samples are relatively easy to obtain in COPD patients and give a lot of information about inflammatory cells and mediators, there are several problems that need to be addressed. Induced sputum samples predominantly derive from large airways and may not reflect the peripheral inflammation that may be important for clinical outcomes in COPD. Sputum induction with hypertonic saline promotes neutrophilic inflammation that persists for 24 h and, thus, repeated sampling within this period is not possible. Solubilization of sputum with dithiothreitol (DTT), which disrupts sulfhydryl bonds, may alter proteins so that they are not recognized by antibodies; this is a particular problem with several cytokines and chemokines. Furthermore, proteases in sputum, particularly in COPD, may degrade certain protein mediators. Recent studies using dialysis to remove DTT and protease inhibitors show that it is possible to increase markedly the concentrations of several cytokines in induced sputum of COPD patients. More work is needed on long-term reproducibility in COPD patients, studying the effect and duration of exacerbations and correlating individual biomarkers with disease severity and progression.

EXHALED GASES

Measuring biomarkers in the breath is a very attractive approach to monitoring inflammation in COPD as it is noninvasive and makes repeated sampling possible.[11] However, there are important issues about reproducibility and sensitivity that need to be addressed before this approach can be recommended as a routine outcome measurement.

Nitric Oxide Exhaled nitric oxide (FE_{NO}) has been extensively investigated in asthma and shown to correlate with airway inflammation and to be reduced by glucocorticoid therapy. The measurement is highly reproducible in normal and asthmatic subjects if careful attention is paid to technique. In COPD, however, conventionally measured FE_{NO} is less useful as the levels are usually normal or only slightly elevated, except during exacerbations; this is likely to be due to the increase in oxidative stress, resulting in formation of peroxynitrite and nitrate so that NO is removed from the gaseous phase. This observation also explains why FE_{NO} is reduced in normal smokers. An increase in FE_{NO} in COPD patients is correlated with increased numbers of eosinophils, an increased bronchodilator response, and steroid responsiveness, and thus may be useful in detecting associated asthma. Recently, the measurement of FE_{NO} has been extended by making measurements of exhaled NO at different flows, so that it is possible to partition airway-derived NO, which is flow-independent, from peripheral NO derived from endothelium via the alveoli and probably from small airways. Using this technique it is possible to show that while airway NO is low or normal in COPD, there is an increase in peripheral NO that is related to disease severity.[12] This may reflect the increase in inducible NO synthase in the lung periphery of patients with COPD. Peripheral NO may prove to be a useful noninvasive biomarker of COPD inflammation, but further studies on reproducibility, relationship to disease severity, and the effects of treatment are now needed.

Carbon Monoxide Although it is easy to measure carbon monoxide (CO) in the breath this has not turned out to be as useful a measurement as FE_{NO}. Exhaled CO is elevated in patients with COPD, but it is also elevated in normal smokers owing to the high CO content in cigarette smoke; however, exhaled CO is elevated to a greater extent in COPD patients than in matched smokers without COPD, and it remains elevated in sustained ex-smokers. Importantly, the signal is low and the measurement is also confounded by highly variable environmental CO levels and the effects of passive smoking.

Hydrocarbons Volatile hydrocarbons, such as ethane and pentane, have been detected in exhaled breath and are biomarkers of lipid peroxidation as a result of oxidative stress. Concentrations of ethane are elevated in patients with COPD and correlate with disease severity. Measurement of ethane by gas chromatography–mass spectrometry offline is difficult and thus unlikely to be useful in clinical trials; smaller and more sensitive detectors for hydrocarbons are now in development.

EXHALED BREATH CONDENSATE

Many mediators have now been detected in exhaled breath condensate (EBC), which has the advantage that it is easy to perform and completely noninvasive.[11] Several factors affect the measurement, and recommendations have recently been formulated by an ERS/ATS task force. A limitation of the technique is the variability of the measurement and the low concentrations of mediators (often close to the limits of detection).

Oxidative/Nitrative Stress Hydrogen peroxide (H_2O_2) is increased in EBC of COPD patients, is further increased during exacerbations, and is related to disease severity. Exhaled H_2O_2 is reported to be reproducible in repeated measurements over 3 days. 8-Isoprostane is a stable marker of oxidative stress and is also increased in EBC of COPD patients. The isoprostanes represent a family of isomers that are derived from the nonoxidative metabolism of arachidonic acid and are stable biomarkers of oxidative stress.[13] Concentrations of 8-isoprostane are greater in COPD patients than in smokers without COPD, are related to disease severity, and are further increased during exacerbations. Certain aldehydes resulting from lipid peroxidation are also increased in COPD patients, but only malondialdehyde is increased in COPD patients compared to smokers without COPD. Increased nitrative stress in COPD is indicated by increased concentrations of nitrite and S-nitrosothiols in EBC.

Mediators Inflammation is associated with tissue acidification, and there is a decrease in pH in EBC of COPD patients. There is considerable variability in exhaled pH in COPD patients, which is greater than in normal subjects, and the lower pH has been ascribed to increased acidity of salivary contaminants. There is an increase in the concentration of leukotriene (LT) B_4 in COPD patients, which is further increased during exacerbations. Increased prostaglandin E_2 and IL-6 have also been reported in COPD patients. It is not yet clear how most of these biomarkers relate to disease severity. Most proteins, including cytokines and enzymes, cannot reliably be measured in EBC. A recent study reported increases in the concentrations of proinflammatory cytokines, including IL-1β, IL-6, and TNF-α, during exacerbations of COPD, but reproducibility was not reported. Chemokines cannot be reliably measured in EBC.

Problems There is a relative high variability in repeated measurements of EBC biomarkers, and this may relate (1) to the extensive variable dilution that occurs from water vapor during condensation, and (2) the low concentrations that may be near to the detection limits of the assays used. Further work is needed to optimize these measurements and to determine the causes of variability. Correction for the variable dilution is one approach. Assays are usually performed using enzyme-linked immunosorbent assay, and these assays have been validated using gas chromatography–mass spectrometry for some mediators.

USE OF BIOMARKERS TO ASSESS RESPONSE TO THERAPY

Many drugs are now in development as potential anti-inflammatory therapies for COPD. Because no effective anti-inflammatory treatments for COPD currently exist, it is not certain how much and how rapidly clinical parameters will change in patients. This uncertainty makes it important to develop reliable biomarkers to quantify inflammation in COPD patients and to validate these against some other measure of disease activity and progression. For assessment of anti-inflammatory treatments, it is important to identify biomarkers that indicate the efficacy of the drug on components of the inflammatory process before proceeding to large and prolonged clinical trials. Biomarkers can facilitate drug development in a number of ways, such as providing evidence that a drug can reach its target and modify that target in some positive way, identifying criteria for dose selection for phase 2 and phase 3 studies, providing "go/no-go" decisions at early stages of the drug development process, identifying populations that are more likely to benefit from a drug, and predicting safety problems.

There are several types of drugs that can be developed for COPD based on whether the drug is intended to improve airflow obstruction, provide symptom relief, modify or prevent exacerbations, alter disease progression, or modify lung structure. The efficacy endpoints that are currently used in phase 3 studies to support registration of a drug for COPD are based on measures that translate to direct benefit of some aspects of the disease that is clinically meaningful to patients, such as improvement of symptoms, functional capacity, or survival. Examples of such endpoints include pulmonary function tests; test of exercise capacity, e.g., treadmill or cycle ergometry; activity scales, e.g., Medical Research Council dyspnea score, Borg scale, Mahler baseline dyspnea index (BDI)/transitional dyspnea index (TDI); health-related quality-of-life (QOL) instruments, e.g., St. George's respiratory questionnaire (SGRQ), chronic respiratory disease questionnaire (CRQ); scores based on patient- or physician-reported symptom severity; and death. With the possible exception of a drug that is intended to improve airflow obstruction, whose efficacy can be relatively easily assessed by measuring FEV_1 in short-term studies, drugs of other types will likely require prolonged studies, often extending to many years. These studies become rather risky expensive endeavors, and this further underscores the need of development of biomarkers.

The biomarkers described elsewhere in this chapter are not sufficiently validated to date for use as evidence of efficacy in phase 3 studies or for supporting specific labeling claims. Nevertheless, these biomarkers are reflective of the disease and have potential use for regulatory purposes. Carefully selected biomarkers, with or without a patient-centered clinically meaningful endpoint, can be used in early phase studies, such as proof-of-action or proof-of-concept studies, based on which a rational decision can be made on further development of the drug. Biomarkers can also be used in either early phase studies or phase 3 studies to support the drug's putative mode of action. In addition, use of the biomarkers in phase 3 studies in conjunction with clinically meaningful endpoints may help validate the use of the biomarker, or even help elevate a biomarker to a surrogate endpoint status.

OVERVIEW

Many biomarkers of inflammation and oxidative/nitrative stress have now been measured in the airways of patients with COPD using a variety of techniques of differing invasiveness. Bronchial biopsies provide valuable information about inflammatory cells and mediators, as well as the spatial relationships between the inflammatory process in the airway wall. However, they may not reflect all pathologic changes in the periphery of the lung that appear to be more important in COPD, and its invasiveness precludes repeated measurements. BAL may provide more information about peripheral inflammation, but there are problems of quantification of mediators because of variable dilution and the same problems as with biopsies in reproducibility. Induced sputum is a valuable procedure giving information about cells, mediators, and markers of oxidative/nitrative stress, but standardization of the technique is important to reduce the high variability in the biomarkers. The technique probably samples more proximal airways and thus may not reflect the inflammatory process in the lung periphery. Exhaled biomarkers are noninvasive and may be repeated but are technique-dependent and have a relatively high variability. For all of these biomarkers, there is a relative lack of information about how they relate to disease severity, how reproducible they are, and how they may be affected by concurrent therapies. In addition, there is little information at present about how they relate to other outcome measurements in COPD, such as rate of decline in FEV_1, exacerbation frequency, and mortality. There is a need for comparison of all pulmonary biomarkers in COPD patients with those in smokers without airflow limitation but matched for smoke exposure (pack-years) and also with those in age-matched nonsmoking control subjects. The effect of smoking itself is rarely documented, and ex-smokers may have a different profile of biomarkers than active smokers. Patients with mixed asthma and COPD and patients who have COPD without smoking also need to be characterized.

COPD involves small airway inflammation and fibrosis as well as alveolar destruction. It is not yet clear whether pulmonary biomarkers will be able to discriminate these two pathophysiologic processes. The recent demonstration by CT scan that MMP-9 is some ninefold higher in COPD patients with emphysema than in those without indicates that sputum biomarkers may be useful in the future in discriminating parenchymal disease from small-airway involvement.[10] How other biomarkers relate to the phenotype of COPD deserves further investigation.

Clinical Perspective Although many pulmonary biomarkers have been described in COPD patients, their clinical relevance is far from certain. None of the approaches described in this chapter are in routine use for the diagnosis of COPD, for predicting disease progression, or for predicting response to therapy. However, progress is now being made in asthma, where monitoring sputum eosinophils and FE_{NO} appears to improve control of asthma and at the same time reduce steroid requirements. Similar studies have not been done in COPD patients, as these patients do not respond well to glucocorticoids. However, measurement of sputum eosinophils and FE_{NO} may be very useful in clinical practice in identifying the patients with COPD who have concomitant asthma and who may respond better to bronchodilators and inhaled glucocorticoids. When more effective anti-inflammatory treatments become available for COPD patients, it is possible that inflammatory cells in sputum may be used to monitor the response to treatment, which may be difficult using physiologic parameters that are likely to improve only very slowly. What is of critical importance is to ensure that there are carefully matched control groups (smokers and nonsmokers) and that the COPD patients are phenotypes in as much detail as possible, ideally with detailed lung function assessments (including lung volumes and gas transfer), exercise performance, measurement of free fat mass, and high-resolution CT scanning.

Which Biomarker? The choice of which pulmonary biomarker is measured will depend on the research question posed or the clinical problem that is being addressed. Bronchial biopsies and BAL provide important information about cellular composition but cannot be repeated, whereas induced sputum and exhaled markers are repeatable. The biomarkers selected for measurement will depend on the nature of the study. For example, assessment of an anti-inflammatory drug will require the measurement of inflammatory cells and specific inflammatory mediators, whereas assessment of an antioxidant may require measurements of oxidative stress and an antiprotease will require measurement of protease activity. Prediction of steroid responsiveness may be given by increased FE_{NO} and sputum eosinophils. In the future it is possible that patterns of pulmonary biomarkers may predict exacerbations, as they do in asthma, and may reflect different mechanisms of exacerbations, discriminating between bacterial, viral, and noninfective mechanisms.

This is an active research area, and further studies addressing several of the issues raised in this chapter are already in progress. Correlation of

pulmonary biomarkers with other outcome measures is essential for the future assessment of the inflammatory destructive process and for measuring the effects of the new anti-inflammatory drugs that are now in development for the treatment of COP, as well as for understanding how disease mechanisms relate to clinical outcomes.

e37 Chagas' Disease: Advances in Diagnosis and Management

Andrei C. Sposito, Jose A. F. Ramires

INTRODUCTION

Chagasic cardiomyopathy is the major complication resulting from infection by *Trypanosoma cruzi,* occurring in up to 30% of individuals who have a positive specific serology. The *T. cruzi* infection is related to the close proximity between humans and triatomines carrying *T. cruzi* and extends from the Southern United States[11] and Mexico to the south of Argentina. According to the World Health Organization Technical Report, among individuals living in Latin American countries, 5–6 million are infected and 25 million are at risk of contracting the infection (Chap. 206).

It usually takes 10–20 years for the infection to manifest the disease in a broad range of clinical presentations including heart failure, cardiac arrhythmias, thromboembolism, and sudden death. Once established, the signs of heart failure result in life expectancy being reduced to ≤5 years. Therefore, strategies to identify the disease in the early phase and characterize predictive signs and potential therapeutic targets have been intensely pursued. In this chapter, we discuss the results from recent, novel research on the diagnosis and management of Chagas' disease.

LABORATORY DIAGNOSIS

Parasitemia During the acute phase of the disease, parasites can easily be found by microscopic observation of fresh blood. Morphologic characteristics of the parasite and differentiation from *T. rangeli* can also be determined by staining the blood smears. When parasitemia is low, procedures for parasite concentration or indirect methods (xenodiagnosis and hemoculture) can be used instead. Parasite concentration could be obtained either by microhematocrit or by the Strout method. In the microhematocrit, blood is centrifuged and the buffy coat examined by microscopy to visualize trypomastigote movements. In the Strout method, blood cells are first eliminated by precipitation and centrifugation. The supernatant is then submitted to a second centrifugation and the precipitate is examined as fresh blood.

The xenodiagnostic method consists of feeding uninfected triatominae with blood from the patient under examination and then investigating the intestinal contents of the insects some days later to search for metacyclic trypomastigotes. Artificial xenodiagnosis is preferred to avoid inconveniences from direct contact between the triatomines and patients' skin. Recently, amplification of *T. cruzi* DNA target sequences by polymerase chain reaction (PCR) has become a preferred method for the detection of parasites in blood and tissues. Such PCR techniques are especially helpful for the follow-up of chemotherapy for *T. cruzi*. However, despite being more sensitive than xenodiagnosis and hemoculture, this sensitivity is equally dependent on the magnitude of the parasitemia.

Immunodiagnosis Infected individuals soon develop antibodies, initially IgM and later IgG, against several epitopes of *T. cruzi* allowing the indirect diagnosis of Chagas' disease. Conventional immunodiagnostic tests are available worldwide and are based on three main techniques: hemagglutination, immunofluorescence, and ELISA. Nonconventional tests using recombinant chimeric proteins, synthetic peptides, or purified antigens have been developed to increase specificity and reduce cross-reactivity with other infections and with autoimmune diseases. In general, conventional tests have elevated sensitivity, and a positive result in two conventional tests is sufficient to diagnose the infection. In parallel with PCR for detecting *T. cruzi* parasitemia, conventional serologic tests could also be used for the follow-up of patients undergoing chemotherapy.

ANATOMIC DIAGNOSIS

Myocardial Fibrosis and Inflammation *T. cruzi* can be easily detected in muscle cells and interstitial histiocytes of individuals in the acute phase of Chagas' disease. However, such a finding is rare in the chronic phase of the disease. Hence, the main finding in the hearts of patients with chronic Chagas' disease is the presence of inflammatory infiltrates. Chagas' myocarditis lesions are spread out over both ventricles and in a large spectrum of severity, transforming myofibers into fibrous tissue and featuring the changes in heart structure and function. Accordingly, myocardial fibrosis caused by Chagas' disease is a strong marker of clinical impairment and ventricular dysfunction.

The histopathologic evaluation of myocardial fibrosis and inflammation can be obtained through a percutaneous and transvenous endomyocardial biopsy of the right ventricle. This diagnostic procedure has been proved to be a powerful tool for both the prediction of clinical outcome and estimation of the severity of myocardial damage in Chagas' disease and in other primary and secondary cardiac diseases. In patients with Chagas' disease who undergo heart transplantation, endomyocardial biopsy is considered the "gold standard" technique in the differentiation between allograft rejection and reactivation of the disease. In such patients, however, the use of endomyocardial biopsy has been limited by the mild, albeit significant, intrinsic risk of the procedure and the lack of evidence-based parameters that may guide clinical decisions. Consequently, noninvasive methods have been developed to explore potential clinical benefits from assessing the degree of myocardial inflammation and fibrosis in patients with Chagas' disease. In our group, the histopathologic findings of myocardial inflammation via endomyocardial biopsy were compared with two noninvasive techniques, gallium-67 myocardial uptake scintigraphy and MRI. Despite both noninvasive techniques detecting Chagas' myocarditis, MRI was more accurate due to the higher spatial resolution.

Myocardial delayed enhancement by MRI has been proved to be efficient in detecting myocardial fibrosis in ischemic and nonischemic myocardial disease. In Chagas' disease, delayed enhanced MRI can detect even traces of myocardial fibrosis in individuals in the indeterminate phase, that is, the period before presentation of cardiac electrical or mechanical abnormalities.[3] Such refined accuracy would potentially be helpful for characterization and treatment of arrhythmogenic foci in patients with Chagas' disease. Moreover, the severity of myocardial fibrosis detected by MRI is proportional to the severity of myocardial dysfunction and clinical symptoms.

In patients in the chronic phase of the disease, myocardial fibrosis is found particularly at the apex and inferolateral regions of the left ventricle. Ischemia, inflammation, mechanical factors, and parasympathetic nerve cell destruction are considered among potential underlying mechanisms for these lesions. In these affected regions, ventricular wall aneurysms would develop in a later stage of Chagas' cardiomyopathy, constituting a classic sign of the disease. Figure e37-1 shows the typical apex lesion with severe myocardial fibrosis in a heart examined at autopsy.

Myocardial Perfusion Myocardial ischemia has been frequently reported in patients with Chagas' disease and normal coronary angiograms. In fact, these patients have chest pain associated with electrocardiographic signs of ischemia simulating obstructive coronary artery disease. From a pathophysiologic standpoint, vascular dysautonomia due to denervation and inflammatory damage of the microcirculation is considered the leading cause of myocardial ischemia in these patients. Figure e37-2 shows myocardial denervation and ischemia by scintigraphic imaging; the denervation demonstrated by the reduced cardiac uptake of ^{123}I-metaiodobenzylguanidine (MIBG) is concordant with the perfusion deficit, but is much larger, suggesting that denervation is the initiating event.

In angiographic studies, endothelium-dependent and -independent impairment in coronary vasodilation have been observed in patients with Chagas' disease.[4] With scintigraphic perfusion imaging using thallium-201, transient and permanent myocardial perfusion abnormalities have been described in patients with the disease (Chaps. 222

FIGURE e37-1 Photo of a heart from a patient with chronic chagasic cardiac disease, exhibiting a typical lesion at the left ventricle.

and e20). These studies demonstrate an elevated topographic correlation between perfusion and wall motion abnormalities. Even though prospective cohorts demonstrating a temporal association between perfusion defects and the development of wall motion dysfunction are lacking, it is plausible to consider that such perfusion defects would represent an early sign of Chagas' cardiomyopathy. In addition, these radionuclide studies also indicate that the perfusion defects are predominantly in the apex and inferolateral regions, which are those most affected by the inflammatory damage and the autonomic denervation.

From a clinical perspective, caution must be taken to interpret the presence of perfusion defects detected by either scintigraphy or MRI as an indication of epicardial coronary disease in patients with Chagas' disease. Actually, both the endothelium-dependent and -independent vasodilatory responses of coronary resistance vessels are also affected in patients with idiopathic dilated cardiomyopathy and angiographically normal coronary arteries. These patients have impairment of the vasodilator responses to both metabolic and pharmacologic stimuli and an increased sensitivity to vasoconstrictors. Such evidence indicates that the segmental microvascular dysfunction observed in patients with Chagas' disease is unlikely to be pathogen-dependent but rather an early sign of ventricular wall disease. Whether such perfusion disturbances also contribute to the detriment of ventricular wall motion is presently unknown.

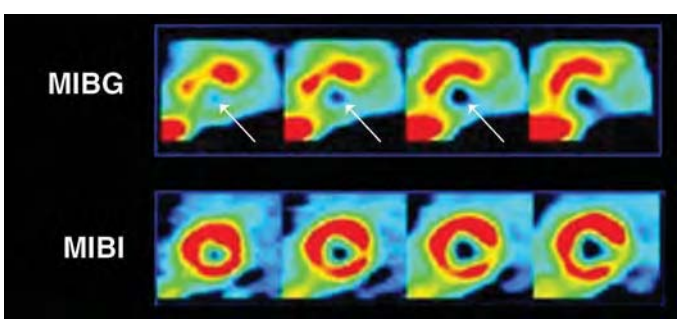

FIGURE e37-2 Myocardial denervation and ischemia detected by scintigraphic imaging. *Above.* The denervation is demonstrated by the reduced cardiac uptake of ^{123}I-metaiodobenzylguanidine (MIBG) (*arrows*). ***Below.*** A permanent perfusion deficit with smaller size as compared with the denervation is demonstrated by scintigraphic perfusion with ^{99m}Tc-sestamibi (MIBI).

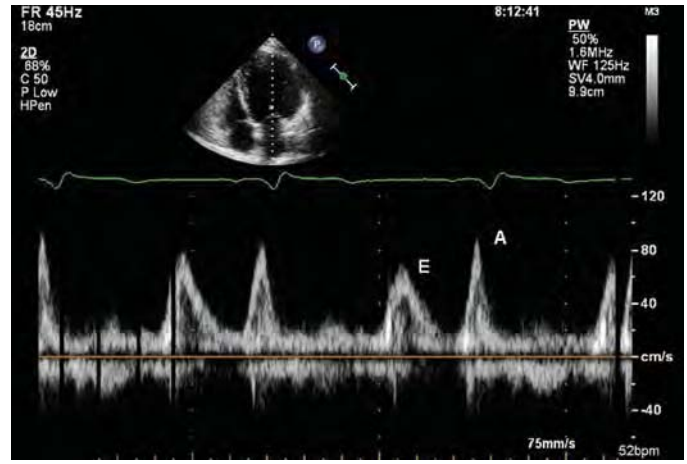

FIGURE e37-3 Echocardiographic analysis of mitral inflow by pulse-wave Doppler showing diastolic function in a patient with Chagas' disease. Normally, the early flow velocity (E) is higher than the late flow velocity (A), which is related to atrial contraction. In this case, there is an inverted E/A relation, indicating the impairment of left ventricular relaxation.

Myocardial Wall Motion In the acute phase of the disease, pericardial effusion and occasionally myocardial wall motion abnormalities have been described. By definition, in the indeterminate phase, chronically infected individuals remain a parasite reservoir without being affected by the disease and consequently have a normal life expectancy. Hence, the appearance of an abnormality of the ventricular wall reflects progression of the disease and must be considered, accordingly, as the onset of the chronic phase of Chagas' disease.

In the chronic phase, thinning, aneurysm formation, and wall motion dysfunction are the most frequent findings detected on echocardiography. In keeping with necropsy, scintigraphic, and MRI studies, these echocardiographic findings are mostly observed in the apex and inferobasal regions of the left ventricle. The segmental thinning of the ventricular wall, particularly at the apex, promotes remodeling of the left ventricle, which may increase mechanical tension and contribute to aneurysm formation in this area. Nevertheless, abnormalities of other left ventricular segments can also be found.

As the disease progresses, the affected segments of the ventricular wall become hypokinetic, akinetic, or even dyskinetic. Frequently, diastolic dysfunction occurs in an early phase of the disease, as shown in Fig. e37-3. The thinning of the apex becomes an aneurysm, and the global systolic function of the left and right ventricles deteriorates. Initially, the systolic dysfunction may be apparent only under pharmacologic stress by dobutamine or phenylephrine, characterizing the reduction of systolic reserve. Echocardiography or MRI can accurately detect these characteristics.

The right ventricle is first and predominantly affected in the majority of patients with Chagas' disease. This may occur even in the absence of any detectable abnormality in the left ventricle. Accordingly, in these patients, the development of heart failure is typically manifested with a predominance of systemic over pulmonary congestion. Because echocardiography has a low accuracy for detecting right ventricular dysfunction, radionuclide angiography or MRI is preferred for evaluation of this chamber.

Rx CHAGAS' DISEASE

ETIOLOGIC TREATMENT Nitrofurans and nitroimidazole derivatives (nifurtimox and benznidazole respectively) have been the cornerstones of trypanosomicidal treatment in recent decades. These compounds seem to exert their trypanosomicidal action by the generation of superoxide radicals causing oxidative stress and cell death in susceptible parasites.

From the clinical point of view, the activity of treatment with both compounds is evident in terms of parasite load reduction and serologic conversion to negative in the acute phase of Chagas' disease and in congenital

infection. In the indeterminate phase, new promising findings have been reported particularly in children and young adults, showing long-lasting disappearance of specific antibodies in 58–98% of treated individuals together with a 10–20% rate reduction of side effects. In general, treatment with nitroimidazole derivatives, especially benznidazole, has been shown to be effective more frequently in reducing parasitemia and specific antibody titers in individuals in the indeterminate phase. Whether this treatment will prevent the development of cardiac or digestive complications of the disease is still unclear. Large randomized controlled trials are required to define this issue.

The effect of trypanosomicidal therapies on parasite load or disease progression in patients in the chronic symptomatic phase of Chagas' disease is even less clear. The disappearance of specific antibodies is uncommon in the chronic phase and may take up to 10–20 years. Parasite DNA is present in several tissues and may induce immune response and perhaps disease progression. Hence, the ideal therapeutic schema or duration for such chronic patients is unknown. In addition, several adverse reactions, such as peripheral neuropathy and skin disorders, have been reported in a large proportion of patients treated with both nifurtimox and benznidazole. Thus, there is insufficient evidence to demonstrate the clinical benefit for trypanosomicidal treatment in patients in the chronic phase of Chagas' disease.

Novel potential targets for trypanosomicidal treatment have been investigated to reduce side effects and increase treatment efficacy. Sterol biosynthesis inhibitors, protein prenylation inhibitors, protease inhibitors, and phospholipid analogues are among potential chemotherapeutic agents for this purpose. Although some of these compounds have already demonstrated potent inhibitory activity in vitro against *T. cruzi*, clinical benefits have not been proved thus far.

COMPLEMENTARY TREATMENT In the acute phase, symptoms disappear in up to 2 months. In rare cases of severe acute myocarditis, an empirical combination of corticoid and trypanosomicidal treatments has been attempted. In animal models, immunosuppressive therapy in combination with benznidazole has been demonstrated to be effective in attenuating the inflammatory response. However, insufficient studies in humans have been done to define the ideal approach in these cases.

The aim of treatment in the chronic phase of Chagas' disease is to attenuate symptoms and prevent complications. The most relevant cardiac complications in the late chronic phase are heart failure and life-threatening arrhythmias. The mortality attributable to Chagas' disease is fundamentally related to these two disorders. Even though few studies have compared the efficacy of the treatment for heart failure in patients with and without Chagas' disease, the standards of clinical treatment are mostly the same. Heart failure in both classes of patients responds equally to digitalis, diuretic, and vasodilator therapy (Chaps. 227 and 231). The use of angiotensin-converting enzyme (ACE) inhibitors has been reported to reduce neurohormonal activation, improving heart failure symptoms and nonlethal arrhythmias. In an animal model, there is evidence that aldosterone blockade with spironolactone attenuates myocardial remodeling and inflammatory infiltration and may reduce mortality in Chagas cardiomyopathy.[8]

As is the case for nonchagasic heart failure, the use of beta blockers is also believed to be beneficial in patients with Chagas' disease. In addition, beta blockers may reduce the transmyocardial pressure gradient and attenuate subendocardial ischemia, which is supposed to participate in the deterioration of ventricular function in Chagas' disease. The blockade of sympathetic activity, which is typically augmented in these patients, may help to attenuate ventricular remodeling and arrhythmias. Thus, despite the lack of specific trials to verify this assumption, beta blocker use in patients with Chagas' disease who also have heart failure is indicated.

There is some evidence that amiodarone can prevent complex arrhythmias in patients with heart failure irrespective of the cause. In small studies in patients with Chagas' disease with sustained ventricular tachyarrhythmias, amiodarone provided longer intervals free of arrhythmic events compared with other antiarrhythmic drugs. The efficacy of amiodarone in preventing ventricular tachyarrhythmias seems to be reduced in patients with severe systolic dysfunction. In these patients, percutaneous catheter ablation, implantation of implanted cardioverter/defibrillators (ICD) or surgical procedures may be attempted.

Reentry is considered to be the major arrhythmogenic mechanism of ventricular tachyarrhythmias in Chagas' disease, it is usually in the periaurysmatic zone or in focal areas of fibrosis in the inferolateral region of the left ventricle. Surgical treatment consists of conventional aneurysmectomy associated with endocardial or myocardial resection and/or isolation of critical sites of reentry by endocardiectomy or cryoablation guided by electrophysiologic mapping. Alternatively, interpapillary endomyocardial cryoablation without electrophysiologic mapping has been attempted in patients with sustained ventricular tachycardia and akinesia or dyskinesia of the inferolateral region of the left ventricle, with efficacy in nearly 60%. Because the mortality of the procedure is high, surgical ablation should be considered only when systolic dysfunction is not severe, the overall surgical risk is low, and when other surgical procedures, such as aneurysmectomy, are not indicated.

Nonsurgical simultaneous epicardial and endocardial catheter ablation has been introduced recently as an alternative approach in the treatment of patients with Chagas' disease and recurrent ventricular tachycardia.[10] Because critical sites of reentry may be endocardial, intramural, or epicardial, this combined approach provides a higher efficacy for treating recurrent ventricular tachycardia. For patients with severe systolic dysfunction, however, the insertion of an ICD is the treatment of choice, particularly in those with left ventricular ejection fractions <30%. Symptomatic or high-risk bradyarrhythmia is frequently manifested in these patients. Thus, implantation of an ICD with pacing capability is often indicated. ICDs are effective in preventing death due to ventricular tachyarrhythmias, but frequent shocks triggered by tachycardias, life-threatening or not, can lead to a reduced quality of life. Therefore, a combination of ICD, antiarrhythmic therapy, and catheter ablation appears to be ideal in these patients.

e38 The Polypill

K. Srinath Reddy, Nitish Naik, Ambuj Roy

Cardiovascular diseases (CVDs) are leading contributors to the global burden of disease, accounting for nearly 30% of global deaths and nearly 20% of disability-adjusted life years (DALYs) lost. Identification of multiple risk factors as well as interventions that alter risk by modifying one or more of them provide opportunities for reducing the risk of CVD through actions that impact on populations or directly on individuals. Major goals of preventive cardiology and clinical medicine are to identify individuals at a high risk of future CVD events and to intervene in order to substantially reduce their risk.

The decision to modify a risk factor has traditionally depended on the measured level of the risk factor, the risk of future CVD associated with that level, and the potential benefit of reducing it to a lower level through interventions that are cost-effective and safe. Evidence from observational studies, especially from large and long-term cohorts, has defined the prevention norms by indicating a continuous relationship between risk factor levels and CVD risk. Evidence from clinical trials has set the thresholds at which interventions are considered beneficial. Over the past two decades, prevention norms and clinical norms have converged because of accumulating new knowledge. For example, in the seventh U.S. Joint National Committee report on hypertension, the definition of normal blood pressure was lowered to <120/80 mmHg from <130/85 mmHg in the sixth report. Similarly, the target goals of low-density lipoprotein (LDL) cholesterol have been lowered progressively in patients with established coronary artery disease (CAD). However, clinical outcome data are scarce in patients when multiple risk factors are simultaneously targeted or when borderline abnormal values are treated. Hence, much interest was generated when Wald and Law proposed a polypill to target multiple risk factors, regardless of their levels, as a potentially effective intervention to reduce the risk of CVD. This chapter reviews the possible benefits and shortcomings of the polypill.

CARDIOVASCULAR DISEASE—MULTIFACTORIAL CAUSATION

Major risk factors related to CVD include behavioral factors, such as smoking, unhealthy diet, physical inactivity, and biologic factors, such as high blood pressure, elevated blood lipids, and diabetes. According to the INTERHEART study, nine risk factors [smoking; higher-than-normal ratio of apolipoprotein (apo) B to apoA; a history of hypertension and diabetes; abdominal obesity; psychological factors; and lack of daily consumption of fruits and vegetables, regular alcohol intake, and regular physical activity] account for ~90% of CVD risk globally, cutting across all major ethnic populations. Interventions, directed toward lowering many of these risk factors, have been shown to lower the risk of subsequent CVD events. Drugs that act on critical steps in the pathogenesis of atherothrombotic events, either by reducing risk factors (e.g., statins) or preventing pathologic processes (e.g., aspirin), have been shown to reduce vascular events. Both lifestyle measures and pharmacotherapy have been demonstrated to prevent or delay the onset of CVD-related clinical events in persons with high levels of one or more risk factors (*primary prevention*). They have also been shown to reduce the risk of recurrent events and to extend survival in persons who have manifest CVD (*secondary prevention*). Optimal drug therapy for secondary prevention of CVD currently includes aspirin, beta blockers, angiotensin-converting enzyme (ACE) inhibitors, and statins. These drugs have been shown to significantly reduce overall coronary and overall CVD event rates in patients with manifest CAD (Fig. e38-1). Some of them have also been demonstrated to be effective in reducing the risk of recurrent cerebrovascular events in persons who have earlier experienced a stroke or transient ischemic attack.

Statins have now become a cornerstone of secondary prevention strategies. They have been shown to improve survival, lower the risk of recurrent myocardial infarction (MI), and reduce the need for revascularization in patients with acute and chronic CAD. These benefits accrue regardless of measured blood cholesterol levels in patients with CAD. There is, however, a threshold of benefit, with little apparent clinical benefit in patients who achieved a <30% reduction in LDL cholesterol levels. In several randomized trials, patients receiving high-dose statin therapy (such as atorvastatin, 80 mg) benefited from a greater reduction in combined endpoints of cardiovascular mortality, MI, stroke, and need for revascularization when compared to patients receiving moderate-dose therapy (such as atorvastatin, 10 mg, pravastatin, 40 mg, or simvastatin, 20 mg/d).

β-Adrenergic blockers have clearly been shown to significantly reduce mortality after MI. In a meta-analysis of 25 trials, beta blockers were shown to reduce relative risk for overall death by 23% and reinfarction by 26%. While these benefits persist for many years on continuing therapy, they disappear on discontinuing therapy. Despite these proven benefits, many patients do not receive the benefit of these drugs for secondary prevention. The EUROASPIRE and WHO-PREMISE studies have shown suboptimal prescribing practices for CVD risk reduction among physicians in Europe and the developing countries, respectively. In a U.S. national survey on prescription patterns after MI, it was observed that beta blockers were not prescribed to nearly two-thirds of eligible patients in some regions. It has been estimated that if all post-MI patients received beta blockers over 20 years, then adverse outcomes of nearly one-fifth could be prevented, with a decrease in sudden death by 32% and a decrease in recurrent MI and revascularization by 27%.

The benefits of ACE inhibitors in patients with acute MI with left ventricular systolic dysfunction, as well as in those with chronic systolic heart failure, are well proven. Benefits of this class of drugs in patients at high risk for cardiovascular events, even without left ventricular dysfunction, have also been demonstrated. The HOPE study, which included patients with CVD or diabetes and at least one cardiovascular risk factor but the absence of left ventricular dysfunction, demonstrated a 26% reduction in cardiovascular death rates and a 16% reduction in overall mortality with ramipril. These benefits were observed even in the presence of other known therapies to lower CVD related events such as aspirin, beta blockers, and lipid-lowering drugs.

In patients with acute MI, aspirin has been shown to effect a 23% risk reduction in vascular mortality and a 10–40% risk reduction in

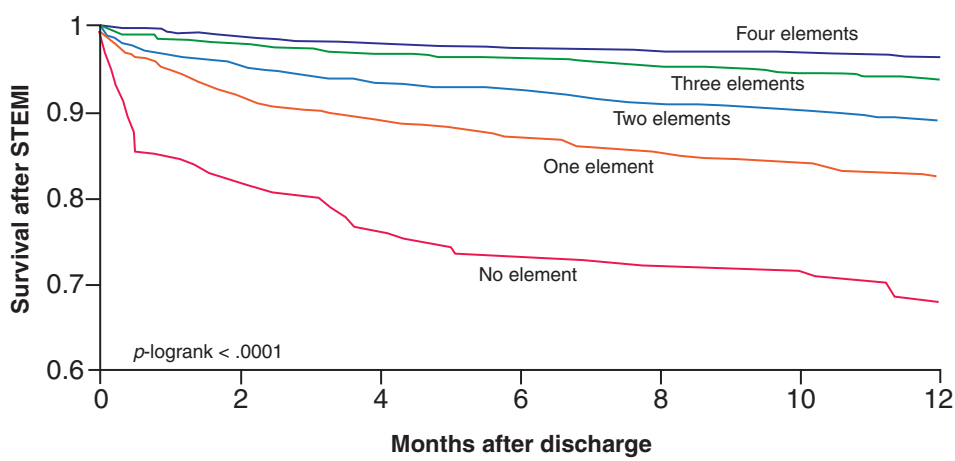

FIGURE e38-1 Post-MI survival in German hospitals is significantly improved in patients who receive four medications (aspirin, beta blocker, ACE inhibitor, and statin) when compared with those who receive zero, one, or two (*p*-logrank < .0001). *(Unpublished results from the MITRA registry. Reproduced from Sleight et al.)*

Copyright © 2008 The McGraw-Hill Companies. All rights reserved.

the composite endpoint of recurrent MI, stroke, or vascular death. However, it is also associated with an increased risk of gastrointestinal bleed and hemorrhagic stroke.

Lowering cardiovascular mortality by combinations of these drugs, when administered together, has been shown in some studies. In the ASCOT BPLA trial, calcium channel blockers and ACE inhibitors were observed to be more effective in controlling blood pressure than the traditional thiazide diuretics and beta blockers. Moreover, adding statins to the treatment led to a highly significant 36% reduction in the combined endpoint of nonfatal MI and fatal coronary heart disease. Analysis from the MITRA study demonstrated improved survival in post-MI patients who received these four medications (aspirin, beta blockers, ACE inhibitors, and statins) as opposed to those who received none to two drugs.

However, the protective role of combinations of these drugs for primary prevention of CVD has not been proved clearly. While statins and aspirin have been shown to reduce events in certain population subsets at high risk for CAD, actual data from clinical trials specifically designed to test the utility of this multidrug combination pharmacotherapy are lacking.

POLYPILL STUDY MODELS

Two studies have attempted to define the possible benefits of pharmacologic treatment of multiple risk factors in reducing cardiovascular events by modeling potentially achievable risk reduction with the use of multiple drugs. Wald and Law, in 2003, combined six drugs to model reduction of four cardiovascular risk factors—LDL cholesterol, blood pressure, serum homocysteine, and platelet function. The combined formulation included a statin (atorvastatin, 10 mg, or simvastatin, 40 mg), three blood pressure–lowering drugs (a thiazide diuretic, a beta blocker, and an ACE inhibitor, all at half the standard dose), folic acid (0.8 mg), and aspirin (75 mg). The authors suggested that the pill be used in all persons above the age of 55 years (as 96% of CVD events occur beyond this age in western populations) and in adult patients of any age with manifest CVD, regardless of their risk factors. In their model, the six drugs were used irrespective of the pretreatment risk factor levels, as the authors asserted that arbitrary thresholds of individual risk factors were poor predictors of future CVD events.

The concept of a continuum of risk was preferred to predefined cutoff levels that attempt to separate "normal" from "abnormal" levels. Published meta-analyses of multiple randomized trials were used to quantify the estimated benefit from this combination of drugs. The model factored a reduction of ischemic heart disease events at 2 years by 61% due to statins, by 46% due to anti-hypertensive drugs, by 16% due to folic acid, and by 32% due to aspirin. By multiplying the relative risk reduction from each class of drugs, the authors estimated that the combined effect of the four drugs would be an 88% reduction in ischemic heart disease events and an 80% reduction in stroke events (Table e38-1). Even if folic acid were omitted from the formulation, the authors estimate that 86% of ischemic heart disease events could still be averted. Similarly, absence of aspirin reduces the advantage of the polypill by only 5 percentage points to 83%. These benefits accrued with a low incidence of projected side effects. It was estimated that only 15% of patients would be expected to have adverse effects due to the formulation, mostly ascribable to aspirin. If all people >55 years used the pill, it was estimated that one in three people would benefit directly, gaining an additional 12–20 years of life-years without a coronary heart disease event or stroke.

Gaziano et al. further quantified these assertions in a subsequent study that examined cost-effectiveness of combination pharmacotherapy in reducing CVD in low-income and middle-income countries. Using a Markov model to assess cost-effectiveness, the authors used a combination of four drugs—aspirin, a calcium channel blocker, an ACE inhibitor, and a statin—for primary prevention. For secondary prevention, the authors substituted a beta blocker for the calcium channel blocker while retaining the other three constituents. For primary prevention, the authors included patients with a 10-year absolute risk of CVD of between 5% and 35%. This strategy thus required an additional hospital visit to assess CVD risk factors such as blood pressure, diabetes, serum cholesterol, and smoking status. The authors estimated that a nearly 50–60% reduction in CVD-related events could be expected if all patients with a 10-year absolute risk >5% were treated. This would lead to at least a 2-year increase in life expectancy in those above the age of 35 years. Using the secondary prevention strategy, the authors predicted a 10–15% reduction in lifetime risk of death due to CVD.

Using this model, the authors reported that the incremental cost-effectiveness of the primary prevention strategy was US$746–890 per quality-adjusted life year (QALY) for patients with a 10-year absolute CVD risk >25%, across six developing regions, as defined by the World Bank. The cost was higher in patients with lower levels of absolute 10-year cardiovascular risk, as more patients needed to be treated to achieve a similar reduction in CVD events, leading to higher expenditure and lower cost-effectiveness. However, incremental cost-effectiveness was still favorable for all primary prevention strategies, except for the strategy of treating all patients >55 years. For secondary prevention, incremental cost-effectiveness of the polypill was most favorable, at US$306–388 per QALY gained.

LIMITATIONS OF THE POLYPILL

Despite the perceived advantages associated with the delivery of multiple drugs in a single pill, including convenience of delivery, ensuring inclusion of all drugs considered essential for primary or secondary prevention, and possible improvements in compliance, several factors need to be accounted for before a polypill can actually be recommended.

The strongest objection to the concept of combination pharmacotherapy is the absence of any clinical trial to substantiate its merits. While several trials have documented the benefits of some of these classes of drugs administered separately in different patient subsets, such as post-MI survivors, those with CAD and left ventricular dysfunction, and other high-risk subsets, there is still paucity of data on the benefit of some of these drugs in certain patient subsets, e.g., ACE inhibitors in low-risk stable patients of CAD without left ventricular dysfunction. In the PEACE trial, which examined the efficacy of ACE inhibitors in lowering CVD events, no significant benefits were found with the use of trandolapril. Similarly, there is a lack of evidence to support the use of beta blockers in all patients with stable CAD. Aspirin also does not have a well-established role in preventing cardiovascular disease events in all women >55 years. Even the addition of a statin to aspirin does not significantly improve cost-effectiveness in primary prevention models, unless absolute risks are high.

TABLE e38-1 EFFECT OF POLYPILL ON RISK OF ISCHEMIC HEART DISEASE (IHD) AND STROKE, AS ESTIMATED BY WALD AND LAW, AFTER 2 YEARS OF TREATMENT AT THE AGE 55–64 YEARS

Risk Factor	Agent	Reduction in Risk Factor	% Reduction in Risk (95% CI)	
			IHD Event	Stroke
LDL cholesterol[a]	Statin[b]	1.8 mmol/L (70 mg/dL) reduction	61 (51–71)	17 (9–25)
Blood pressure	Three classes of drugs at half standard dose	11 mmHg diastolic	46 (39–53)	63 (55–70)
Serum homocysteine	Folic acid (0.8 mg/d)	3 μmol/L	16 (11–20)	24 (15–33)
Platelet function	Aspirin (75 mg/d)	Not quantified	32 (23–40)	16 (7–25)
Combined effect	All		88 (84–91)	80 (71–87)

[a]LDL, Low-density lipoprotein.
[b]Atorvastatin, 10 mg/d, or simvastatin or lovastatin, 40 mg/d taken in the evening or 80 mg/d taken in the morning.

The projected benefits of these combinations of drugs have been assumed using mathematical multiplication of relative risks. For some drugs, the authors have included the best-case scenario figures for risk reduction. For example, Wald and Law assumed a relative risk reduction of 61% of CVD events with the use of statins. However, data from many large randomized trials of statins have estimated the relative risk reduction to be at a more conservative level of 35%. These assumptions therefore need to be verified by an actual clinical trial. This is especially important in the case of primary prevention.

In secondary prevention trials, the sequential evaluation of cardioprotective drugs has seen each new drug being tested for incremental benefit when added to previously tested drugs and only then becoming standard therapy. Thus the value of combination therapy of multiple drugs (given separately and not as a single pill) is well proven. However, multiple drugs have not been used in such an incremental manner in primary prevention trials. It is essential that trial evidence, using major event-related endpoints, be generated for such multidrug combinations when used for primary prevention. In the case of secondary prevention, evidence on bioavailability, pharmacokinetics, and intermediate variables (risk factor levels) may suffice. Even in secondary prevention, some questions remain: Are beta blockers useful for secondary prevention of stroke? Are diuretics needed for secondary prevention of CAD?

The actual incidence of adverse events or other side effects associated with the use of the polypill is also unknown. Beta blockers, ACE inhibitors, calcium channel blockers, statins, and aspirin are all known to produce side effects requiring discontinuation of therapy. Although Wald and Law estimated that 15% of patients would be expected to discontinue therapy due to side effects, the actual incidence may be higher. Polypills would need to be available in different formulations to avoid anticipated side effects due to one or more components in susceptible persons. The dilemma of primary prevention becomes more obvious when an attempt is made to treat all patients alike, regardless of their absolute risk with one fixed combination of drugs. On the one hand, many asymptomatic persons with low absolute risk of events would be treated with little or no expected benefit; however, they would be exposed to the adverse effects of combination multidrug therapy. On the other hand, there would be high-risk patients who would be undertreated and might not reach the desired therapeutic goals. Without appropriate risk profiling, the latter patients would be diligently taking drugs but not accruing the maximum benefits. Although the population risk would still be lowered by such an approach, the individual at risk would not derive optimum benefit in spite of drug therapy.

Whether the polypill will necessarily improve compliance is not known. Although a low daily pill count does improve compliance, it is also affected by many other social and behavioral factors that are not necessarily overcome with the convenience associated with a polypill. Patient motivation and counselling, educational status, health education campaigns, and economic considerations are among the many factors that impact adherence positively and are unaffected by combination pharmacotherapy. Patients with overt clinical heart disease are more receptive to information regarding personal health behavior and its modification and are also more compliant with drug therapy. Long-term adherence to advice about behavior and drugs is lower when it is used for primary prevention in "real-world" settings. This can have a significant negative impact on the projected benefits.

An important assumption made by Wald and Law in targeting multiple risk factors simultaneously is that there are no clear demarcations between "normal" and "abnormal" levels of risk factors. They proposed, after appraising data from many observational and randomized trials, that there is a continuum of risk, with no specific risk factor thresholds that need to be targeted. It was recommended that interventions to modify risk factors should be guided by a person's level of absolute cardiovascular risk rather than the level of individual risk factors. Thus, patients with what is currently considered borderline elevation of multiple risk factors would derive benefit from interventions designed to modify those risk factors. However, data from the Framingham study suggest that 90% of CVD events occur in individuals with at least one preexisting major cardiovascular risk factor. Clustering of these risk factors is frequently observed in individuals and contributes to high level of absolute risk of CVD. Therefore, it is important to screen the population for these risk factors and then treat individuals at a high absolute risk with the combination pharmacotherapy, rather than treat the entire population >55 years with a blanket therapy. The ideal approach would be to assess an individual's global (absolute) cardiovascular risk, based on available algorithms for different populations, to maximize the benefits of the polypill and thus make it cost-effective, as shown in the study by Gaziano.

Another concern with use of a widespread pharmacologic intervention at the population level is the likely sense of complacency among both users and health care providers. Critics have expressed a fear that emphasis on healthy diet, physical activity, smoking cessation, and other lifestyle changes, which are essential elements in the management of these chronic diseases, may not be treated with the seriousness that they deserve. The polypill will not reduce the number of individuals acquiring a high-risk status in any population—it can only avert their future risk, if detected and treated. On the other hand, population-wide changes in diet, physical activity, and tobacco use are likely to reduce the number of individuals who enter this high-risk zone. Many other factors such as physician attitudes, cost-effectiveness, and long-term affordability have to be addressed before the promise of the polypill can be realized. These concerns would be best addressed by clinical trials that examine the benefits in the setting of both primary and secondary prevention.

IMPACT ON DEVELOPING COUNTRIES

CAD is an emerging epidemic in low- and middle-income countries. By 2020, >80% of all CVD-related deaths worldwide are expected to occur in the developing world. Moreover, even as age-adjusted cardiovascular disease rates are declining in the developed world, rates of CVD are rising rapidly in these low- and middle-income countries. The same risk factors responsible for CAD in the western population are operative in these countries, as shown by the INTERHEART study.

In the absence of well-resourced CVD prevention programs and limited public awareness of risk factors, the polypill appears attractive for such populations, especially for secondary prevention and high-risk primary preventions. It overcomes the problems of inadvertent drug omission by under-informed physician and provides the opportunity to include generic drugs such as lovastatin or simvastatin, enalapril, and propranolol to lower the cost of pharmacotherapy. The presence of a strong pharmaceutical industry in countries such as India offers the opportunity to lower the costs of drug production significantly, making the therapy more affordable and applicable. A World Health Organization report on chronic diseases suggests that a polypill could be made available for a little over US$1 per patient per month, using these generic products. Moreover, with the expected low side-effect profile of these pills, it may be possible to shift identification and treatment of high-risk individuals to non-physician health workers in these resource-poor countries, thereby lowering the cost and widening the access for effective risk reduction. However, the developing countries would need to place even greater emphasis on policies and educational interventions that protect their populations from the risk of CVD, while judiciously applying interventions such as the polypill.

CONCLUSIONS

The concept of a polypill to reduce the burden of CVD is attractive and seems to have great potential, especially in secondary and high-risk primary prevention. However, its role is presently speculative and needs to be assessed in randomized trials. It should not distract clinicians from the importance of managing risk factor levels; rather, it should enable persons at high risk of CVD to access affordable and easy-to-consume therapy for reducing that risk. It is also important that the polypill should not lull the patient and the physician into a false sense of security—continued emphasis on targeting modifiable risk behaviors such as smoking, sedentary lifestyle, and unhealthy diet

would continue to yield equal dividends. They would also be applicable to the wider population, with greater safety.

e39 Mitochondrial DNA and Heritable Traits and Diseases

Karl Skorecki, Hanna Mandel

Mitochondria are cytoplasmic organelles whose major function is to generate ATP by the process of oxidative phosphorylation under aerobic conditions. This process is mediated by the respiratory electron transport chain (ETC) multiprotein enzyme complexes I–V, and the two electron carriers, coenzyme Q (CoQ) and cytochrome-c. Other cellular processes to which mitochondria make a major contribution include apoptosis (programmed cell death), as well as additional cell-type specific functions (Table e39-1). The efficiency of the mitochondrial ETC in ATP production is a major determinant of overall body energy balance and thermogenesis. In addition, mitochondria serve as the predominant source for the generation of reactive oxygen species (ROS), whose rate of production also relates to the coupling of ATP production to oxygen consumption. Given the centrality of oxidative phosphorylation to the normal activities of almost all cells, it is not surprising that mitochondrial dysfunction can affect almost any organ system (Fig. e39-1). Thus, physicians in many specialties might encounter patients with mitochondrial diseases and should be aware of their existence and characteristics.

The integrated activity of several hundred proteins is required for normal mitochondrial biogenesis, function, and integrity. Most of these are encoded by nuclear genes and thus follow the rules and patterns of nuclear genomic inheritance (see Part 3, Genetics and Disease). These nuclear-encoded proteins are synthesized in the cell cytoplasm and imported to their location of activity in mitochondria through a complex biochemical process. In addition, the mitochondria themselves have their own genome consisting of numerous copies (polyploidy) per mitochondrion of a circular, double-strand mitochondrial DNA (mtDNA) molecule consisting of a 16,569-nucleotide sequence. This mtDNA sequence contains a total of 37 genes, of which 13 encode mitochondrial protein components of the ETC (Fig. e39-2). The remaining 22 tRNA- and 2 rRNA-encoding genes are dedicated to the process of translation of the 13 mtDNA-encoded proteins. This dual genetic control of mitochondrial function can result in fascinating patterns of inheritance, which may be challenging to unravel. The current chapter focuses on diseases and heritable traits related to the mtDNA component of the dual genetic control of mitochondrial function. The reader is referred elsewhere for consideration of mitochondrial disease originating from mutations in the nuclear genome. The latter include (1) nuclear genomic mutations that disrupt the integrity of the mitochondrial genome itself (mtDNA deletion and depletion states), (2) disorders due to mutations in nuclear genes encoding structural components or assembly factors of the oxidative phosphorylation complexes, and (3) mitochondrial disorders due to mutations in nuclear genes encoding proteins indirectly related to oxidative phosphorylation.

Heme synthesis
Hepatic ammonia detoxification
Neurotransmitter metabolism

MITOCHONDRIAL DNA (mtDNA) STRUCTURE AND FUNCTION

As a result of its circular structure and extranuclear location, the replication and transcription mechanisms of mtDNA differ from the corresponding mechanisms in the nuclear genome, whose nucleosomal packaging and structure is more complex. In terms of mtDNA replication, at least two major models have been proposed, which differ principally in whether the two strands of the mtDNA double helix replicate simultaneously or consecutively. Since each mitochondrion contains many copies of mtDNA, and because the number of mitochondrion per cell can vary during the lifetime of a cell through the processes of fission, fusion, and mitochondrial biogenesis, mtDNA copy number per mitochondrion and per cell can also vary within the lifetime of a cell, and it is not directly coordinated with the cell cycle. Thus, it is not surprising that vast differences in mtDNA copy number are observed between different cell types and tissues and during the lifetime of a cell. Another important feature of the mtDNA replication process is a greatly reduced stringency of proofreading and replication error correction, leading to a much greater degree of sequence variation compared to the nuclear genome. Some of these sequence variants are silent polymorphisms that do not

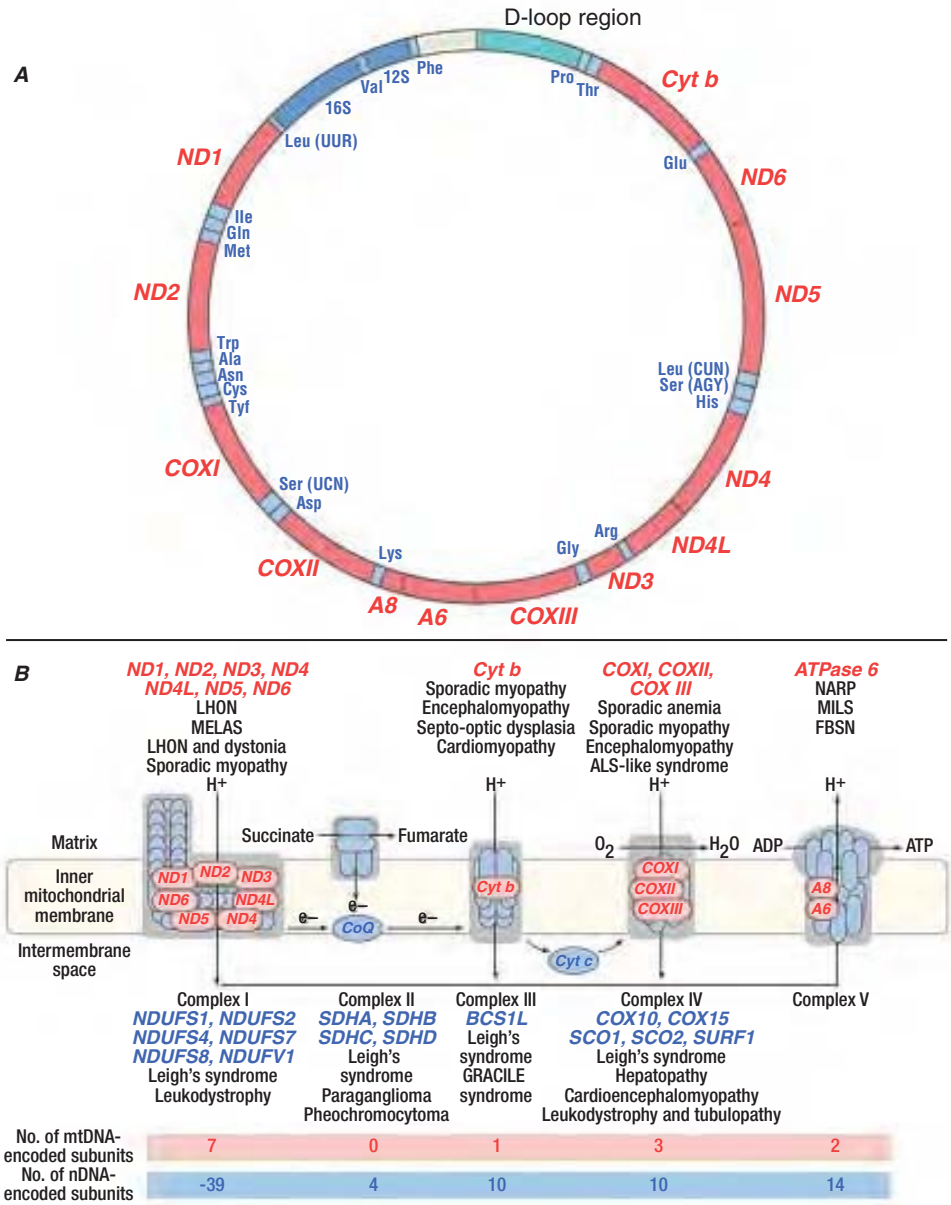

FIGURE e39-2 Mitochondrial DNA (mtDNA) and the mitochondrial respiratory chain. ***A.*** The map of the human mitochondrial genome. The protein-coding genes—seven subunits of complex I (ND), three subunits of cytochrome-c oxidase (COX), the cytochrome-b subunit of complex III (Cyt b), and two subunits of adenosine triphosphate (ATP) synthase (A6 and A8)—are shown in red. The protein-synthesis genes—the 12S and 16S ribosomal RNAs and the 22 transfer RNAs (three-letter amino acid symbols)—are shown in blue. The D-loop region controls the initiation of replication and transcription of mtDNA. ***B.*** The subunits of the respiratory chain encoded by nuclear DNA (nDNA) are shown in blue and the subunits encoded by mtDNA are shown in red. As electrons (e^-) flow along the electron-transport chain, protons (H^+) are pumped from the matrix to the intermembrane space through complexes I, III, and IV and then back into the matrix through complex V, to produce ATP. Coenzyme Q (CoQ) and cytochrome-c (Cyt c) are electron-transfer carriers. Genes responsible for the indicated respiratory-chain disorders are also shown. ATPase 6 denotes ATP synthase 6; BCS1L, cytochrome b–c complex assembly protein (complex III); NDUF, NADH dehydrogenase–ubiquinone oxidoreductase; SCO, synthesis of cytochrome oxidase; SDHA, SDHB, SDHC, and SDHD, succinate dehydrogenase subunits; SURF1, surfeit gene 1; FBSN, familial bilateral striatal necrosis; LHON, Leber hereditary optic neuropathy; MELAS, mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes; MILS, maternally inherited Leigh's syndrome; NARP, neuropathy, ataxia, and retinitis pigmentosa; GRACILE, growth retardation, aminoaciduria, lactic acidosis, and early death; and ALS, amyotrophic lateral sclerosis. *(Reproduced with permission from DiMauro and Schon.)*

have the potential for a phenotypic or pathogenic effect, whereas others may be considered pathogenic mutations.

With respect to transcription, initiation can occur on both strands and proceeds through the production of an intronless polycistronic precursor RNA that is then processed to produce the 13 individual mRNA and 24 individual tRNA and rRNA products. The 37 mtDNA genes comprise fully 93% of the 16,569 nucleotides of the mtDNA in what is known as the *coding region*. The *control region* consists of ~1.1 kilobases (kb) of noncoding DNA, thought to have a major role in replication and transcription initiation. The mutation rate is considerably higher in the control region, which contains a displacement, or D, loop, in turn containing two adjacent hypervariable regions (HVR-I and HVR-II) that give rise to large interindividual variability within the human population. Indeed mtDNA sequence variants at both the coding and control regions are more highly partitioned across geographically defined populations than sequence variants in other parts of the ge-

nome, and combinations of these sequence variants define phylogeographic mtDNA haplogroups and haplotypes. A major active research question is whether or not differences in these haplotypes are of medical significance in terms of disease predisposition. The foregoing structural and functional features of mtDNA lead to the expectation that phenotypic inheritance and disease patterns for disorders related to mtDNA sequence variation and mutation should be quite different from the more familiar inheritance and disease patterns attributed to variation and mutation of nuclear DNA. Intensive research during the past two decades has confirmed that this is, indeed, the case.

MATERNAL INHERITANCE AND LACK OF RECOMBINATION

The nuclear genome is characterized by homologous pairs of chromosomes of biparental origin. With the exception of the nonrecombining region of the Y chromosome in males, these homologous pairs undergo meiotic recombination during gametogenesis, which, together with mutation, serves as the source of universal genetic diversity. In contrast, mtDNA molecules do not undergo recombination, such that mutational events represent the only source of mtDNA genetic diversification. Moreover, with very rare exceptions, it is only the maternal DNA that is transmitted to the offspring. The fertilized oocyte degrades mtDNA carried from the sperm in a complex process involving the ubiquitin proteasome system. Thus, while mothers transmit their mtDNA to both their sons and daughters, only the daughters are able to transmit the inherited mtDNA to future generations. Accordingly, mtDNA sequence variation and associated phenotypic traits and diseases are inherited exclusively along maternal lines.

As will be noted below, because of the complex relationship between mtDNA mutations and disease expression, sometimes this maternal inheritance is difficult to recognize at the clinical or pedigree level. However, evidence of paternal transmission can almost certainly rule out an mtDNA genetic origin of phenotypic variation or disease; conversely, a disease affecting both sexes without evidence of paternal transmission strongly suggests a heritable mtDNA disorder (Fig. e39-3). One interesting consequence of uniparental inheritance and lack of recombination is the utility of mtDNA marker and sequence analysis in tracing matrilineal ancestry in phylogenetic research.

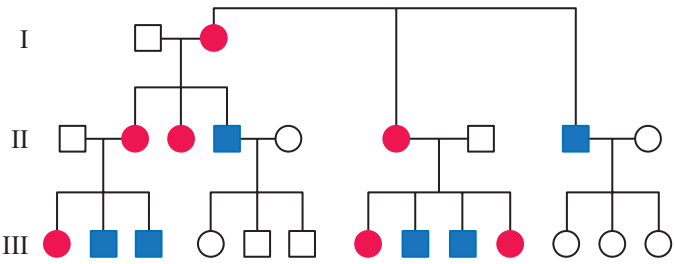

FIGURE e39-3 Maternal inheritance of mtDNA disorders and heritable traits. Affected women (filled circles) transmit the trait to their children. Affected men (filled square) do not transmit the trait to any of their offspring.

MULTIPLE COPY NUMBER (POLYPLOIDY), MITOTIC SEGREGATION, AND HIGH MUTATION RATE

Each aerobic cell in the body has multiple mitochondria, often numbering many hundreds or more in cells with extensive energy production requirements. Furthermore, the number of copies of mtDNA within each mitochondrion varies from several to hundreds; this is true of both somatic as well as germ cells, including oocytes in females. In the case of somatic cells, this means that the impact of each individual, newly acquired somatic mutation is likely to be very small in terms of total cellular or organ system function; however, because of the manyfold higher mutation rate during mtDNA replication, numerous different mutations may accumulate with the aging of the organism. It has been proposed that the total cumulative burden of acquired somatic mtDNA mutations with age may result in an overall perturbation of mitochondrial function, contributing to age-related reduction in the efficiency of oxidative phosphorylation and increased production of damaging ROS. According to this formulation, the high somatic mtDNA mutation rate and the global effect on mitochondrial function counterbalance the reduced impact of the multiple copy number of each individual mtDNA mutation. The potential contribution of such acquired somatic mtDNA mutations to aging and to common age-related disturbances, such as metabolic syndrome and diabetes, cancer, neurodegenerative, and cardiovascular disease, will be considered in greater detail below.

It is evident that just as in the case of acquired somatic mutations in the nuclear genome, so, too, the somatic mutations in mtDNA are not carried forward to the next generation. Therefore, in terms of heritable traits and disease, it is important to focus on the consequence of mtDNA polyploidy within the germ cells of the female reproductive system. The multiple mtDNA copy number within the maternal germ cells result in the phenomenon of heteroplasmy of inherited mtDNA mutations. Heteroplasmy for a given mtDNA sequence variant or mutation arises as a result of the coexistence within the oocyte of mtDNA molecules bearing both versions of the sequence variant (Fig. e39-4). In the case of pathogenic mutations, this means coexistence within the oocyte of both the wild-type and mutant versions. For each oocyte, the percentage of mtDNA molecules bearing each version of the polymorphic sequence variant or mutation depends on stochastic events related to partitioning of mtDNA molecules during the process of oogenesis itself. Thus, oocytes differ from each other in the degree of heteroplasmy for that sequence variant or mutation. In turn, the heteroplasmic state is carried forward to the zygote and then, to varying degrees, depending on mitotic segregation of mtDNA molecules, during organ system development and maintenance.

Mitotic segregation refers to the unequal distribution of wild-type and mutant versions of the mtDNA molecules during all cell divisions that occur during prenatal development and subsequently throughout the lifetime of an individual. The particular mtDNA sequence variant may be entirely silent in terms of phenotype or disease predisposition

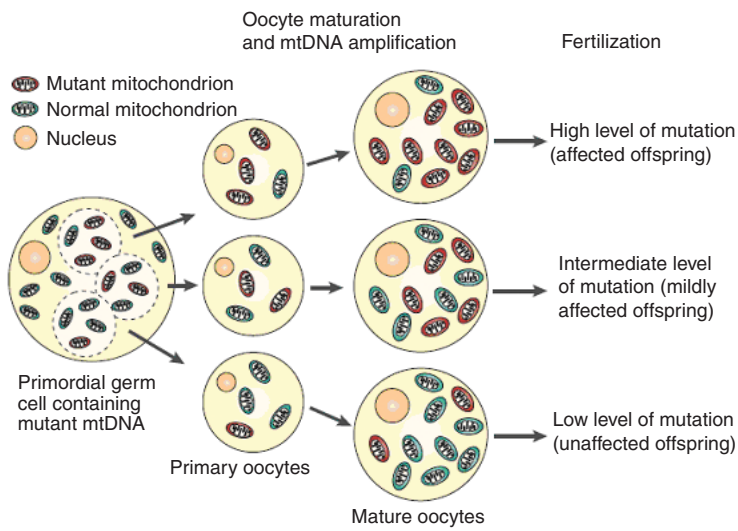

FIGURE e39-4 Heteroplasmy and the mitochondrial genetic bottleneck. During the production of primary oocytes, a selected number of mitochondrial DNA (mtDNA) molecules are transferred into each oocyte. Oocyte maturation is associated with the rapid replication of this mtDNA population. This restriction-amplification event can lead to a random shift of mtDNA mutational load between generations and is responsible for the variable levels of mutated mtDNA observed in affected offspring from mothers with pathogenic mtDNA mutations. Mitochondria that contain mutated mtDNA are shown in red, and those with normal mtDNA are shown in green. *(Reproduced with permission from Taylor and Turnbull.)*

and only detectable upon mtDNA sequencing. By contrast, the mtDNA sequence variant may affect one or more aspects of mitochondrial function in a manner that gives rise to a phenotypic effect or predisposes to a disease. The phenotypic effect or disease impact of a given mtDNA sequence variant will be a function not only of its inherent disruptive effect (pathogenicity) on the mtDNA-encoded gene (coding region mutations) or integrity of the mtDNA molecule (control region mutations), but also of its distribution among the multiple copies of mtDNA in the various mitochondria, cells, and tissues of the affected individual. This leads to the notion of a "threshold" effect, wherein the actual expression of disease depends upon the relative percentage of mitochondria whose function is disrupted by mtDNA mutations. Consequently, there is tremendous heterogeneity in disease penetrance and severity, as well as complexity of organ system involvement among the offspring of women with pathogenic heteroplasmic mutations. This heterogeneity arises from differences in the degree of heteroplasmy among oocytes and with subsequent mitotic segregation of the pathogenic mutation during tissue and organ development, and throughout the lifetime of the individual. This may create difficulty in recognizing a maternal pattern of inheritance and making the diagnosis of an mtDNA genetic cause of disease.

During the course of human evolution, certain heteroplasmic mtDNA sequence variants may drift to a state of homoplasmy, wherein all of the mtDNA molecules in the organism contain the new sequence variant. This arises due to a "bottleneck" effect followed by genetic drift during the very process of oogenesis itself (Fig. e39-4). In other words, during certain stages of oogenesis, the mtDNA copy number becomes substantially reduced, such that the particular mtDNA species bearing the novel or derived sequence variant may become the increasingly predominant, and eventually exclusive, version of the mtDNA for that particular nucleotide site. The offspring of a woman bearing an mtDNA sequence variant or mutation that has become homoplasmic will also be homoplasmic for that variant, and the female offspring will transmit it forward in subsequent generations; this process establishes a new mtDNA haplotype in the human population.

Considerations of reproductive fitness limit the evolutionary or population emergence of homoplasmic mutations that are lethal or cause severe disease in infancy or childhood. Thus, with a number of notable exceptions (e.g., mtDNA mutations causing Leber hereditary optic neuropathy; see below), most homoplasmic mutations were considered to be neutral markers of human evolution—useful and interesting in the population genetics analysis of shared maternal ancestry but with little significance in human phenotypic variation or disease predisposition. However, recent research and clinical attention have focused on the potential for certain of these homoplasmic mtDNA sequence variants to contribute to the evolutionary adaptation of populations to their climatic environment or to predispose to heritable late postreproductive and age-associated disease predisposition.

MITOCHONDRIAL DNA DISEASE

The true prevalence of mtDNA disease is difficult to estimate because of the phenotypic heterogeneity that occurs as a function of heteroplasmy, the challenge of detecting and assessing heteroplasmy in different affected tissues, and the other unique features of mtDNA function and inheritance described above. Very rough estimates suggest that heteroplasmic germ-line pathogenic mtDNA mutations may affect up to approximately 1 in 5000 individuals. The true overall impact of mtDNA mutation in human health and disease is certainly much greater, if the potential contribution of homoplasmic mtDNA sequence variation to common complex diseases appearing in the postreproductive age is also considered. Only when the ability to distinguish a completely neutral sequence variant from a true phenotype-modifying or pathogenic mutation is achieved, and when an accurate assessment of heteroplasmy can be determined with fidelity, will the true extent and contribution of mtDNA sequence variation to human traits and health be determined. In addition, the combination of interactions of mtDNA sequence variation with mutations in the nuclear genome also complicates our ability to ascertain the extent of contribution of heritable mtDNA mutations to human illness. Finally, assessment of the impact of the accumulation of acquired somatic mtDNA mutations on late-onset common disease predisposition, or on diseases arising from exposure to metabolic stress, also needs to be considered in order to appreciate the full impact of mtDNA in human health and disease.

OVERVIEW OF CLINICAL AND PATHOLOGIC FEATURES OF HUMAN mtDNA DISEASE

Given the vital roles of mitochondria in all nucleated cells, it is not surprising that mtDNA mutations can affect numerous tissues with pleiotropic effects. More than 200 different disease-causing mtDNA mutations have been described to date, all affecting ETC function. **Figure e39-5** provides an mtDNA map of some of the better characterized disorders. A number of clues can increase the index of suspicion for mtDNA mutation as an etiology of a heritable trait or disease, including (1) familial clustering with absence of paternal transmission; (2) adherence to one of the classic syndromes (see below) or paradigmatic combinations of disease phenotypes involving several organ systems that normally do not fit together within a single nuclear genomic mutation category; (3) a complex of laboratory and pathologic abnormalities that reflect disruption in cellular energetics (e.g., lactic acidosis and neurodegenerative and myodegenerative symptoms with the finding of ragged red fibers, reflecting the accumulation of abnormal mitochondria under the muscle sarcolemmal membrane); or (4) a mosaic pattern reflecting a heteroplasmic state.

Heteroplasmy can sometimes be elegantly demonstrated at the tissue level using histochemical staining for enzymes in the oxidative phosphorylation pathway, with a mosaic pattern indicating heterogeneity of the genotype for the coding region for the mtDNA-encoded enzyme. Complex II, CoQ, and cytochrome-c are exclusively encoded by nuclear DNA. In contrast, complexes I, III, IV, and V contain at least some subunits encoded by mtDNA. Just 3 of the 13 subunits of the ETC complex IV enzyme, cytochrome-c oxidase, are encoded by mtDNA, and, therefore, this enzyme has the lowest threshold for dysfunction when a threshold of mutated mtDNA is reached. Histochemical staining for cytochrome-c oxidase activity in tissues of patients affected with heteroplasmic inherited mtDNA mutations (or with the somatic accumulation of mtDNA mutations, see below) can show a mosaic pattern of reduced histochemical staining in comparison with histochemical staining for the complex II enzyme, succinate dehydrogenase **(Fig. e39-6)**. Heteroplasmy can also be detected at the genetic level through direct mtDNA genotyping under special conditions. It is not always possible to detect heteroplasmy readily in genomic samples extracted from whole blood. Only when a substantial proportion of mtDNA molecules carry the mutant genotype within a sampled tissue does heteroplasmy become detectable by more conventional sequencing or genotyping approaches.

Clinically, the most striking overall characteristic of mitochondrial genetic disease is the phenotypic heterogeneity associated with mtDNA mutations. This extends to intrafamilial phenotypic heterogeneity for the same mtDNA pathogenic mutation and, conversely, to the overlap of phenotypic disease manifestations with distinct mutations. Thus, while fairly consistent and well-defined "classic" syndromes have been attributed to specific mutations, frequently "nonclassic" combinations of disease phenotypes ranging from isolated myopathy to extensive multisystem disease are often encountered, rendering genotype-phenotype correlation challenging. In both classic and nonclassic mtDNA disorders, there is often a clustering of some combination of abnormalities affecting the neurologic system (including optic nerve atrophy, pigment retinopathy, sensorineural hearing loss), cardiac and skeletal muscle (including extraocular muscles), and endocrine and metabolic systems (including diabetes mellitus). Additional organ systems that may be affected include the hematopoietic, renal, hepatic, and gastrointestinal systems, though these are more frequently involved in infants and children. Disease-causing mtDNA coding region mutations can affect either one of the 13 protein encoding genes, or one of the 24 protein synthetic

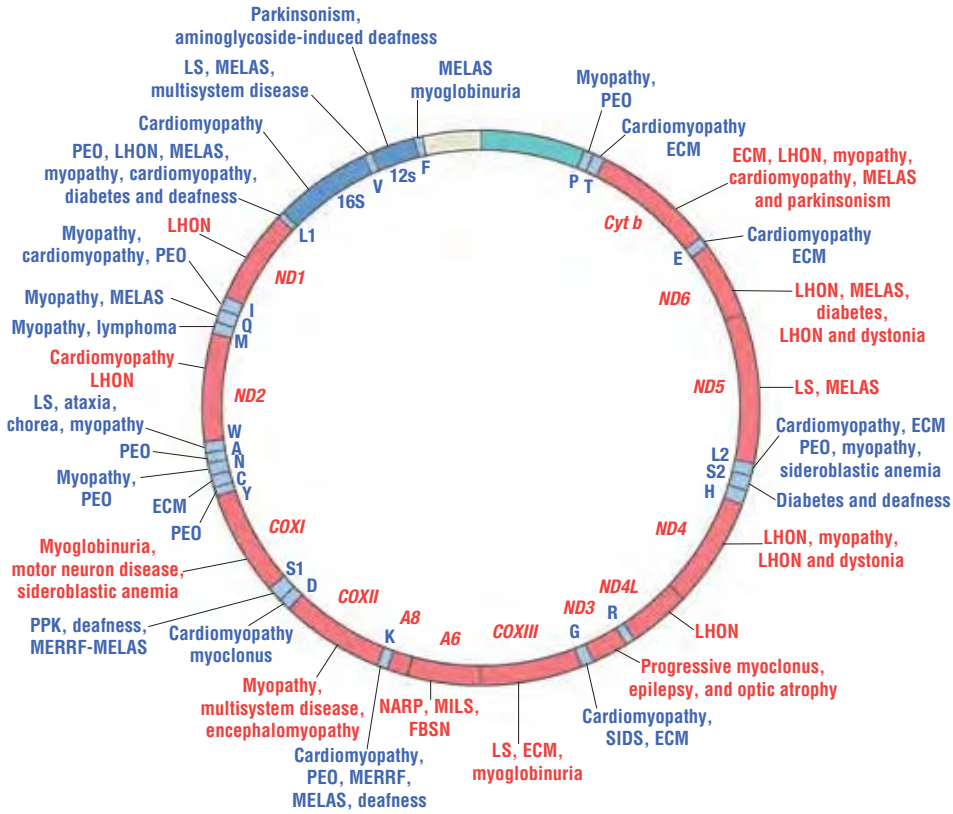

FIGURE e39-5 Mutations in the human mitochondrial genome known to cause disease. Disorders that are frequently or prominently associated with mutations in a particular gene are shown in boldface. Diseases due to mutations that impair mitochondrial protein synthesis are shown in blue. Diseases due to mutations in protein-coding genes are shown in red. ECM denotes encephalomyopathy; FBSN, familial bilateral striatal necrosis; LHON, Leber hereditary optic neuropathy; LS, Leigh's syndrome; MELAS, mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes; MERRF, myoclonic epilepsy with ragged red fibers; MILS, maternally inherited Leigh's syndrome; NARP, neuropathy, ataxia, and retinitis pigmentosa; PEO, progressive external ophthalmoplegia; PPK, palmoplantar keratoderma; and SIDS, sudden infant death syndrome. *(Reproduced with permission from DiMauro and Schon.)*

genes. Clinical manifestations do not readily distinguish these two categories, though lactic acidosis and muscle pathologic findings tend to be more prominent in the latter. In all cases, either defective ATP production due to disturbances in the ETC or enhanced generation of reactive oxygen species has been invoked as the mediating biochemical mechanism between mtDNA mutation and disease manifestation.

mtDNA DISEASE PRESENTATIONS

The clinical presentation of adult patients with mtDNA disease can be divided into three categories: (1) clinical features suggestive of mitochondrial disease (Table e39-2), but not a well-defined classic syndrome; (2) classic mtDNA syndromes; and (3) clinical presentation confined to one organ system (e.g., isolated sensorineural deafness, cardiomyopathy, or diabetes mellitus).

Table e39-3 provides a summary of eight illustrative classic mtDNA syndromes or disorders that affect adult patients and highlights some of the most interesting features of mtDNA disease in terms of molecular pathogenesis, inheritance, and clinical presentation. The first five of these syndromes result from heritable point mutations in either protein encoding or protein synthetic mtDNA genes; the other three result from rearrangements or deletions that usually do not involve the germ line.

Leber hereditary optic neuropathy (LHON) is a common cause of maternally inherited visual failure. LHON typically presents during young adulthood with subacute painless loss of vision in one eye, with symptoms developing in the other eye 6–12 weeks after the initial onset. In some instances, cerebellar ataxia, peripheral neuropathy, and cardiac conduction defects are observed. In >95% of cases, LHON is due to one of three homoplasmic point mutations of mtDNA that affect genes encoding different subunits of complex I of the mitochondrial ETC; however, not all individuals who inherit a primary LHON mtDNA mutation develop optic neuropathy, indicating that additional environmental (e.g., tobacco exposure) or genetic factors are important in the etiology of the disorder. Both the nuclear as well as mitochondrial genomic background modify disease penetrance. Thus, for example, LHON has a greater penetrance and severity in men than in women, pointing to an epistatic interaction with the nuclear genome. Moreover, disease susceptibility for a given mutation is modulated by mtDNA haplotype background, with certain haplotypes being protective. Of interest, patients with this syndrome are often homoplasmic for the disease-causing mutation. The somewhat later onset in young adulthood and modifying effect of genetic background may have enabled homoplasmic pathogenic mutations to have escaped evolutionary censoring.

Mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes (MELAS) is probably the most common mtDNA disease, consisting of a progressive encephalomyopathy characterized by repeated stroke-like events involving mainly posterior cerebral areas. Of note, brain lesions do not respect the distribution of vascular territories. Recurrent migraine-like headache and vomiting, exercise intolerance, seizures, short stature, and lactic acidosis are other frequent clinical features. The most commonly described pathogenic point mutations are A3243G and T3271C in the gene encoding the leucine tRNA.

Myoclonic epilepsy with ragged red fibers (MERRF) is a multisystem disorder characterized by myoclonus, seizures, ataxia, and myopathy with ragged red fibers. Hearing loss, exercise intolerance, neuropathy, and short stature are often present. Almost all MERRF patients have

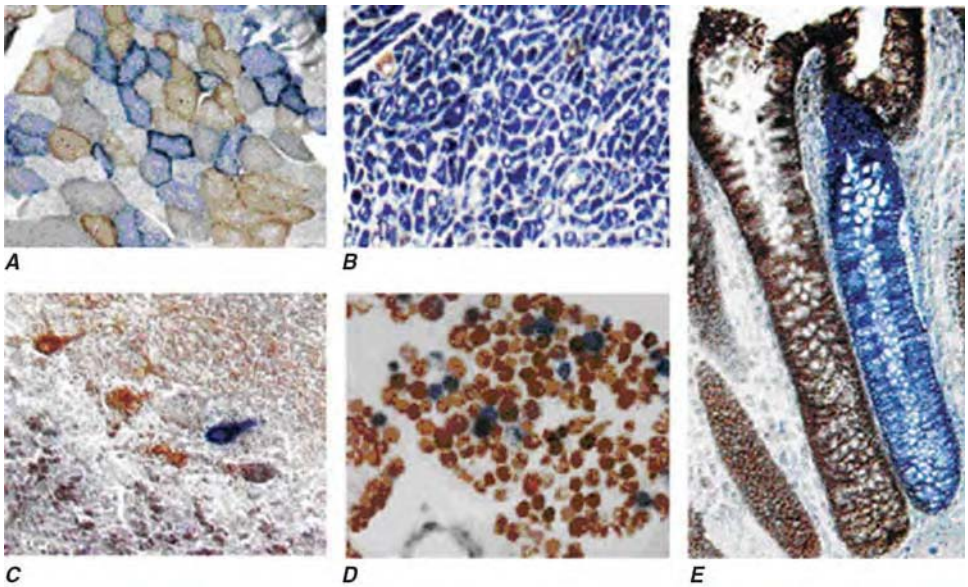

FIGURE e39-6 Cytochrome-c oxidase deficiency in mitochondrial DNA–associated disease. Transverse tissue sections that are reacted for both cytochrome-c oxidase (COX) and succinate dehydrogenase (SDH) activities sequentially, with COX-positive cells shown in brown and COX-deficient cells shown in blue. ***A.*** Skeletal muscle from a patient with a heteroplasmic mitochondrial tRNA point mutation. The section shows a typical "mosaic" pattern of COX activity, with many muscle fibers harboring levels of mutated mtDNA that are above the crucial threshold to produce a functional enzyme complex. ***B.*** Cardiac tissue (left ventricle) from a patient with a homoplasmic tRNA mutation that causes hypertrophic cardiomyopathy, whichdemonstrates an absence of COX in most cells. ***C.*** A section of cerebellum from a patient with mtDNA rearrangement that highlights the presence of COX-deficient neurons. ***D, E.*** Tissues that show COX deficiency due to clonal expansion of somatic mtDNA mutations within single cells—a phenomenon that is seen in both postmitotic cells (***D***; extraocular muscles) and rapidly dividing cells (***E***; colonic crypt) in aging humans. *(Reproduced with permission from Taylor and Turnbull.)*

mutation in the mtDNA $tRNA^{lys}$ gene and the A8344G mutation in the mtDNA gene encoding the lysine amino acid tRNA is responsible for 80–90% of MERRF cases.

Neurogenic weakness, ataxia, and retinitis pigmentosa (NARP) is characterized by moderate diffuse cerebral and cerebellar atrophy and symmetric lesions of the basal ganglia on MRI. A heteroplasmic T8993G mutation in the gene ATPase 6 subunit gene has been identified as causative. Ragged red fibers are not observed in muscle biopsy. When >95% of mtDNA molecules are mutant, a more severe clinical, neuroradiologic and neuropathologic picture (Leigh's syndrome) emerges. Point mutations in the mtDNA gene encoding the 12S rRNA result in heritable nonsyndromic hearing loss. One such mutation causes heritable ototoxic susceptibility to aminoglycoside antibiotics, which opens a pathway for a simple pharmacogenetic test in the appropriate clinical settings.

Kearns-Sayre syndrome (KSS), sporadic progressive external ophthalmoplegia (PEO), and Pearson syndrome are three disease phenotypes caused by large-scale mtDNA rearrangements including partial deletions or partial duplication. The majority of single large-scale rearrangements of mtDNA are thought to result from clonal amplification of a single sporadic mutational event, occurring in the maternal oocyte or during early embryonic development. Since germ line involvement is rare, most cases are sporadic rather than inherited.

KSS is characterized by the triad of onset before age 20, chronic progressive external ophthalmoplegia, and pigmentary retinopathy. Cerebellar syndrome, heart block, increased cerebrospinal fluid protein content, diabetes, and short stature are also part of the syndrome. Single deletions/duplication can also result in milder phenotypes such as PEO, characterized by late-onset progressive external ophthalmoplegia, proximal myopathy, and exercise intolerance. In both KSS and PEO, diabetes mellitus and hearing loss are frequent accompaniments. Pearson syndrome is also characterized by diabetes mellitus from pancreatic insufficiency, together with pancytopenia and lactic acidosis, caused by the large-scale sporadic deletion of several mtDNA genes.

TABLE e39-2 COMMON FEATURES OF mtDNA-ASSOCIATED DISEASES IN ADULTS

Neurologic: stroke, epilepsy, migraine headache, peripheral neuropathy, cranial neuropathy (optic atrophy, sensorineural deafness, dysphagia, dysphasia)
Skeletal myopathy: ophthalmoplegia, exercise intolerance, myalgia
Cardiac: conduction block, cardiomyopathy
Respiratory: hypoventilation, aspiration pneumonitis
Endocrine: diabetes mellitus, premature ovarian failure, hypothyroidism, hypoparathyroidism
Ophthalmologic: cataracts, pigment retinopathy, neurologic and myopathic (optic atrophy, ophthalmoplegia)

THE INVESTIGATION OF SUSPECTED mtDNA DISEASE

The clinical presentations of classic syndromes, groupings of disease manifestations in multiple organ systems, or unexplained isolated presentations of one of the disease features of a classic mtDNA syndrome should prompt a systematic clinical investigation as outlined in Fig. e39-7. Despite the centrality of disruptive oxidative phosphorylation, an elevated blood lactate level is neither specific nor sensitive because there are many causes of blood lactic acidosis, and many patients with mtDNA defects presenting in adulthood have normal blood lactate. A raised cerebrospinal fluid lactate is a more specific test for mitochondrial disease if there is central neurologic involvement. The serum creatine kinase may be elevated but is often normal, even in the presence of a proximal myopathy. Urine organic and amino acids may also be abnormal. Every patient with seizures or cognitive decline should have an electroencephalogram. A brain CT scan may show calcified basal ganglia or bilateral hypodense regions with cortical atrophy. MRI is indicated in patients with brain stem signs or stroke-like episodes.

For some mitochondrial diseases, it is possible to obtain an accurate diagnosis with a simple molecular genetic screen. For examples, 95% of patients with LHON harbor one of three mtDNA point mutations (A11778G, A3460G, and T14484C). These patients have very high levels of mutated mtDNA in peripheral blood cells, and it is, therefore, appropriate to send a blood sample for molecular genetic analysis by polymerase chain reaction (PCR) or restriction fragment length polymorphism. The same is true for most MERRF patients who harbor a point mutation in the lysine tRNA gene at position 8344. In contrast, patients with the A3243G MELAS mutation often have low levels of mutated mtDNA in blood. If clinical suspicion is strong enough to warrant peripheral blood testing, then patients with a negative result should be investigated further by performing a skeletal muscle biopsy.

Muscle biopsy histochemical analysis is the cornerstone for investigation of patients with suspected mitochondrial disease. Histochemical analysis may show subsarcolemmal accumulation of mitochondria with the appearance of ragged red fibers. Electron microscopy might show abnormal mitochondria with paracrystalline inclusions. Muscle histochemistry may show cytochrome-c oxidase (COX)–deficient fi-

TABLE e39-3 MITOCHONDRIAL DISEASES DUE TO mtDNA POINT MUTATIONS AND LARGE-SCALE REARRANGEMENTS

Disease	Phenotype	Most Frequent mtDNA Mutations	Homoplasmy or Heteroplasmy	Inheritance
Leber hereditary optic neuropathy (LHON)	Loss of central vision leading to blindness in young adult life	G1778A, T14484C, G3460A	Homoplasmic (usually)	Maternal
NARP, Leigh's disease	*N*europathy, *a*taxia, *r*etinitis *p*igmentosa, developmental delay, mental retardation, lactic acidemia	Point mutation in ATPase subunit 6 gene	Heteroplasmic	Maternal
MELAS	*M*itochondrial *e*ncephalomyopathy, *l*actic *a*cidosis, and *s*troke-like episodes; may manifest only as diabetes	Point mutation in $tRNA^{leu}$	Heteroplasmic	Maternal
MERRF	*M*yoclonic *e*pilepsy, *r*agged *r*ed *f*ibers in muscle, ataxia, increased CSF protein, sensorineural deafness, dementia	Point mutation in $tRNA^{lys}$	Heteroplasmic	Maternal
Deafness	Progressive sensorineural deafness, often induced by aminoglycoside antibiotics.	A1555G mutation in 12S rRNA	Homoplasmic	Maternal
	Nonsyndromic sensorineural deafness	A7445G mutation in 12S rRNA	Homoplasmic	Maternal
Chronic *p*rogressive *e*xternal *o*phthalmoplegia (PEO)	Late-onset bilateral ptosis and ophthalmoplegia, proximal muscle weakness, and exercise intolerance	Single deletions or duplications	Heteroplasmic	Mostly sporadic, somatic mutations
Pearson syndrome	Pancreatic insufficiency, pancytopenia, lactic acidosis	Large deletion	Heteroplasmic	Sporadic, somatic mutations
Kearn-Sayre syndrome (KSS)	External ophthalmoplegia, heart-block, retinal pigmentation, ataxia	The 5-kb "common deletion"	Heteroplasmic	Sporadic, somatic mutations

Note: CSF, cerebrospinal fluid.

bers, which indicate mitochondrial dysfunction (Fig. e39-6). Respiratory chain complex assays may also show a deficiency. Either of these two abnormalities confirm that a patient has mitochondrial disease, and this should lead to in-depth molecular genetic analysis.

IMPACT OF HOMOPLASMIC SEQUENCE VARIATION ON HERITABLE TRAITS AND DISEASE

The relationship among the degree of heteroplasmy, tissue distribution of the mutant mtDNA, and disease phenotype simplifies inference of a clear causative relationship between heteroplasmic mutation and disease. With the exception of certain mutations (e.g., those causing most cases of LHON), drift to homoplasmy of such mutations would be precluded normally by the severity of impaired oxidative phosphorylation and the consequent reduction in reproductive fitness. Therefore, it has been previously thought that sequence variants that have reached homoplasmy should be neutral in terms of human evolution and useful only for tracing human evolution, demography, and migration; however, recent studies have suggested that some homoplasmic mtDNA sequence variants may affect heritable traits or health through one or more mechanisms.

The first such mechanism relates to locally adaptive evolutionary forces. As noted above, homoplasmic mtDNA sequence variants that partition population groups are designated as defining maternal "haplogroups." Striking discontinuities have been observed in mtDNA haplogroup distribution among climatic zones across the globe. For example, of the extensive mtDNA sequence diversity in Africa, only a limited number of haplogroups and their derivative lineages successfully colonized all of Eurasia and then the Americas. Furthermore, it was shown that ancient missense mutations that define these haplogroups alter amino acids that are as highly conserved in evolution as are those known to result from pathogenic mutations. Retention of mutations altering such highly conserved amino acids, over many tens of thousands of years, suggests that they must be adaptive since they could not have been maintained if they were pathogenic and destructive to reproductive fitness. This phenomenon has been attributed to adaptive differences in the efficiency of oxidative phosphorylation and consequent thermogenesis, according to differences in prevailing climates in different global geographic regions during much of human evolution. A potential health implication of this finding is the possibility that these same mutations might result in deleterious effects on energy metabolism and caloric balance in the current era of human transglobal migration or climate control.

A much broader extrapolation of the foregoing mechanism states that many homoplasmic mtDNA mutations affect human health in the postreproductive age only and therefore escaped evolutionary censoring altogether. In the modern era of increased median life span, such mutations are thought to account for a considerable burden of age-associated common complex disease. Mean life expectancy has risen from ~47 years to ~77 years during the past century alone; there-

fore, late-onset effects of a subset of homoplasmic mtDNA mutations may contribute significantly to the burden of human illness only in the current era when a relatively higher percentage of the population is surviving beyond reproductive age. Many homoplasmic mtDNA variants have been and will continue to be identified by whole mtDNA sequencing in various global populations. The challenge is to identify the subsets that modify mtDNA function and contribute to late-onset, common complex disease. Indeed, given the finding that global populations are more differentiated at the level of mtDNA than they are at the level of the nuclear genome, it also attractive to postulate that population differences in the predisposition to certain late-onset common complex metabolic diseases may be attributed in part to population-based mtDNA sequence variation. The diseases that have been of particular interest are those that affect the very organ systems familiar from the known classic mtDNA syndromes described above.

METABOLIC SYNDROME AND TYPE 2 DIABETES MELLITUS (T2DM)

Insulin release by pancreatic beta cells is modulated in response to ATP metabolism, and insulin action is perturbed by metabolites of mitochondrial fatty acid oxidation. This has led investigators to consider mtDNA itself as a potential genomic locus for susceptibility to T2DM. A rather clear-cut case is that of a mutation in mtDNA nucleotide 3243 encoding the mitochondrial tRNA for the amino acid leucine. Even a low level of heteroplasmy for a particular point mutation in the mtDNA tRNA gene encoding the leucine tRNA is thought to contribute to the pathogenesis of up to 1% of all cases of T2DM. This and other findings at the biochemical and population genetics levels have motivated the search for more definitive evidence of the role of homoplasmic variants in the predisposition to metabolic syndrome and T2DM. Such evidence has been obtained with the finding of significant segregation of a homoplasmic mtDNA tRNA mutation (T→ C transition in the nucleotide immediately 5′ to the isoleucine tRNA anticodon) with metabolic syndrome phenotypes in a large Caucasian kindred.

Since the metabolic syndrome is so common, and can result from numerous different genetic susceptibility loci and environmental causes, and since its pathogenesis involves a large number of recently identified genetic susceptibility loci coupled with environmental factors—additional features in this particular reported kindred—researchers were able to tease out affected from unaffected individuals for purposes of the association study. The affected individuals had signs of hypomagnesemia, hypertension, and hypercholesterolemia. This finding highlights the problem of underdiagnosing homoplasmic mtDNA sequence variants as pathogenic causes of common symptoms and syndromes. This particular mutation in a tRNA-encoding mtDNA gene also highlights the expected difference in the phenotypic impact of mutations in genomic regions encoding tRNAs in the mitochondrial versus the nuclear genome.

In the case of the mitochondrial genome, mutations affecting mtDNA-encoded tRNAs perturb the translation of only up to 13 protein products and may be compatible with life. In contrast, severe loss of function of nuclear genome–encoded tRNA might be expected to perturb the function of a much greater array of nuclear-encoded proteins. It is also of interest to contrast the anticipated effects of point mutations in one of the 13 protein-coding genes of mtDNA with those of the 24 genes encoding tRNAs and rRNAs. Whereas the former would disrupt the function of a single protein product, the latter group would perturb translation of up to all 13 of the mtDNA-encoded proteins. Under these circumstances, a tolerable loss of function of all 13 proteins might be compatible with life, although it would be expected to cause a pleiotropic multiorgan heritable syndrome, as was indeed observed for the mtDNA isoleucine tRNA mutation causing an extended metabolic syndrome phenotype. At the population level, the finding of an apparent excess of maternal inheritance in T2DM suggests the potential involvement of mtDNA. A common variant mtDNA sequence variant (T16189C) has been related to both low birth weight, impaired glucose tolerance, and metabolic syndrome in specific populations. However, rigorous population-based association studies using case-control designs have not yet provided definitive evidence for a relationship between mtDNA haplogroups and susceptibility to T2DM or its complications.

NEURODEGENERATIVE DISEASE

The prominence of neurologic injury in classic mtDNA diseases, together with the presumed role of reactive oxygen species in neuronal injury and late age of onset of neurodegenerative diseases, have led investigators to consider the possibility that homoplasmic variants in mtDNA sequence that define population haplogroups might also modify the susceptibility to neurodegenerative diseases such as Parkinson's and Alzheimer's disease. Thus, for example, particular configurations of mtDNA sequence polymorphisms that define population haplogroups designated in phylogenetics by the labels J, T, U, and K have been reported to be potentially protective against Parkinson's disease in different populations. In the case of Alzheimer's disease, some studies have shown haplogroup J to increase risk, with haplogroup D decreasing risk. Mutations located in the mtDNA control region do not produce defective polypeptide products but affect both the light and heavy strand promoters, as well as the heavy strand origin of replication, and thus may modulate mtDNA replication and transcription. Mitochondrial DNA control region sequence variants (e.g., T414G) have been identified in Alzheimer's disease brains in association with a significant reduction in mtDNA copy number and reduction in specific transcripts. A number of studies have focused on the interaction of mtDNA haplogroup–designating mutations with the well-established Alzheimer's disease risk alleles at the nuclear APOE4 locus. From these studies it was postulated that ETC-uncoupling mutations that minimize ROS production are those that confer protection against neuronal injury, but definitive proof of this postulate awaits further studies.

OTHER DISEASES AND NONDISEASE HERITABLE TRAITS

Consideration of the potential contribution of mtDNA mutations to numerous heritable traits and common complex diseases requires consideration of the common variant–common phenotype model (including disease phenotype) versus the rare variant–common phenotype model, which are also applicable to the nuclear genome. According to the common variant–common phenotype model, DNA sequence variants inherited identically by descent and present in large numbers of individuals within one or more populations, may predispose to common phenotypes. In the rare variant–common phenotype model, different mutations within one or more genetic loci involved in a particular molecular pathway may predispose to a common phenotype or disease. In this regard, the entire mtDNA can be considered as a single genomic locus. Genome-wide association studies have been utilized to try to map common variants responsible for common diseases, using case-control or multiplex family approaches. These approaches have been applied to common variants in mtDNA sequence as well, as noted above for metabolic syndrome and neurodegenerative disease. Additional examples include the variable length of an mtDNA control region polycytosine stretch (16189 variant) as a contributing genomic influence in the onset of age-related cardiomyopathy with T2DM. An association of mtDNA haplogroup T, and a polymorphism at position 13368 with hypertrophic cardiomyopathy has been reported in a European population, and a number of studies have suggested an association between mtDNA mutations and mitochondrial dysfunction in heart failure predisposition. In the case of age-related cancers as well, the association of a number of heritable homoplasmic mtDNA mutations with certain cancers has been reported, including prostate, kidney, and breast cancer.

The association of mtDNA haplogroups with at least two nondisease heritable traits has also been studied. These are life expectancy and exercise endurance. Several mtDNA control region mutations, including the C150T mutation that shifts the heavy chain origin of replication, have been reported to accumulate with age in specific tissues, including lymphocytes of centenarians and their twins. The relationship between the C150T mutation and longevity has been replicated in Italian, Finnish, and Japanese populations—suggesting a common ancient origin.

Copyright © 2008 The McGraw-Hill Companies. All rights reserved.

The alternative of evolutionary convergence of this mutation for longevity seems less likely, as trait does not confer reproductive advantage. The association of haplogroup J and its sub-haplogroups with longevity has been demonstrated in north Italian, north Irish, and Finnish sample sets. At least in the Italian study, this association was shown to be population specific, since it was not reproduced in sample sets of southern Italian communities. Furthermore, in the case of the north Italian communities, an additional interaction of the mtDNA haplogroup designated as J2 with several different mutations adjacent to replication origins, including the aforementioned C150T, has been noted.

The functional importance of one or more of the mutations designated as haplogroup J is further strengthened by the finding of the interesting interaction with the mtDNA mutations causing LHON, as noted previously. Reduced disease predilection suggests that one or more of the ancient sequence variants designated as haplogroup J appear to attenuate predisposition to degenerative disease, in the face of other risk factors. It has been proposed that the mtDNA haplogroups associated with exceptional longevity favor a relatively uncoupled state of the ETC, with reduced efficiency of production of ATP and ROS and increased thermogenesis. While this has not been demonstrated biochemically, the notion is strengthened by the finding of a relative paucity of these mtDNA haplogroups among successful endurance athletes, for whom maximum efficiency of oxidative phosphorylation confers an athletic competitive advantage.

It should be noted that not all studies have replicated associations of mtDNA haplogroups with longevity, athletic performance, or other heritable phenotypes. Most of these studies are limited by small sample sizes and the possibility of population stratification or ethnic ancestry bias. Since mtDNA haplogroups are so prominently partitioned along phylogeographic lines, it is difficult to rule out the possibility that a haplogroup for which an association has been found is simply a marker for differences in populations with a societal or environmental difference or with different allele frequencies at other genomic loci, which are actually causally related to the heritable trait or disease of interest. The difficulty in generating cellular or animal models to test the functional influence of homoplasmic sequence variants (as a result of mtDNA polyploidy) further compounds the challenge. The most likely formulation is that different mtDNA haplogroup–defining homoplasmic mutations serve to provide different "risk backgrounds" for common age-related diseases whose major molecular pathogenesis emanates from a combination of mutations in the nuclear genome, together with environmental influences. Progress in minimizing potentially misleading associations in mtDNA heritable trait and disease studies should include ensuring adequate sample size taken from a large sample recruitment base, together with the use of carefully matched controls, and analysis that takes into account the interaction with other genomic loci and environmental factors.

IMPACT OF ACQUIRED SOMATIC mtDNA MUTATION ON HUMAN HEALTH AND DISEASE

Studies on aging humans and animals have shown a potentially important correlation of age with the accumulation of heterogeneous mtDNA mutations, especially in those organ systems that undergo the most prominent age-related degenerative tissue phenotype. Sequencing of PCR-amplified single mtDNA molecules has demonstrated an average of two to three point mutations per molecule in elderly subjects when compared with younger ones. Point mutations observed include those responsible for known heritable heteroplasmic mtDNA disorders, such as the A3344G and A3243G mutations responsible for the MERRF and MELAS syndromes, respectively. However, the cumulative burden of these acquired somatic point mutations with age was observed to remain well below the threshold expected for phenotypic expression (<2%). Point mutations at other sites not normally involved in inherited mtDNA disorders have also been shown to accumulate to much higher levels in some tissues of elderly individuals, with the description of tissue-specific "hot spots" for mtDNA point mutations. Along the same lines, an age-associated and tissue-specific accumulation of mtDNA deletions has been observed, including deletions involved in known heritable mtDNA disorders, as well as others. The accumulation of functional mtDNA deletions in a given tissue is expected to be associated with mitochondrial dysfunction, as reflected in an age-associated patchy and reduced cytochrome-c oxidase activity upon histochemical staining, especially in skeletal and cardiac muscle and brain. A particularly well studied and potentially important example is the accumulation of mtDNA deletions and cytochrome-c oxidase deficiency observed in neurons of the substantia nigra in Parkinson's disease patients.

The progressive accumulation of ROS has been proposed as the key factor connecting mtDNA mutations with aging and age-related disease pathogenesis (Fig. e39-8). As noted above, ROS are a byproduct of oxidative phosphorylation and are removed by detoxifying antioxidants into less harmful moieties; however, exaggerated production of ROS or impaired removal results in their accumulation. One of the main targets for ROS-mediated injury is DNA, and mtDNA is particularly vulnerable because of its lack of protective histones and less efficient injury repair systems compared with nuclear DNA. In turn, accumulation of mtDNA mutations results in inefficient oxidative phosphorylation, with the potential for excessive production of ROS, generating a "vicious cycle" of cumulative mtDNA damage. Indeed, measurement of the oxidative stress biomarker 8-hydroxy-2-deoxyguanosine has been used to measure age-dependent increases in mtDNA oxidative damage at a rate exceeding that of nuclear DNA. It should be noted that mtDNA mutation can potentially occur in postmitotic cells as well, since mtDNA replication is not synchronized with the cell cycle. Two other proposed links between mtDNA mutation and aging, besides ROS-mediated tissue injury, are the perturbations in efficiency of oxidative phosphorylation with disturbed cellular aerobic function and perturbations in apoptotic pathways, whose execution steps involve mitochondrial activity.

Genetic intervention studies in animal models have sought to clarify the potential causative relationship between acquired somatic mtDNA mutation and the aging phenotype, and the role of ROS in particular.

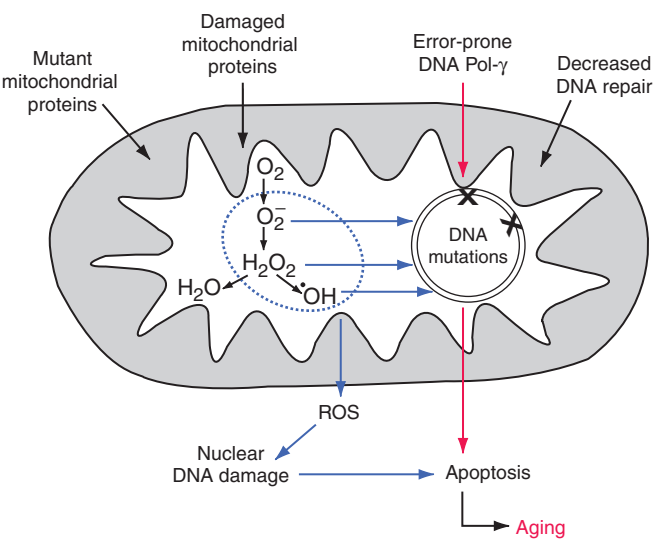

FIGURE e39-8 Multiple pathways of DNA damage and aging. Mitochondrial DNA damage and aging. Multiple factors may impinge on the integrity of mitochondria that lead to loss of cell function, apoptosis, and aging. The classic pathway is indicated with blue arrows; the generation of ROS (superoxide anion, hydrogen peroxide, and hydroxyl radicals), as a by-product of mitochondrial oxidative phosphorylation, results in damage to mitochondrial macromolecules including the mtDNA, the latter leading to deleterious mutations. When these factors damage the mitochondrial energy-generating apparatus beyond a functional threshold, proteins are released from the mitochondria that activate the caspase pathway leading to apoptosis, cell death, and aging. *(Reproduced with permission from Loeb L et al.)*

Replication of the mitochondrial genome is mediated by the activity of the nuclear-encoded polymerase gamma gene. A transgenic homozygous mouse knock-in mutation of this gene renders the polymerase enzyme deficient in proofreading and results in a three- to fivefold increase in mtDNA mutation rate. Such mice develop a premature aging phenotype, which includes subcutaneous lipoatrophy, alopecia, kyphonia, and weight loss with premature death. However, not all animal models of enhanced mtDNA mutation rate have shown a similar accelerated aging phenotype. Furthermore, it has been difficult to demonstrate a consistent relationship between rates of mtDNA mutation and ROS production. While the finding of increased in mtDNA mutation and mitochondrial dysfunction with age has been solidly established, the causative role and specific contribution of mitochondrial ROS to aging and age-related disease has yet to be proved. Similarly, while many tumors display higher levels of heterogeneous mtDNA mutations, a causal relationship to tumorigenesis has not been proved.

Besides the age-dependent acquired accumulation in somatic cells of heterogeneous point mutations and deletions, a quite different effect of nonheritable and acquired mtDNA mutation has been described affecting tissue stem cells. In particular, disease phenotypes attributed to acquired mtDNA mutation have been observed in sporadic and apparently nonfamilial cases involving a single individual or even tissue, usually skeletal muscle. The presentation consists of decreased exercise tolerance and myalgias, sometimes progressing to rhabdomyolysis. As in the case of the sporadic heteroplasmic large-scale deletion classic syndromes of chronic PEO, Pearson syndrome, and KSS, the absence of a maternal inheritance pattern, together with the finding of limited tissue distribution, suggests a molecular pathogenic mechanism emanating from mutations arising de novo in muscle stem cells after germ-line differentiation (somatic mutations that are not sporadic and occur in tissue-specific stem cells during fetal development or in the postnatal maintenance or postinjury repair stage). Such mutations would be expected to be propagated only within the progeny of that stem cell and affect a particular tissue within a given individual, without evidence of heritability.

PROSPECTS FOR PREVENTION AND TREATMENT OF mtDNA DISEASE

GENETIC COUNSELING IN mtDNA DISORDERS

The provision of accurate genetic counseling and reproductive options to families with mtDNA mutations is complicated by the unique genetic features of mtDNA that distinguish it from Mendelian genetics. While there is no risk of disease transmission from an affected male, the risk of maternal transmission of disease phenotypes associated with heteroplasmic mutations is a function of differential segregation and copy number of mutant mtDNA during oogenesis and subsequently, following tissue and organ development in the offspring. This is rarely predictable with any degree of accuracy. In addition, interactions with the mtDNA haplotype background or nuclear human genome (as in the case of LHON) serve as an additional important determinant of disease penetrance. Environmental interactions are also of importance, as in the case of ototoxic susceptibility to aminoglycosides in the case of the A1555G mutation of the 12SrRNA encoding gene.

The value of prenatal genetic testing is also questionable, partly owing to the absence of data on the rules that govern the segregation of wild-type and mutant mtDNA species (heteroplasmy) among tissue in the developing embryo. Three factors are required to ensure the reliability of prenatal testing: (1) a close correlation between the mutant load and the disease severity, (2) a uniform distribution of mutant load among tissues, and (3) no major change in mutant load with time. These criteria are suggested to be fulfilled for the NARP T8993G mutation but do not seem to apply to other mtDNA disorders. In fact, the level of mutant mtDNA in a chorionic villous or amniotic fluid sample may be very different from the level in the fetus, and it would be difficult to deduce whether the mutational load in the prenatal samples provide clinically useful information regarding the postnatal and adult state.

TREATMENT OF mtDNA DISORDERS

The polyploid nature of the mitochondrial genome, the inability to deliver therapeutic nucleic acids to the organelle through mitochondrial transfection, and the phenomenon of heteroplasmy coupled with the relative unavailability of useful preclinical experimental models have hampered progress in the development of curative treatments for mtDNA disease. One possible approach to "diluting" or even entirely eliminating the mutant mtDNA is applicable only in the earliest embryonic state and in effect represents a form of germ-line preventive therapy. This would involve cytoplasmic transfer of normal mitochondria into the oocyte of a woman affected with the heteroplasmic mtDNA mutation or, more radically, the use of a normal donor oocyte that has been enucleated and into which the nucleus of the affected recipient mother has been introduced. These approaches have not yet been met with widely reported clinical success. On the hopeful side, the threshold effect suggests that even a small increase in nonmutant mtDNA copies or limited amelioration of metabolic dysfunction might greatly improve the disease phenotype and benefit patient health. Therefore counteracting the most damaging metabolic changes currently represents the mainstay of treatment. Combined treatment strategies include dietary intervention and removal of toxic metabolites. Cofactors and vitamin supplements are widely used in the treatment of diseases of mitochondrial oxidative phosphorylation, although there is little evidence, apart from anecdotal reports, to support their use. This includes administration of artificial electron acceptors, including vitamin K_3, vitamin C, and ubiquinone (coenzyme Q_{10}); administration of cofactors (coenzymes) including riboflavin, carnitine, and creatine; and use of oxygen radical scavengers, such as vitamin E, copper, selenium, ubiquinone, and idebenone. Drugs that could interfere with mitochondrial defects, such as the anesthetic agent propofol, barbiturates, and high doses of valproate, should be avoided. Supplementation with the nitric oxide synthase substrate, L-arginine, has been advocated as a vasodilator treatment during stroke-like episodes.

In the case of homoplasmic mtDNA variants that predispose to late-onset common complex disease, it is more realistic to think of using their identification in a given patient as a nonmodifiable risk factor, which guides the aggressiveness of medical intervention for the associated modifiable risk factors for the same disorder. For example, the identification of a haplogroup-defining homoplasmic mtDNA mutation that confers added risk for metabolic syndrome should trigger intensive dietary, lifestyle, and medical intervention to reduce other factors that promote the metabolic syndrome and its complications. In the case of acquired somatic mutations—to the extent that a vicious cycle of ROS production with mtDNA mutation plays a role—effective antioxidant and ROS scavenging therapeutic strategies may prove to be of benefit.

Appendix: Laboratory Values of Clinical Importance

Alexander Kratz, Michael A. Pesce, Daniel J. Fink

INTRODUCTORY COMMENTS

The following are tables of reference values for laboratory tests, special analytes, and special function tests. A variety of factors can influence reference values. Such variables include the population studied, the duration and means of specimen transport, laboratory methods and instrumentation, and even the type of container used for the collection of the specimen. The reference or "normal" ranges given in this appendix may therefore not be appropriate for all laboratories, and these values should only be used as general guidelines. Whenever possible, reference values provided by the laboratory performing the testing should be utilized in the interpretation of laboratory data. Values supplied in this Appendix reflect typical reference ranges in adults. Pediatric reference ranges may vary significantly from adult values.

In preparing the Appendix, the authors have taken into account the fact that the system of international units (SI, système international d'unités) is used in most countries and in some medical journals. However, clinical laboratories may continue to report values in "conventional" units. Therefore, both systems are provided in the Appendix. The dual system is also used in the text except for (1) those instances in which the numbers remain the same but only the terminology is changed (mmol/L for meq/L or IU/L for mIU/mL), when only the SI units are given; and (2) most pressure measurements (e.g., blood and cerebrospinal fluid pressures), when the conventional units (mmHg, mmH_2O) are used. In all other instances in the text the SI unit is followed by the traditional unit in parentheses.

REFERENCE VALUES FOR LABORATORY TESTS

TABLE 1 HEMATOLOGY AND COAGULATION

Analyte	Specimen[a]	SI Units	Conventional Units
Activated clotting time	WB	70–180 s	70–180 seconds
Activated protein C resistance (Factor V Leiden)	P	Not applicable	Ratio > 2.1
$Alpha_2$ antiplasmin	P	0.87–1.55	87–155%
Antiphospholipid antibody panel			
PTT-LA (Lupus anticoagulant screen)	P	Negative	Negative
Platelet neutralization procedure	P	Negative	Negative
Dilute viper venom screen	P	Negative	Negative
Anticardiolipin antibody	S		
IgG		0–15 arbitrary units	0–15 GPL
IgM		0–15 arbitrary units	0–15 MPL
Antithrombin III	P		
Antigenic		220–390 mg/L	22–39 mg/dL
Functional		0.7–1.30 U/L	70–130%
Anti-Xa assay (heparin assay)	P		
Unfractionated heparin		0.3–0.7 kIU/L	0.3–0.7 IU/mL
Low-molecular-weight heparin		0.5–1.0 kIU/L	0.5–1.0 IU/mL
Danaparoid (Orgaran)		0.5–0.8 kIU/L	0.5–0.8 IU/mL
Autohemolysis test	WB	0.004–0.045	0.4%–4.50%
Autohemolysis test with glucose	WB	0.003–0.007	0.3%–0.7%
Bleeding time (adult)		<7.1 min	<7.1 min
Bone marrow: see Table 8			
Clot retraction	WB	0.50–1.00/2 h	50–100%/2 h
Cryofibrinogen	P	Negative	Negative
D-Dimer	P	0.22–0.74 μg/mL	0.22–0.74 μg/mL
Differential blood count	WB		
Neutrophils		0.40–0.70	40–70%
Bands		0.0–0.05	0–5%
Lymphocytes		0.20–0.50	20–50%
Monocytes		0.04–0.08	4–8%
Eosinophils		0.0–0.6	0–6%
Basophils		0.0–0.02	0–2%
Eosinophil count	WB	150–300/μL	$150–300/mm^3$
Erythrocyte count	WB		
Adult males		$4.30–5.60 \times 10^{12}$/L	$4.30–5.60 \times 10^6/mm^3$
Adult females		$4.00–5.20 \times 10^{12}$/L	$4.00–5.20 \times 10^6/mm^3$
Erythrocyte life span	WB		
Normal survival		120 days	120 days
Chromium labeled, half life ($t_{1/2}$)		25–35 days	25–35 days
Erythrocyte sedimentation rate	WB		
Females		0–20 mm/h	0–20 mm/h
Males		0–15 mm/h	0–15 mm/h
Euglobulin lysis time	P	7200–14400 s	120–240 min
Factor II, prothrombin	P	0.50–1.50	50–150%
Factor V	P	0.50–1.50	50–150%
Factor VII	P	0.50–1.50	50–150%
Factor VIII	P	0.50–1.50	50–150%
Factor IX	P	0.50–1.50	50–150%
Factor X	P	0.50–1.50	50–150%
Factor XI	P	0.50–1.50	50–150%
Factor XII	P	0.50–1.50	50–150%
Factor XIII screen	P	Not applicable	Present
Factor inhibitor assay	P	< 0.5 Bethesda Units	< 0.5 Bethesda Units

TABLE 1 HEMATOLOGY AND COAGULATION (CONTINUED)

Analyte	Specimen[a]	SI Units	Conventional Units
Fibrin(ogen) degradation products	P	0–1 mg/L	0–1 μg/mL
Fibrinogen	P	2.33–4.96 g/L	233–496 mg/dL
Glucose-6-phosphate dehydrogenase (erythrocyte)	WB	< 2400 s	<40 min
Ham's test (acid serum)	WB	Negative	Negative
Hematocrit	WB		
Adult males		0.388–0.464	38.8–46.4
Adult females		0.354–0.444	35.4–44.4
Hemoglobin			
Plasma	P	6–50 mg/L	0.6–5.0 mg/dL
Whole blood	WB		
Adult males		133–162 g/L	13.3–16.2 g/dL
Adult females		120–158 g/L	12.0–15.8 g/dL
Hemoglobin electrophoresis	WB		
Hemoglobin A		0.95–0.98	95–98%
Hemoglobin A_2		0.015–0.031	1.5–3.1%
Hemoglobin F		0–0.02	0–2.0%
Hemoglobins other than A, A_2, or F		Absent	Absent
Heparin-induced thrombocytopenia antibody	P	Negative	Negative
Joint fluid crystal	JF	Not applicable	No crystals seen
Joint fluid mucin	JF	Not applicable	Only type I mucin present
Leukocytes			
Alkaline phosphatase (LAP)	WB	0.2–1.6 μkat/L	13–100 μ/L
Count (WBC)	WB	$3.54–9.06 \times 10^9$/L	$3.54–9.06 \times 10^3$/mm^3
Mean corpuscular hemoglobin (MCH)	WB	26.7–31.9 pg/cell	26.7–31.9 pg/cell
Mean corpuscular hemoglobin concentration (MCHC)	WB	323–359 g/L	32.3–35.9 g/dL
Mean corpuscular hemoglobin of reticulocytes (CH)	WB	24–36 pg	24–36 pg
Mean corpuscular volume (MCV)	WB	79–93.3 fL	79–93.3 μm^3
Mean platelet volume (MPV)	WB	9.00–12.95 fL	9.00–12.95 μm^3
Osmotic fragility of erythrocytes	WB		
Direct		0.0035–0.0045	0.35–0.45%
Index		0.0030–0.0065	0.30–0.65%
Partial thromboplastin time, activated	P	26.3–39.4 s	26.3–39.4 s
Plasminogen	P		
Antigen		84–140 mg/L	8.4–14.0 mg/dL
Functional		0.70–1.30	70–130%
Plasminogen activator inhibitor 1	P	4–43 μg/L	4–43 ng/mL
Platelet aggregation	PRP	Not applicable	> 65% aggregation in response to adenosine diphosphate, epinephrine, collagen, ristocetin, and arachidonic acid
Platelet count	WB	$165–415 \times 10^9$/L	$165–415 \times 10^3$/mm^3
Platelet, mean volume	WB	6.4–11 fL	6.4–11.0 μm^3
Prekallikrein assay	P	0.50–1.5	50–150%
Prekallikrein screen	P		No deficiency detected
Protein C	P		
Total antigen		0.70–1.40	70–140%
Functional		0.70–1.30	70–130%
Protein S	P		
Total antigen		0.70–1.40	70–140%
Functional		0.65–1.40	65–140%
Free antigen		0.70–1.40	70–140%
Prothrombin gene mutation G20210A	WB	Not applicable	Not present
Prothrombin time	P	12.7–15.4 s	12.7–15.4 s
Protoporphyrin, free erythrocyte	WB	0.28–0.64 μmol/L of red blood cells	16–36 μg/dL of red blood cells
Red cell distribution width	WB	< 0.145	< 14.5%
Reptilase time	P	16–23.6 s	16–23.6 s
Reticulocyte count	WB		
Adult males		0.008–0.023 red cells	0.8–2.3% red cells
Adult females		0.008–0.020 red cells	0.8–2.0% red cells
Reticulocyte hemoglobin content	WB	>26 pg/cell	>26 pg/cell
Ristocetin cofactor (functional von Willebrand factor)	P		
Blood group O		0.75 mean of normal	75% mean of normal
Blood group A		1.05 mean of normal	105% mean of normal
Blood group B		1.15 mean of normal	115% mean of normal
Blood group AB		1.25 mean of normal	125% mean of normal
Sickle cell test	WB	Negative	Negative
Sucrose hemolysis	WB	<0.1	<10% hemolysis
Thrombin time	P	15.3–18.5 s	15.3–18.5 s
Total eosinophils	WB	$150–300 \times 10^6$/L	150–300/mm^3
Transferrin receptor	S, P	9.6–29.6 nmol/L	9.6–29.6 nmol/L
Viscosity			
Plasma	P	1.7–2.1	1.7–2.1
Serum	S	1.4–1.8	1.4–1.8

(continued)

TABLE 1 HEMATOLOGY AND COAGULATION (CONTINUED)

Analyte	Specimen[a]	SI Units	Conventional Units
Von Willebrand factor (vWF) antigen (factor VIII:R antigen)	P		
Blood group O		0.75 mean of normal	75% mean of normal
Blood group A		1.05 mean of normal	105% mean of normal
Blood group B		1.15 mean of normal	115% mean of normal
Blood group AB		1.25 mean of normal	125% mean of normal
Von Willebrand factor multimers	P	Normal distribution	Normal distribution
White blood cells: see "leukocytes"			

[a]P, plasma; JF, joint fluid; PRP, platelet-rich plasma; S, serum; WB, whole blood.

TABLE 2 CLINICAL CHEMISTRY AND IMMUNOLOGY

Analyte	Specimen[a]	SI Units	Conventional Units
Acetoacetate	P	20–99 μmol/L	0.2–1.0 mg/dL
Adrenocorticotropin (ACTH)	P	1.3–16.7 pmol/L	6.0–76.0 pg/mL
Alanine aminotransferase (AST, SGPT)	S	0.12–0.70 μkat/L	7–41 U/L
Albumin	S		
Female		41–53 g/L	4.1–5.3 g/dL
Male		40–50 g/L	4.0–5.0 g/L
Aldolase	S	26–138 nkat/L	1.5–8.1 U/L
Aldosterone (adult)			
Supine, normal sodium diet	S, P	55–250 pmol/L	2–9 ng/dL
Upright, normal sodium diet	S, P		2–5-fold increase over supine value
Supine, low-sodium diet	S, P		2–5-fold increase over normal sodium diet level
	U	6.38–58.25 nmol/d	2.3–21.0 μg/24 h
Alpha fetoprotein (adult)	S	0–8.5 μg/L	0–8.5 ng/mL
$Alpha_1$ antitrypsin	S	1.0–2.0 g/L	100–200 mg/dL
Ammonia, as NH_3	P	11–35 μmol/L	19–60 μg/dL
Amylase (method dependent)	S	0.34–1.6 μkat/L	20–96 U/L
Androstenedione (adult)	S	1.75–8.73 nmol/L	50–250 ng/dL
Angiotensin-converting enzyme (ACE)	S	0.15–1.1 μkat/L	9–67 U/L
Anion gap	S	7–16 mmol/L	7–16 mmol/L
Apo B/Apo A-1 ratio		0.35–0.98	0.35–0.98
Apolipoprotein A-1	S	1.19–2.40 g/L	119–240 mg/dL
Apolipoprotein B	S	0.52–1.63 g/L	52–163 mg/dL
Arterial blood gases			
$[HCO_3^-]$		22–30 mmol/L	22–30 meq/L
P_{CO_2}		4.3–6.0 kPa	32–45 mmHg
pH		7.35–7.45	7.35–7.45
P_{O_2}		9.6–13.8 kPa	72–104 mmHg
Aspartate aminotransferase (AST, SGOT)	S	0.20–0.65 μkat/L	12–38 U/L
Autoantibodies			
Anti-adrenal antibody	S	Not applicable	Negative at 1:10 dilution
Anti-double-strand (native) DNA	S	Not applicable	Negative at 1:10 dilution
Anti–glomerular basement membrane antibodies	S		
Qualitative		Negative	Negative
Quantitative		<5 kU/L	<5 U/mL
Anti-granulocyte antibody	S	Not applicable	Negative
Anti-Jo-1 antibody	S	Not applicable	Negative
Anti-La antibody	S	Not applicable	Negative
Anti-mitochondrial antibody	S	Not applicable	Negative
Antineutrophil cytoplasmic autoantibodies, cytoplasmic (C-ANCA)	S		
Qualitative		Negative	Negative
Quantitative (antibodies to proteinase 3)		< 2.8 kU/L	< 2.8 U/mL
Antineutrophil cytoplasmic autoantibodies, perinuclear (P-ANCA)	S		
Qualitative		Negative	Negative
Quantitative (antibodies to myeloperoxidase)		< 1.4 kU/L	< 1.4 U/mL
Antinuclear antibody	S	Not applicable	Negative at 1:40
Anti–parietal cell antibody	S	Not applicable	Negative at 1:20
Anti-Ro antibody	S	Not applicable	Negative
Anti-platelet antibody	S	Not applicable	Negative
Anti-RNP antibody	S	Not applicable	Negative
Anti-Scl 70 antibody	S	Not applicable	Negative
Anti-Smith antibody	S	Not applicable	Negative
Anti-smooth-muscle antibody	S	Not applicable	Negative at 1:20
Anti-thyroglobulin	S	Not applicable	Negative
Anti-thyroid antibody	S	< 0.3 kIU/L	<0.3 IU/mL

(continued)

TABLE 2 CLINICAL CHEMISTRY AND IMMUNOLOGY (CONTINUED)

Analyte	Specimen[a]	SI Units	Conventional Units
B type natriuretic peptide (BNP)	P	Age and gender specific: < 167 ng/L	Age and gender specific: < 167 pg/mL
Bence Jones protein, serum	S	Not applicable	None detected
Bence Jones protein, urine, qualitative	U	Not applicable	None detected in 50× concentrated urine
Bence Jones Protein, urine, quantitative	U		
Kappa		<25 mg/L	<2.5 mg/dL
Lambda		<50 mg/L	<5.0 mg/dL
β_2-Microglobulin			
	S	<2.7 mg/L	<0.27 mg/dL
	U	<120 μg/d	<120 μg/day
Bilirubin	S		
Total		5.1–22 μmol/L	0.3–1.3 mg/dL
Direct		1.7–6.8 μmol/L	0.1–0.4 mg/dL
Indirect		3.4–15.2 μmol/L	0.2–0.9 mg/dL
C peptide (adult)	S, P	0.17–0.66 nmol/L	0.5–2.0 ng/mL
C1-esterase-inhibitor protein	S		
Antigenic		124–250 mg/L	12.4–24.5 mg/dL
Functional		Present	Present
CA 125	S	0–35 kU/L	0–35 U/mL
CA 19-9	S	0–37 kU/L	0–37 U/mL
CA-15-3	S	0–34 kU/L	0–34 U/mL
CA27-29	S	0–40 kU/L	0–40 U/mL
Calcitonin	S		
Male		3–26 ng/L	3–26 pg/mL
Female		2–17 ng/L	2–17 pg/mL
Calcium	S	2.2–2.6 mmol/L	8.7–10.2 mg/dL
Calcium, ionized	WB	1.12–1.32 mmol/L	4.5–5.3 mg/dL
Carbon dioxide content (TCO_2)	P (sea level)	22–30 mmol/L	22–30 meq/L
Carboxyhemoglobin (carbon monoxide content)	WB		
Nonsmokers		0–0.04	0–4%
Smokers		0.04–0.09	4–9%
Onset of symptoms		0.15–0.20	15–20%
Loss of consciousness and death		>0.50	>50%
Carcinoembryonic antigen (CEA)	S		
Nonsmokers		0.0–3.0 μg/L	0.0–3.0 ng/mL
Smokers	S	0.0–5.0 μg/L	0.0–5.0 ng/mL
Ceruloplasmin	S	250–630 mg/L	25–63 mg/dL
Chloride	S	102–109 mmol/L	102–109 meq/L
Cholesterol: see Table 5			
Cholinesterase	S	5–12 kU/L	5–12 U/mL
Complement			
C3	S	0.83–1.77 g/L	83–177 mg/dL
C4	S	0.16–0.47 g/L	16–47 mg/dL
Total hemolytic complement (CH50)	S	50–150%	50–150%
Factor B	S	0.17–0.42 g/L	17–42 mg/dL
Coproporphyrins (types I and III)	U	150–470 μmol/d	100–300 μg/d
Cortisol			
Fasting, 8 A.M.–12 noon	S	138–690 nmol/L	5–25 μg/dL
12 noon–8 P.M.		138–414 nmol/L	5–15 μg/dL
8 P.M.–8 A.M.		0–276 nmol/L	0–10 μg/dL
Cortisol, free	U	55–193 nmol/24 h	20–70 μg/24 h
C-reactive protein	S	0.2–3.0 mg/L	0.2–3.0 mg/L
Creatine kinase (total)	S		
Females		0.66–4.0 μkat/L	39–238 U/L
Males		0.87–5.0 μkat/L	51–294 U/L
Creatine kinase-MB	S		
Mass		0.0–5.5 μg/L	0.0–5.5 ng/mL
Fraction of total activity (by electrophoresis)		0–0.04	0–4.0%
Creatinine	S		
Female		44–80 μmol/L	0.5–0.9 ng/mL
Male		53–106 μmol/L	0.6–1.2 ng/mL
Cryoproteins	S	Not applicable	None detected
Dehydroepiandrosterone (DHEA) (adult)			
Male	S	6.2–43.4 nmol/L	180–1250 ng/dL
Female		4.5–34.0 nmol/L	130–980 ng/dL
Dehydroepiandrosterone (DHEA) sulfate	S		
Male (adult)		100–6190 μg/L	10–619 μg/dL
Female (adult, premenopausal)		120–5350 μg/L	12–535 μg/dL
Female (adult, postmenopausal)		300–2600 μg/L	30–260 μg/dL
Deoxycorticosterone (DOC) (adult)	S	61–576 nmol/L	2–19 ng/dL
11-Deoxycortisol (adult) (compound S) (8:00 A.M.)	S	0.34–4.56 nmol/L	12–158 ng/dL
Dihydrotestosterone			
Male	S, P	1.03–2.92 nmol/L	30–85 ng/dL
Female		0.14–0.76 nmol/L	4–22 ng/dL

(continued)

TABLE 2 CLINICAL CHEMISTRY AND IMMUNOLOGY (CONTINUED)

Analyte	Specimen[a]	SI Units	Conventional Units
Dopamine	P	< 475 pmol/L	< 87 pg/mL
Dopamine	U	425–2610 nmol/d	65–400 μg/d
Epinephrine	P		
Supine (30 min)		< 273 pmol/L	< 50 pg/mL
Sitting		< 328 pmol/L	< 60 pg/mL
Standing (30 min)		< 491pmol/L	< 90 pg/mL
Epinephrine	U	0–109 nmol/d	0–20 μg/d
Erythropoietin	S	4–27 U/L	4–27 U/L
Estradiol	S, P		
Female			
Menstruating:			
Follicular phase		74–532 pmol/L	<20–145 pg/mL
Mid-cycle peak		411–1626 pmol/L	112–443 pg/mL
Luteal phase		74–885 pmol/L	<20–241 pg/mL
Postmenopausal		217 pmol/L	<59 pg/mL
Male		74 pmol/L	< 20 pg/mL
Estrone	S, P		
Female			
Menstruating:			
Follicular phase		55–555 pmol/L	15–150 pg/mL
Luteal phase		55–740 pmol/L	15–200 pg/mL
Postmenopausal		55–204 pmol/L	15–55 pg/mL
Male		55–240 pmol/L	15–65 pg/mL
Fatty acids, free (nonesterified)	P	<0.28–0.89 mmol/L	<8–25 mg/dL
Ferritin	S		
Female		10–150 μg/L	10–150 ng/mL
Male		29–248 μg/L	29–248 ng/mL
Follicle stimulating hormone (FSH)	S, P		
Female			
Menstruating:			
Follicular phase		3.0–20.0 IU/L	3.0–20.0 mIU/mL
Ovulatory phase		9.0–26.0 IU/L	9.0–26.0 mIU/mL
Luteal phase		1.0–12.0 IU/L	1.0–12.0 mIU/mL
Postmenopausal		18.0–153.0 IU/L	18.0–153.0 mIU/mL
Male		1.0–12.0 IU/L	1.0–12.0 mIU/mL
Free testosterone, adult			
Female	S	2.1–23.6 pmol/L	0.6–6.8 pg/mL
Male		163–847 pmol/L	47–244 pg/mL
Fructosamine	S	<285 μmol/L	<285 μmol/L
Gamma glutamyltransferase	S	0.15–0.99 μkat/L	9–58 U/L
Gastrin	S	<100 ng/L	<100 pg/mL
Glucagon	P	20–100 ng/L	20–100 pg/mL
Glucose (fasting)	P		
Normal		4.2–6.1 mmol/L	75–110 mg/dL
Impaired glucose tolerance		6.2–6.9 mmol/L	111–125 mg/dL
Diabetes mellitus		>7.0 mmol/L	>125 mg/dL
Glucose, 2 h postprandial	P	3.9–6.7 mmol/L	70–120 mg/dL
Growth hormone (resting)	S	0.5–17.0 μg/L	0.5–17.0 ng/mL
Hemoglobin A_{Ic}	WB	0.04–0.06 Hb fraction	4.0–6.0%
High-density lipoprotein (HDL) (see Table 5)			
Homocysteine	P	4.4–10.8 μmol/L	4.4–10.8 μmol/L
Human chorionic gonadotropin (hCG)	S		
Non-pregnant female		< 5 IU/L	< 5 mIU/mL
1–2 weeks postconception		9–130 IU/L	9–130 mIU/mL
2–3 weeks postconception		75–2600 IU/L	75–2600 mIU/mL
3–4 weeks postconception		850–20,800 IU/L	850–20,800 mIU/mL
4–5 weeks postconception		4000–100,200 IU/L	4000–100,200 mIU/mL
5–10 weeks postconception		11,500–289,000 IU/L	11,500–289,000 mIU/mL
10–14 weeks postconception		18,300–137,000 IU/L	18,300–137,000 mIU/mL
Second trimester		1400–53,000 IU/L	1400–53,000 mIU/mL
Third trimester		940–60,000 IU/L	940–60,000 mIU/mL
β-Hydroxybutyrate	P	0–290 μmol/L	0–3 mg/dL
5-Hydroindoleacetic acid [5-HIAA]	U	10.5–36.6 μmol/d	2–7 mg/d
17-Hydroxyprogesterone (adult)	S		
Male		0.15–7.5 nmol/L	5–250 ng/dL
Female			
Follicular phase		0.6–3.0 nmol/L	20–100 ng/dL
Midcycle peak		3–7.5 nmol/L	100–250 ng/dL
Luteal phase		3–15 nmol/L	100–500 ng/dL
Postmenopausal		≤ 2.1 nmol/L	≤ 70 ng/dL
Hydroxyproline	U, 24 hour	38–500 μmol/d	38–500 μmol/d
Immunofixation	S	Not applicable	No bands detected

(continued)

TABLE 2 CLINICAL CHEMISTRY AND IMMUNOLOGY (CONTINUED)

Analyte	Specimen[a]	SI Units	Conventional Units
Immunoglobulin, quantitation (adult)			
IgA	S	0.70–3.50 g/L	70–350 mg/dL
IgD	S	0–140 mg/L	0–14 mg/dL
IgE	S	24–430 μg/L	10–179 IU/mL
IgG	S	7.0–17.0 g/L	700–1700 mg/dL
IgG_1	S	2.7–17.4 g/L	270–1740 mg/dL
IgG_2	S	0.3–6.3 g/L	30–630 mg/dL
IgG_3	S	0.13–3.2 g/L	13–320 mg/dL
IgG_4	S	0.11–6.2 g/L	11–620 mg/dL
IgM	S	0.50–3.0 g/L	50–300 mg/dL
Insulin	S, P	14.35–143.5 pmol/L	2–20 μU/mL
Iron	S	7–25 μmol/L	41–141 μg/dL
Iron-binding capacity	S	45–73 μmol/L	251–406 μg/dL
Iron-binding capacity saturation	S	0.16–0.35	16–35%
Joint fluid crystal	JF	Not applicable	No crystals seen
Joint fluid mucin	JF	Not applicable	Only type I mucin present
Ketone (acetone)	S, U	Negative	Negative
17 Ketosteroids	U	0.003–0.012 g/d	3–12 mg/d
Lactate	P, arterial	0.5–1.6 mmol/L	4.5–14.4 mg/dL
	P, venous	0.5–2.2 mmol/L	4.5–19.8 mg/dL
Lactate dehydrogenase	S	2.0–3.8 μkat/L	115–221 U/L
Lactate dehydrogenase isoenzymes	S		
Fraction 1 (of total)		0.14–0.26	14–26%
Fraction 2		0.29–0.39	29–39%
Fraction 3		0.20–0.25	20–26%
Fraction 4		0.08–0.16	8–16%
Fraction 5		0.06–0.16	6–16%
Lipase (method dependent)	S	0.51–0.73 μkat/L	3–43 U/L
Lipids: see Table 5			
Lipoprotein (a)	S	0–300 mg/L	0–30 mg/dL
Low-density lipoprotein (LDL) (see Table 5)			
Luteinizing hormone (LH)	S, P		
Female			
Menstruating			
Follicular phase		2.0–15.0 U/L	2.0–15.0 U/L
Ovulatory phase		22.0–105.0 U/L	22.0–105.0 U/L
Luteal phase		0.6–19.0 U/L	0.6–19.0 U/L
Postmenopausal		16.0–64.0 U/L	16.0–64.0 U/L
Male		2.0–12.0 U/L	2.0–12.0 U/L
Magnesium	S	0.62–0.95 mmol/L	1.5–2.3 mg/dL
Metanephrine	P	<0.5 nmol/L	<100 pg/mL
Metanephrine	U	30–211 mmol/mol creatinine	53–367 μg/g creatinine
Methemoglobin	WB	0.0–0.01	0–1%
Microalbumin urine	U		
24-h urine		0.0–0.03 g/d	0–30 mg/24 h
Spot urine		0.0–0.03 g/g creatinine	0–30 μg/mg creatinine
Myoglobin	S		
Male		19–92 μg/L	19–92 μg/L
Female		12–76 μg/L	12–76 μg/L
Norepinephrine	U	89–473 nmol/d	15–80 μg/d
Norepinephrine	P		
Supine (30 min)		650–2423 pmol/L	110–410 pg/mL
Sitting		709–4019 pmol/L	120–680 pg/mL
Standing (30 min)		739–4137 pmol/L	125–700 pg/mL
N-telopeptide (cross linked), NTx	S		
Female, premenopausal		6.2–19.0 nmol BCE	6.2–19.0 nmol BCE
Male		5.4–24.2 nmol BCE	5.4–24.2 nmol BCE
Bone collagen equivalent (BCE)			
N-telopeptide (cross linked), NTx	U		
Female, premenopausal		17–94 nmol BCE/mmol creatinine	17–94 nmol BCE/mmol creatinine
Female, postmenopausal		26–124 nmol BCE/mmol creatinine	26–124 nmol BCE/mmol creatinine
Male		21–83 nmol BCE/mmol creatinine	21–83 nmol BCE/mmol creatinine
Bone collagen equivalent (BCE)			
5′ Nucleotidase	S	0.02–0.19 μkat/L	0–11 U/L
Osmolality	P	275–295 mOsmol/kg serum water	275–295 mOsmol/kg serum water
	U	500–800 mOsmol/kg water	500–800 mOsmol/kg water
Osteocalcin	S	11–50 μg/L	11–50 ng/mL
Oxygen content	WB		
Arterial (sea level)		17–21	17–21 vol%
Venous (sea level)		10–16	10–16 vol%
Oxygen percent saturation (sea level)	WB		
Arterial		0.97	94–100%
Venous, arm		0.60–0.85	60–85%

(continued)

TABLE 2 CLINICAL CHEMISTRY AND IMMUNOLOGY (CONTINUED)

Analyte	Specimen[a]	SI Units	Conventional Units
Parathyroid hormone (intact)	S	8–51 ng/L	8–51 pg/mL
Phosphatase, alkaline	S	0.56–1.63 μkat/L	33–96 U/L
Phosphorus, inorganic	S	0.81–1.4 mmol/L	2.5–4.3 mg/dL
Porphobilinogen	U	None	None
Potassium	S	3.5–5.0 mmol/L	3.5–5.0 meq/L
Prealbumin	S	170–340 mg/L	17–34 mg/dL
Progesterone	S, P		
Female			
Follicular		<3.18 nmol/L	<1.0 ng/mL
Midluteal		9.54–63.6 nmol/L	3–20 ng/mL
Male		<3.18 nmol/L	< 1.0 ng/mL
Prolactin	S	0–20 μg/L	0–20 ng/mL
Prostate-specific antigen (PSA)	S		
Male			
<40 years		0.0–2.0 μg/L	0.0–2.0 ng/mL
>40 years		0.0–4.0 μg/L	0.0–4.0 ng/mL
PSA, free; in males 45–75 years, with PSA values between 4 and 20 μg/mL	S	>0.25 associated with benign prostatic hyperplasia	>25% associated with benign prostatic hyperplasia
Protein fractions	S		
Albumin		35–55 g/L	3.5–5.5 g/dL (50–60%)
Globulin		20–35 g/L	2.0–3.5 g/dL (40–50%)
Alpha$_1$		2–4 g/L	0.2–0.4 g/dL (4.2–7.2%)
Alpha$_2$		5–9 g/L	0.5–0.9 g/dL (6.8–12%)
Beta		6–11 g/L	0.6–1.1 g/dL (9.3–15%)
Gamma		7–17 g/L	0.7–1.7 g/dL (13–23%)
Protein, total	S	67–86 g/L	6.7–8.6 g/dL
Pyruvate	P, arterial	40–130 μmol/L	0.35–1.14 mg/dL
	P, venous	40–130 μmol/L	0.35–1.14 mg/dL
Rheumatoid factor	S, JF	<30 kIU/L	<30 IU/mL
Serotonin	WB	0.28–1.14 μmol/L	50–200 ng/mL
Serum protein electrophoresis	S	Not applicable	Normal pattern
Sex hormone binding globulin (adult)	S		
Male		13–71 nmol/L	13–71 nmol/L
Female		18–114 nmol/L	18–114 nmol/L
Sodium	S	136–146 mmol/L	136–146 meq/L
Somatomedin-C (IGF-1) (adult)	S		
16–24 years		182–780 μg/L	182–780 ng/mL
25–39 years		114–492 μg/L	114–492 ng/mL
40–54 years		90–360 μg/L	90–360 ng/mL
>54 years		71–290 μg/L	71–290 ng/mL
Somatostatin	P	<25 ng/L	<25 pg/mL
Testosterone, total, morning sample	S		
Female		0.21–2.98 nmol/L	6–86 ng/dL
Male		9.36–37.10 nmol/L	270–1070 ng/dL
Thyroglobulin	S	0.5–53 μg/L	0.5–53 ng/mL
Thyroid-binding globulin	S	13–30 mg/L	1.3–3.0 mg/dL
Thyroid-stimulating hormone	S	0.34–4.25 mIU/L	0.34–4.25 μIU/mL
Thyroxine, free (fT$_4$)	S	10.3–21.9 pmol/L	0.8–1.7 ng/dL
Thyroxine, total (T$_4$)	S	70–151 nmol/L	5.4–11.7 μg/dL
(Free) thyroxine index	S	6.7–10.9	6.7–10.9
Transferrin	S	2.0–4.0 g/L	200–400 mg/dL
Triglycerides (see Table 5)	S	0.34–2.26 mmol/L	30–200 mg/dL
Triiodothyronine, free (fT$_3$)	S	3.7–6.5 pmol/L	2.4–4.2 pg/mL
Triiodothyronine, total (T$_3$)	S	1.2–2.1 nmol/L	77–135 ng/dL
Troponin I	S		
Normal population, 99 %tile		0–0.08 μg/L	0–0.08 ng/mL
Cut-off for MI		>0.4 μg/L	>0.4 ng/mL
Troponin T	S		
Normal population, 99 %tile		0–0.1 μg/L	0–0.01 ng/mL
Cut-off for MI		0–0.1 μg/L	0–0.1 ng/mL
Urea nitrogen	S	2.5–7.1 mmol/L	7–20 mg/dL
Uric acid	S		
Females		0.15–0.33 μmol/L	2.5–5.6 mg/dL
Males		0.18–0.41 μmol/L	3.1–7.0 mg/dL
Urobilinogen	U	0.09–4.2 μmol/d	0.05–25 mg/24 h
Vanillylmandelic acid (VMA)	U, 24h	<30 μmol/d	<6 mg/d
Vasoactive intestinal polypeptide	P	0–60 ng/L	0–60 pg/mL

[a]P, plasma; S, serum; U, urine; WB, whole blood; JF, joint fluid.

TABLE 3 TOXICOLOGY AND THERAPEUTIC DRUG MONITORING

Drug	Therapeutic Range		Toxic Level	
	SI Units	Conventional Units	SI Units	Conventional Units
Acetaminophen	66–199 µmol/L	10–30 µg/mL	>1320 µmol/L	>200 µg/mL
Amikacin				
Peak	34–51 µmol/L	20–30 µg/mL	>60 µmol/L	>35 µg/mL
Trough	0–17 µmol/L	0–10 µg/mL	>17 µmol/L	>10 µg/mL
Amitriptyline/nortriptyline (total drug)	430–900 nmol/L	120–250 ng/mL	>1800 nmol/L	>500 ng/mL
Amphetamine	150–220 nmol/L	20–30 ng/mL	>1500 nmol/L	>200 ng/mL
Bromide				
Sedation	1.3–6.3 mmol/L	10–50 mg/dL		
Epilepsy	9.4–18.8 mmol/L	75–150 mg/dL		
Mild toxicity			6.4–18.8 mmol/L	51–150 mg/dL
Severe toxicity			>18.8 mmol/L	>150 mg/dL
Lethal			>37.5 mmol/L	>300 mg/dL
Carbamazepine	17–42 µmol/L	4–10 µg/mL	85 µmol/L	>20 µg/mL
Chloramphenicol				
Peak	31–62 µmol/L	10–20 µg/mL	>77 µmol/L	>25 µg/mL
Trough	15–31 µmol/L	5–10 µg/mL	>46 µmol/L	>15 µg/mL
Chlordiazepoxide	1.7–10 µmol/L	0.5–3.0 µg/mL	>17 µmol/L	>5.0 µg/mL
Clonazepam	32–240 nmol/L	10–75 ng/mL	>320 nmol/L	>100 ng/mL
Clozapine	0.6–2.1 µmol/L	200–700 ng/mL	>3.7 µmol/L	>1200 ng/mL
Cocaine			>3.3 µmol/L	>1.0 µg/mL
Codeine	43–110 nmol/mL	13–33 ng/mL	>3700 nmol/mL	>1100 ng/mL, lethal
Cyclosporine				
Renal transplant				
0–6 months	208–312 nmol/L	250–375 ng/mL	>312 nmol/L	>375 ng/mL
6–12 months after transplant	166–250 nmol/L	200–300 ng/mL	>250 nmol/L	>300 ng/mL
>12 months	83–125 nmol/L	100–150 ng/mL	>125 nmol/L	>150 ng/mL
Cardiac transplant				
0–6 months	208–291 nmol/L	250–350 ng/mL	>291 nmol/L	>350 ng/mL
6–12 months after transplant	125–208 nmol/L	150–250 ng/mL	>208 nmol/L	>250 ng/mL
>12 months	83–125 nmol/L	100–150 ng/mL	>125 nmol/L	>150 ng/mL
Lung transplant				
0–6 months	250–374 nmol/L	300–450 ng/mL	>374 nmol/L	>450 ng/mL
Liver transplant				
0–7 days	249–333 nmol/L	300–400 ng/mL	>333 nmol/L	>400 ng/mL
2–4 weeks	208–291 nmol/L	250–350 ng/mL	>291 nmol/L	>350 ng/mL
5–8 weeks	166–249 nmol/L	200–300 ng/mL	>249 nmol/L	>300 ng/mL
9–52 weeks	125–208 nmol/L	150–250 ng/mL	>208 nmol/L	>250 ng/mL
>1 year	83–166 nmol/L	100–200 ng/mL	>166 nmol/L	>200 ng/mL
Desipramine	375–1130 nmol/L	100–300 ng/mL	>1880 nmol/L	>500 ng/mL
Diazepam (and metabolite)				
Diazepam	0.7–3.5 µmol/L	0.2–1.0 µg/mL	>7.0 µmol/L	>2.0 µg/mL
Nordiazepam	0.4–6.6 µmol/L	0.1–1.8 µg/mL	>9.2 µmol/L	>2.5 µg/mL
Digoxin	0.64–2.6 nmol/L	0.5–2.0 ng/mL	>3.1 nmol/L	>2.4 ng/mL
Disopyramide	>7.4 µmol/L	2.5 µg/mL	20.6 µmol/L	>7 µg/mL
Doxepin and nordoxepin				
Doxepin	0.36–0.98 µmol/L	101–274 ng/mL	>1.8 µmol/L	>503 ng/mL
Nordoxepin	0.38–1.04 µmol/L	106–291 ng/mL	>1.9 µmol/L	>531 ng/mL
Ethanol				
Behavioral changes			>4.3 mmol/L	>20 mg/dL
Legal limit			≥17 mmol/L	≥80 mg/dL
Critical with acute exposure			>54 mmol/L	>250 mg/dL
Ethylene glycol				
Toxic			>2 mmol/L	>12 mg/dL
Lethal			>20 mmol/L	>120 mg/dL
Ethosuximide	280–700 µmol/L	40–100 µg/mL	>700 µmol/L	>100 µg/mL
Flecainide	0.5–2.4 µmol/L	0.2–1.0 µg/mL	>3.6 µmol/L	>1.5 µg/mL
Gentamicin				
Peak	10–21 µmol/mL	5–10 µg/mL	>25 µmol/mL	>12 µg/mL
Trough	0–4.2 µmol/mL	0–2 µg/mL	>4.2 µmol/mL	>2 µg/mL
Heroin (diacetyl morphine)			>700 µmol/L	>200 ng/mL (as morphine)
Ibuprofen	49–243 µmol/L	10–50 µg/mL	>97 µmol/L	>200 µg/mL
Imipramine (and metabolite)				
Desimipramine	375–1130 nmol/L	100–300 ng/mL	>1880 nmol/L	>500 ng/mL
Total imipramine + desimipramine	563–1130 nmol/L	150–300 ng/mL	>1880 nmol/L	>500 ng/mL
Lidocaine	5.1–21.3 µmol/L	1.2–5.0 µg/mL	>38.4 µmol/L	>9.0 µg/mL
Lithium	0.5–1.3 mmol/L	0.5–1.3 meq/L	>2 mmol/L	>2 meq/L
Methadone	1.3–3.2 µmol/L	0.4–1.0 µg/mL	>6.5 µmol/L	>2 µg/mL
Methamphetamine	1.3–4.0 µmol/L	2–6 µg/dL	4.0–33.5 µmol/L 67.0–268.0 µmol/L	60-500-1.0 µg/dL, toxic 1000–4000 µg/dL, lethal

(continued)

TABLE 3 TOXICOLOGY AND THERAPEUTIC DRUG MONITORING (CONTINUED)

Drug	Therapeutic Range		Toxic Level	
	SI Units	Conventional Units	SI Units	Conventional Units
Methanol			>6 mmol/L >16 mmol/L >28 mmol/L	>20 mg/dL, toxic >50 mg/dL, severe toxicity >89 mg/dL, lethal
Methotrexate				
Low-dose	0.01–0.1 µmol/L	0.01–0.1 µmol/L	>0.1 mmol/L	>0.1 mmol/L
High-dose (24 h)	<5.0 µmol/L	<5.0 µmol/L	>5.0 µmol/L	>5.0 µmol/L
High-dose (48 h)	<0.50 µmol/L	<0.50 µmol/L	>0.5 µmol/L	>0.5 µmol/L
High-dose (72 h)	<0.10 µmol/L	<0.10 µmol/L	>0.1 µmol/L	>0.1 µmol/L
Morphine	35–250 µmol/L	10–70 ng/mL	180–14000 µmol/L	50–4000 ng/mL
Nitroprusside (as thiocyanate)	103–499 µmol/L	6–29 µg/mL	860 µmol/L	>50 µg/mL
Nortriptyline	190–569 nmol/L	50–150 ng/mL	>1900 nmol/L	>500 ng/mL
Phenobarbital	65–172 µmol/L	15–40 µg/mL	>215 µmol/L	>50 µg/mL
Phenytoin	40–79 µmol/L	10–20 µg/mL	>118 µmol/L	>30 µg/mL
Phenytoin, free	4.0–7.9 µmol/L	1–2 µg/mL	>13.9 µmol/L	>3.5 µg/mL
% Free	0.08–0.14	8–14%		
Primidone and metabolite				
Primidone	23–55 µmol/L	5–12 µg/mL	>69 µmol/L	>15 µg/mL
Phenobarbital	65–172 µmol/L	15–40 µg/mL	>215 µmol/L	>50 µg/mL
Procainamide				
Procainamide	17–42 µmol/L	4–10 µg/mL	>51 µmol/L	>12 µg/mL
NAPA (*N*-acetylprocainamide)	22–72 µmol/L	6–20 µg/mL	>126 µmol/L	>35 µg/mL
Quinidine	6.2–15.4 µmol/L	2.0–5.0 µg/mL	>31 µmol/L	>10 µg/mL
Salicylates	145–2100 µmol/L	2–29 mg/dL	>2172 µmol/L	>30 mg/dL
Sirolimus (trough level)				
Kidney transplant	4.4–13.1 nmol/L	4–12 ng/mL	>16 nmol/L	>15 ng/mL
Tacrolimus (FK506) (trough)				
Kidney and liver				
0–2 months posttransplant	12–19 nmol/L	10–15 ng/mL	>25 nmol/L	>20 ng/mL
> 2 months posttransplant	6–12 nmol/L	5–10 ng/mL		
Heart				
0–2 months posttransplant	19–25 nmol/L	15–20 ng/mL	>25 nmol/L	>20 ng/mL
3–6 months posttransplant	12–19 nmol/L	10–15 ng/mL		
>6 months posttransplant	10–12 nmol/L	8–10 ng/mL		
Theophylline	56–111 µmol/L	10–20 µg/mL	>140 µmol/L	>25 µg/mL
Thiocyanate				
After nitroprusside infusion	103–499 µmol/L	6–29 µg/mL	860 µmol/L	>50 µg/mL
Nonsmoker	17–69 µmol/L	1–4 µg/mL		
Smoker	52–206 µmol/L	3–12 µg/mL		
Tobramycin				
Peak	11–22 µmol/L	5–10 µg/mL	>26 µmol/L	>12 µg/mL
Trough	0–4.3 µmol/L	0–2 µg/mL	>4.3 µmol/L	>2 µg/mL
Valproic acid	350–700 µmol/L	50–100 µg/mL	>1000 µmol/L	>150 µg/mL
Vancomycin				
Peak	14–28 µmol/L	20–40 µg/mL	>55 µmol/L	>80 µg/mL
Trough	3.5–10.4 µmol/L	5–15 µg/mL	>14 µmol/L	>20 µg/mL

Specimen	Analyte[a]	Reference Range	
		SI Units	Conventional Units
Aluminum	S	<0.2 μmol/L	<5.41 μg/L
	U, random	0.19–1.11 μmol/L	5–30 μg/L
Arsenic	WB	0.03–0.31 μmol/L	2–23 μg/L
	U, 24 h	0.07–0.67 μmol/d	5–50 μg/d
Cadmium	WB	<44.5 nmol/L	<5.0 μg/L
Coenzyme Q10 (ubiquinone)	P	433–1532 μg/L	433–1532 μg/L
B carotene	S	0.07–1.43 μmol/L	4–77 μg/dL
Copper			
	S	11–22 μmol/L	70–140 μg/dL
	U, 24 h	<0.95 μmol/d	<60 μg/d
Folic acid	RC	340–1020 nmol/L cells	150–450 ng/mL cells
Folic acid	S	12.2–40.8 nmol/L	5.4–18.0 ng/mL
Lead (adult)	S	<0.5 μmol/L	<10 μg/dL
Mercury			
	WB	3.0–294 nmol/L	0.6–59 μg/L
	U, 24 h	<99.8 nmol/L	<20 μg/L
Selenium	S	0.8–2.0 μmol/L	63–160 μg/L
Vitamin A	S	0.7–3.5 μmol/L	20–100 μg/dL
Vitamin B_1 (thiamine)	S	0–75 nmol/L	0–2 μg/dL
Vitamin B_2 (riboflavin)	S	106–638 nmol/L	4–24 μg/dL
Vitamin B_6	P	20–121 nmol/L	5–30 ng/mL
Vitamin B_{12}	S	206–735 pmol/L	279–996 pg/mL
Vitamin C (ascorbic acid)	S	23–57 μmol/L	0.4–1.0 mg/dL
Vitamin D_3, 1,25-dihydroxy	S	60–108 pmol/L	25–45 pg/mL
Vitamin D_3, 25-hydroxy	P		
Summer		37.4–200 nmol/L	15–80 ng/mL
Winter		34.9–105 nmol/L	14–42 ng/mL
Vitamin E	S	12–42 μmol/L	5–18 μg/mL
Vitamin K	S	0.29–2.64 nmol/L	0.13–1.19 ng/mL
Zinc	S	11.5–18.4 μmol/L	75–120 μg/dL

[a]P, plasma; RC, red cells; S, serum; WB, whole blood; U, urine.

TABLE 5 CLASSIFICATION OF LDL, TOTAL, AND HDL CHOLESTEROL

LDL cholesterol, mg/dL (mmol/L)	
<70 (<1.81)	Therapeutic option for very high risk patients
<100 (<2.59)	Optimal
100–129 (2.59–3.34)	Near optimal/above optimal
130–159 (3.36–4.11)	Borderline high
160–189 (4.14–4.89)	High
≥190 (≥4.91)	Very high
Total cholesterol, mg/dL (mmol/L)	
<200 (<5.17)	Desirable
200–239 (5.17–6.18)	Borderline high
≥240 (≥6.21)	High
HDL cholesterol, mg/dL (mmol/L)	
<40 (<1.03)	Low
≥60 (≥1.55)	High

Note: LDL, low-density lipoprotein; HDL, high-density lipoprotein

REFERENCE VALUES FOR SPECIFIC ANALYTES

TABLE 6 CEREBROSPINAL FLUID (CSF)[a]

Constituent	Reference Range	
	SI Units	Conventional Units
Osmolarity	292–297 mmol/kg water	292–297 mosmol/L
Electrolytes		
Sodium	137–145 mmol/L	137–145 meq/L
Potassium	2.7–3.9 mmol/L	2.7–3.9 meq/L
Calcium	1.0–1.5 mmol/L	2.1–3.0 meq/L
Magnesium	1.0–1.2 mmol/L	2.0–2.5 meq/L
Chloride	116–122 mmol/L	116–122 meq/L
CO_2 content	20–24 mmol/L	20–24 meq/L
P_{CO_2}	6–7 kPa	45–49 mmHg
pH	7.31–7.34	
Glucose	2.22–3.89 mmol/L	40–70 mg/dL
Lactate	1–2 mmol/L	10–20 mg/dL
Total protein		
Lumbar	0.15–0.5 g/L	15–50 mg/dL
Cisternal	0.15–0.25 g/L	15–25 mg/dL
Ventricular	0.06–0.15 g/L	6–15 mg/dL
Albumin	0.066–0.442 g/L	6.6–44.2 mg/dL
IgG	0.009–0.057 g/L	0.9–5.7 mg/dL
IgG index[b]	0.29–0.59	
Oligoclonal bands	<2 bands not present in matched serum sample	
Ammonia	15–47 μmol/L	25–80 μg/dL
Creatinine	44–168 μmol/L	0.5–1.9 mg/dL
Myelin basic protein	<4 μg/L	
CSF pressure		50–180 mmH_2O
CSF volume (adult)	~150 mL	
Red blood cells	0	0
Leukocytes		
Total	0–5 mononuclear cells per μL	0–5 mononuclear cells per mm^3
Differential		
Lymphocytes	60–70%	
Monocytes	30–50%	
Neutrophils	None	

[a]Since cerebrospinal fluid concentrations are equilibrium values, measurements of the same parameters in blood plasma obtained at the same time are recommended. However, there is a time lag in attainment of equilibrium, and cerebrospinal levels of plasma constituents that can fluctuate rapidly (such as plasma glucose) may not achieve stable values until after a significant lag phase.

[b]IgG index = CSF IgG(mg/dL) × serum albumin(g/dL)/Serum IgG(g/dL) × CSF albumin(mg/dL).

TABLE 7 URINE ANALYSIS

	Reference Range	
	SI Units	Conventional Units
Acidity, titratable	20–40 mmol/d	20–40 meq/d
Ammonia	30–50 mmol/d	30–50 meq/d
Amylase		4–400 U/L
Amylase/creatinine clearance ratio [(Cl_{am}/Cl_{cr}) × 100]	1–5	1–5
Calcium (10 meq/d or 200 mg/d dietary calcium)	<7.5 mmol/d	<300 mg/d
Creatine, as creatinine		
Female	<760 μmol/d	<100 mg/d
Male	<380 μmol/d	<50 mg/d
Creatinine	8.8–14 mmol/d	1.0–1.6 g/d
Eosinophils	<100,000 eosinophils/L	<100 eosinophils/mL
Glucose (glucose oxidase method)	0.3–1.7 mmol/d	50–300 mg/d
5-Hydroxyindoleacetic acid (5-HIAA)	10–47 μmol/d	2–9 mg/d
Iodine, spot urine		
WHO classification of iodine deficiency		
Not iodine deficient	>100 μg/L	>100 μg/L
Mild iodine deficiency	50–100 μg/L	50–100 μg/L
Moderate iodine deficiency	20–49 μg/L	20–49 μg/L
Severe iodine deficiency	<20 μg/L	<20 μg/L
Microalbumin		
Normal	0.0–0.03 g/d	0–30 mg/d
Microalbuminuria	0.03–0.30 g/d	30–300 mg/d
Clinical albuminuria	>0.3 g/d	>300 mg/d
Microalbumin/creatinine ratio		
Normal	0–3.4 g/mol creatinine	0–30 μg/mg creatinine
Microalbuminuria	3.4–34 g/mol creatinine	30–300 μg/mg creatinine
Clinical albuminuria	>34 g/mol creatinine	>300 μg/mg creatinine
Oxalate		
Male	80–500 μmol/d	7–44 mg/d
Female	45–350 μmol/d	4–31 mg/d
pH	5.0–9.0	5.0–9.0
Phosphate (phosphorus) (varies with intake)	12.9–42.0 mmol/d	400–1300 mg/d
Potassium (varies with intake)	25–100 mmol/d	25–100 meq/d
Protein	<0.15 g/d	<150 mg/d
Sediment		
Red blood cells	0–2/high power field	
White blood cells	0–2/high power field	
Bacteria	None	
Crystals	None	
Bladder cells	None	
Squamous cells	None	
Tubular cells	None	
Broad casts	None	
Epithelial cell casts	None	
Granular casts	None	
Hyaline casts	0–5/low power field	
Red blood cell casts	None	
Waxy casts	None	
White cell casts	None	
Sodium (varies with intake)	100–260 mmol/d	100–260 meq/d
Specific gravity	1.001–1.035	1.001–1.035
Urea nitrogen	214–607 mmol/d	6–17 g/d
Uric acid (normal diet)	1.49–4.76 mmol/d	250–800 mg/d

Note: WHO, World Health Organization.

TABLE 8 DIFFERENTIAL NUCLEATED CELL COUNTS OF BONE MARROW ASPIRATES[a]

	Observed Range, %	95% Confidence Intervals, %	Mean, %
Blast cells	0–3.2	0–3.0	1.4
Promyelocytes	3.6–13.2	3.2–12.4	7.8
Neutrophil myelocytes	4–21.4	3.7–10.0	7.6
Eosinophil myelocytes	0–5.0	0–2.8	1.3
Metamyelocytes	1–7.0	2.3–5.9	4.1
Neutrophils			
Males	21.0–45.6	21.9–42.3	32.1
Females	29.6–46.6	28.8–45.9	37.4
Eosinophils	0.4–4.2	0.3–4.2	2.2
Eosinophils plus eosinophil myelocytes	0.9–7.4	0.7–6.3	3.5
Basophils	0–0.8	0–0.4	0.1
Erythroblasts			
Male	18.0–39.4	16.2–40.1	28.1
Females	14.0–31.8	13.0–32.0	22.5
Lymphocytes	4.6–22.6	6.0–20.0	13.1
Plasma cells	0–1.4	0–1.2	0.6
Monocytes	0–3.2	0–2.6	1.3
Macrophages	0–1.8	0–1.3	0.4
M:E ratio			
Males	1.1–4.0	1.1–4.1	2.1
Females	1.6–5.4	1.6–5.2	2.8

TABLE 9 STOOL ANALYSIS

	Reference Range	
	SI Units	Conventional Units
Amount	0.1–0.2 kg/d	100–200 g/24 h
Coproporphyrin	611–1832 nmol/d	400–1200 μg/24 h
Fat		
Adult		<7 g/d
Adult on fat-free diet		<4 g/d
Fatty acids	0–21 mmol/d	0–6 g/24 h
Leukocytes	None	None
Nitrogen	<178 mmol/d	<2.5 g/24 h
pH	7.0–7.5	
Occult blood	Negative	Negative
Trypsin		20–95 U/g
Urobilinogen	85–510 μmol/d	50–300 mg/24 h
Uroporphyrins	12–48 nmol/d	10–40 μg/24 h
Water	<0.75	<75%

TABLE 10 RENAL FUNCTION TESTS

	Reference Range	
	SI Units	**Conventional Units**
Clearances (corrected to 1.72 m^2 body surface area)		
Measures of glomerular filtration rate		
Inulin clearance (Cl)		
Males (mean ± 1 SD)	2.1 ± 0.4 mL/s	124 ± 25.8 mL/min
Females (mean ± 1 SD)	2.0 ± 0.2 mL/s	119 ± 12.8 mL/min
Endogenous creatinine clearance	1.5–2.2 mL/s	91–130 mL/min
Measures of effective renal plasma flow and tubular function		
p-Aminohippuric acid clearance (Cl_{PAH})		
Males (mean ± 1 SD)	10.9 ± 2.7 mL/s	654 ± 163 mL/min
Females (mean ± 1 SD)	9.9 ± 1.7 mL/s	594 ± 102 mL/min
Concentration and dilution test		
Specific gravity of urine		
After 12-h fluid restriction	>1.025	>1.025
After 12-h deliberate water intake	≤1.003	≤1.003
Protein excretion, urine	<0.15 g/d	<150 mg/d
Specific gravity, maximal range	1.002–1.028	1.002–1.028
Tubular reabsorption, phosphorus	0.79–0.94 of filtered load	79–94% of filtered load

TABLE 11 CIRCULATORY FUNCTION TESTS

	Results: Reference Range	
Test	**SI Units (Range)**	**Conventional Units (Range)**
Arteriovenous oxygen difference	30–50 mL/L	30–50 mL/L
Cardiac output (Fick)	2.5–3.6 L/m^2 of body surface area per min	2.5–3.6 L/m^2 of body surface area per min
Contractility indexes		
Max. left ventricular *dp/dt*(*dp/dt*)/DP when DP = 5.3 kPa (40 mmHg) (DP, diastolic pressure)	220 kPa/s (176–250 kPa/s) (37.6 ± 12.2)/s	1650 mmHg/s (1320–1880 mmHg/s) (37.6 ± 12.2)/s
Mean normalized systolic ejection rate (angiography)	3.32 ± 0.84 end-diastolic volumes per second	3.32 ± 0.84 end-diastolic volumes per second
Mean velocity of circumferential fiber shortening (angiography)	1.83 ± 0.56 circumferences per second	1.83 ± 0.56 circumferences per second
Ejection fraction: stroke volume/end-diastolic volume (SV/EDV)	0.67 ± 0.08 (0.55–0.78)	0.67 ± 0.08 (0.55–0.78)
End-diastolic volume	70 ± 20.0 mL/m^2 (60–88 mL/m^2)	70 ± 20.0 mL/m^2 (60–88 mL/m^2)
End-systolic volume	25 ± 5.0 mL/m^2 (20–33 mL/m^2)	25 ± 5.0 mL/m^2 (20–33 mL/m^2)
Left ventricular work		
Stroke work index	50 ± 20.0 (g•m)/m^2 (30–110)	50 ± 20.0 (g•m)/m^2 (30–110)
Left ventricular minute work index	1.8–6.6 [(kg•m)/m^2]/min	1.8–6.6 [(kg•m)/m^2]/min
Oxygen consumption index	110–150 mL	110–150 mL
Maximum oxygen uptake	35 mL/min (20–60 mL/min)	35 mL/min (20–60 mL/min)
Pulmonary vascular resistance	2–12 (kPa•s)/L	20–130 (dyn•s)/cm^5
Systemic vascular resistance	77–150 (kPa•s)/L	770–1600 (dyn•s)/cm^5

TABLE 12 GASTROINTESTINAL TESTS

Test	Results	
	SI Units	Conventional Units
Absorption tests		
D-Xylose: after overnight fast, 25 g xylose given in oral aqueous solution		
Urine, collected for following 5 h	25% of ingested dose	25% of ingested dose
Serum, 2 h after dose	2.0–3.5 mmol/L	30–52 mg/dL
Vitamin A: a fasting blood specimen is obtained and 200,000 units of vitamin A in oil is given orally	Serum level should rise to twice fasting level in 3–5 h	Serum level should rise to twice fasting level in 3–5 h
Bentiromide test (pancreatic function): 500 mg bentiromide (chymex) orally; *p*-aminobenzoic acid (PABA) measured		
Plasma		>3.6 (±1.1) μg/mL at 90 min
Urine	>50% recovered in 6 h	>50% recovered in 6 h
Gastric juice		
Volume		
24 h	2–3 L	2–3 L
Nocturnal	600–700 mL	600–700 mL
Basal, fasting	30–70 mL/h	30–70 mL/h
Reaction		
pH	1.6–1.8	1.6–1.8
Titratable acidity of fasting juice	4–9 μmol/s	15–35 meq/h
Acid output		
Basal		
Females (mean ± 1 SD)	0.6 ± 0.5 μmol/s	2.0 ± 1.8 meq/h
Males (mean ± 1 SD)	0.8 ± 0.6 μmol/s	3.0 ± 2.0 meq/h
Maximal (after SC histamine acid phosphate, 0.004 mg/kg body weight, and preceded by 50 mg promethazine, or after betazole, 1.7 mg/kg body weight, or pentagastrin, 6 μg/kg body weight)		
Females (mean ± 1 SD)	4.4 ± 1.4 μmol/s	16 ± 5 meq/h
Males (mean ± 1 SD)	6.4 ± 1.4 μmol/s	23 ± 5 meq/h
Basal acid output/maximal acid output ratio	≤0.6	≤0.6
Gastrin, serum	0–200 μg/L	0–200 pg/mL
Secretin test (pancreatic exocrine function): 1 unit/kg body weight, IV		
Volume (pancreatic juice) in 80 min	>2.0 mL/kg	>2.0 mL/kg
Bicarbonate concentration	>80 mmol/L	>80 meq/L
Bicarbonate output in 30 min	>10 mmol	>10 meq

TABLE 13 NORMAL VALUES OF DOPPLER ECHOCARDIOGRAPHIC MEASUREMENTS IN ADULTS

	Range	Mean
RVD (cm), measured at the base in apical 4-chamber view	2.6–4.3	3.5 ± 0.4
LVID (cm), measured in the parasternal long axis view	3.6–5.4	4.7 ± 0.4
Posterior LV wall thickness (cm)	0.6–1.1	0.9 ± 0.4
IVS wall thickness (cm)	0.6–1.1	0.9 ± 0.4
Left atrial dimension (cm), antero-posterior dimension	2.3–3.8	3.0 ± 0.3
Aortic root dimension (cm)	2.0–3.5	2.4 ± 0.4
Aortic cusps separation (cm)	1.5–2.6	1.9 ± 0.4
Percentage of fractional shortening	34–44%	36%
Mitral flow (m/s)	0.6–1.3	0.9
Tricuspid flow (m/s)	0.3–0.7	0.5
Pulmonary artery (m/s)	0.6–0.9	0.75
Aorta (m/s)	1.0–1.7	1.35

Note: RVD, right ventricular dimension; LVID, left ventricular internal dimension; LV, left ventricle; IVS, interventricular septum.

TABLE 14 SUMMARY OF VALUES USEFUL IN PULMONARY PHYSIOLOGY

	Symbol	Typical Values	
		Man, Age 40, 75 kg, 175 cm Tall	Woman, Age 40, 60 kg, 160 cm Tall
Pulmonary Mechanics			
Spirometry—volume-time curves			
Forced vital capacity	FVC	4.8 L	3.3 L
Forced expiratory volume in 1 s	FEV_1	3.8 L	2.8 L
FEV_1/FVC	FEV_1%	76%	77%
Maximal midexpiratory flow	MMF (FEF 25–27)	4.8 L/s	3.6 L/s
Maximal expiratory flow rate	MEFR (FEF 200–1200)	9.4 L/s	6.1 L/s
Spirometry—flow-volume curves			
Maximal expiratory flow at 50% of expired vital capacity	V_{max} 50 (FEF 50%)	6.1 L/s	4.6 L/s
Maximal expiratory flow at 75% of expired vital capacity	V_{max} 75 (FEF 75%)	3.1 L/s	2.5 L/s
Resistance to airflow			
Pulmonary resistance	RL (R_L)	<3.0 (cmH_2O/s)/L	
Airway resistance	Raw	<2.5 (cmH_2O/s)/L	
Specific conductance	SGaw	>0.13 cmH_2O/s	
Pulmonary compliance			
Static recoil pressure at total lung capacity	Pst TLC	25 ± 5 cmH_2O	
Compliance of lungs (static)	CL	0.2 L cmH_2O	
Compliance of lungs and thorax	C(L + T)	0.1 L cmH_2O	
Dynamic compliance of 20 breaths per minute	C dyn 20	0.25 ± 0.05 L/cmH_2O	
Maximal static respiratory pressures			
Maximal inspiratory pressure	MIP	>90 cmH_2O	>50 cmH_2O
Maximal expiratory pressure	MEP	>150 cmH_2O	>120 cmH_2O
Lung Volumes			
Total lung capacity	TLC	6.4 L	4.9 L
Functional residual capacity	FRC	2.2 L	2.6 L
Residual volume	RV	1.5 L	1.2 L
Inspiratory capacity	IC	4.8 L	3.7 L
Expiratory reserve volume	ERV	3.2 L	2.3 L
Vital capacity	VC	1.7 L	1.4 L
Gas Exchange (Sea Level)			
Arterial O_2 tension	Pa_{O_2}	12.7 ± 0.7 kPa (95 ± 5 mmHg)	
Arterial CO_2 tension	Pa_{CO_2}	5.3 ± 0.3 kPa (40 ± 2 mmHg)	
Arterial O_2 saturation	Sa_{O_2}	0.97 ± 0.02 (97 ± 2%)	
Arterial blood pH	pH	7.40 ± 0.02	
Arterial bicarbonate	HCO_3^-	24 + 2 meq/L	
Base excess	BE	0 ± 2 meq/L	
Diffusing capacity for carbon monoxide (single breath)	DL_{CO}	0.42 mL CO/s/mmHg (25 mL CO/min/mmHg)	
Dead space volume	V_D	2 mL/kg body wt	
Physiologic dead space; dead space-tidal volume ratio	V_D/V_T		
Rest		≤35% V_T	
Exercise		≤20% V_T	
Alveolar-arterial difference for O_2	$P(A - a)_{O_2}$	≤2.7 kPa ≤20 kPa (≤20 mmHg)	

TABLE 15 BODY FLUIDS AND OTHER MASS DATA

	Reference Range	
	SI Units	**Conventional Units**
Ascitic fluid: See Table 44-1		
Body fluid,		
Total volume (lean) of body weight	50% (in obese) to 70%	
Intracellular	0.3–0.4 of body weight	
Extracellular	0.2–0.3 of body weight	
Blood		
Total volume		
Males	69 mL per kg body weight	
Females	65 mL per kg body weight	
Plasma volume		
Males	39 mL per kg body weight	
Females	40 mL per kg body weight	
Red blood cell volume		
Males	30 mL per kg body weight	1.15–1.21 L/m^2 of body surface area
Females	25 mL per kg body weight	0.95–1.00 L/m^2 of body surface area
Body mass index	18.5–24.9 kg/m^2	18.5–24.9 kg/m^2

TABLE 16 RADIATION-DERIVED UNITS

Quantity	Old Unit	SI Unit	Name for SI Unit (and Abbreviation)	Conversion
Activity	curie (Ci)	Disintegrations per second (dps)	becquerel (Bq)	1 Ci = 3.7×10^{10} Bq 1 mCi = 37 mBq 1 μCi = 0.037 MBq or 37 GBq 1 Bq = 2.703×10^{-11} Ci
Absorbed dose	rad	joule per kilogram (J/kg)	gray (Gy)	1 Gy = 100 rad 1 rad = 0.01 Gy 1 mrad = 10^{-3} cGy
Exposure	roentgen (R)	coulomb per kilogram (C/kg)	—	1 C/kg = 3876 R 1 R = 2.58×10^{-4} C/kg 1 mR = 258 pC/kg
Dose equivalent	rem	joule per kilogram (J/kg)	sievert (Sv)	1 Sv = 100 rem 1 rem = 0.01 Sv 1 mrem = 10 μSv

ACKNOWLEDGMENT

cardiovascular disease and, 2262
clinical features of, 2260
diagnosis of, 1555, 2260–2261, 2261f
edema in, 233, 2262
electrocardiography in, 2260
glucocorticoid-remediable, 281, 395, 1556, 1557t, 2268
hypernatremia in, 2260
hyperreninemic, secondary, 293–294
hypertension in, 1551, 1554–1556, 1554t, 2260–2262
hypokalemia in, 281, 281t, 2260–2261
hypomagnesemia in, 2373t
hypophosphatemia in, 2370t
idiopathic, 2260
left ventricular hypertrophy in, 2260, 2262
metabolic acidosis in, 293
metabolic alkalosis in, 293t
in pregnancy, 2262
primary, 281, 1551–1552, 1555–1556, 2259–2262, 2261f
secondary, 281, 1551–1552, 1555, 2261–2262, 2261f
treatment of, 2261–2262
Alefacept
adverse effects of, 317t
for psoriatic arthritis, 317t, 2116
Alemtuzumab
action of, 502t
adverse effects of, 1739
for B cell chronic lymphoid leukemia/small lymphocytic lymphoma, 694
for breast cancer, 502t
for chronic lymphocytic leukemia, 502t
for graft-versus-host disease prevention, 844
for lung cancer, 502t
for renal transplantation, 1779
Alendronate
adverse effects of, 2406

for osteoporosis, 2405–2406, 2405f
for Paget disease of bone, 2411, 2411t
Aleukemic leukemia, 663t
Alexander technique, 63t
Alexia, 163
pure, 164–165, 164t
Alfimeprase, 747
Algal infections, **1267**
Alginic acid, for gastroesophageal reflux disease, 245
Alkaline phosphatase, 1921, 1925, 1926t, 2014
in jaundiced patient, 263–264
Alkali therapy
adverse effects of, 293–294, 293t
for hyperkalemia, 285
for lactic acidosis, 290
for metabolic acidosis, 290
for uremic acidosis, 292
Alkaloids, adverse effects of, 264, 264t
Alkaptonuria, 2471t, **2473**
Alkylating agents, 520–524, 521t
action of, 520–521, 521t
adverse effects of, 299t, 345, 361, 520, 664t, 677, e91t
carcinogenicity of, 487t
Allele, 396
segregation of, 399f
Allele frequency, 404
Allele-sharing methods, 403t
Allelic association, 404
Allelic exclusion, 400, 700, 2035
Allelic heterogeneity, 389f, 396–397, 397t
Allelic loss, 574
Allergens, 2063
triggers of asthma, 1597, 1600–1601
Allergic angiitis and granulomatosis. *See* Churg-Strauss syndrome
Allergic bronchopulmonary aspergillosis, 1257, 1257t, 1259–1260, 1260t, 1610
bronchiectasis in, 1629
in cystic fibrosis, 1634
diagnosis of, 1326, 1609–1610, 1610t
pulmonary infiltrate in, 1610t
Allergic granulomatosis, 333
Allergic reaction, to transfusions, 711
Allergic rhinitis, 205, **2068**
asthma and, 2068
clinical features of, 2068–2069
diagnosis of, 2069, 2070f
olfactory dysfunction in, 197t
pathophysiology of, 2068–2069
predisposing factors, 2068
prevention of, 2069
seasonal, 2068

nonscarring, 322–323, 322t
scarring, 322–323, 322t
traumatic, 322, 322t, 323t
treatment of, 323t
Alopecia areata, 322, 322t, 323t, e63f
Alosetron
adverse effects of, 1902
for carcinoid syndrome, 2353
for irritable bowel syndrome, 1902, 1903t
α_1-acid glycoprotein, 30
Alpha$_2$-adrenergic agonists
for glaucoma, 186
overdose/poisoning with, e288t
Alpha-adrenergic receptors, 1550
genetic polymorphisms in, 1369t
Alpha blockers
for acute renal failure, 1760
adverse effects of, 220, 234t, 2578t
for benign proliferative disease of prostate, 600
for hypertension, 1560, 1560t
for nephrolithiasis, 1817
Alpha chain disease, *Campylobacter jejuni* and, 967
Alpha fetoprotein
in carcinoma of unknown primary, 614, 615t
ectopic production of, 618
in hepatocellular carcinoma, 582
in testicular cancer, 601–602
as tumor marker, 483t
Alpha heavy chain disease, **707**
Alpha-lipoic acid, for glossodynia, 220
Alpha radiation, 1358
Alpha rhythm, e261, e261f
Alpha toxin, *Clostridium perfringens,* 904, 906
Alphavirus, 1227t
Alport syndrome, 1783, 1785t, 1791t, **1794**, **2469**
diagnosis of, 2469
hearing loss in, 200, 201t
incidence of, 2469
molecular defects in, 2469
renal biopsy in, e57f
Alprazolam
for depression, 74
for essential tremor, 2560
for fibromyalgia, 2177
for generalized anxiety disorder, 2712, 2713t
for panic disorder, 2711
for stress disorders, 2715
Alprostadil, for erectile dysfunction
intracavernosal self-injection, 299
intraurethral, 299
ALS/parkinsonian/dementia complex of Guam, 2537t, 2548
Alteplase, 746–747
action of, 745–746
domain structure of, 746, 747f
for occluded catheter, 460
Alternative medicine. *See* Complementary and alternative medicine

INDEX

Gastritis (*Cont.*)
classification of, 1870t
eosinophilic, 1870t, 1871
granulomatous, 1870t, 1871
halitosis in, 221
Helicobacter pylori-induced, 946–947, 947f, 1870–1871, 1871f
lymphocytic, 1870t, 1871
postcholecystectomy, 1998
stress-induced, 1869
superficial, 1870
varioliform, 1871
Gastroduodenostomy, for peptic ulcer disease, 1866
Gastroenteric cyst, 1660
Gastroenteritis
abdominal pain in, 94t
adenovirus, 1205t, 1208
Aeromonas, 927
astrovirus, 1205t, 1208
bacterial, 1206t
calicivirus, 1205–1206, 1205t
coronavirus, 1208
diagnosis of, 1915t, 1916
gram-negative enteric bacilli, 945
influenza virus, 1208
irritable bowel syndrome and, 1901
Listeria monocytogenes, 896
norovirus, 1205–1206, 1205t
picobirnavirus, 1208
reovirus, 1213
rotavirus, 1205t, 1206–1208
Salmonella, 956, 960
sapovirus, 1205–1206, 1205t
torovirus, 1208
Vibrio, 971–972, 971t
viral, **1204**, 1206t
Gastroesophageal reflux disease, 243–245, 1832, **1851**
abdominal pain in, 94t
alarm symptoms in, 244t
approach to, 244
asthma and, 1601, 1605
chest pain in, 87t, 88t, 89, 1851
clinical features of, 1851
cough in, 225–227
diagnosis of, 243–244, 1851–1852
dysphagia in, 239
endoscopic findings in, 1843–1844
esophageal cancer and, 570t
extraesophageal manifestations of, 1851
Helicobacter pylori and, 946–948, 947f
nausea and vomiting in, 241, 241t
pathophysiology of, 1851
sleep disorders in, 176
smoking and, 1852
in systemic sclerosis, 2103
treatment of, 245, 1852
Gastrointestinal bleeding, **257**, 366, 1833, 1833t
approach to, 258–260, 259f, 260f
aspirin-induced, 737
azotemia in, 270
diagnostic procedures in, 259, 259f, 260, 260f
in diverticular disease, 1903–1904
endoscopic findings in, 1838–1842
in enteric fever, 957–958
in esophageal varices, 257–258, 257t
in gastrointestinal disease, 1833, 1833t
hemoptysis in, 227t
in hemorrhagic and erosive gastropathy, 257t, 258
initial evaluation of, 1839–1840
lower tract sources, 259–260, 260f
in Mallory-Weiss tears, 257t, 258
obscure, 259–260
occult, 257, 260
in peptic ulcer disease, 257–258, 257t, 1861, 1866
small-intestinal, 258–259
upper tract sources, 257–259, 259f
Gastrointestinal cancer, **570**
carcinoma of unknown primary, 615t, 617
paraneoplastic syndromes in, 618t, 619–622
weight loss in, 255
Gastrointestinal disease
abdominal pain in, 1832, 1833t
abnormalities in
altered digestion and absorption, 1831–1832
altered gut immune function, 1832
altered gut transit, 1832
altered secretion, 1832
impaired blood flow, 1832
in adrenal insufficiency, 2263
in alcohol abuse, 2725–2726
altered bowel habits in, 1833, 1833t
approach to, **1831**
in Chagas' disease, 1301–1302
in chronic kidney disease, 1763t, 1768
classification of, 1831–1832
clinical features of, 1832–1833
cytomegalovirus, 1110t, 1111
in diabetes mellitus, 2289–2290
diagnosis of, 1834
dysphagia in, 1833
endoscopic findings in, 1834, **1836**, **e195**
functional testing in, 1835
gastroesophageal reflux in, 1832
genetic factors in, 1832
histopathology of, 1835
history in, 1833
in HIV infection, 1174–1176
infections in cancer patients, 535–536
jaundice in, 1833, 1833t
luminal contents in, 1834
malabsorption syndromes, **1872**
measles, 1215t, 1216
nausea and vomiting in, 241, 241t, 1832–1833, 1833t
nerve agent exposure, 1356
obesity and, 470t
physical examination in, 1833–1834
polyposis syndromes, 575t
in pregnancy, 47–48
prevention in travelers, 784, 786
in sepsis/septic shock, 1698
sulfur mustard exposure, 1355
syphilitic, 1041
in systemic lupus erythematosus, 2079, 2079t
in systemic sclerosis, 2100, 2103, 2105
treatment of, 1835–1836
directed outside the gut, 1836
nutritional manipulation, 1835
pharmacotherapy, 1835
specialized nutritional support, 456–457, 457t
surgery, 1836
tuberculosis, 1013
weight loss in, 256, 256t
Gastrointestinal endoscopy, 1834, **1836**, **e195.** *See also* Colonoscopy; Sigmoidoscopy
in anemia, 1844–1845
antibiotic prophylaxis for, 1838, 1840t
in Barrett's esophagus, 1837f, 1852, e195f
for cancer staging, 1846
in celiac sprue, 1844, 1845f, e201f

in Dieulafoy's lesion, 1841, 1841f, e198f
in duodenal ulcers, 1836f, e195f
in dyspepsia, 1843
in dysphagia, 1844
elective, **1843**
in esophageal obstruction, 1842
in esophageal stricture, 1844, 1844f, e200f
in esophageal varices, 1841f, e198f
in esophagitis, 1844f, e200f
in fecal occult blood, 1844
in gastric outlet obstruction, 1842
in gastric ulcer, 1836f, e195f
in gastroesophageal reflux disease, 1843–1844
in gastrointestinal obstruction, 1842
indications for, 1834t
in inflammatory bowel disease, 1889–1890, 1892t
in internal hemorrhoids, 1846f, e201f
in Mallory-Weiss tears, 1841, 1841f, e198f
open-access, **1846**, 1847t
in peptic ulcer, 1840f, 1844, 1861, 1862f, e198f
procedures, **1836**
risks of, 1838
in Schatzki's ring, 1844f, e200f
therapeutic capabilities of, 1835, **1836**
urgent, **1838**
in variceal bleeding, 1841
in vascular ectasia, 1841, 1841f, e199f
in Zollinger-Ellison syndrome, 1869
Gastrointestinal function tests, reference values for, A-14t
Gastrointestinal motility test, 242
Gastrointestinal neuroendocrine tumor, **2347**, 2347t. *See also* Carcinoid tumor; Pancreatic endocrine tumor
active peptide secreted, 2348t
clinical features of, 2348t
genetic syndromes associated with, 2350t
prognostic factors in, 2349–2350, 2349t
tumor localization, 2348t, 2357, 2357f
well-differentiated, 2348
Gastrointestinal obstruction, 1842
Gastrointestinal pseudoobstruction, 1842
Gastrointestinal scintigraphy, 1835
Gastrointestinal stromal tumor, 571, **573**, 611
treatment of, 502, 502t
Gastrointestinal tract
anaerobic flora of, 999–1000, 999t
anatomy of, 1831
decontamination in poisoning, e285
functions of, 1831
microbial entry through, 754
Gastrojejunostomy, 461t
for peptic ulcer disease, 1866
Gastroparesis
nausea and vomiting in, 241–242, 241t
in pancreatitis, 2015
in systemic sclerosis, 2103
treatment of, 242
Gastropathy
gastrointestinal bleeding with, 257
hemorrhagic and erosive, bleeding in, 257t, 258
prolapse, 258
Gastroplasty, vertical banded, 473
Gastrostomy tube feeding, 461t
in dysphagia, 238
Gatekeeper genes, 493
Gatifloxacin
adverse effects of, 2307
for anaerobic infections, 1005, 1005t
for chlamydia, 1078
for meningococcal infections, 913
for nontuberculous mycobacteria, 1029
for pneumonia, 870t
for tuberculosis, 1015
Gaucher cells, 2455
Gaucher disease, 671, **2455**
lung disease in, 1643t, 1650
lymphadenopathy in, 370t
splenomegaly in, 373–374, 374t
Gaze disorders
horizontal gaze, 194, 195f
supranuclear, 194
vertical gaze, 194
Gaze stabilization reflex, 181
GB virus, 1153
G cells, 1870
Gefitinib, 502t
action of, 502t, 528, 528f
adverse effects of, 345, 524t, 1738
for head and neck cancer, 550
for hepatocellular carcinoma, 584t
for lung cancer, 502, 502t, 553
Gegenhalten, 147
Gemcitabine
action of, 523t, 526
adverse effects of, 523t, 526, 1737
for bladder cancer, 591
for breast cancer, 569
for carcinoma of unknown primary, 617
for cholangiocarcinoma, 585
for lung cancer, 561
for ovarian cancer, 606
for pancreatic cancer, 589
for soft tissue sarcoma, 611
Gemella morbillorum, 889
endocarditis, 794, 7954t
Gemfibrozil
adverse effects of, 2428t, 2694, 2700
for diabetic patients, 1507
drug interactions of, 36t
for lipodystrophy, 1178
for lipoprotein disorders, 2426, 2428t
for metabolic syndrome, 1513
Gemifloxacin
for anaerobic infections, 1005
for meningococcal infections, 913
for pneumonia, 1069t, 1623t
Gemtuzumab ozogamicin, 528
adverse effects of, 1736–1737, 1739
for acute myeloid leukemia, 682t, 683
adverse effects of, 524t
Gender bias, e14
Gender differences, 39
Gene
assortment and segregation during meiosis, 387–388
cloning of, 390
